Knowledge base question answering (KBQA) is an important task in Natural Language Processing. Existing approaches face significant challenges including complex question understanding, necessity for reasoning, and lack of large end-to-end training datasets. In this work, we propose Neuro-Symbolic Question Answering (NSQA), a modular KBQA system, that leverages (1) Abstract Meaning Representation (AMR) parses for task-independent question understanding; (2) a simple yet effective graph transformation approach to convert AMR parses into candidate logical queries that are aligned to the KB; (3) a pipeline-based approach which integrates multiple, reusable modules that are trained specifically for their individual tasks (semantic parser, entity and relationship linkers, and neuro-symbolic reasoner) and do not require end-to-end training data. NSQA achieves state-of-the-art performance on two prominent KBQA datasets based on DBpedia (QALD-9 and LC-QuAD 1.0). Furthermore, our analysis emphasizes that AMR is a powerful tool for KBQA systems.

1 Introduction

Knowledge base question answering (KBQA) is a sub-field within Question Answering with desirable characteristics for real-world applications. KBQA requires a system to answer a natural language question based on facts available in a Knowledge Base (KB) (Zou et al., 2014; Vakulenko et al., 2019; Diefenbach et al., 2020; Abdelaziz et al., 2021). Facts are retrieved from a KB through structured queries (in a query language such as SPARQL), which often contain multiple triples that represent the steps or antecedents required for obtaining the answer. This enables a transparent and self-explanatory form of QA, meaning that intermediate symbolic representations capture some of the steps from natural language question to answer.

With the rise of neural networks in NLP, various KBQA models approach the task in an end-to-end manner. Many of these approaches formulate text-to-query-language as sequence-to-sequence problem, and thus require sufficient examples of paired natural language and target representation pairs. However, labeling large amounts of data for KBQA is challenging, either due to the requirement of expert knowledge (Usbeck et al., 2017), or artifacts introduced during automated creation (Trivedi et al., 2017). Real-world scenarios require solving complex multi-hop questions i.e. secondary unknowns within a main question and questions employing unusual expressions. Pipeline approaches can delegate language understanding to pre-trained semantic parsers, which mitigates the data problem, but are considered to suffer from error propagation. However, the performance of semantic parsers for well-established semantic representations has greatly improved in recent years. Abstract Meaning Representation (AMR) (Banarescu et al., 2013; Dorr et al., 1998) parsers recently reached above 84% F-measure (Bevilacqua et al., 2021), an improvement of over 10 points in the last three years.

In this paper we propose Neuro-Symbolic Question Answering (NSQA), a modular knowledge base question answering system with the following objectives: (a) delegating the complexity of understanding natural language questions to AMR parsers; (b) reducing the need for end-to-end (text-to-SPARQL) training data with a pipeline architecture where each module is trained for its specific sub-task; (c) facilitating the use of an independent reasoner via an intermediate logic form.

```
SELECT DISTINCT ?actor WHERE {
   ?movie  rdf:type       dbo:Film .
   ?movie  dbo:country    dbr:Spain .
   ?movie  dbo:producer   dbr:Benicio_del_Toro .
   ?movie  dbo:starring   ?actor .
}
```

Figure 1: Real NSQA prediction for the sentence *Which actors starred in Spanish movies produced by Benicio del Toro?*. In underlined, we show the representation for the two unknown variables across all stages including: AMR-aligned tokens in sentence (*Which*, *movies*), AMR graph (*unknown*, *movie*), paths representation (same as AMR), logical representation (*actor*, *movie*) and SPARQL interpretation (*?actor*, *?movie*). Displayed stage outputs: AMR (green), Entity Linking (blue), Relation Linking (orange)

The contributions of this work are as follows:

- The first system to use Abstract Meaning Representation for KBQA achieving state of the art performance on two prominent datasets on DBpedia (QALD-9 and LC-QuAD 1.0).

- A novel, simple yet effective path-based approach that transforms AMR parses into intermediate logical queries that are aligned to the KB. This intermediate logic form facilitates the use of neuro-symbolic reasoners such as Logical Neural Networks (Riegel et al., 2020), paving the way for complex reasoning over knowledge bases.

- A pipeline-based modular approach that integrates multiple, reusable modules that are trained specifically for their individual tasks (e.g. semantic parsing, entity linking, and relationship linking) and hence do not require end-to-end training data.

2 Approach Overview

Figure 1 depicts the pipeline of our NSQA system. Given a question in natural language, NSQA: (i) parses questions into an Abstract Meaning Representation (AMR) graph; (ii) transforms the AMR graph to a set of candidate KB-aligned logical queries, via a novel but simple graph transformation approach; (iii) uses a Logical Neural Network (LNN) (Riegel et al., 2020) to reason over KB facts and produce answers to KB-aligned logical queries. We describe each of these modules in the following sections.

2.1 AMR Parsing

NSQA utilizes AMR parsing to reduce the complexity and noise of natural language questions. An AMR parse is a rooted, directed, acyclic graph. AMR nodes represent concepts, which may include normalized surface symbols, Propbank frames (Kingsbury and Palmer, 2002) as well as other AMR-specific constructs to handle named entities, quantities, dates and other phenomena. Edges in an AMR graph represent the relations between concepts such as standard OntoNotes roles but also AMR specific relations such as polarity or mode.

As shown in Figure 1, AMR provides a representation that is fairly close to the KB representation. A special *amr-unknown* node, indicates the missing concept that represents the answer to the given question. In the example of Figure 1, *amr-unknown* is a *person*, who is the subject of *act-01*. Furthermore, AMR helps identify intermediate variables that behave as secondary unknowns. In this case, a *movie* produced by *Benicio del Toro* in *Spain*.

NSQA utilizes a stack-Transformer transition-based model (Naseem et al., 2019; Astudillo et al., 2020) for AMR parsing. An advantage of transition-based systems is that they provide explicit question text to AMR node alignments. This allows encoding closely integrated text and AMR input to multiple modules (Entity Linking and Relation Linking) that can benefit from this joint input.

2.2 AMR to KG Logic

The core contribution of this work is our next step where the AMR of the question is transformed to a query graph aligned with the underlying knowledge graph. We formalize the two graphs as follows:

AMR graph $\mathcal{G}$ is a rooted edge-labeled directed acyclic graph $\langle \mathcal{V}_\mathcal{G}, \mathcal{E}_\mathcal{G} \rangle$. The edge set $\mathcal{E}_\mathcal{G}$ consists of non-core roles, quantifiers, and modifiers. The vertex set $\mathcal{V}_\mathcal{G} \in$ *amr-unknown* $\cup \mathcal{A}_\mathcal{P} \cup \mathcal{A}_\mathcal{C}$ where where $\mathcal{A}_\mathcal{P}$ are set of propbank predicates and $\mathcal{A}_\mathcal{C}$ are rest of the nodes. [1]. Propbank predicates are *n-ary* with multiple edges based on their definitions. *amr-unknown* is a special concept node in the AMR graph indicating *wh-questions*.

Further, we enrich the AMR Graph $\mathcal{G}$ with explicit links to entities in the KG. For example, the question in Figure 1 contains two entities *Spain* and *Benicio Del Toro* that need to be identified and linked to DBpedia entries, *dbr:Spain* and *dbr:Benicio_del_toro*. Linking these entities is absolutely necessary for any KBQA system (Zou et al., 2014; Vakulenko et al., 2019). To do so, we trained a BERT-based neural mention detection model and used BLINK (Devlin et al., 2018) for disambiguation. The entities are linked to AMR nodes based on the AMR node-text alignment information. The linking is a bijective mapping from $\mathcal{V}_e \rightarrow E$ where $\mathcal{V}_e$ is the set of AMR entity nodes, and E is the set of entities in the underlying KG.

Query graph $\mathcal{Q}$ is a directed edge-labeled graph $\langle \mathcal{V}_\mathcal{Q}, \mathcal{E}_\mathcal{Q} \rangle$, which has a similar structure to the underlying KG. $\mathcal{V}_\mathcal{Q} \in \mathcal{V}_\mathcal{E} \cup \mathcal{V}$ where $\mathcal{V}_\mathcal{E}$ is a set of entities in the KG and $(\mathcal{V})$ is a set of unbound variables. $\mathcal{E}_\mathcal{Q}$ is a set of binary relations among $\mathcal{V}_\mathcal{Q}$ from the KG. The Query Graph $\mathcal{Q}$ is essentially the WHERE clause[2] in the SPARQL query.

Our goal is to transform the AMR graph $\mathcal{G}$ into its corresponding query graph $\mathcal{Q}$. However such transformation faces the following challenges:

N-ary argument mismatch: Query graph $\mathcal{Q}$ represents information using binary relations, whereas AMR graph contain Propbank framesets that are n-ary. For example, the node *produce-01*[3] from $\mathcal{A}_\mathcal{P}$ in $\mathcal{G}$ has four possible arguments, whereas its corresponding KG relation in $\mathcal{Q}$ (*dbo:producer*) is a binary relation.

Structural and Granular mismatch: The vertex set of the query graph $\mathcal{Q}$ represent entities (or unbound variables). On the other hand, AMR Graph $\mathcal{G}$ contains nodes that are concepts or PropBank predicates which can correspond to both entities and relationships. For example in Figure 1, *produce-01, star-01,* and *Spain* are nodes in the AMR graph. So the AMR graph $\mathcal{G}$ has to be transformed such that nodes primarily correspond to entities and edges (edge labels) correspond to relationships. Furthermore, it is possible for multiple predicates and concepts from $\mathcal{G}$ to jointly represent a single binary relation in $\mathcal{Q}$ because the underlying KG uses a completely different vocabulary. An example of such granular mismatch is shown in Figure 2.

2.2.1 Path-based Graph Transformation

We address the challenges mentioned above by using a path-based approach for the construction of Query Graphs. In KBQA, query graphs (i.e. SPARQL queries) constrain the unknown variable based on paths to the grounded entities. In Figure 1, the constraints in the SPARQL query are based on paths from *?actor* to *dbr:Benicio_del_toro* and *dbr:Spain* as shown below.

- `?actor → dbo:starring → ?movie → dbo:country → dbr:Spain`
- `?actor → dbo:starring → ?movie → dbo:producer → dbr:Benicio del Toro`

Based on this intuition of finding paths from the unknown variable to the grounded entities, we have developed a path-based approach depicted in Algorithm 1 that shows the steps for transforming the AMR Graph $\mathcal{G}$ into Query Graph $\mathcal{Q}$. As *amr-unknown* is the unknown variable in the AMR Graph, we retrieve all shortest paths (line 11 in Algorithm 1) between the *amr-unknown* node and the nodes $\mathcal{V}_E$ of the AMR Graph $\mathcal{G}$ that have mappings

---

[1] https://www.isi.edu/~ulf/amr/help/amr-guidelines.pdf

[2] The Query Graph does not include the type constraints in the SPARQL WHERE Clause.

[3] http://verbs.colorado.edu/propbank/framesets-english-aliases/produce.html

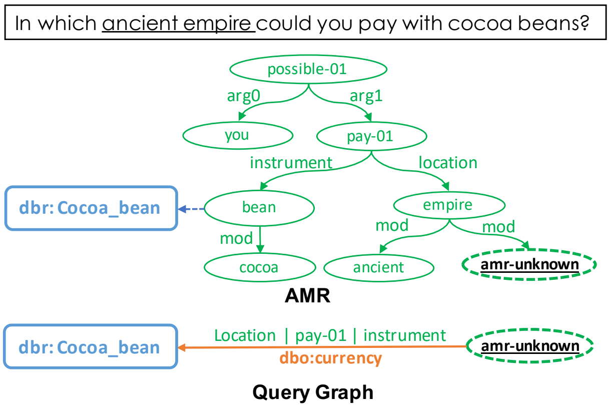

Figure 2: An example of granularity and structural mismatch between AMR and query graphs of the question *In which ancient empire could you pay with cocoa beans?*. The binary relation *dbo:currency* corresponds to the combination of two edges (*location*, *instrument*) and one node (*pay-01*) in the AMR graph.

to the KG entity set. Figure 1 shows an example of both the AMR and query graph for the question "Which actors starred in Spanish movies produced by Benicio del Toro?" Selecting the shortest paths reduces the n-ary predicates of AMR graph to only the relevant binary edges. For instance, the edge *(act-01, arg0, person)* in the AMR graph in Figure 1 will be ignored because it is not in the path between *amr-unknown* and any of the entities *dbr:Spain* and *dbr:Benicio_del_Toro*.

Structural and granularity mismatch between the AMR and query graph occurs when multiple nodes and edges in the AMR graph represent a single relationship in the query graph. This is shown in Figure 2. The path consists of one AMR node and 2 edges between *amr-unknown* and *cocoa bean*: (*amr-unknown*, location, *pay-01*, instrument, *cocoa-bean*)[4]. In such cases, we collapse all nodes that represent predicates (like *pay-01*, *star-01*, etc.) into an edge, and combine it with surrounding edge labels, giving (*location* | *pay-01* | *instrument*). This is done by line 18 of Algorithm 1 where the eventual query graph $\mathcal{Q}$ will have one edge with merged predicated from AMR graph $\mathcal{G}$ between the non-predicates ($\mathcal{A}_\mathcal{C}$).

Returning to the example in Figure 1, Algorithm 1 (line 25) outputs the query graph $\mathcal{Q}$ with the following two paths, which bear structural similarity to the knowledge graph:

Algorithm 1: AMR to triples

```
1  Input : Question text $t$, AMR graph $\mathcal{G} : \langle \mathcal{V}_\mathcal{G}, \mathcal{E}_\mathcal{G} \rangle$
     having a set of nodes $\mathcal{V}_e \in \mathcal{V}_\mathcal{G}$, each linked to a
     named entity in the KG
2  Returns : Query graph $\mathcal{Q} : \langle \mathcal{V}_\mathcal{Q}, \mathcal{E}_\mathcal{Q} \rangle$
   Initialize $\mathcal{Q} : \langle \mathcal{V}_\mathcal{Q}, \mathcal{E}_\mathcal{Q} \rangle, \mathcal{V}_\mathcal{Q} := \{\}, \mathcal{E}_\mathcal{Q} := \{\}$
3  if $t$ is imperative then
4      let source node (imperative predicate) be $r$
5      set $q$ as amr-unknown where
         $edge(r, q, \text{'arg1'}) \in \mathcal{G}_\mathcal{E}$
6      delete $r$ and its edges from $\mathcal{G}$
7  $a :=$ amr-unknown node
8  if $\exists\, b : edge(a, b, \text{'mod'}) \in \mathcal{E}_\mathcal{G}$ then
9      $a := b$
10 for $e$ in $\mathcal{V}_e$ do
11     $amrPath :=$ getShortestPath$(\mathcal{G}, a, e)$
12     let $amrPath$ be $[a, n_1, n_2, ..., n_k]$, where
         $n_k = e$
13     $collapsedPath := [a]$
14     $n' := a$
15     $relBuilder :=$ ‘ ’
16     for $i : 1 \rightarrow k$ do
17         if $n_i \in \mathcal{A}_\mathcal{P}$ then
18             $relBuilder :=$
               $relBuilder +$ getRel$_\mathcal{G}(n', n_i)$
19         else if $n_i \in \mathcal{A}_\mathcal{C}$ then
20             append $n_i$ to $collapsedPath$
21             add node $n'$ to $\mathcal{V}_\mathcal{Q}$
22             add $edge(n', n_i, relBuilder)$ to $\mathcal{E}_\mathcal{Q}$
23             $n' := n_i$
24             $relBuilder :=$ ‘ ’
       end
   end
25 $\mathcal{Q} := doRelLinking(\mathcal{Q})$
26 return $\mathcal{Q}$
```

- `amr-unknown → star-01 → movie → country → Spain`
- `amr-unknown → star-01 → movie → produce-01 → Benicio del Toro`

Note that in the above paths, edge labels reflect the predicates from the AMR graph (*star-01*, *produce-01*, and *mod*). Our next step is to resolve these edge labels to its corresponding relationships from the underlying KG. To do so, we perform relation linking as described below.

Relationship Linking. NSQA uses SemREL (Naseem et al., 2021), a state-of-the-art relation linking system that takes in the question text and AMR predicate as input and returns a ranked list of KG relationships for each triple. The cartesian product of this represents a ranked list of candidate query graphs, and we choose the highest-ranked *valid* query graph (a KG subgraph with unbound variables). As shown in Figure 1, the output of this module produces query graph $\mathcal{Q}$ with *star-01* and *produce-01* mapped to DBpedia rela-

---

[4] Nodes are indicated by boldface, and the rest are edges. For the purposes of path generation, the nodes *amr-unknown* and *empire* are considered equivalent because the *mod* edge is a descriptor in AMR (line 8 in Algorithm 1)

tions *dbo:starring* and *dbo:producer*. This will be the WHERE clause of the final SPARQL query.

2.2.2 Logic Generation

Our query graph can be directly translated to the WHERE clause of the SPARQL. We use existential first order logic (FOL) as an intermediate representation, where the non-logical symbols consist of the binary relations and entities in the KB as well as some additional functions to represent SPARQL query constructs (e.g. COUNT). We use existential FOL instead of directly translating to SPARQL because: (a) it enables the use of any FOL reasoner which we demonstrate in our next Section 2.3; (b) it is compatible with reasoning techniques beyond the scope of typical KBQA, such as temporal and spatial reasoning; (c) it can also be used as a step towards query embedding approaches that can handle incompleteness of knowledge graphs (Ren and Leskovec, 2020; Cohen et al., 2020; Sun et al., 2020). The Query Graph from Section 2 can be written as a conjunction in existential first order logic as shown in Figure 1.

The current logic form supports SPARQL constructs such as SELECT, COUNT, ASK, and SORT which are reflected in the types of questions that our system is able to answer in Table 4. The heuristics to determine these constructs from AMR are as follows:

Query Type: This rule determines if the query will use the ASK or SELECT construct. Boolean questions will have AMR parses that either have no *amr-unknown* variable or have an *amr-unknown* variable connected to a *:polarity* edge (indicating a true/false question). In such cases, the rule returns ASK, otherwise it returns SPARQL.

Target Variable: This rule determines what unbound variable follows a SPARQL statement. As mentioned in Section 2, the *amr-unknown* node represents the missing concept in a question, so it is used as the target variable for the query. The one exception is for questions that have an AMR predicate that is marked as imperative, e.g. in Figure 3 (middle) a question beginning with "Count the awards ..." will have *count-01* marked as imperative. In these cases, the algorithm uses the *arg1* of the imperative predicate as the target variable (see Algorithm 1, line 3).

Sorting: This rule detects the need for sorting by the presence of superlatives and quantities in the query graph prior to relation linking. Superlatives are parsed into AMR with *most* and *least* nodes and quantities are indicated by the PropBank frame *have-degree-91*, whose arguments determine: (1) which variable in $\mathcal{V}$ represents the quantity of interest, and (2) the direction of the sort (ascending or descending).

Counting: This rule determines if the COUNT aggregation function is needed by looking for PropBank frame *count-01* or AMR edge *:quant* connected to *amr-unknown*, indicating that the question seeks a numeric answer. However, questions such as "How many people live in London?" can have *:quant* associated to *amr-unknown* even though the correct query will use *dbo:population* to directly retrieve the numeric answer without the COUNT aggregation function. We therefore exclude the COUNT aggregation function if the KB relation corresponding to *:quant* or *count-01* has a numeric type as its range.

2.3 Reasoner

With the motivation of utilizing modular, generic systems, NSQA uses a First Order Logic, neuro-symbolic reasoner called Logical Neural Networks (LNN) (Riegel et al., 2020). This module currently supports two types of reasoning: type-based, and geographic. Type-based reasoning is used to eliminate queries based on inconsistencies with the type hierarchy in the KB. On the other hand, a question like "Was Natalie Portman born in United States?" requires geographic reasoning because the entities related to *dbo:birthPlace* are generally cities, but the question requires a comparison of countries. This is addressed by manually adding logical axioms to perform the required transitive reasoning for property *dbo:birthPlace*. We wish to emphasize that the intermediate logic and reasoning module allow for NSQA to be extended for such complex reasoning in future work.

3 Experimental Evaluation

The goal of the work is to show the value of AMR as a generic semantic parser on a modular KBQA system. In order to evaluate this, we first perform an end-to-end evaluation of NSQA (Section 3.2). Next, we discuss some qualitative and quantitative results on the value of AMR for different aspects of our KBQA system (Section 3.3). Finally, in support of our modular architecture, we evaluate the individual modules that are used in comparison to other state of the art approaches (Section 3.4).

	Dataset	P	R	F
WDAqua	QALD-9	26.09	26.7	24.99
gAnswer	QALD-9	29.34	**32.68**	29.81
NSQA	QALD-9	**31.89**	32.05	**31.26**
WDAqua	LC-QuAD 1.0	22.00	38.00	28.00
QAMP	LC-QuAD 1.0	25.00	**50.00**	33.00
NSQA	LC-QuAD 1.0	**44.76**	45.82	**44.45**

Table 1: NSQA performance on QALD-9 and LC-QuAD 1.0

3.1 Datasets and Metrics

To evaluate NSQA, we used two standard KBQA datasets on DBpedia.

QALD - 9 (Usbeck et al., 2017) dataset has 408 training and 150 test questions in natural language, from DBpedia version 2016-10. Each question has an associated SPARQL query and gold answer set. Table 4 shows examples of all the question types in the QALD dev set.

LC-QuAD 1.0 (Trivedi et al., 2017) is a dataset with 5,000 questions based on templates and more than 80% of its questions contains two or more relations. Our modules are evaluated against a random sample of 200 questions from the training set. LC-QuAD 1.0 predominantly focuses on the multi-relational questions, aggregation (e.g. COUNT) and simple questions from Table 4.

Dev Set. We also created a randomly chosen development set of 98 QALD-9 and 200 LC-QuAD 1.0 questions for evaluating individual modules.

Metrics. We report performance based on standard precision, recall and F-score metrics for the KBQA system and other modules. For the AMR parser we use the standard Smatch metric (Cai and Knight, 2013).

3.2 End-to-end Evaluation

Baselines: We evaluate NSQA against four systems: GAnswer (Zou et al., 2014), QAmp (Vakulenko et al., 2019), WDAqua-core1 (Diefenbach et al., 2020), and a recent approach by (Liang et al., 2021). GAnswer is a graph data-driven approach and is the state-of-the-art on the QALD dataset. QAmp is another graph-driven approach based on message passing and is the state-of-the-art on LC-QuAD 1.0 dataset. WDAqua-core1 is knowledge base agnostic approach that, to the best of our knowledge, is the only technique that has been evaluated on both QALD-9 and LC-QuAD 1.0 on different versions of DBpedia. Lastly, Liang et al. (Liang et al., 2021) is a recent approach that uses an ensemble of entity and relation linking modules and train a Tree-LSTM model for query ranking.

	AMR3.0	QALD-9	LC-QuAD 1.0
stack-Transformer	80.00	87.91	84.03

Table 2: AMR parsing performance (Smatch) on the AMR3.0 test and QALD-9, LC-QuAD 1.0 dev sets.

Results: Table 1 shows the performance of NSQA compared to state-of-the-art approaches on QALD and LC-QuAD 1.0 datasets. On QALD-9 and LC-QuAD 1.0, NSQA achieves state-of-the-art performance. It outperforms WDAqua and gAnswer on QALD-9. Furthermore, NSQA's performance on LC-QuAD 1.0 significantly outperforms QAmp by 11.45 percentage points on F1.

Due to difference in evaluation setup in Liang et al. (2021), we reevaluated their system on the same setup and metrics as the above systems. Given the test set and the evaluation, (Liang et al., 2021)'s F1 score reduces to 29.2%[5]. We exclude this work from our comparison due to lack of standard evaluation.

3.3 Performance Analysis of AMR

AMR Parsing. We manually created AMRs for the train and dev sets of QALD and LC-QuAD 1.0 questions. The performance of our stack-transformer parser on both of these datasets is shown in Table 2. The parser is trained on the combination of human annotated treebanks and a synthetic AMR corpus. Human annotated treebanks include AMR3.0 and 877 questions sentences (250 QALD train + 627 LC-QuAD 1.0 train sentences) annotated in-house. The synthetic AMR corpus includes 27k sentences obtained by parsing LC-QuAD 1.0 and LC-QuAD 2.0 (Dubey et al., 2019) training sentences, along the lines of (Lee et al., 2020).

AMR-based Query Structure NSQA leverages many of the AMR features to decide on the correct query structure. As shown in Section 2.2.2, NSQA relies on the existence of certain PropBank predicates in the AMR parse such as *have-degree-91*, *count-01*, *amr-unknown* to decide on which SPARQL constructs to add. In addition, the AMR parse determines the structure of the WHERE clause. In Table 3, we show the accuracy of each one of

---

[5] Liang et al. (2021) report an F1 score of 68% on a different subset of LC-QuAD 1.0. They also consider only questions that returns an answer which is a different setup from the rest of the systems.

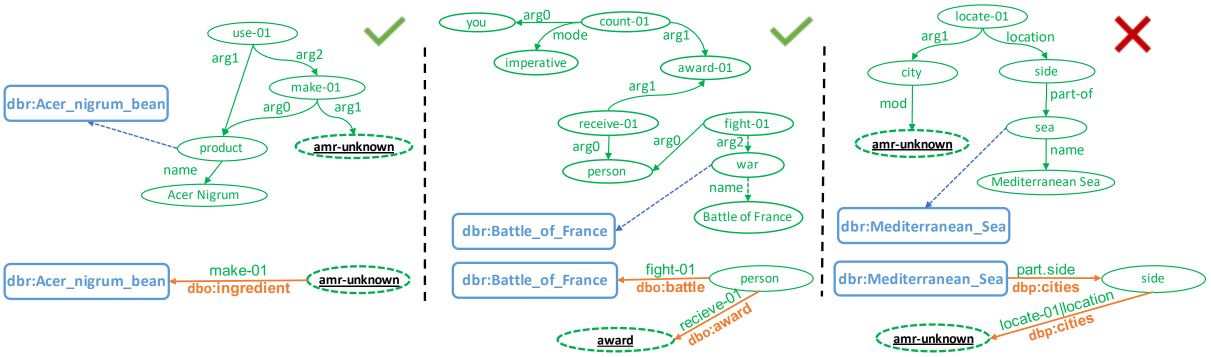

Figure 3: AMR and query graphs for the questions *"Acer nigrum is used in making what?"*, *"Count the awards received by the ones who fought the battle of france?"* and *"What cities are located on the sides of mediterranean sea?"* from LC-QuAD 1.0 dev set

Query Feature	Correct	Total	Correct (%)
SELECT	164	186	88.2
ASK	14	9	64.3
COUNT	25	31	80.6
1-Hop	50	63	79.4
2-Hop	96	137	70.1

Table 3: Query constructs prediction (LC-QuAD 1.0 dev)

these rules on LC-QuAD 1.0 dev dataset. Overall, NSQA identified 64% of ASK (boolean) questions correctly and achieved more than 80% accuracy for COUNT and SELECT questions. Using AMR and the path-based approach, NSQA was able to correctly predict the total number of constraints with comparable accuracies of 79% and 70% for single and two-hops, respectively. NSQA finds the correct query structure for complex questions almost as often as for simple questions, completely independent of the KG.

Figure 3 shows two examples illustrating how AMR lends itself to an intuitive transformation to the correct query graph, as well as a third example where we fail. Here the AMR semantic parse can not be matched to the underlying KG, since 'side' is an extra intermediate variable that leads to an additional constraint in the query graph.

Supported Question Types. Table 4 shows the reasoning and question types supported by NSQA . Our transformation algorithm applied to AMR parses supports simple, multi-relational, count-based, and superlative question types. LNN performs geographic reasoning as well as type-based reasoning to rank candidate logic forms. Addressing comparative and temporal reasoning is a part of our future work.

3.4 Individual Module Evaluation

Entity and Relation Linking. NSQA's EL module (NMD+BLINK) consists of a BERT-based neural mention detection (NMD) network, trained on LC-QuAD 1.0 training dataset comprising of 3,651 questions with manually annotated mentions, paired with an off-the-shelf entity disambiguation model – BLINK (Wu et al., 2019b). We compare the performance of NMD+BLINK approach with Falcon (Sakor et al., 2019) in Table 5. NMD+BLINK performs 24% better on F1 than Falcon (state-of-the-art) on LC-QuAD 1.0 dev set and 3% better on QALD-9 dev set. Similarly, we evaluate Relation Linking on both QALD and LC-QuAD 1.0 dev sets. In particular, we used SemREL (Naseem et al., 2021); state-of-the-art relation linking approach which performs significantly better compared to both Falcon (Sakor et al., 2019) and SLING (Mihindukulasooriya et al., 2020) on various datasets. On LC-QuAD 1.0 dev, SemREL acheives F1 = 0.55 compared to 0.43 by SLING and 0.42 by Falcon. On QALD-9, SemREL achieves 0.54 compared to 0.64 and 0.46 F1 for SLING and Falcon, respectively.

Reasoner. We investigate the effect of using LNN as a reasoner equipped with axioms for type-based and geographic reasoning. We evaluated NSQA's performance under two conditions: (a) with an LNN reasoner with intermediate logic form and (b) with a deterministic translation of query graphs to SPARQL. On LC-QuAD 1.0 dev set, NSQA achieves an F1 score of 40.5 using LNN compared to 37.6 with the deterministic translation to SPARQL. Based on these initial promising results,

Question Type/Reasoning	Example	Supported
Simple	Who is the mayor of Paris	✓
Multi-relational	Give me all actors starring in movies directed by William Shatner.	✓
Count-based	How many theories did Albert Einstein come up with?	✓
Superlative	What is the highest mountain in Italy?	✓
Comparative	Does Breaking Bad have more episodes than Game of Thrones?	
Geographic	Was Natalie Portman born in the United States?	✓
Temporal	When will start [*sic*] the final match of the football world cup 2018?	

Table 4: Question types supported by NSQA , with examples from QALD

	Dataset	P	R	F1
Falcon	QALD-9	0.81	0.83	0.82

we intend to explore more uses of such reasoners for KBQA in the future.

4 Related Work

Early work in KBQA focused mainly on designing parsing algorithms and (synchronous) grammars to semantically parse input questions into KB queries (Zettlemoyer and Collins, 2007; Berant et al., 2013), with a few exceptions from the information extraction perspective that directly rely on relation detection (Yao and Van Durme, 2014; Bast and Haussmann, 2015). All the above approaches train statistical machine learning models based on human-crafted features and the performance is usually limited.

Deep Learning Models. The renaissance of neural models significantly improved the accuracy of KBQA systems (Yu et al., 2017; Wu et al., 2019a). Recently, the trend favors translating the question to its corresponding subgraph in the KG in an end-to-end learnable fashion, to reduce the human efforts and feature engineering. This includes two most commonly adopted directions: (1) embedding-based approaches to make the pipeline end-to-end differentiable (Bordes et al., 2015; Xu et al., 2019); (2) hard-decision approaches that generate a sequence of actions that forms the subgraph (Xu et al., 2018; Bhutani et al., 2019).

On domains with complex questions, like QALD and LC-QuAD, end-to-end approaches with hard-decisions have also been developed. Some have primarily focused on generating SPARQL sketches (Maheshwari et al., 2019; Chen et al., 2020) where they evaluate these sketches (2-hop) by providing gold entities and ignoring the evaluation of selecting target variables or other aggregation functions like sorting and counting. (Zheng and Zhang, 2019) generates the question subgraph via filling the entity and relationship slots of 12 predefined question template. Their performance on these datasets show significant improvement due to the availability of these manually created templates. Having the advantage of predefined templates does not qualify for a common ground to be compared to generic and non-template based approaches such as NSQA, WDAqua, and QAmp.

Graph Driven Approaches. Due to the lack of enough training data for KBQA, several systems adopt a training-free approach. WDAqua (Diefenbach et al., 2017) uses a pure rule-based method to convert a question to its SPARQL query. gAnswer (Zou et al., 2014) uses a graph matching algorithm based on the dependency parse of question and the knowledge graph. QAmp (Vakulenko et al., 2019) is a graph-driven approach that uses message passing over the KG subgraph containing all identified entities/relations where confidence scores get propagated to the nodes corresponding to the correct answers. Finally, (Mazzeo and Zaniolo, 2016) achieved superior performance on QALD-5/6 with a hand-crafted automaton based on human analysis of question templates. A common theme of these approaches, is that the process of learning the subgraph of the question is heavily KG specific, while our approach first delegates the question understanding to KG-independent AMR parsing.

Modular Approaches. Frankenstein (Singh et al., 2018) is a system that emphasize the aspect of reusuability where the system learns weights for each reusuable component conditioned on the questions. They neither focus on any KG-independent parsing (AMR) not their results are comparable to any state of the art approaches. (Liang et al., 2021) propose a modular approach for KBQA that uses an ensemble of phrase mapping techniques and a TreeLSTM-based model for ranking query candidates which requires task specific training data.

5 Discussion

The use of semantic parses such as AMR compared to syntactic dependency parses provides a number of advantages for KBQA systems. First, independent advances in AMR parsing that serve many other purposes can improve the overall performance of the system. For example, on LC-QUAD-1 dev set, a 1.4% performance improvement in AMR Smatch improved the overall system's performance by 1.2%. Recent work also introduces multilingual and domain-specific (biomedical) AMR parsers, which expands the possible domains of application for this work. Second, AMR provides a normalized form of input questions that makes NSQA resilient to subtle changes in input questions with the same meaning. Finally, AMR also transparently handles complex sentence structures such as multi-hop questions or imperative statements.

Nevertheless, the use of AMR semantic parses in NSQA comes with its own set of challenges: 1) Error propagation: Although AMR parsers are very performant (state-of-the-art model achieves an Smatch of over 84%), inter-annotator agreement is only 83% on newswire sentences, as noted in (Banarescu et al., 2013). Accordingly, AMR errors can propagate in NSQA's pipeline and cause errors in generating the correct answer, 2) Granularity mismatch: our proposed path-based AMR transformation is generic and not driven by any domain-specific motivation, but additional adjustments to the algorithm may be needed in new domains due to the different granularity between AMR and SPARQL 3) Optimization mismatch: Smatch, the optimization objective for AMR training, is sub-optimal for KBQA. NSQA requires a particular subset of paths to be correctly extracted, whereas the standard AMR metric Smatch focuses equally on all edge-node triples. We are therefore exploring alternative metrics and how to incorporate them into model training.

6 Conclusion and Future Work

To the best of our knowledge, NSQA is the first system that successfully harnesses a generic semantic parser, particularly AMR, for a KBQA task. Our path-based approach to map AMR to the underlying KG such as DBpedia is first of its kind with promising results in handling compositional queries. NSQA is a modular system where each modules are trained separately for its own task, hence not requiring end-to-end KBQA training. In future, we will explore the potential of the more expressive intermediate logic form with the neuro-symbolic reasoner for KBQA. Particularly, we intend to focus on extending NSQA for temporal reasoning and making it robust to handle incompleteness and inconsistencies in knowledge bases.

On the Gap between Adoption and Understanding in NLP

Abstract

There are some issues with current research trends in NLP that can hamper the free development of scientific research. We identify five of particular concern: 1) the early adoption of methods without sufficient understanding or analysis; 2) the preference for computational methods regardless of risks associated with their limitations; 3) the resulting bias in the papers we publish; 4) the impossibility of re-running some experiments due to their cost; 5) the dangers of unexplainable methods. If these issues are not addressed, we risk a loss of reproducibility, reputability, and subsequently public trust in our field. In this position paper, we outline each of these points and suggest ways forward.

1 Early Adoption

When BERT (Devlin et al., 2019) was introduced in 2019, it revolutionized Natural Language Processing (NLP), showing impressive capabilities on many tasks in various languages (Nozza et al., 2020). However, papers soon highlighted its limits (Ettinger, 2020; Bender and Koller, 2020) and identified issues with bias (Nozza et al., 2021), i.e., that contextual models show different performances for different genders and ethnic groups (Zhang et al., 2020). While Rogers et al. (2020a)'s "BERTology" paper outlines what we know about BERT, much remains unexplored. We do not really know what BERT "understands", but, as Bender and Koller (2020) pointed out, we frequently overestimate its understanding capabilities. E.g., Ettinger (2020) shows that BERT has very low sensitivity to the concept of negation shows. This is not to say that we should stop using BERT; indeed, it is hard to imagine the field today without it. But it does illustrate the *gap between adoption and understanding* (GAU) of a new technology. As the field grows, this situation is likely to play out more frequently, as it is aided by various circumstances.

Early adoption of novel methods and their rigorous testing by the field are a strength of NLP. This approach has propelled insights through cascading waves of novel methods. However, the adoption of new technologies without full awareness of their potential and side effects is a risky proposition. In the 1950s and 1960s, a German pharmaceuticals company aggressively marketed a new drug called "Contergan" to treat sleeping problems as well as morning sickness during pregnancy. The drug had been classified as safe after extensive trials, and was widely prescribed. However, the trials had actually excluded pregnant women, so it was only after its approval that the effects of the drug's main component, thalidomide, became clear: thousands suffered severe birth defects and miscarriages (Criado Perez, 2019).

NLP is not a chemical product, and its effects are not as physically harmful. Using a model that later turns out to be overfitting is not in the same category as failing to protect people from bodily harm. However, it has other consequences. Say researcher A publishes a new result with method X, which becomes the number to beat. Many try and fail, not publishing their results or being ignored. Later, method X is found to be wrong. But the insights that were shelved or ignored in between are lost, unable to unseat method X's false supremacy. Maybe A retracts their initial result, but the damage is done. If others have built on X in the meantime, they will also be affected by its collapse. Imagine for a moment the ripple effects if a central paper like BERT turned out to be wrong. More likely, though, is that A, satisfied with the results of X, simply moves on. The barrier to new, better work remains in place, the faulty method is not identified as such, and instead a method heralded as revolutionary causes stagnation in the field.

Social psychology has struggled with this "win-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3895–3901
August 1–6, 2021.

ner's curse" (Ioannidis, 2008) of unreplicable results. The cause there was the prevalence of false positives that appeared significant, but were just lucky flukes (Ioannidis, 2005). Simmons et al. (2011) found that in many cases, a researcher's decision (conscious or subconscious) had influenced the results. While the causes are different, the resulting issue is the same in NLP.

We will see in the subsequent sections how, counter-intuitively, the GAU creates incentives to publish faster, focus on methods, and drop experiments that do not lead to state-of-the-art results.

A way forward We need to create an environment that makes negative findings and exploration of shortcomings possible, and preferably not just as afterthoughts. Workshops on negative results (Rogers et al., 2020b) and the stress-testing idea of build-it, break-it (Ettinger et al., 2017) are steps in the right direction.

2 Computational Papers

The method-driven nature of NLP makes it necessary to constantly explore new techniques, and the upsides are readily apparent. However, it has also tipped the balance of papers away from introspection and linguistically motivated studies. This development seems rooted in the statistical revolution that began in the 1990s, when method-driven papers outperformed theory-motivated ones. By now, it seems this attitude is very much ingrained in our community, where new models are appreciated more than purely linguistic results. To be fair, purely methodological papers are easier to evaluate objectively. This situation invites two questions, though: (i) Are modeling results more important than linguistics insights? And (ii) should computational papers be evaluated differently?

Norvig (2017) has remarked on the tension between rationalism, which wants models that can be understood, and empiricism, which wants models that work.[1] There is likely always going to be a pendulum swing between these extremes. But to make true progress, we do need both approaches.

While to date no survey has quantified the most popular methods in NLP research, it seems anecdotally that many of the accepted papers at top conferences in the field introduce novel models. Assuming that modeling results are important in our field, we need to understand if we are evaluating these papers in the correct way. This brings up the question of replicability: there has recently been a push to find ways to require authors to share their code and parameters, but this is not enough. Papers often fail to include the complete setup on which they base their models. Even the slightest difference in the setting can bring huge differences in the results: changing between CUDA versions can affect the results on GPU. Moreover, papers' repositories are often incomplete, failing to include the dependencies that would allow others to easy replicate experiments or, worse, containing only poorly documented Jupyter notebooks. Code is a fundamental component of science and should be regarded as such. Code should not just enable researchers to re-run a given experiment, but to apply the same method to other data sets. Bad code is not useful, and the cost of re-implementation, combined with the risk of not being able to get the original results, is often too high to justify the investment of researchers' time. Writing bad code should be akin to writing a bad paper; it does not necessarily make the research wrong, but it makes it less reproducible.

This situation brings up another question: Should authors be responsible for actively maintaining code? Once a new paper is published and the code released, reviewers might ask for comparisons. However, it is common to see repositories on GitHub that have many unanswered questions.

Methodological errors can slow research; as shown by Musgrave et al. (2020), due to methodological flaws in the experiments, the increase of performance in metric learning was wrongly reported in several papers. Moreover, a few hyperparameters can make a huge difference in the results of a given experiment (Ruffinelli et al., 2020). Well-documented methodological design and code make it easier to find bugs and experimental problems. Often systematic evaluations are run to compare different state-of-the-art methods and show that the results are sometimes on par with baselines (Dacrema et al., 2019; Errica et al., 2020).

A way forward Following Bender and Friedman (2018) on providing a data statement, we believe that a code statement similar to that offered by Mitchell et al. (2019) should be provided along with a paper. Code is part of the scientific contribution similar to the experiments we run to prove a hypothesis. While there can be different opinions

---

[1] The empiricist preference can be summed up with statistician George Box's aphorism, "All models are wrong, but some are useful."

on how to write good or bad code, writing documented code that is at least easy to use (with the use of high-level interfaces and convenient wrappers) can be required practice. Moreover, this can be of help in the context of systematic evaluation initiatives like code base that integrate multiple algorithms (Terragni et al., 2021): this process can help in reducing methodological errors in the evaluation. We can cite HuggingFace[2] as a notable example of a repository with good systematicity that has allowed many researchers to replicate most of the recent and popular research in the NLP field. Similarly, Sentence BERT (Reimers and Gurevych, 2019) - a method for sentence embeddings based on BERT - was released with a well organized and easy-to-use source code[3] that made it possible to use the models as a baseline or as the foundation of many other research works (Li et al., 2020; Ke et al., 2020; Zemlyanskiy et al., 2021; Bianchi et al., 2021c,b, inter alia), suggesting that this kind of release can be of great benefit to the community.

3 Publication Bias

Most researchers want to publish in A+ venues and Q1 journals as academic positions use publication output as a criterion for promotions. While quality *should* play into this assessment, it would be wrong to assume university committees are familiar enough with all venues and subfields in a discipline to make an accurate assessment of the relative value of each contribution. So the number of papers and citation count often trump other considerations, especially when publications give universities PR.

Proponents of "slow science" have argued for a shift away from this emphasis on quantity. But while laudable in theory, committing to slowness in practice does not align with the needs of especially junior researchers. They might well prefer less publication pressure, but they can likely not afford the trade-off between a theoretically desirable publication model and losing their job. Given all that, it would be unfair to put the responsibility for addressing the publication bias feeding the GAU on junior scholars. Furthermore, it is not clear what makes a paper worthy of an A+ venue. For NLP conferences, that decision is left to three reviewers and one area chair. Faced with an increasing number of papers to review, reviewers have found themselves with less and less time to make a well-rounded decision on each one. As a consequence, many good papers do not get published.

To keep up with publication demands, authors can 1) make their papers easier to judge based on a quick read or 2) find alternative venues. The former means focusing on a single, easily recognizable contribution—much easier for method papers (see also the previous section). The latter means many authors are now deciding to build the foundation of their publication record by publishing on ArXiv. There is nothing wrong with ArXiv itself. Thanks to it, researchers can make and share valuable contributions with other researchers online. However, ArXiv is a new, and changeable, venue. Keeping the current pace of NLP research, it is bound to also publish models that are biased. So publication records built on ArXiv are set on quicksand and might fall over: the GAU we described previously. While it is encouraging to see that we as a field subsequently work on reducing the bias of those models, we are still allowing anyone to use and deploy those biased models in the meanwhile, contributing to the GAU.

A way forward Short of changing the incentive structure, we can do more to strengthen the review process. Tutorials on reviewing (Cohen et al., 2020) and the implementation of their recommendations would go a long way toward ensuring that we maintain a high standard at a high volume.

4 Computationally Unobtainable

The previous sections have argued that the GAU is a consequence of a strong preference within the field for computational methods, amplified by existing publication bias. But even if all of the solutions we suggested were adopted, there would still be issues that affect reproducibility.

In a panel discussion at EurNLP 2019, Phil Blunsom correctly remarked that "[t]he future of NLP is not about bigger models, it's about bigger ideas."[4] Indeed, there are many arguments against simply making models bigger. However, there is a difference between having the possibility of running a bigger model and not needing it, and needing a bigger model but not having it.

Popular methods like BERT or GPT-3 are now impossible to develop without huge amounts of funding. Developing a new algorithm means run-

---

[2] `huggingface.co`

[3] `https://github.com/UKPLab/sentence-transformers`

[4] `https://twitter.com/glorisonne/status/1182693114672271360`

ning multiple experiments, multiple times, adjusting parameters and configurations. So there is not just the already prohibitive cost of pre-training one BERT model, but the cost of pre-training BERT dozens of times.

Asking authors to provide results by re-training models is too high a cost for many academic researchers. True, other fields have to invest much more money to run experiments. E.g., neurosciences require universities to buy ECG or MEG devices that can cost up to 2 million dollars. On the other hand, those devices are much more consistently reused than a single pre-trained model, so costs are much more distributed.

It is also unclear what constitutes a "bigger" model. Parameter sizes have grown exponentially for the last few years (Bender et al., 2021), and what was considered preposterously large five years ago is now pretty standard. But even old standards are becoming hard to match for universities. This situation creates an unbridgeable gap between industry and academia. Even within those two groups, there are rapidly emerging differences between the players. Only rich universities can afford to re-pre-train models from scratch. Demanding that all actors have access to the same resources would be unreasonable (however desirable). Industry players need to maintain a competitive edge, and we can hardly hope to address the inequality between national academic systems and their funding. But this reality creates a situation where reproducibility becomes impossible. If team A presents results from a model that only team A can train, then the rest of us need to take those results at face value. Whether we believe them or not becomes irrelevant. In addition to this problem, consider the environmental concerns generated by the training of large models (Strubell et al., 2019), and bigger does not necessarily equate better for reproducibility.

Lack of reproducibility, though, is a danger to scientific reliability. The fallout from the reproducibility crisis in social psychology (see Section 4) has tainted the reputation of the entire field. But it has also led to remarkable innovations. Studies now need to be pre-registered to prevent "fishing expeditions" to find the most "interesting" result. International research teams have organized trials to replicate famous experiments—often disproving canonical theories, but also re-opening avenues of research that had been wrongly foreclosed (Collaboration, 2015). And while NLP researchers generally favor reproducibility (Mieskes et al., 2019), we are not yet doing it. Fokkens et al. (2013) already identified five parameters for better reproducibility. A study by Belz et al. (2021), though, found that only 15.61% of 506 papers they checked were independently reproducible. This is in contrast to the high level of data shared in NLP (Mieskes, 2017), which should aid reproduction.

A way forward We need to consider the value as well as the cost of computation in terms of resources, people, and money. If it becomes impossible to replicate some experiments because of those factors, we need to foster computationally-affordable solutions that can be tested by everyone.

5 Unexplainable Methods

A final important issue is the low explainability of our models. This argument recalls the rationalism vs. empiricism debate we mentioned earlier, and is valid for most deep learning models. However, it has recently become more prevalent due to the low effort needed to set up and run these models.

GPT-3 (Brown et al., 2020) made it to the public quickly, most notably as "author" of an auto-generated Guardian article (GPT-3, 2020), which also generated a lot of opinions. The final article was the heavily-edited output of several GPT-3 runs to get a coherent version. So while still not an autonomous contribution, the potential impact that this technology is clear: It has allowed people to create eye-catching, interesting applications that capture the public's imagination. Those creations go beyond natural language. For example, GPT-3 can output HTML and CSS just from an input description of the desired outcome (Szőgyényi, 2020).

So while sensational results are picked up by the media and easily make their way to the general public (GPT-3, 2020), more nuanced comments and limitations of those results tend to be confined to in-domain newsfeeds (Marcus and Davis, 2020; Floridi and Chiriatti, 2020). Indeed, the public is left with the idea that these methods are either a panacea for all problems of the day, or the next step on the path to machine domination. But as scientists, we should realize that sensationalizing what we do comes with great responsibilities.

Easy availability of this technology can bring harm: it is not difficult to imagine the consequences of early access to this kind of technology, like biased auto-generated articles and fake news. However, it is difficult to predict which unwanted outcomes as of yet unknown models could generate. This is not a new argument: face recognition models have already created problems with racial bias, such as identifying images of Black people as "gorillas" (Zhang, 2015).

This point is even more poignant when we realize that different studies have pointed out that GPT-3 is not exhibiting what we as humans would call "intelligence" (Marcus and Davis, 2020; Floridi and Chiriatti, 2020) and have suggested that learning just from text and without including external experience might be a difficult task (Bisk et al., 2020; Bender and Koller, 2020; Bianchi et al., 2021a). Intelligent beings can explain their decisions and reason about their process. But GPT-3 and similar models make (unexplainable) decisions that *look* intelligent. This level of unexplainability hinders the future applications of this technology to areas that crucially depend on post-hoc explanations of the process. E.g., fields like medicine and law.

A way forward This problem does not have a solution – yet. We need to better engage with the media and public to make sure that what comes from our field is not only the great news of spectacular possibilities. It is difficult to also share the limitations: it might bore the public, detract from the undeniable successes, and it requires more effort to explain than simple, glowing success stories. But it is the only way to be sure that everyone has understood the full range of possible outcomes of unexplainable models.

6 Conclusion

We have argued that the current publication model of NLP fosters a gap between adoption and understanding of models, making it easier to meet publication demands with method papers, while shelving more unwieldy studies that include negative results and more epistemological approaches.

This issue is compounded by the rise of ever-larger models, which are unobtainable by all but a few researchers, and make it harder to explain how our methods work. As a result, reproducibility might suffer, and consequently endanger NLP's credibility and the public's trust in the field.

We do not make the argument that these are the only issues that our community has to take care of. For example, environmental sustainability (Strubell et al., 2019) of the models and the possible dual-use problem (Leins et al., 2020) are important topics that require a separate discussion.

Ethical Considerations

The main topic of this paper, reproducibility, is related to issues of ethics in NLP, with respect to fairness and accessibility. With this paper, we hope to contribute to that literature. Our paper does not contain new data sets or methods that pose a potential dual-use or bias problem.

Abstract

With the rapid growth of social media in the past decade, the news are no longer controlled by just a few mainstream sources. Users themselves create large numbers of potentially fictitious rumours, necessitating automated veracity classification systems. Here we present a novel approach towards automatically classifying rumours circulating on Twitter with respect to their veracity. We use a model built on Variational Autoencoder which disentangles the informational content of a tweet from the manner in which the information is written. This is achieved by obtaining latent topic vectors in an adversarial learning setting using the auxiliary task of stance classification. The latent vectors learnt in this way are used to predict rumour veracity, obtaining state-of-the-art accuracy scores on the PHEME dataset.[1]

1 Introduction

Anyone can publish rumours online with the potential to influence and pose as news. Since it is impossible to manually check the vast volume of circulating tweets, there is increasing need for machine learning algorithms to assist with rumour veracity assessment.

Given a rumour of unknown veracity introduced by a tweet in a conversation thread and the responses to it, our goal is to automatically determine the veracity of the rumour by assigning it one of the classes *true*, *false*, or *unverified*. Prior approaches to rumour veracity classification have primarily relied on careful feature engineering. For example, Li et al. (2019a) used meta-features such as user credibility together with more traditional features to top the leaderboard in SemEval 2019 Task 7 (Gorrell et al., 2019). This task encouraged teams to use the stances of responses to the rumour to assist in veracity classification, which has previously been shown to be predictive of rumour veracity (Dungs et al., 2018). A number of approaches (Kochkina et al., 2018; Li et al., 2019b) also showed benefits of using stance classification as an auxiliary task in a multitask learning setup. Some recent approaches exploit the structure of the conversation discussing a rumour. Kochkina et al. (2018) used LSTM to model linear branches extracted from the conversation tree, while Ma et al. (2018) and Bian et al. (2020) modelled a tree structure to capture information from responses.

Zeng et al. (2019) presented an unsupervised approach built on Variational Autoencoder (VAE) to jointly model topic content and discourse behaviour in microblog conversations. We propose a novel architecture which incorporates a VAE with adversarial learning to disentangle topics which are informative for stance classification from those which are not. We then derive tweet representations based on the word representations learned in the latent stance-dependent topic space. Our results show that using such tweet representations for rumour veracity classification achieves superior performance on the PHEME dataset. In summary, we have made the following contributions:

- We have proposed a disentanglement based approach to rumour veracity classification which achieves state-of-the-art performance for classifying rumours from previously unseen events, as they would emerge in real life.
- We have demonstrated that there remains significant overlap between separate rumourous events with distinct vocabularies, facilitating transfer learning between such events.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3902–3908
August 1–6, 2021.

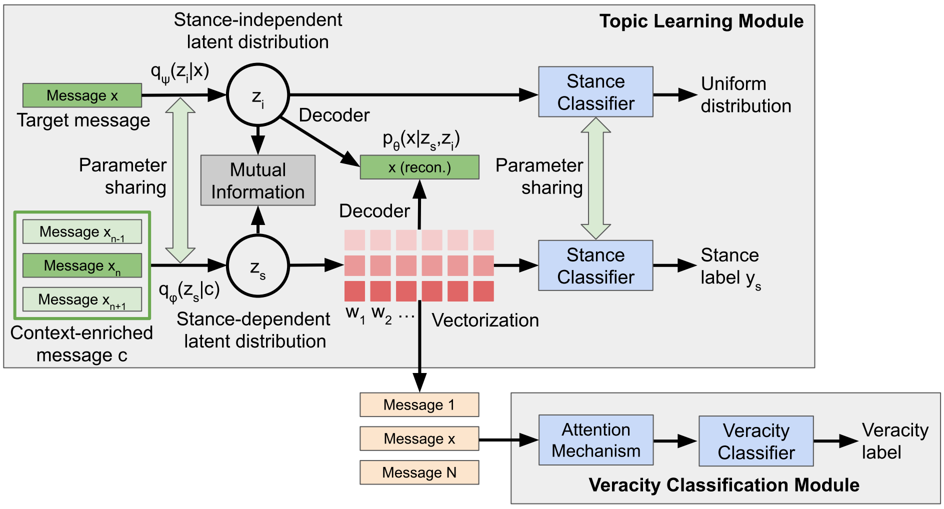

Figure 1: Model Architecture. Note the separate *Topic Learning* and *Veracity Classification* modules, and that the context-enriched message often uses a fixed size window of messages rather than the full conversation.

2 Proposed Model

Our proposed Stance-Augmented VAE Disentanglement framework (SAVED) is shown in Figure 1. It consists of two main modules, the *Topic Learning* module and the *Veracity Classification* module.

The idea is to separate the factual content of twitter rumours from their mannerisms[2], using the latter to predict rumour veracity. This technique is well-suited to rumour veracity prediction for emergent real-life events as it overcomes their factual distinctness - we hypothesise that mannerisms transfer better between different rumourous events. The PHEME dataset is designed for this purpose, with rumours grouped together according to their originating event. In our experiments we use both the source tweet originating the rumour and its conversation thread together since both are useful for veracity prediction.

2.1 Topic Learning

In microblog conversations, a source tweet could have multiple responses, forming a conversation tree. Here we flatten the tree into a chronologically ordered sequence of tweets, defined as $\boldsymbol{d} = \{\boldsymbol{x}_1, \boldsymbol{x}_2, ..., \boldsymbol{x}_N\}$, where N denotes the total number of posts in the conversation. For each message $\boldsymbol{x}_n \in \boldsymbol{d}$, we construct its context-enriched message by taking a window of M messages before and M messages after the target message, denoted as $\boldsymbol{c}_n = \{\boldsymbol{x}_{n-M}, \cdots \boldsymbol{x}_{n-1}, \boldsymbol{x}_n, \boldsymbol{x}_{n+1}, \cdots, \boldsymbol{x}_{n+M}\}$.

Assuming a post $\boldsymbol{x}$[3] is associated with a stance label y and each post can be generated from a stance-dependent latent topic $\boldsymbol{z}_s$ (determined by the context-enriched message $\boldsymbol{c}$) and a stance-independent latent topic $\boldsymbol{z}_i$, we aim to learn a model which maximises the joint data and label log-likelihood, $\log p(\boldsymbol{x}, y)$:

$$\log p(\boldsymbol{x}, y) = \log \int_{\boldsymbol{z}_s} \int_{\boldsymbol{z}_i} p(\boldsymbol{x}, y, \boldsymbol{z}_s, \boldsymbol{z}_i) d\boldsymbol{z}_s d\boldsymbol{z}_i$$
$$\geq E_{q_\phi(\boldsymbol{z}_s|\boldsymbol{c},y),q_\psi(\boldsymbol{z}_i|\boldsymbol{x})}[\log p_\theta(\boldsymbol{x}|\boldsymbol{z}_s, \boldsymbol{z}_i)]$$
$$+ E_{q_\phi(\boldsymbol{z}_s|\boldsymbol{c},y),q_\psi(\boldsymbol{z}_i|\boldsymbol{x})}[\log p_\theta(y|\boldsymbol{z}_s)]$$
$$- KL(q_\phi(\boldsymbol{z}_s|\boldsymbol{c}, y)||p(\boldsymbol{z})) - KL(q_\psi(\boldsymbol{z}_i|\boldsymbol{x})||p(\boldsymbol{z}_i))$$

Following the idea of Zeng et al. (2019), we can compute a variational approximation to an intractable posterior using MLPs. We aim to minimise the reconstruction loss for each context-enriched message $\boldsymbol{c}$ and for each message $\boldsymbol{x}$ (see Figure 1), with a Monte Carlo approximation using L independent samples:

$$\mathcal{L}_{\boldsymbol{c}} \approx \frac{1}{L} \sum_{l=1}^{L} \sum_{n=1}^{N} \log p(c_n|\boldsymbol{z}_s^{(l)}) - KL(q_\phi(\boldsymbol{z}_s|\boldsymbol{c}, y)||p(\boldsymbol{z}_s)) \tag{1}$$

$$\mathcal{L}_{\boldsymbol{x}} \approx \frac{1}{L} \sum_{l=1}^{L} \sum_{n=1}^{N} \log p(x_n|\boldsymbol{z}_s^{(l)}, \boldsymbol{z}_i^{(l)}) - KL(q_\psi(\boldsymbol{z}_i|\boldsymbol{x})||p(\boldsymbol{z}_i)) \tag{2}$$

We assume that the latent stance-independent topics, $\boldsymbol{z}_i$, are independent of stance classes, and hence, when feeding into a stance classifier, should generate a uniform stance class distribution (similar to adversarial learning). On the contrary, the

---

[2] For an example of this, see Figure 5 in (Zeng et al., 2019).

[3] We drop the subscript n for clarity here.

latent stance-dependent, $\boldsymbol{z}_s$, should bear essential information to discriminate between stance classes. Therefore, we can define the following two cross-entropy losses for stance classification:

$$\mathcal{L}_{adv} = -E_{q_\phi(\boldsymbol{z}_i)} \sum_{s=1}^{S} \frac{1}{S} \log p(\hat{y}_s|\boldsymbol{z}_i) \tag{3}$$

$$\mathcal{L}_{stance} = -E_{q_\psi(\boldsymbol{z}_s)} \sum_{s=1}^{S} y_s \log p(\hat{y}_s|\boldsymbol{z}_s) \tag{4}$$

where S is the total number of stance classes, $\frac{1}{S}$ represents the uniform stance class distribution.

To disentangle the latent stance-independent topics, $\boldsymbol{z}_i$, and and latent stance-dependent topics, $\boldsymbol{z}_s$, we minimise the mutual information between them:

$$\mathcal{L}_{MI} = E_{q_\phi(\boldsymbol{z}_i)q_\psi(\boldsymbol{z}_s)} \log \frac{p(\boldsymbol{z}_i, \boldsymbol{z}_s)}{p(\boldsymbol{z}_i)p(\boldsymbol{z}_s)} \tag{5}$$

Our final objective function is:

$$\mathcal{L} = \mathcal{L}_{\boldsymbol{c}} + \mathcal{L}_{\boldsymbol{x}} + \alpha\mathcal{L}_{adv} + \beta\mathcal{L}_{stance} + \gamma\mathcal{L}_{MI} \tag{6}$$

where α, β and γ control the relative contribution of various loss functions.

We exclude the source tweet from this input since it is worded differently from the other tweets and is hence detrimental to overall performance.

2.2 Veracity Module

Once the Topic Learning Module is trained, we use the decoder weights, i.e., weights linking between the stance-dependent latent vector z_s and the bag-of-words representation of the reconstructed message (see the shaded pink blocks in Figure 1) to generate the input to the Veracity Module by deriving a vector for each tweet in the conversation tree - the mean average of the tweet's constituent words. This two-module approach is advantageous since it allows tweets to be weighted based on their position in the (unflattened) conversation tree, and forgoes use of the window of size M employed by the Topic Module. Vectorised tweets are grouped into 3 different importance tiers based on their positions in the conversation tree: the source tweet, direct responses, and all other responses. The rationale for this is in the observation that the later responses in long conversations tend to be less relevant to the verification of the rumour (Zubiaga et al., 2016). The Veracity Module itself consists of an attention layer followed by two dense hidden layers with leaky ReLU activation (Maas et al., 2013). The attention layer learns weights for each of the tweet tiers. The conversation representation is then obtained as a weighted average: $(\boldsymbol{w}_1\boldsymbol{v}_1 + \boldsymbol{w}_2\boldsymbol{v}_2 + \boldsymbol{w}_3\boldsymbol{v}_3)/n$, where $\boldsymbol{w}_t$ denotes the learnable weight for tier $\boldsymbol{t}$, $\boldsymbol{v}_t$ denotes the sum of the vectors of tweets in $\boldsymbol{t}$ and n denotes the number of tweets in the entire tree. In our experiments the presence of these weights increases model performance. We found that the model tends to give the highest weight to the source tweet, followed by direct responses and finally the rest. To mitigate the class imbalance, the loss attributed to instances of each class is weighted inversely to their frequency in the training data.

3 Experimental Setup

Dataset We use the PHEME-5 dataset (Kochkina et al., 2018), which consists of Twitter rumours around 5 high profile real-world events. Statistics regarding the dataset can be found in the Appendix. The PHEME dataset was chosen as it is a particularly challenging dataset due to class imbalance and a leave-one-event out cross validation setting, reflecting a real-world evaluation scenario.

Baseline Models We perform comparison of the proposed model SAVED with existing state-of-the-art models (Kochkina et al., 2018; Li et al., 2019b; Cheng et al., 2020) and several strong baselines, described in this section.

BERT We use the pretrained BERT$_{\text{BASE}}$ (Devlin et al., 2019), uncased, which consists of 12 self-attention layers, and returns a 768-dimension vector representation of a sentence. We generate BERT representations for each tweet in the conversation before feeding them into the Veracity Module.

VAED is a version of SAVED, where the Topic Learning Module is reduced to only its VAE component, without the stance classifiers from Section 2.1. The loss is $\mathcal{L}_{\boldsymbol{c}} + \mathcal{L}_{\boldsymbol{x}} + \gamma\mathcal{L}_{MI}$.

VAED Without Disentanglement (VAE) is a simplified version of VAED, where the Topic Learning Module is reduced to only using loss from the context-enriched latent factor without the target message (disentanglement). The loss is $\mathcal{L}_{\boldsymbol{c}}$.

VAED With Veracity (VAED+V) is an end-to-end classifier based on the Topic Learning Module, in which the context-enriched segment of the VAED z_s is connected to the veracity classifier. This model does not include a stance classifier, nor the adversarial component. The loss is $\mathcal{L}_{\boldsymbol{c}} + \mathcal{L}_{\boldsymbol{x}} + \beta\mathcal{L}_{veracity} + \gamma\mathcal{L}_{MI}$.

Model	False	True	Unverified	Accuracy	MacroF1
Kochkina et al. (2018)	0.212	**0.647**	0.330	0.492	0.396
Cheng et al. (2020)	**0.504**	0.480	0.465	0.521	**0.484**
Li et al. (2019b)	-	-	-	0.483	0.418
BERT Baseline	0.113	0.592	0.326	0.405	0.345
VAE	0.201	0.413	0.407	0.395	0.339
VAED	0.206	0.474	0.388	0.380	0.362
VAED+V	0.273	0.418	0.420	0.389	0.376
SAVED	0.164	0.642	**0.531**	**0.528**	0.434

Table 1: Comparison with baselines and previous results. For comparability, we pool together the results of all five events *before* calculating any F1 scores - the same approach used by the prior work in this table.

Parameter Settings The dimensionality of each latent factor was tuned via grid search, with peak performance found at 10 dimensions for the latent stance-dependent vector, z_s, and 6 dimensions for the latent stance-independent vector, z_i. See Appendix for further details.

Evaluation Metrics For comparability with prior work, F1 scores are calculated *after* combining the results of each fold.

4 Experimental Results

Overall Results The results of our experiments are shown in Table 1. All of the models outperformed the VAE baseline. The VAED model alone (with disentanglement, without any other modifications or stance/veracity classifiers) scores 0.363, showcasing the efficacy of disentanglement *per se*. The BERT-based model only outperformed VAE.

The proposed SAVED model outperforms those of prior work on overall accuracy and the *True* and *Unverified* classes. However, results for the *False* class are rather low - which is in fact the case for most of the models in Table 1, with only Cheng et al. (2020) being an exception. Results of VAED+V are lower than that of SAVED, in line with the knowledge that stance is related to veracity (Dungs et al., 2018). This suggests that stance is also a worthwhile intermediate classification target.

Table 2: Per-fold evaluation results of SAVED.

Per-fold Results Table 2 shows the per-fold results in our leave-one-event-out setting. Interestingly, the model tends to perform best on rumors of *True* veracity and worst on those which are *False*. Performance on the *Unverified* class is adequate, except for the 'Ferguson' event in which the model F1 score is 0.906. Overall, the F1 scores of *True* and *Unverified* classes are rather high (0.642 and 0.531 respectively) compared with that of the *False* class (0.164).

Ablation studies The results of ablation studies are shown in Table 3, which were obtained by varying which latent factor of the Topic Learning Module were fed to the Veracity Module. We found that stance-dependent latent vectors performed better than stance-independent ones for rumour veracity classification, although each performed adequately. Creating an ensemble of both latent vectors was not helpful since the respective models had similar strengths and weaknesses.

Components Used	MacroF1
Stance-dependent	0.434
Stance-independent	0.375
Both together	0.395

Table 3: Varying the latent factor used by the Veracity Classification Module of SAVED.

Visualisation To examine the effectiveness of our conversation tree representations derived from the Topic Learning Module, we visualised the representative vector for each tree using t-SNE (van der Maaten and Hinton, 2008). This was done in the context of the model SAVED (See Sec. 2). Since learned tree-position weights $\boldsymbol{w}_t$ are an important part of generating the representation of the conversation but are not part of the Topic Learning Module, we obtained them from the attention component of the veracity module. Figure 2 depicts the resulting clusters of points, with each cluster roughly corresponding to a class. The "*Unverified*" cluster is particularly distinct. This cluster is largely comprised of tweets from the 'Ferguson' event, which contains most of the unverified rumours in the dataset. This further demonstrates that our Stance-Augmented VAE Model generates representations which are useful for veracity prediction.

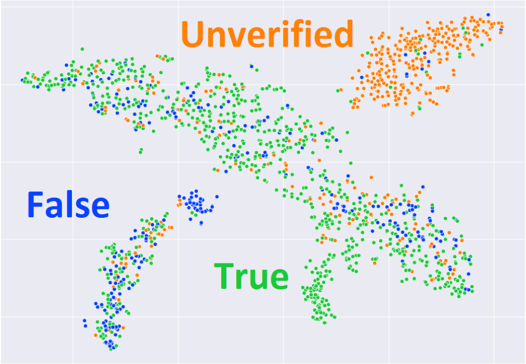

Figure 2: Visualisation of the stance-dependent latent factor for the 'Charlie Hebdo'-excluded fold.

Number of Responses and Performance We investigated how the number of responses to a rumour affect the model's accuracy. Whilst rumours with more responses provide more context for the model, responses too far down the response-tree have been noted to lose some of their relevance to the source rumour. We found the average number of responses for correctly classified rumours from the 'Charlie' fold, where 'Charlie Hebdo' is used as a testing set, to be 14.8 tweets, whilst incorrectly classified ones had an average length 12.2. This seemed stronger for the 'Ferguson' fold with averages of 22.2 and 14.7 respectively (note that the model only observes up to 20 responses per thread).

Using the 2-tailed Mann-Whitney test, these results approach statistical significance (p=0.08 for each fold). If there is an effect here, it can partially be explained by rumours with 3 or fewer responses, since when these were excluded the averages became 17.1 vs 15.4 for 'Charlie' and 25.2 vs 20.2 for 'Ferguson'.

Error Analysis Our model, similar to those of Kochkina et al. (2018) and others but not Cheng et al. (2020), fails to perform well for the *False* class. To our knowledge, this under-performance has not been previously investigated.

The PHEME dataset is imbalanced, containing 1,012 *True*, 393 *False* and *571* Unverified rumours. Although we attempted to account for this imbalance by weighting the model's loss inversely to class frequency, it is possible that the imbalance contributed to the poor performance on *False*. Interestingly more rumours were classified as *Unverified* than as *False*, although there was no clear pattern of misclassification.

The numbers of responses are largely unchanged when restricted to the *False* class alone, with 13.0 (correct) and 10.7 (incorrect) for the 'Charlie' fold, so this does not explain the performance deficit.

Manual investigation of the rumours themselves led to the observation that correctly classified *False* rumours tended to be more straightforward than those which were incorrectly classified. The latter seemed more likely to be vague or contain multiple parts, examples of which can be found in the Appendix. Thus a *False* rumour may contain both false and true statements, potentially lowering the utility of user responses for classification. Accordingly, the model by Cheng et al. (2020) appears to rely less on responses than ours and that of Kochkina et al. (2018).

5 Conclusion

We present a novel disentanglement-based approach to rumour veracity classification, achieving state-of-the-art results for accuracy, towards classification on previously unseen events from the PHEME dataset. Our results suggest that although unique events each have their own vocabulary, there is still sufficient common ground between them for stance-dependent driven rumour veracity classification to be effective.

A Dataset

Table A1 shows the overall statistics of the PHEME dataset. It can be observed that the dataset is highly imbalanced with nearly 50% 'True' instances and relatively few 'False' instances.

Event	#Rumours	#True	#False	#Unverified
Charlie Hebdo	458	193	116	149
Ferguson	284	10	8	266
Germanwings Crash	238	94	111	33
Ottawa Shooting	470	329	72	69
Sydney Siege	522	382	86	54
Total	1972	1012	393	571

Table A1: Dataset (PHEME-5) overview.

B Data Preprocessing

We perform pre-processing on the PHEME data by using special tokens for URLs, username, hashtags, and numbers. We also lowercase text and expand words with apostrophes (e.g., '*we're*' becomes '*we are*'). The Topic-Learning module also excludes words which occur fewer than 20 times throughout the training corpus.

C Model Details

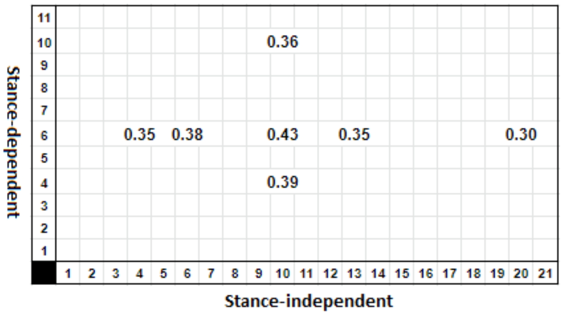

Figure A1: Grid search of the dimensions of the latent stance-dependent and stance-independent vectors.

The Topic-Learning Model has 15M parameters and takes around 6 hours to train on a computer with RTX 1080 Ti. The Veracity Model takes around 15 minutes to train on the same machine. We perform grid search on the dataset to identify the optimal setting of the dimensions of latent stance-dependent and stance-independent vectors, with the dimension of the former varying between 4 and 20, while the dimension of the latter varying between 4 and 10. The results are shown in Figure A1. The veracity classification results are obtained by evaluating on the validation set. It can be observed that the model achieves the best result when the dimension of the latent stance-dependent vector is set to 10 while that of the latent stance-independent vector is set to 6. For further model details, such as layer sizes and activations, the reader is advised to look at the linked source code.

D False Rumour Examples

Note that a rumour being of a certain type (as below) does not guarantee its predicted class or the correctness of its classification.

Abstract

We introduce a novel dataset of human judgments of machine-edited text and initial models of those perceptions. Six machine-editing methods ranging from character swapping to variational autoencoders are applied to collections of English-language social media text and scientific abstracts. The edits are judged in context for detectability and the extent to which they preserve the meaning of the original. Automated measures of semantic similarity and fluency are evaluated individually and combined to produce composite models of human perception. Both meaning preservation and detectability are predicted within 6% of the upper bound of human consensus labeling.

1 Introduction

Machine-editing systems produce new versions of text using text as input. They contribute to tasks such as automatic summarization, simplification, natural language generation and generative adversarial NLP systems. These tasks have communicative goals, for example shorter, more accessible, or more appropriate text, and system developers are encouraged to improve their correlation with human performance on these tasks. While the measured task performance of machine-editing systems continues to improve, one might consider how humans perceive machine-edited text compared to human-produced text. One-off human evaluation of editing systems is expensive, incomparable, and must be constantly repeated. In this work we make first attempts at direct, general-purpose modeling of human perception of these texts and develop a model of human perception as it relates to two goals: to maximally maintain the meaning of an original and be minimally perceptible as machine output.

We present a dataset of human judgments about detectability and meaning preservation for machine-edited text.[1] This dataset consists of 14,400 judgments about contextualized pairs of machine-edited sentences. The original texts are English-language and come from two domains: scientific papers and social media. The edits are created by six different algorithms using a variety of techniques. By comparing trivial editors to more subtle approaches under the same evaluation framework, we move toward generic models of perception of edited text.

Our analysis finds high interannotator agreement and examines human preference among the six machine editors that generated the candidates. Existing measures of similarity and fluency are evaluated as models of perception. We find that reference-informed models come close to human consensus of meaning preservation and detectability. However, language models that don't have access to the reference text have less success as generic models of detection. This dataset and analysis constitute a step toward modeling meaning preservation and detectability under a variety of machine-editing conditions representative of the state of the practice.

2 Background

Machine editing is a component of multiple tasks that balance meaning preservation and fluency differently.

2.1 Machine-Editing Tasks

Text simplification (Saggion, 2017) and summarization (Narayan et al., 2018) produce new versions of text that are simpler or shorter, intended to be useful to a human reader. Evaluation measures informativeness relative to a reference. Abstractive techniques that fully rewrite the text have recently

become viable alternatives to extractive techniques that build new texts from portions of the original text.

Paraphrase generation is the task of producing semantically equivalent variants of a sentence and can underlie applications like question answering and data augmentation. Recent approaches include a component that generates alternatives and a component that estimates their quality as paraphrase (Li et al., 2018; Kumar et al., 2020).

Natural language watermarking of text (Venugopal et al., 2011) and text steganography (Wilson et al., 2014) are conditional text generation practices that require both a meaningful surface form and the hidden encoding of additional information. In this case, it's essential that the text appear plausible as readers should not suspect the encoded information (Wilson et al., 2015).

Edited texts are used in adversarial learning and attacks for text processing systems. Adversarial inputs change a system output without altering some relevant aspect of human perception of the text, e.g. sentiment when attacking a sentiment analysis system (Alzantot et al., 2018). In cases of adversarial learning, where edited texts are used only to promote system robustness, human perception is not a concern (Jia and Liang, 2017). In contrast, adversarial attack vectors rely on human perception of the attack, whether it be communicating meaning regardless of detectability (Eger et al., 2019) or guaranteeing fluency (Zhang et al., 2019a). While authors have quantified the effect of adversarial perturbations on metrics of text quality like word modification rate and count of grammatical errors (Zeng et al., 2020), the relation of these automatic metrics to human perception is not yet studied.

2.2 Meaning Preservation

Machine editing often aims to guarantee semantic similarity or *meaning preservation* between input and output. Meaning preservation can be insensitive to surface forms such as tokenization, casefolding, stylistic variation in punctuation, spacing, font choice, and tense. Compact text representations (e.g. Morse code) tend to regularize all potential surface forms.

Semantic textual similarity and paraphrase identification are active areas of investigation in the NLP community (Cer et al., 2017). Natural language inference (NLI) also relies on notions of semantic similarity to recognize a larger set of relations between texts (Bowman et al., 2015). These subfields of NLP investigate semantic relatedness between *human-authored* texts.

Meaning preservation is related to the concept of *informativeness* used in automatic summarization and *adequacy* for machine translation. Summarization metrics tend to lean toward recall to make sure the central concepts of reference summaries are produced and MT metrics tend to lean toward precision to penalize systems that generate something outside of the references.

Many adversarial text editors don't require strict paraphrase, but simply that their perturbations not change the input's classification to a human reader (Ren et al., 2019; Lei et al., 2019; Alzantot et al., 2018; Ebrahimi et al., 2018). Other authors ask judges about similarity to the unperturbed original (Zhao et al., 2018; Alzantot et al., 2018; Ribeiro et al., 2018; Jin et al., 2020). New work correlates automatic metrics with human judgments capturing both semantic similarity and fluency about three word- and character-swapping algorithms (Michel et al., 2019).

2.3 Detectability

Language models were introduced early in both automatic speech recognition (Bahl et al., 1983) and statistical machine translation (Brown et al., 1990) to make output text more readable. They aimed to avoid decoding results that appeared computer-generated.

Recent work in several natural language generation tasks augments automatic evaluation, which approximates informativeness, with one-off human evaluations that estimate text quality. Authors elicit judgment for abstractive summaries about readability (Paulus et al., 2018), fluency (Hardy and Vlachos, 2018), and preference between human and machine-written abstracts (Fan et al., 2018). Desai et al. (2020) elicit human judgements of grammaticality for a compressive summarization system that deletes plausible spans. In image captioning and dialogue systems, several learned metrics judge system output to be higher quality when it is less distinguishable from human text (Cui et al., 2018; Lowe et al., 2017)

Several methods of generating adversarial text have been evaluated through surveys of human perception, for example by asking humans to detect the location of machine edits (Liang et al., 2018), or to judge the likelihood that a sentence is mod-

	arxiv	reddit

Table 1: Dataset size in words.

Which better preserves the meaning of the reference?

Reference: Later on that day I emailed the company that I purchased my order from and they confirmed it was delivered to that address.
A. Later that day I emailed the company I bought my order, and they confirmed that was delivered to that address.
B. Later in that time i received the website and i sent my email from what it said it was delivered for customer address.

Location: Florida I didn't know what to flair. About a month ago a package I ordered was delivered to my old apartment complex. When I went to the front office to ask if a package with my name was turned in they said no such thing had occurred. ________ I don't know how to move forward from this.

Which sentence reads more like it was altered by a machine?

A. When thi applied voltage is ifcreased to a few mV we find a strong declease of the spin injection efficiency.
B. While the required voltage is required to a tunnel voltage to obtain a lower amount of the joule injection injection.

Semiconductor spintronics will need to control spin injection phenomena in the non-linear regime. In order to study these effects we have performed spin injection measurements from a dilute magnetic semiconductor [(Zn,Be,Mn)Se] into nonmagnetic (Zn,Be)Se at elevated bias. ________ The observed behavior is modelled by extending the charge-imbalance model for spin injection to include band bending and charge accumulation at the interface of the two compounds. We find that the observed effects can be attributed to repopulation of the minority spin level in the magnetic semiconductor.

Figure 1: Sample prompts from the meaning preservation task on Reddit (top) and the detection task on ArXiv (bottom.)

ified by a machine (Ren et al., 2019) or written by a human (Lei et al., 2019). Other authors ask human annotators about proxies like grammaticality (Jin et al., 2020), fluency (Zhang et al., 2019b) or readability (Hsieh et al., 2019) as a proxy for detectability.

Far more work asks whether computers can detect machine-edited text. Research on text generated with large language models finds that the output is easy to detect automatically because of the probabilities of the particular language model itself (Adelani et al., 2020; Gehrmann et al., 2019; Zellers et al., 2019). In fact, the generation setting that best fools humans produces output that is easy to detect automatically (Ippolito et al., 2020). This suggests human perception of such edits is different from machine detection.

Detectability and meaning preservation are not independent variables, but they represent different aspects of human perception. Destroying the fluency of a text can make it detectable as an edit in a high quality research document, but rewriting a section of chat in standard English can make it detectable in context. One can often transpose digits in scientific measurements to indetectably destroy meaning, and one could rewrite an abstract in randomized case patterns to raise suspicion without altering meaning.

3 Methods

3.1 Dataset Construction

We present a dataset of human judgments about two tasks, meaning preservation and detection, in each of two domains, social media and science writing. For each task and domain, we distributed packets of 600 multiple-choice questions to six judges. Each question was an AB test for a pair of editing systems both operating on a sentence in context. The first 105 questions of each packet were the same for all judges and are used to measure interannotator agreement. The remaining 495 sentences were the same, but the pairs of systems compared by judges varied. The judges were all native English speakers who work in AI research and were unfamiliar with the processes used to edit the original text.

Source sentences for the ArXiv dataset were randomly selected from all sentences in ArXiv abstracts submitted between its start in 1991 and the end of January, 2018. The Reddit sentences were randomly selected from all sentences in Reddit posts made in January, 2018. The two source collections were roughly the same size. Sentences less than 10 tokens or longer than 40 tokens were avoided in both collections to ensure judge productivity. To satisfy IRB and to minimize the likelihood of negative effects on judges, we excluded all posts from the subreddits listed on the official *nsfw* list, and any that were no longer reachable by September 2019. Table 1 describes statistics about the sentences selected for editing and the contexts provided for judges.

The meaning preservation task involved AB judgments on six different editing systems. For the detection task, we included the original texts among the edited variants for a total of seven systems. We refer to this as the `null` editor. An all-pairs design of six systems requires 15 pairs and an all-pairs design of seven systems requires 21 pairs. Both designs were iterated to yield 600 pairs of system variants, truncating the final seven system pattern early. The first 105 example editing pairs (seven full all-pairs sets for meaning and five for detection) were identical for all judges and the remaining 495 in each packet were chosen from the possible pairs according to *independent permutations* to encourage balance.

This can be described again for more clarity. $C(6,2) = 15$ (meaning preservation) and $C(7,2) = 21$ (detectability). 600 examples lines up perfectly with a 15-item boundary but not with a 210 item boundary. Thus, there are 12 examples left over from a complete set of all-pairs of 7 systems in detectability when truncating to 600 items per source per judge. The first 105 system pair assignments come from 7 cycles through $C(6,2)$ pairs or 5 cycles through $C(7,2)$. The remaining sequences of pairs for each judge are all-pairs cycles through independently randomized permutations of the systems. Machine edit assignment to positions A and B were independently shuffled for each judge and the questions were presented to each judge in randomly shuffled order. Judges were instructed to choose between the two alternatives.

Each item was presented as a choice between two edited versions of the same sentence, presented with the rest of the Reddit post or ArXiv abstract as context. Figure 1 shows examples and the specific prompts used to elicit judgments. In the meaning preservation example, the candidates were produced by round-trip machine translation and the VAE. In the detection example, the candidates were produced by charswap and the VAE. Cases where detection paired the `null` system against a machine editor were collected to determine how often each editor was preferred to the original.

Less than half of one percent of detectability items are automatically marked as ties. These include cases where the edited text is the same string as the original, disregarding casing and punctuation, or where the VIPER editor (described below) produced an alternative that rendered identically in packets. These are included in the analysis to capture the intuition that a perceptual model should score ties the same.

3.2 Machine-Editing Systems

We employ six editing systems to capture the effect that varied systems have on human perception. Each takes just the sentence to be edited, without context.

3.2.1 Swapping editors

Simple word- and character-swapping editors are prevalent in literature about adversarial attacks and data augmentation (Michel et al., 2019). Our **charswap** editor is inspired by several works in adversarial NLP that examine character swapping as a minimal change to text inputs that can degrade system performance (Belinkov and Bisk, 2018; Ebrahimi et al., 2018). Our implementation randomly swaps 1 to 3 lower-case ASCII characters per input for other ASCII characters, selecting the least likely of 100 alternatives under the GPT-2 language model (Radford et al., 2019).

VIPER is a character-swapping algorithm informed by visual closeness, inspired by a common strategy used to avoid keyword filters, for example in online forums Eger et al. (2019). The VIPER algorithm replaces random characters with their nearest neighbors among embeddings based on their glyph e.g. l→1 and 0→O. We further bias the open source implementation toward visual closeness by randomly swapping between 1 and 3 characters, with the probability of each swap weighted by its visual similarity.

The **AddCos** system uses word embedding distance to replace a single word with a paraphrase. The algorithm is adapted from a machine translation metric that measures the fit of words that are not in a reference, using the cosine similarity of the proposed replacement and the sum of vectors for sentence context (Apidianaki et al., 2018). We adapt the open source implementation as a machine editor, obtaining candidate replacements from the Penn Paraphrase Database (Ganitkevitch et al., 2013) and selecting the one best replacement.

3.2.2 Rewriting editors

Machine translation (MT) has recently become reliable and on-par with human translation capabilities in some cases (Bojar et al., 2018). We utilized **round trip MT** (from source English text to another language and then back) as a type of text editor. Three of the authors performed a blind assessment of approximately one hundred candidate languages available from an online MT provider and determined that $en \rightarrow pt \rightarrow en$ is a high-quality round trip route.

A **variational autoencoder (VAE)** learns a semantically meaningful latent space. We use an implementation[2] based on the model of Zhang et al. (2017) to train a VAE for each domain with 200,000 sequences of up to 40 tokens. Edits are obtained by encoding an original sentence and sampling from the latent distribution.

Syntactically controlled paraphrase networks (SCPNs) encode sentences and decode them according to a target constituency parse (Iyyer et al., 2018). Unlike swapping editors, this system introduces syntactic variation. Using the open source code and default templates, we generate ten paraphrases per sentence. We select the paraphrase with the best GPT-2 language model score.

3.3 Modeling Human Perception

We evaluate a set of automatic metrics as models of human perception. To test a metric as a model of the collected judgments, the metric scores each edited sentence and chooses the item in the pair with the better score. The choice is compared to the judge's preference.

In addition, we learn a combination system that scores sentences by weighting each component metric. One combination is learned for each task, using the data from both domains. The data is split into a training set of 80% used for fitting the combination, a validation set of 10% and a final test set of 10% of examples. For items repeated among judges, all six instances are assigned to the same partition.

Our objective function, maximizing agreement on AB tests, is neither continuous, smooth, nor particularly amenable to a logistic transform. We search for our mixture parameters using the Dlib `MaxLIPO+TR` Lipschitz function and trust region search algorithm (King, 2009). The model is optimized to minimize the errors in the training set with an L1 regularization term. A best combination is selected using forward feature selection and validation set accuracy.

4 Experiments

We examine text similarity and fluency metrics that originate from several tasks in NLP as possible models of human perception. We first present the portfolio of metrics we use.

4.1 Measures of Meaning Preservation

Levenshtein edit distance measures the minimum number of character operations needed to change one string into another (Levenshtein, 1966). We compute both the classical Levenshtein distance over *character* edits and *word* edits (WER).

NLP Task Metrics. We evaluated several metrics used to measure the quality of NLP system output compared to a human reference for tasks including machine translation, summarization, and image captioning. **BLEU** is a machine translation evaluation method based on word n-gram precision, with a brevity penalty (Papineni et al., 2002). The **METEOR** metric uses stemming and WordNet synsets to characterize acceptable synonymy in translation (Banerjee and Lavie, 2005). **CIDEr** also uses stemming and incorporates importance weighting for ngrams based on corpus frequency (Vedantam et al., 2015). The **ROUGE-L** metric, used in summarization and image captioning, is based on longest common subsequence between a reference and hypothesis (Lin, 2004). **ChrF** and variants like chrF++ compare bags of character and ngram substrings to capture sub-word similarity without language-specific resources (Popović, 2016, 2017). The **BEER** metric is trained to correlate with human judgment at a sentence level using features like character n-grams and permutation trees that are less sparse at that level (Stanojević and Sima'an, 2014).

Neural Network-based Similarities. Recent work uses trained, neural-network vector representations to quantify semantic similarity. We experiment with three based on BERT, a neural network trained on Wikipedia and the Google Books Corpus (Devlin et al., 2019). **BERTScore** computes an F1-based similarity score between the contextual embeddings for subword tokens in a candidate and reference sentence (Zhang et al., 2020). The metric can also be computed as **RoBERTaScore** using weights from RoBERTa pretraining (Liu et al., 2019). **BLEURT** fine tunes BERT to predict sentence-level machine translation quality scores (Sellam et al., 2020). **Sentence-BERT** measures similarity using a model finetuned with a paraphrase objective to create semantically meaningful sentence vectors that can be directly compared (Reimers and Gurevych, 2019).

Table 2: Probability that system wins in A/B test or is preferred to original. Rows are sorted by first column.

4.2 Measures of Detectability

Detectability is a property of text in context, without regard for a reference. We evaluate language model scores, which measure fluency, as proxies for detectability.

We evaluate a **Kneser-Ney 5-gram** language model trained on a full English Wikipedia dump (Wikipedia contributors, 2020) with KenLM (Heafield, 2011). We estimate the model using modified Kneser-Ney smoothing without pruning. We also evaluate the language model score given by **GPT-2**, a large neural transformer-based language model trained on 8 million web pages (Radford et al., 2019). We use the technique described in Salazar et al. (2020) to obtain a **BERT Masked Language Model (MLM)** that accounts for the model's self-attention. We compute each language model score under two conditions: using only the edited sentence, and including one sentence before and after the edited sentence (*+context*).

Predictions from **BERT's Next Sentence Prediction (NSP)** task estimate the likelihood for a sequence of sentences. This classifier is trained to discriminate sequences of two sentences found in the pretraining corpus from sequences drawn using negative sampling (Devlin et al., 2019).

5 Results

Table 2 illustrates the relative success of the machine-editing systems. Success is measured using the number of A/B tests where an edit by the system was selected (for meaning) or the other item selected (for detectability), divided by the number of prompts involving the editor. *Preference* refers to only the portion of the detectability dataset where the edited text is compared to the original. The swapping algorithms are most often chosen as preserving meaning. The visual perturbations of VIPER have little effect on perception of meaning. The preference for these editors is not as strong on detectability items. For both tasks, the round-trip machine translation model is preferred in slightly over half of comparisons, while the VAE and SCPN perform quite poorly. One substantial difference in these conditional generation algorithms may be that MT is trained on web-scale data, while the others are trained in-house with relatively small datasets.

Among detectability items, human judges prefer an edited version over the original (`null` system) 4.9% of the time, 101 of 2054 relevant judgments. These prompts most commonly include the round trip machine translation editor, but all editing systems were preferred over the original at least once. Round-trip machine translation is picked over the original reference 20% of the time in ArXiv and 10% of the time in Reddit, suggesting that these outputs are more fluent or more typical for the domain than the original. For these items, the character swapping algorithms are most detectable.

5.1 Annotator Consistency

One hundred five prompts per task were presented to all judges to measure interannotator agreement. As judgments are made between constructed, randomized flips and pairwise tests, we compare to the raw prior of 50% agreement. For ArXiv, the probability of agreement among pairs of judges was 82.2% for meaning and 75.6% for detection. For Reddit, the probabilities were 86.7% and 75.9% respectively. The lower interannotator agreement in the science and technology domain may reflect lower familiarity with the subjects of the abstracts.

A consensus vote is determined by a plurality of the six judges, or randomly in cases of ties. The probability of agreement of a random judge with the consensus is reported in Table 3 as an upper bound for the performance of automatic systems.

5.2 Correspondence of Metrics with Human Judgment

Table 3 shows the correspondence of the best metrics with the 630 multiply-annotated prompts and includes the upper bound of human consensus. The table shows only metrics with accuracy within five items of the best. Table 4 shows agreement with the entire dataset and over the full set of systems tested. The meaning metrics are also evaluated as measures of detectability. At editing time, they can be used to estimate the detectability of a candidate edit. However, they are not practical as generic

Table 7: Components in the detect and meaning combo systems ranked by influence ($\sigma|w|$).

detection models sniffing out machine edits in the wild where no original is available.

Several automatic metrics show good correspondence with meaning. The best systems include large, neural models intended to capture subtle synonymy as well as simple metrics like chrF. In general, the recall component of BERTScore-based metrics correlates better than the precision component. Though the BLEURT metric is trained to predict human judgements of translation quality, it seems a poor fit for perceptions of meaning preservation in our dataset.

Applied to the detection task, the reference-informed metrics also approach the upper bound of human consensus. Using RoBERTaScore as a single model of both meaning preservation and detectability reaches over 81% agreement with consensus.

The language model metrics fall behind in performance on detection but still perform well above the level of chance. We find that including additional context improves performance for the same system and the large, neural models greatly outperform the traditional 5-gram model. Across the board, models with RoBERTa training perform better than their BERT-based counterparts.

Table 5 shows performance for predicting the detection items for which the judge preferred the edited text to the original. A baseline system that always selects the original gets around 95% accuracy, but cannot identify an edited text that a human accepts as a substitute. All of the detection systems tested were able to identify some substitutable edits. The best overall are large language models with context, reaching 0.241 F1.

As shown in Table 6, learned combinations of metrics are able to achieve better performance than the single best metric for each task. The components of those systems are specified in Table 7, sorted by their importance in the combination as calculated by the product of the standard deviation of their values (σ) and the magnitude of their weights (w).

6 Conclusion

We introduced a novel dataset of human judgments of machine-edited texts and initial models of those perceptions. A portfolio of automated metrics was assessed for the ability to predict judges' preferences on meaning preservation and detectability. Automated measures of semantic similarity and fluency were evaluated individually and combined to produce factored models of human perception. Both meaning preservation and detectability are modeled within 6% accuracy of the upper bound of human consensus labeling. However, we observe that existing metrics poorly predict whether humans find an edited text to appear more human-like than the original.

Future work could explore deeper models and other factors of human perception not modeled by the metrics present here. For example, humans are sensitive to capitalization and correct spacing but many automatic metrics perform tokenization and normalization. Direct modeling of human perception drives understanding of human factors involving text variation. Adaptive models of human text perception would enable text editing to target understanding by individual readers.

Abstract

State of the art end-to-end coreference resolution models use expensive span representations and antecedent prediction mechanisms. These approaches are expensive both in terms of their memory requirements as well as compute time, and are particularly ill-suited for long documents. In this paper, we propose an approximation to end-to-end models which scales gracefully to documents of any length. Replacing span representations with token representations, we reduce the time/memory complexity via token windows and nearest neighbor sparsification methods for more efficient antecedent prediction. We show our approach's resulting reduction of training and inference time compared to state-of-the-art methods with only a minimal loss in accuracy.

1 Introduction

Recent advances in coreference resolution (Lee et al., 2018; Joshi et al., 2019, 2020; Wu et al., 2020) have been largely based on the end-to-end model proposed by Lee et al. (2017). However, these models are costly both in terms of training and inference time, as well as memory requirements, especially for long documents. The large computational cost makes the models infeasible to run for a typical user on large document collections in domains such as blogs, stories, books, etc. Moreover, a reduction in energy use of these models can be of benefit to cloud service providers' costs and there can also be environmental benefits (Strubell et al., 2019; Schwartz et al., 2020).

There are two main computational bottlenecks in using end-to-end coreference models on long documents: (i) span and span-pair representations for all spans in the document are simultaneously considered, and (ii) the coreference decision for a mention requires considering all candidate antecedent spans.

In this paper, we propose an approximation to the end-to-end coreference model (Lee et al., 2017) that scales to long documents by addressing both these bottlenecks. Our proposed approach operates at the token level instead of the span level, removing the quadratic dependence on the number of mention spans in a document and addressing bottleneck (i). We propose token level scoring functions for the bilinear inference model originally proposed by Lee et al. (2018). To address bottleneck (ii), we use token windows, token-level k-nearest neighbor relationships along with low-rank matrix approximations of the token similarity matrix thereby improving time/memory efficiency. We also propose an approach to drop token representations from memory to reduce memory requirements while still maintaining the accuracy.

We evaluate our approach on three coreference datasets: CoNLL-2012 (Pradhan et al., 2012), Litbank (Bamman et al., 2019), and MedMentions (Mohan and Li, 2019) and observe competitive accuracy to state of the art coreference models based on end-to-end training while achieving both faster training and inference running times. Our approach is also more memory efficient and up to 10x faster than the recently proposed memory-based incremental coreference resolution model on Litbank (Toshniwal et al., 2020b). Finally, we demonstrate the scalability of our approach by running it on a novel of two million tokens in 14 minutes while requiring just 12GB of GPU RAM, while previous work can only scale to documents of just around eleven thousand tokens even with up to 48GB of GPU RAM.

Concurrent to our work, Kirstain et al. (2021) also proposes a bilinear token level scoring function for coreference. The focus of our work however

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3921–3931
August 1–6, 2021.

is on long documents and we further introduce a token k-nn graph approximation, a low-rank matrix factorization and an approach to drop non essential candidate antecedents to improve mem/time scalablity.

2 Background: End-to-end Within-Document Coreference

End-to-end within-document coreference resolution models jointly discover a set of mentions, $\mathcal{M}$ in a document $\mathcal{D}$ and determine which of the mentions are coreferent. We use $\mathcal{D}$ to refer to the ordered set of tokens in the document $\mathcal{D} = \{x_1, x_2, \dots, x_T\}$. Each mention is a token span $s = x_i, \dots, x_j$[1]. We use $\boldsymbol{x}_i$ to refer to the contextualized embedding of the token i (see Section 4.1 for more details on the encoder). The model comprises of two parts which are jointly trained: (a) a mention-proposer, and (b) an antecedent-predictor. The mention-proposer model evaluates all spans $\mathcal{S}$ in the dataset and proposes a small set of potential mentions $\mathcal{M} \subset \mathcal{S}$. The antecedent prediction model evaluates the mentions suggested by the mention proposer and produces coreference clusters (chains) $\mathcal{C} \subset \mathcal{P}(\mathcal{M})$, where $\mathcal{P}(\cdot)$ is the powerset.

Recent work (Lee et al., 2018; Joshi et al., 2020; Xu and Choi, 2020, inter alia) has built upon the first neural, end-to-end coreference model (Lee et al., 2017). Each of these models introduce two scoring functions $\mathsf{s}_{\mathsf{m}}(s)$ and $\mathsf{s}_{\mathsf{a}}(m_1, m_2)$. $\mathsf{s}_{\mathsf{m}}(s)$ represents the scores that a span s is a mention, and $\mathsf{s}_{\mathsf{a}}(m_1, m_2)$ is the score for mention m_1 being an antecedent of mention m_2. These scoring functions are used to define the joint mention proposal and antecedent prediction model for coreference.

Mention proposer: The previous works use a neural network for $\mathsf{s}_{\mathsf{m}} : \mathcal{S} \to \mathbb{R}$. The architecture takes in a mention span and outputs a score. For each mention span s, the model computes a vector representation $\boldsymbol{g}_s \in \mathbb{R}^d$. The scoring functions take these vector representations as input:

$$\mathsf{s}_{\mathsf{m}}(s) = \boldsymbol{w}_{\mathrm{m}} \cdot \mathrm{FFNN}_{\mathrm{m}}(\boldsymbol{g}_s) \tag{1}$$

and $\boldsymbol{g}_s$ is computed as:

$$\boldsymbol{g}_s = [\boldsymbol{x}_{\mathrm{START}(s)}, \boldsymbol{x}_{\mathrm{END}(s)}, \hat{\boldsymbol{x}}_s, \phi(s)] \tag{2}$$

where $\boldsymbol{x}_{\mathrm{START}(s)}, \boldsymbol{x}_{\mathrm{END}(s)}$ are the boundary representations of span s, $\hat{\boldsymbol{x}}_s$ is a self-attention representation of span s, and $\phi(s)$ encodes the width (number of tokens) of span s. For efficiency, the model selects top $0.4T$ scoring mention spans where T is the number of tokens of the document. We refer to this set of selected mention spans as $\mathcal{M}$. We use an ordering of the mentions $m \in \mathcal{M}$ based on their start/end offsets.

Antecedent Prediction: Previous work has explored several models for antecedent prediction. The most computationally efficient being a bilinear scoring model (Lee et al., 2018):

$$\mathsf{s}^{\mathsf{bi}}_{\mathsf{a}}(m_1, m_2) = \mathbf{g}_{s_{m_1}} W^T \mathbf{g}_{s_{m_2}} \tag{3}$$

Higher-order inference models, which use deep models to capture coreference relationships between mentions, have also been considered (Lee et al., 2018). For example,

$$\mathsf{s}^{\mathsf{hoi}}_{\mathsf{a}}(m_1, m_2) = \boldsymbol{w}_{\mathrm{a}} \cdot \mathrm{FFNN}_{\mathrm{a}}([\boldsymbol{g}_{m_1}; \boldsymbol{g}_{m_2}; \quad \boldsymbol{g}_{m_1} \odot \boldsymbol{g}_{m_2}, \phi_{m_1,m_2}]) \tag{4}$$

We refer the reader to Xu and Choi (2020) for a detailed analysis of higher order inference models.

The prediction of the antecedent of each mention, which we refer to as *inference*, is done by *backwards chaining*. Clusters of mentions are determined by finding for each mention, the highest scoring antecedent among the mentions appearing earlier in the document and adding the mention to the antecedent's cluster. This can be described as finding the connected components of a graph G. Coarse-to-fine inference (Lee et al., 2018) and the standard bi-linear model can be differentiated by different ways of constructing the adjacency matrix of the graph G with nodes being the mentions $\mathcal{M}$. We refer to this adjacency matrix as A, and use $A_{i,j} = 1$ to indicate the existence of an edge between mention m_i and m_j. The adjacency matrix of the bilinear model can be written as:

$$A^{\mathsf{bi}}_{i,j} = \mathbb{I}[j = \operatorname*{argmax}_{h \le i} \mathsf{s}^{\mathsf{bi}}(m_i, m_h)] \tag{5}$$

$$\mathsf{s}^{\mathsf{bi}}(m_i, m_j) = \mathsf{s}^{\mathsf{bi}}_{\mathsf{a}}(m_i, m_j) + \mathsf{s}_{\mathsf{m}}(m_i) + \mathsf{s}_{\mathsf{m}}(m_j) \tag{6}$$

The adjacency matrix of the higher-order model can be written as:

$$A^{\mathsf{hoi}}_{i,j} = \mathbb{I}[j = \operatorname*{argmax}_{h \le i} \mathsf{s}^{\mathsf{hoi}}(m_i, m_h)] \times \mathbb{I}[j \in \operatorname*{argtopk}_{h \le i} \mathsf{s}^{\mathsf{bi}}(m_i, m_h)] \tag{7}$$

---

[1] In our work as well as most work on within document coreference (Lee et al., 2017, 2018; Joshi et al., 2019) we only consider contiguous mention spans rather than allowing spans to be arbitrary sets of tokens (non-contiguous).

$$\mathsf{s}^{\text{hoi}}(m_i, m_j) = \mathsf{s}_{\mathsf{a}}^{\text{hoi}}(m_i, m_j) + \mathsf{s}_{\mathsf{a}}^{\text{bi}}(m_i, m_j) + \mathsf{s}_{\mathsf{m}}(m_i) + \mathsf{s}_{\mathsf{m}}(m_j) \quad (8)$$

where k for $\operatorname{argtopk}$ is a hyperparameter.

End-to-end training The mention proposal and antecedent prediction models are trained by relaxing the adjacency matrix A, replacing the argmax operation with a softmax (i.e., setting a weighted edge between i and j with weight $\mathsf{s}(m_i, m_j)$). The training objective is to maximize the log-likelihood of a ground truth adjacency matrix $A^\star$, where $A^\star_{i,j} = 1$ if m_i and m_j are coreferent and $i < j$ under the relaxed adjacency matrix. The $\operatorname{argtopk}$ operation is not relaxed. A *nil* antecedent is introduced, which provides similarity (s_{a}) of 0 to any mention span is incorporated in the training objective. The number of candidate antecedents is also restricted by a hyperparameter (Lee et al., 2018).

3 Efficient Approximations for End-to-End Coreference

We describe our proposed approach for efficiently approximating the *span-based* end-to-end coreference model with a *token-level* model. Our model jointly predicts which tokens are in the same mention spans (i.e., mention proposal) and what tokens are coreferent with one another (i.e., antecedent prediction). By operating at the token level, we remove the dependence on considering quadratically many phrases. We show the structure of our approximation allows for a *sparsification* technique that reduces the number of antecedent predictions that need to be considered using k-nearest neighbor relationships between tokens and by splitting documents into windows with certain computations made independently for each window. We describe how low-rank matrix approximations can be used to improve inference efficiency.

3.1 Mention Proposer

Observe that computing the set $\mathcal{M}$ requires us to evaluate $\mathsf{s}_{\mathsf{m}}(\cdot)$ for all candidate spans $\mathcal{S}$ in the document (which grows roughly quadratically with the number of tokens). Recall that $\mathsf{s}_{\mathsf{m}}(\cdot)$ is a function of the start and end tokens of each span, producing a score that is high if the pair of tokens likely form a span. This approach can be thought of as having each token t in the document predict whether or not another token u is the last token in a span beginning with t.

We first model for each token t whether it is a start (st) or end (en) token of some phrase using a linear model:

$$M_t^{\mathsf{st}} = w_{\mathsf{st}}^T \boldsymbol{x}_t \qquad M_t^{\mathsf{en}} = w_{\mathsf{en}}^T \boldsymbol{x}_t \quad (9)$$

These terms weighs each token by how likely it is to be part of *some* mention span.

Following Kirstain et al. (2021), we find that there can an empirical benefit(described in Section 6) to additionally modelling the relationship between u and t, i.e., whether it is reasonable for the span beginning with t to end in u. To do this we use a asymmetric (bilinear) scoring function. Further, we restrict the spans to be contiguous and follow the rule-based span criteria of previous work (Lee et al., 2017).

$$M_{t,u} = \begin{cases} \boldsymbol{x}_t^T \, W_{\mathsf{M}} \boldsymbol{x}_u & t \text{ to } u \text{ is a valid span} \\ -\infty & \text{otherwise} \end{cases} \quad (10)$$

For each token, we predict candidate end-tokens for a mention span starting at the given token. We assign a score per span by sum of Eq. 9 & 10 and follow previous work to select the top $0.4T$ scoring spans (mentions). We can replace the mention scoring mechanism used in previous works $\mathsf{s}_{\mathsf{m}}(\cdot)$ with an approximation based on the token level score:

$$\widehat{\mathsf{s}_{\mathsf{m}}}(m_i) = M^{\mathsf{st}}_{\text{START}(m_i)} + M^{\mathsf{en}}_{\text{END}(m_i)} + M_{\text{START}(m_i),\text{END}(m_i)} \quad (11)$$

Rather than having to instantiate a d-dimensional span representation for all $|\mathcal{S}|$ spans, our approach simply uses the output token representations from the encoder. This requires $O(T)$ space compared to $O(|\mathcal{S}|)$ space. Note that computing $\widehat{\mathsf{s}_{\mathsf{m}}}(m_i)$ for all mentions requires at most two matrix multiplications, each with just T rows. Observe that this leads to a drastic reduction in time and space complexity. As noted by previous work (Toshniwal et al., 2020b), the mention proposal step requires the most memory usage because of the quadratic dependency. We validate the reduction in time and memory requirements of our token level mention detection in Section 4.5 & 4.6.

Pretraining For Mention Detection Previous work (Wu et al., 2020; Toshniwal et al., 2020b) has shown that pre-training models for mention detection is beneficial, especially in cases where predicting singleton mentions is required (e.g., LitBank (Bamman et al., 2019)). Given a set of ground truth mentions $\mathcal{M}^\star$ and the set of mentions from a given document $\mathcal{M}$, we use a mention detection loss which minimizes:

$$\begin{aligned} -\sum_{m_i \in \mathcal{M}} & \log \sigma(\widehat{\mathsf{s}_\mathsf{m}}(m_i))\mathbb{I}[m_i \in \mathcal{M}^\star] \\ & + \log \sigma(1 - \widehat{\mathsf{s}_\mathsf{m}}(m_i))\mathbb{I}[m_i \notin \mathcal{M}^\star] \end{aligned} \tag{12}$$

We use it as a multi-task objective in training the models and as well as a pre-training objective. We detect singleton mentions by using a threshold on the mention score value $\widehat{\mathsf{s}_\mathsf{m}}(m_i)$ which is tuned on the development set according to the downstream performance.

3.2 Antecedent Scoring

Next, we would like to model coreference relationships between tokens to approximate the span-level scoring function (s_a, Eq. 3, 5). We predict for each token, the other tokens with which it is coreferent. These predictions are then aggregated to make span level predictions.

First, we consider approximating bilinear scoring function at the token level ($\mathsf{s}_\mathsf{a}^\mathsf{bi}$). We use a bilinear model applied to the encoded token representations. We parameterize four asymmetric similarity functions. Note that the backwards-chaining property of inference motivates our use of the asymmetric function. We model the similarity between tokens that are the start or end tokens of phrases separately:

$$S_{i,j}^{\mathsf{ss}} = \boldsymbol{x}_{\text{START}(i)} W_{\mathsf{st}}^T \boldsymbol{x}_{\text{START}(j)} \tag{13}$$

$$S_{i,j}^{\mathsf{es}} = \boldsymbol{x}_{\text{END}(i)} W_{\mathsf{st}}^T \boldsymbol{x}_{\text{START}(j)} \tag{14}$$

$$S_{i,j}^{\mathsf{se}} = \boldsymbol{x}_{\text{START}(i)} W_{\mathsf{en}}^T \boldsymbol{x}_{\text{END}(j)} \tag{15}$$

$$S_{i,j}^{\mathsf{ee}} = \boldsymbol{x}_{\text{END}(i)} W_{\mathsf{en}}^T \boldsymbol{x}_{\text{END}(j)} \tag{16}$$

We use these similarities to approximate the bilinear antecedent scoring function (Eq. 3) as:

$$\widehat{\mathsf{s}_\mathsf{a}^\mathsf{bi}}(m_i, m_j) = S_{i,j}^{\mathsf{ss}} + S_{i,j}^{\mathsf{es}} + S_{i,j}^{\mathsf{se}} + S_{i,j}^{\mathsf{ee}} \tag{17}$$

Observe how $\widehat{\mathsf{s}_\mathsf{a}^\mathsf{bi}}(\cdot,\cdot)$ reduces the memory requirements compared to $\mathsf{s}_\mathsf{a}^\mathsf{bi}(\cdot,\cdot)$. We do not need to instantiate the span representations, only use the encoded token representations. Computing $\widehat{\mathsf{s}^\mathsf{bi}}(m_i, m_j)$ requires at most $O(T^2)$ instead of $O(|\mathcal{S}|^2)$ work. We can compute each of the $S_{i,j}^{\cdot}$ (Eq. 16) in space $O(T^2)$ and as matrix multiplication between matrices of $O(T)$ rows.

For training and inference in our model, we define the adjacency matrix A with $\hat{A}$:

$$\widehat{A^{\mathsf{bi}}}_{i,j} = \mathbb{I}[j = \operatorname*{argmax}_{h \le i} \widehat{\mathsf{s}^\mathsf{bi}}(m_i, m_h)] \tag{18}$$

$$\begin{aligned} \widehat{\mathsf{s}^\mathsf{bi}}(m_i, m_j) = & \widehat{\mathsf{s}_\mathsf{a}^\mathsf{bi}}(m_i, m_j) + \widehat{\mathsf{s}_\mathsf{m}}(m_i) \\ & + \widehat{\mathsf{s}_\mathsf{m}}(m_j) \end{aligned} \tag{19}$$

Inference can then be done as exactly as before, using connected-components based inference.

3.3 Token Windows & Sparsifying Antecedent Scoring with k-NN Graphs

We can use the backwards-chaining structure of the inference procedure and divide a document into smaller token windows (non-overlapping), reducing the number of tokens that need to be encoded in any one component. We can propose mentions independently in each window. We then perform antecedent scoring using the K-NN sparsification described below for each window. By batching the long document into these windows, we never need to store more than the final encoded token representations for the tokens appearing in some entity cluster.

The approximation method presented thus far reduces the complexity of end-to-end coreference approaches from depending on the number of spans to the number of tokens. However, for long documents scaling quadratically in the number of tokens is still prohibitively expensive, both in terms of time complexity and also in terms of memory. Observe that computing and storing each of the $\widehat{\mathsf{s}^\mathsf{bi}}(\cdot,\cdot)$ may become prohibitively expensive for all pairs of tokens in the document. We would like to reduce the time and space complexity of this approach.

We propose to approximate the top scoring pairs of mention spans according to $\widehat{\mathsf{s}^\mathsf{bi}}(\cdot,\cdot)$ (i.e., further approximating $\mathsf{s}^\mathsf{bi}(\cdot,\cdot)$). We do this by only allowing two mentions m_i and m_j to be coreferent if the start/end tokens of m_j are in the k-nearest neighbors of the start/end tokens of m_i. More precisely, we will maintain the k nearest neighbors of each token for each of the four similarity functions S^{ss}, S^{se}, S^{es}, S^{ee} (Eq. 16). To align with inference procedure, we select these k nearest neighbors for each token only from the preceding tokens in the document. we define $S^{\mathsf{ss}}_{\mathrm{knn}i,j}$ to be non-zero only if j is in the top-k values of $S^{\mathsf{ss}}_{i,\cdot}$

$$S^{\mathsf{ss}}_{\mathrm{knn}i,j} = \begin{cases} S^{\mathsf{ss}}_{i,j} & \text{if } j \in \mathrm{argtopk}_h \, S^{\mathsf{ss}}_{i,h} \\ 0 & \text{otherwise} \end{cases} \tag{20}$$

We define $S^{\mathsf{se}}_{\mathrm{knn}i,j}, S^{\mathsf{es}}_{\mathrm{knn}i,j}, S^{\mathsf{ee}}_{\mathrm{knn}i,j}$ analogously.We then build an further approximation of $\widehat{\mathsf{s}^{\mathsf{bi}}}$ using these $S^{\cdot}_{\mathrm{knn}}$ values:

$$\widehat{\mathsf{s}^{\mathsf{bi}}_{\mathsf{a}}}_{\mathrm{knn}}(m_i, m_j) = S^{\mathsf{ss}}_{\mathrm{knn}i,j} + S^{\mathsf{es}}_{\mathrm{knn}i,j} + S^{\mathsf{se}}_{\mathrm{knn}i,j} + S^{\mathsf{ee}}_{\mathrm{knn}i,j} \tag{21}$$

Observe that storing $S^{\mathsf{ss}}_{\mathrm{knn}i,j}$ can use sparse matrices and therefore provide better scalability to long documents for which storing $O(4Tk)$ is advantageous over $O(T^2)$.

End-to-end Training We use the same end-to-end training procedure that was used by previous work (Section 2) using our approximated mention proposal and antecedent scoring procedures. We note that the use of token windows and KNN sparsification of the antecedent scoring term do not change training at all, this is only applied at inference time.

3.4 Low-dimensional Approximations

Much of the computation time of the k-NN graph approximation model comes from the computation of the top-k nearest tokens. The computation bottleneck mostly depends on the high dimensionality of the encoded token representations, which are from transformer-based language models (Joshi et al., 2020).

To produce lower dimensional embeddings of each token, which preserve similarities in the original space, we use low-rank matrix approximation methods, specifically the Nyström method (Williams and Seeger, 2001; Musco and Musco, 2017, inter alia). We hope to approximate the matrices $S^{\mathsf{ss}}_{i,j}, S^{\mathsf{se}}_{i,j}, S^{\mathsf{es}}_{i,j}, S^{\mathsf{ee}}_{i,j}$. While these are asymmetric, we can consider an equivalent symmetrized version where each token appears two times (on left/right of bilinear term) to apply Nyström. The lower dimensional embedding produced by Nyström is done

The Nyström method provides a low-rank approximation of a symmetric pairwise similarity matrix $S \in RR^{N\times N}$, by selecting ℓ *landmark* points uniformly at random among the N rows of S. We use L_i to be column vector one-hot representation of the i^{th} landmark. We assume $L \in \mathbb{R}^{N\times\ell}$ to be a matrix of such one-hot representations. The approximation of S is given by: $\hat{S} = LS(L^TSL)^{-1}L^TS$. The term LS is a ℓ dimensional embedding of the rows, which is defined by the similarity of each row with each of the ℓ landmarks (ℓ is the reduced dimension). Similarly, $(L^TSL)^{-1}L^TS$ can be thought of as providing a ℓ dimensional embedding of each column of S, which is based on the similarity and the (inverse) of the landmark similarities.

3.5 Limiting Num. of Candidate Antecedents

In the aforementioned approach, the number of candidate antecedents scales with the document length. We would like to determine a mechanism for using a fixed number of candidate antecedents if desired. Previous work other work uses entity-level representations to achieve this (Toshniwal et al., 2020b; Xia et al., 2020).

In our work, we operate at the mention level, removing mentions as candidate antecedents. We define a hyperparameter, ρ, which is maximum number of antecedents that would be kept after processing each window of the document. Our approach removes mentions as candidate antecedents which (1) belong to large coreference clusters (2) are not frequently selected as antecedents. We achieve this by dropping mentions in the order of $|\mathcal{C}_m|$ - $\sum_i A_{i,m}$, where $|\mathcal{C}_m|$ is the size of the cluster of the mention m and $\sum_i A_{i,m}$ is the degree of the mention in the antecedent graph.

4 Experiments

In this section, we compare our proposed approach for scalable coreference on long documents to various state-of-the-art methods in terms of accuracy as well as efficiency of training and inference. We perform a detailed scalability analysis, which characterizes the time/memory used by each method as a function of the length of documents. We also report timing results on novels of ~ 2 million tokens.

4.1 Datasets

We evaluate each method on the following datasets: **CoNLL-2012 Shared Task:** The CoNLL-2012 shared task (Pradhan et al., 2012) uses the v5.0 of the OntoNotes corpus for the task of coreference resolution in English, Chinese, and Arabic languages. We use only the English version for our experiments. The training set contains 2802 training, 343 development, and 348 test documents. The training documents contain on average of 454 tokens and a maximum of 4009 tokens. **Litbank:** We also use the Litbank dataset (Bamman et al., 2019) which consists of 210,532 tokens evenly drawn from 100 different English language literary texts. The average document length in Litbank is much longer (around 2,000 tokens). Following (Bamman et al., 2019; Toshniwal et al., 2020b), we use a 10-fold cross-validation setup with 80% of the data as training data and rest 10% each as validation and test data. The final evaluation is reported as the average of all 10 test runs. Note that the family of end-to-end approaches that we are approximating with our method do not predict singletons as is typically done for Litbank. Mention pretraining is performed as described in Section 3.1 **MedMentions** We also repurpose MedMentions (Mohan and Li, 2019) an existing entity linking dataset in the biomedical domain for coreference resolution. We treat the entity labels as the ground truth cluster assignments of each mention for coreference training/analysis. We use the ST21PV subset that is recommended by (Mohan and Li, 2019). **Artamène ou le Grand Cyrus (Artamène, or Cyrus the Great)**. To further asses the scalability of our approach, we run our method on an English translation of the 17th century French novel that is one of the longest books available in English the public domain (Scudery, 1601). The work contains *1.99 million* tokens and over two million sub-tokens. We use this data to illustrate the scalability of our approach to really long documents.

4.2 Methods

We compare our end-to-end coreference approximation with and without the token windows, KNN sparsification approach (i.e. Ours and Ours (Sp.), Section 3.3). We denote the number of neighbors used in the sparsification approach as k and the size of the window used as w. We compare these to the methods that they are approximating: the bilinear scoring function-based method (E2E (bi)) (Lee et al., 2017) as described in Eq. 3 and the coarse-to-fine higher-order inference based approach (E2E (hoi)) (Lee et al., 2018). All models use spanbert-large (Joshi et al., 2020) to encode tokens. The encoder parameters are trained along with the coreference specific model parameters (see Section 4.4 for details). E2E (bi), E2E (hoi) use additional features such as speaker and genre, we do not use this metadata in our proposed approximation approach.

4.3 Coreference Performance

In Table 1, we report the coreference performance (along with the running time and memory usage) for each method on the three datasets. We observe that our approximate approach is achieves comparable performance to the E2E approaches on CoNLL-2012 and MedMentions, performing slightly worse on Litbank. We hypothesize that the token level representations can be effective at these tasks due to the expressiveness of the contextualized embeddings. We observe that the performance of our model is relatively unchanged with and without the sparsification approach applied.

Recently, Toshniwal et al. (2020b); Xia et al. (2020) have proposed memory-based models optimising memory usage. Toshniwal et al. (2020b) trains for improve mention detection by another pretraining process. These papers achieve state-of-the-art results on Litbank and are focused on reducing the running time and memory usage of coreference models by storing *entity* representations instead of *mention* representations in a bounded memory architecture. We compare inference running time and coreference performance of our method with them in Table 1. We find that our models run 10x faster and are slightly more memory efficient than UMem(Toshniwal et al., 2020b) while matching their performance on litbank.

4.4 Experimental Details

We use the hyperparameter settings from (Xu and Choi, 2020) in all applicable cases. We use 512 as the segment length. On CoNLL and Medmentions we train all models for 24 epochs with maximum training sentences set to 3. On Litbank, we train for 120 epochs and pick parameters from (Toshniwal et al., 2020b). We use 0.4 as the ratio to pick the top spans(mentions) among all candidate spans.

4.5 Inference Time and Memory Usage

In Figure 1, we compare the time and memory used by the end-to-end coreference models and our

		Inference		Overall	MUC			CEAF			B^3		
		Mem.	Time	F1	R	P	F1	R	P	F1	R	P	F1
CoNLL	E2E (hoi)	7.77	30	**79.6**	84.8	86.1	85.4	77.3	79.3	78.3	74.7	76	75.4

	Ours (Sp.)	**1.57**	45.3	61.49	66.87	63.48	65.13	59.65	59.34	59.49	62.12	57.69	59.82

Table 1: **Accuracy & Efficiency** on the three benchmarks. Memory in GB, time in seconds.

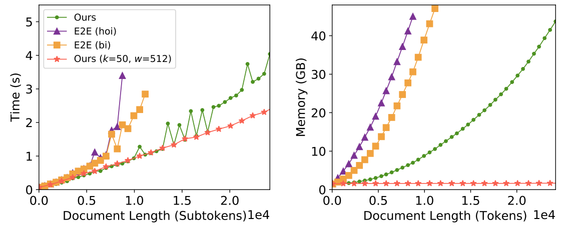

Figure 1: **Time and GPU Memory Comparison of different models on the book "Little Women".**

proposed family of approximations. We select a book at random from the Litbank corpus (*Little Women*) and report the time and memory used by each method to perform coreference as a function of the number tokens analyzed. We plot a curve for each, reporting the statistics until the method runs out of GPU memory (48GB). We cut off the x-axis of the graph where our proposed approach without the backwards chaining runs out of memory. Our token level models only scales upto 24K tokens. We note that Ours (Sp.) is able to run on the entire book requiring only marginally higher memory for higher document lengths. This is in contrast with previous E2E methods which run out of memory for documents longer than 1e4 tokens.

4.6 Training Time and Memory Usage

We report in Table 2 the training time and memory requirements for each of the methods. For each dataset, we train all the methods in focus for the same number of epochs/updates. We train for 24 epochs on CoNLL, 120 epochs on Litbank and 24 epochs on MedMentions. We observe that our approach greatly reduces GPU memory requirements and are also slightly faster. This gap is wider for datasets containing longer documents as shown by the numbers on LitBank. Note that the sparsification approximation is simply an inference time approximation and uses the same trained model as our approach with the K-NN approximation.

		Training	
		Time	Mem.
CoNLL	Ours	**6.8**	**13.69**
	E2E (hoi)	11.75	19.39
	E2E (bi)	7.5	15.7
Litbank	Ours	**2.9**	**19.43**
	E2E (bi)	3.2	22.7
	E2E (hoi)	5	27.0
MedM.	Ours	**5.5**	**13.8**
	E2E (hoi)	8.75	18.5
	E2E (bi)	6.25	15.6

Table 2: **Training time(hours) and memory(GB) usage**. Our approach requires less time and memory than the competing end-to-end approaches.

4.7 Scaling to Long Documents

We run Ours (Sp.) on the full text of *Artamène or Cyrus the Great*, which has 1.99M tokens ($>$ 2M subtokens). To our knowledge, this is the largest single document a neural within document coreference system has been applied to. In Figure 2, we show that our approach runs in about 14 minutes. Further, we demonstrate how the hyperprameters of the sparsification can be adjusted depending on the system requirements. We show that the window size parameter can be set to be the minimal amount (w=512) to require just 13 GB of GPU RAM. Table 3 suggests using small window sizes are also advantageous in terms of accuracy.

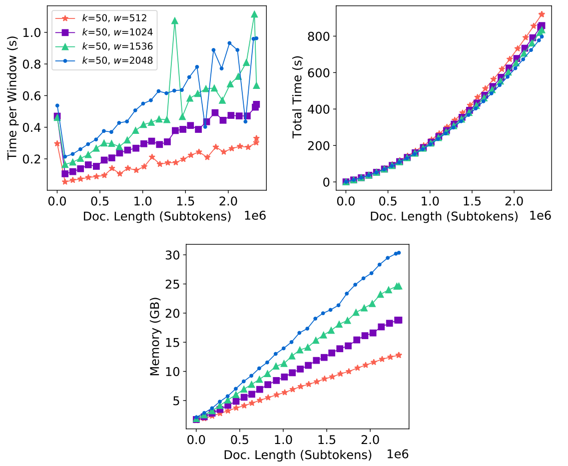

Figure 2: **Scalability to 2 million tokens** Time and memory usage of our K-NN based methods on Artaméne a book with millions of tokens.

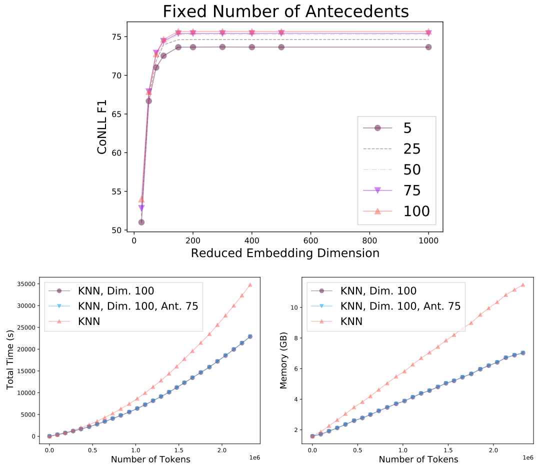

Figure 3: **Reduced Dimensionality & Candidate Antecedents**. We report CoNLL F1 on CoNLL and Time and Memory Usage on *Artamène or Cyrus the Great*.

5 Model Analysis

K-NN Sparsification Performance Analysis

In Table 3, we show the CoNLL F1 as a function of the number of neighbors k and window size w in Ours (Sp.). We observe that we can achieve high quality results even with a small number of neighbors, providing an empirical justification for our approximation. In our case, using just 10 nearest neighbors ($k = 10$) puts Ours (Sp.) within 99% of the performance of the version of our approach without sparsification. Litbank however required to use a higher value of K due to the presence of long distance coreference links in literary texts.

Dimensionality Reduction & Limiting Number of Antecedents

Window Size	512	1024	1536
k=10	77.16	77.33	77.25
k=50	77.59	77.55	77.56
k=80	77.68	77.62	77.61
k=∞	78.03	78.03	78.03

Table 3: **Sensitivity to Approximation in K-NN sparsified approach on CoNLL (F1)**.

Type	E2E (hoi)	E2E (bi)	Ours	Ours (Sp.)
Pronoun	33.74	34.57	33.62	33.50
Noun	40.59	39.98	40.36	40.00

Table 4: **Performance on mention types (F1)**.

Figure 3, shows the performance of the reduced dimensionality method 3.4 and limiting antecedents 3.5. A reduced dimension of 200 can match the performance of encoder embeddings dimension while significantly improving running time. Further, the model performs well while just keeping 75 mentions from each window of size 512(comprises squared number of possible mention spans) in the memory. We note that a reduction in memory can be achieved by dropping antecedents and using sparse matrices. However, this is not as efficient as using dense matrices on the gpu.

6 Performance Analysis

Comparisons with Baselines

To give a sense of how the proposed approximations work, we performed a simple analysis among E2E (hoi), Ours and Ours (Sp.) on the last fold of Litbank dataset. In the first experiment, we keep only the pronomial mentions in the predicted clusters and evaluate coref scores. In the second experiment we keep all mentions containing atleast one noun. Table 4 shows the final numbers. The gap in performance between E2E (hoi) and Ours seems to be equal in both categories. Ours (Sp.) and Ours have similar performance gap in both categories as well. Thus our models seem to be approximating fairly across different categories.

Table 5 shows the analysis of distance between antecedents predicted by each model on the last litbank fold. Our models seem to have a higher average distance between antecedents. This shows that the models proposed are capable to identifying long distance links. Note that distance between antecedent does not determine accuracy. A mention linked to any mention in its golden coreference cluster will have the same effect.

Type	E2E (hoi)	E2E (bi)	Ours	Ours (Sp.)
Mean	149	189.7	301.19	447.8
Max	2117	2104	2303	2303
Std.	296.8	342.9	403.01	588

Table 5: **Analysis of distance between mention and antecedent for all models in subtoken units**.

		P	R	F
CNL	Ours	78.19	77.86	78.03
	Ours - SS	78.14	77.54	77.84
	Ours - BM	78.84	77.26	78.04
Litbank	Ours	76.09	75.89	75.93
	Ours - SS	75.21	76.22	75.58
	Ours - BM	70.81	74.40	72.18
	Ours - SS - MT	68.35	68.22	68.24
MM	Ours	63.77	59.92	61.76
	Ours - SS	63.4	59.2	61.13
	Ours - BM	60.84	62.35	61.58

Table 6: **Effect of the removal of different components in Ours**. CNL - CoNLL, MM - Medmentions

Effects of model components

We further analyse the effect of other heuristics that went into the model. We use a Subtoken Strategy (SS) where we restrict the candidate mentions to align with subtoken starts, ends. As shown in Table 6, (SS) seems to have improved the results on all the datasets. Also, for litbank, mention pretraining & mention training (MT) seem to have helped significantly. Mention training forces the score of golden mentions to be higher thereby making it easy to use a threshold for singletons at inference. Bilinear mention (BM) term described in Eq.10 seemed to have helped in litbank and medmentions.

7 Related Work

With the growing computational cost of deep learning, NLP researchers have started to focus on more efficient models (Strubell et al., 2019; Schwartz et al., 2020). As coreference is a document-level phenomena, it is particularly challenging to scale, especially for long documents. While most of the work in coreference has focused on genres of text with short documents such as news articles and blogs (Pradhan et al., 2012), there has been renewed focus in long text documents such as novels (Bamman et al., 2019; Toshniwal et al., 2020b). Coreference in long text is particularly interesting due to the introduction of long-range anaphora.

Span based end-to-end coreference systems (Lee et al., 2017, 2018; Joshi et al., 2020; Wu et al., 2020) have been the state-of-the-art in short-document coreference resolution (Lu and Ng, 2020). These systems avoid training a separate mention detector. However, end-to-end coreference models are challenging to scale to long text documents due to their large memory footprint as well as slow training and inference. Thus, research on long-document coreference so far has focused on incremental (memory-based) coreference resolution (Xia et al., 2020; Toshniwal et al., 2020a,b). Memory-based approaches model coreference as online clustering by picking the most similar entity to every new mention where the cluster representations (i.e., entity representations) are also updated. However, the underlying recurrent nature of these models and the frequent read-write memory operations make these models slow. In this work, we focus on the end-to-end coreference system and show gains both in speed as well as memory.

We note that this paper's novel token-level model ideas presented in this paper were concurrently introduced by Kirstain et al. (2021). We also introduce token windows, k-nearest neighbor based sparsification techniques. Furthermore, we provide empirical results on documents with about two million tokens, which we believe to be one of the longest documents to which neural coreference models have been applied. We also note that Wu et al. (2020) hold state-of-the-art results on CoNLL (83F1). Wu et al. (2020) uses a question-answering cross-encoder style model to perform coreference. However, the method is very computationally expensive and so it is difficult to scale to the long documents which is the focus of this paper.

8 Conclusion

In this paper, we introduce a new scalable approach for performing coreference that scales to long documents. Our approach replaces costly span-based operations with token-level decisions for proposing mentions and determining antecedents. Our approach uses token similarity in the form of k-nearest neighbor graphs along with processing documents in span windows to reduce the time and memory complexity. We evaluate our proposed approach empirically and demonstrate that it achieves competitive coreference F1 scores while improving time and memory usage requirements. We demonstrate the scalability of our method by applying it to novels with about two million tokens. We further propose and demonstrate the use of low rank approximations and dropping of non essential tokens to improve memory/time efficiency.

Broader Impact and Discussion of Ethics

While our model is not tuned for any specific real-world application, our method could be used in sensitive contexts such as legal or health-care settings, and it is essential that any work using our method undertake extensive quality-assurance and robustness testing before using it in their setting. The datasets used in our work do not contain any sensitive information to the best of our knowledge.

Replicability: As part of our contributions, we will release the code used for training and evaluation in this work, as well as all the trained models at https://github.com/raghavlite/Scalable-Coreference.

LEWIS: Levenshtein Editing for Unsupervised Text Style Transfer

Machel Reid[*]

`vzhong@cs.washington.edu`

Abstract

Many types of text style transfer can be achieved with only small, precise edits (e.g. sentiment transfer from `I had a terrible time...` to `I had a great time...`). We propose a coarse-to-fine editor for style transfer that transforms text using Levenshtein edit operations (e.g. insert, replace, delete). Unlike prior single-span edit methods, our method concurrently edits multiple spans in the source text. To train without parallel style text pairs (e.g. pairs of +/- sentiment statements), we propose an unsupervised data synthesis procedure. We first convert text to style-agnostic templates using style classifier attention (e.g. `I had a SLOT time...`), then fill in slots in these templates using fine-tuned pretrained language models. Our method outperforms existing generation and editing style transfer methods on sentiment (YELP, AMAZON) and politeness (POLITE) transfer. In particular, multi-span editing achieves higher performance and more diverse output than single-span editing. Moreover, compared to previous methods on unsupervised data synthesis, our method results in higher quality parallel style pairs and improves model performance.[1]

1 Introduction

In text style transfer, a model changes the style of a source text (e.g. sentiment, politeness) into a target style, while otherwise changing as little as possible about the input. Many types of style transfer can be performed with only small, precise edits instead of generation from scratch. Consider the task of transforming a negative sentiment sentence such as `the worst ribs I've ever had!` to a positive sentence such as `probably the best ribs ever!`. Here, we need only invert the negative sentiment phrase around `worst` — the references to `ribs` should be left as-is. Recent and concurrent work on text style transfer propose single-span editing (for insertion and replacement) (Wu et al., 2019; Malmi et al., 2020) as an alternative to generating the target text from scratch (Prabhumoye et al., 2018; He et al., 2020b; John et al., 2019; Shen et al., 2017; Fu et al., 2018).

We introduce a more flexible and powerful multi-span editing method that identifies multiple style-specific components of the text and concurrently edits them into the target style. Given a source text, we first predict the sequence of coarse-grain Levenshtein edit types (e.g. insert, replace, delete) that transform the source text to the target text, then fill insertion and replacement edits using a generator. In the previous example, the operations correspond to inserting the word `probably` before `the`, replacing `worst` with `best`, and removing the words `I've` and `had`. This example is illustrated in detail in Figure 1.

Learning to edit requires supervised source-target text pairs. How do we learn high-quality editors when no such supervised parallel data exists? Given a style text, we synthesize its pair by identifying style-specific content and replacing it with samples from style-specific masked language-models. In our sentiment transfer example, the style-specific content of the sentence `I had a great time at the theatre` is `had a great time`. We can replace this phrase by `saw a fantastic movie today` to synthesize an alternative positive-sentiment sentence, or by `got ripped off today` to synthesize a negative-sentiment sentence. Figure 3 illustrates this example in detail.

We evaluate our editing and synthesis framework, which we call LEWIS (Levenshtein editing with unsupervised synthesis), on three style transfer tasks in sentiment (YELP, AMAZON) and polite-

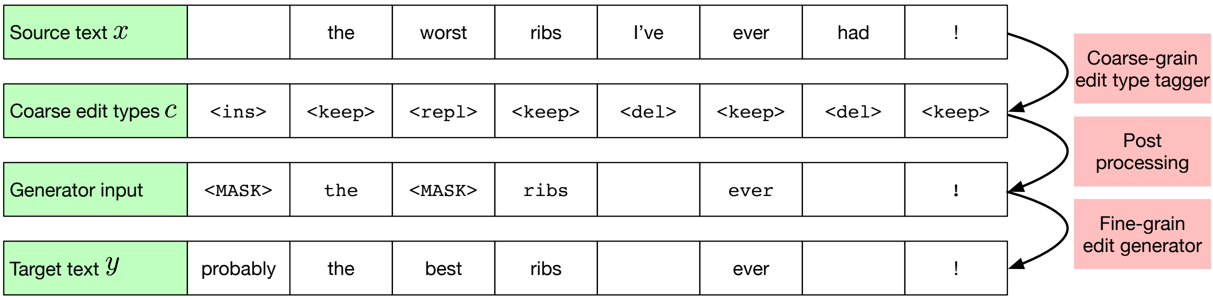

Figure 1: Coarse-to-fine Levenshtein editor. Given the source text, the two-step editor first generates coarse edit types via a tagger. A subsequent generator fills in insertions and replacements while taking into account the source text and the edit types.

ness (POLITE) transfer, and achieve state-of-the-art results in terms of retention of style-agnostic content, similarity to the annotated target text, and transfer accuracy. LEWIS significantly outperforms prior state-of-the-art methods by 2.6-13.5% accuracy depending on the task. In further analyses, we show that (1) compared to concurrent work on editing for style transfer, our editor achieves 33.3% higher accuracy when trained on the same data; (2) compared to a competitive BART (Lewis et al., 2020) pure generation baseline, our editor achieves 5.8% higher accuracy when trained on the same data; (3) compared to concurrent work on unsupervised synthesis of style transfer data, our synthesis procedure improves performance by 9.5 BLEU when used to train the same model. Our experiments show that our editor significantly outperforms both pure generation and editing prior methods, that our editor yields more diverse text transfer and that training on our synthesized data improves performance more than prior synthesis methods.

2 LEWIS

LEWIS consists of coarse-to-fine editing and data synthesis. The editing component, shown in Figure 1, performs local, precise edits of style-specific content of the source text to produce the target text. The data synthesis component, shown in Figure 3, produces supervised source-target text pairs, which do not exist in naturally, to train the editor. To apply our method to transfer text from a source style to a target style, we first train style-specific masked language models, with which we synthesize source-target text pairs. We then compute Levenshtein operations for these source-target text pairs and train the coarse-to-fine editor to reproduce these operations. The full LEWIS is shown in Figure 2. For ease of exposition, we first describe the editor, then describe how to synthesize parallel data to train the editor.

2.1 Style transfer via Levenshtein editing

We propose a coarse-to-fine editor that first predicts coarse-grain Levenshtein edit types (Levenshtein, 1966), then fills in fine-grain edits with a generator. Figure 1 illustrates the editor.

Suppose we are to transfer text from a source style into a target style. Let x denote the source text, which we would like to edit into the target text y. In the example shown in Figure 1, we transform the source text `the worst ribs I've ever had!` into `probably the best ribs ever!` Our approach has two parts: The source text is first tagged with a sequence of coarse-grain Levenshtein transition types c that transform x into y. A generator then fills in phrases for insertion and replacement operations. The set of coarse Levenshtein transition types are `insert`, `keep`, `replace`, and `delete`. In the running example, the sequence of operations are to insert before `the`, replace `worst`, and delete `I've` and `had`.

First, we train a RoBERTa-tagger (Liu et al., 2019) to generate these coarse edit types, which produces coarse edit types for each token in the source text. To accommodate the insertion operation, we produce two tags for each token. The first tag is a binary indicator of whether an additional phrase should be inserted before this token. The second tag is the non-insertion operation to take for this token. In the previous example, for instance, the word `the` triggers both insertion and keep operations.

$$c = \mathrm{RoBERTa}_c(x; \Phi_c) \tag{1}$$

Next, we train a fine-grain edit generator to produce the target text. Unlike the coarse-grain edit type

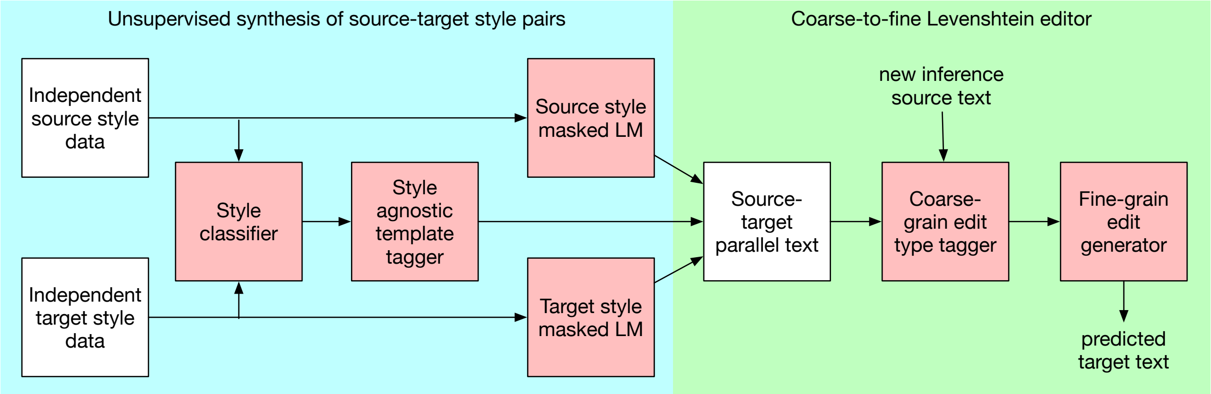

Figure 2: LEWIS consists of two components. Given source-target style text pairs, a coarse-to-fine Levenshtein editor (yellow) first identifies coarse-grain Levenshtein edit types to perform for each token in the source text (e.g. insert, replace, delete), then fills in the final edits with a fine-grain generator to produce the target text. In most applications, supervised source-target style text pairs rarely exist. To resolve this lack of annotated data, we perform unsupervised synthesis of source-target style pairs (blue) by first learning to produce style-agnostic templates given arbitrary style text. Next, we fill in slots in the template by sampling from style-specific masked language-models. In this figure, source and intermediate data are shown in white while model components are shown in red.

generator which only observes the source text, the fine-grain edit generator observes both the original source text and the source text with the coarse-grain edit types applied x_c. We use the edit types produced by the Levenshtein algorithm during training and the edit types predicted by the RoBERTa-tagger during inference.

$$y = \text{BART}_y(x, x_c; \Phi_{\text{fn}}) \tag{2}$$

Our generator is a BART-based (Lewis et al., 2020) masked sequence-to-sequence model. The input to BART is the concatenation of the original source text x and the source text with the coarse-grain edit types applied x_c. The generator is trained to fill in phrases for coarse-grain edit types `<ins>` and `<repl>`. In the example, BART_y is given the input text `the worst ribs I've ever had! SEP <MASK> the <MASK> ribs ever !` and respectively fills in the two `<MASK>`s with `probably` and `best`.

2.2 Unsupervised synthesis of source-target style pairs

Training an editor requires large quantities of source-target text pairs. While there exists an abundant amount of style-specific data, parallel source-target pairs are difficult to collect and annotate. How do we train editing style transfer methods when no such data exists? We hypothesize that pre-trained masked language-models, when carefully constrained to generate only style-specific content, can provide high-quality source-target pairs for style transfer.

Our synthesis procedure, shown in Figure 3, is two-fold. First, given a text s from either style, we identify a style-agnostic template t, in which style-specific content are replaced with slots. For instance, for the style text `I had a great time at the theatre`, the style-agnostic template is `I SLOT at the theatre`. To identify style-specific content, we train a RoBERTa-based style classifier that differentiates between text from each style. Vaswani et al. (2017) and Hoover et al. (2020) show that heavily attended-tokens correlate strongly with tokens that are indicative of the target class. We observe similar results when inspecting the attention matrices computed by the 12-layer Transfomer for the sentiment classification task. Namely, the penultimate layer's attention weights correlate strongly with words humans identify as strongly indicative of positive vs. negative sentiment. Hence, we define style-specific content as tokens that have higher-than-average attention weights in the classifier.

Consider the multi-head attention matrix A in the penultimate Transformer layer, where A_{ij} represents the attention weight of the jth attention head on the i's token, normalized across all tokens. First, we max-pool A_i over all attention heads to form a_i. Conceptually, a_i represents the maximum extent to which the ith word was attended to by any

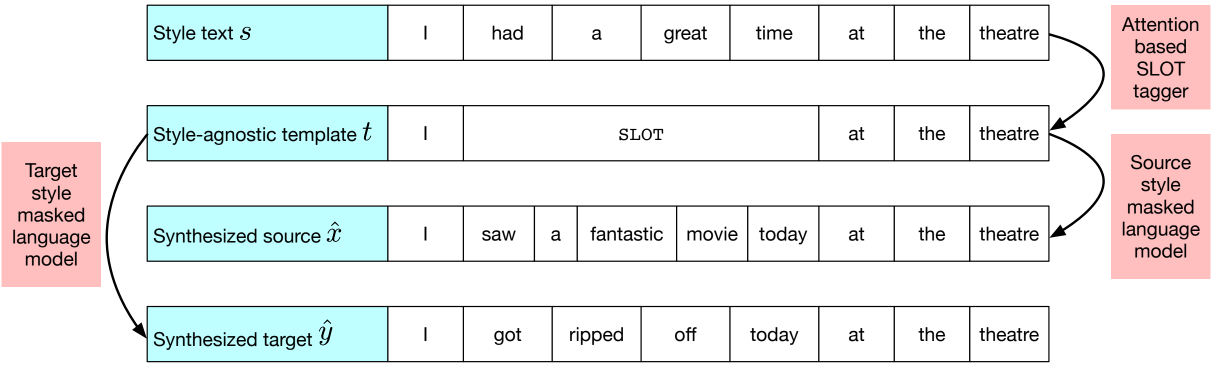

Figure 3: Unsupervised synthesis of source-target style pairs. We first train an attentive style classifier, whose attention weights we use to identify style-specific content. Next, we remove style-specific content with slots to form a style-agnostic template. This template is finally filled using style-specific masked language-models for each style to synthesize parallel style text pairs.

attention head.

$$a_i = \max_j A_{ij} \tag{3}$$

Let N denote the sequence length. We compute the average attention weight $\tilde{a}$ as

$$\tilde{a} = \frac{\sum_i^N a_i}{N} \tag{4}$$

To modify the style text s into the style-agnostic template t, we keep tokens that have above-average attention weight.

$$t_i = \begin{cases} \texttt{SLOT}, & \text{if } a_i \geq \tilde{a} \\ s_i, & \text{if } a_i < \tilde{a} \end{cases} \tag{5}$$

We merge consecutive `SLOT` tokens in t. In the running example, for the style text `I had a great time at the theatre`, the tagger generates `I SLOT SLOT SLOT SLOT at the theatre`, which after merging becomes `I SLOT at the theatre`.

We then fine-tune style-specific masked language-models BART_x and BART_y to fill in slots in the template and recover the style-specific text. During training, phrases in the input sentence are randomly discarded and the model is trained to fill the phrases back in (Lewis et al., 2020). Having trained style-specific masked language-models for both the source and target styles, we use both models to generate source and target filled-in text given style-agnostic templates.

$$\hat{x} = \text{BART}_x(t; \Theta_x) \tag{6}$$

$$\hat{y} = \text{BART}_y(t; \Theta_y) \tag{7}$$

In our running example, sampling with the positive language model yields the sentence `I saw a fantastic movie today at the theatre`, while sampling with the negative language model yields the sentence `I got ripped off today at the theatre`.

The last step we perform is a filtering step using the classifier. For synthesized examples in style k, we keep examples for which the style classifier predicts k. In other words, we keep only examples where the language models and the classifier agree. We find that this improves data quality and editor performance. We use the collection of synthesized source and target text pairs $\hat{x}$, $\hat{y}$ to train the editor.

3 Experimental Setup

We focus on two types of text style transfer: (1) **Sentiment transfer**, in which we transform a positive sentiment sentence to a corresponding negative sentiment sentence or vice-versa without changing the core content (i.e. attributes of the sentence not concerned with sentiment) (2) **Politeness transfer**, in which we transform the tone of a sentence from impolite to polite.

DATASET	**Attributes**	**Train**	**Valid**	**Test**
YELP	Positive	270K	2000	500
	Negative	180K	2000	500

ness reviews for training and 1000 sentences released by Li et al. (2018) for testing, AMAZON (He and McAuley, 2016) consists of 540K sentences from product reviews for training and 1000 sentences for testing, and POLITE (Madaan et al., 2020), produced by filtering through the Enron Email corpus, consisting of 420K sentences for training and 800 sentences for testing. We list dataset statistics in Table 1.

3.1 Training Setup

We implement our models using `fairseq`[2] (Ott et al., 2019) and HuggingFace[3] (Wolf et al., 2020) — both based on the PyTorch library (Paszke et al., 2019). For BART-based generation models, we initialize with BART-base (Lewis et al., 2020), and train using a batch size of 65K tokens for 30000 iterations. We use a linear warmup schedule, reaching the peak of 3×10^{-5} at 5000 iterations, and then proceed to decay the learning rate with a polynomial decay schedule. For regularization, we use a dropout value of 0.3 and a weight decay value of 0.1. We optimize using Adam, with hyperparameters $\beta_1 = 0.9, \beta_2 = 0.98$ and cross entropy loss. For RoBERTa-based taggers and classifiers, we initialize with RoBERTa-base (Liu et al., 2019), and train using a batch size of 256 for 5000 iterations. We optimize using Adam, warm up the learning rate to 1×10^{-6} and then decay with a cosine schedule. We train all models using mixed precision (Micikevicius et al., 2018) for faster training. Similar to prior work (Wu et al., 2019; Malmi et al., 2020), we decode using a beam width of 5 and rerank outputs produced by beam search using the likelihood of the classifier trained in Section 2.2.

3.2 Comparison with existing methods

We compare LEWIS to five prior methods: Delete, Retrieve, Generate (Li et al., 2018), a retrieval method that finds text from the target domain corpus whose style-agnostic form is similar to that of the source text; Tag and Generate (Madaan et al.,

Delete, Retrieve, Generate (Li et al., 2018)	—	11.8	—
Tag and Generate (Madaan et al., 2020)	84.8	70.4	71.6
LEWIS	**87.4**	**75.3**	**81.4**

Table 4: Results on POLITE

Model	Acc	SBLEU	BLEU	SBERT	BERT
LM fill	90.3	42.9	17.4	58.9	41.6
Seq2Seq	87.3	50.0	19.3	68.5	**50.0**
LEWIS w/o filtering	91.2	50.1	23.3	69.8	48.0
LEWIS	**93.1**	**58.5**	**24.0**	**72.2**	**50.0**

Table 5: Ablation on YELP. “LM fill” is the ablation experiment in which we convert the source style text to a style-agnostic template and directly use the target style language model to synthesize a target style text (e.g. the editor is not used). “Seq2Seq” is a pretrained BART model that is fine-tuned on the synthesized data (e.g. a from-scratch generation model trained on the same data as the editor).

2020), a generation method that conditionally generates target text from style-agnostic source text; DeepLatentSeq (He et al., 2020b), an unsupervised machine translation-based approach where generators in each domain are regularized by a language model-based latent prior. Finally, we compare to previous editing approaches proposed by Malmi et al. (2019, 2020) where a single span in the source text two domain-specific language models disagree on is replaced.

3.3 Evaluation

Automatic Evaluation We use five evaluation metrics: BLEU (Papineni et al., 2002) measured against the reference (denoted as **BLEU**) to evaluate lexical overlap with human annotation; Self-BLEU measured against the source to measure content preservation (denoted as **SBLEU**); BERTScore and Self-BERTScore (Zhang et al., 2020) measured against the reference and the source (denoted as **BERT** and **SBERT** respectively); and accuracy measured against an external classifier (denoted as **Accuracy**) to measure how well the style was transferred.

		BLEU	BERT
Ref	great place , great food !	—	—
Hyp 1	pathetic place , great food !	**76.0**	71.5
Hyp 2	amazing place , awesome food !	0.0	**78.6**

Table 6: Example comparing BERTScore vs BLEU. **Ref** denotes the reference sentence and **Hyp 1** and **Hyp 2** represent two example hypotheses.

While measuring BLEU, Self-BLEU, and accuracy are standard for this task, we propose additionally using BERTScore due to its higher correlation with human judgments (Zhang et al., 2020). Compared to BLEU and Self-BLEU which are n-gram based, BERTScore is measured using token-wise cosine similarity between representations produced by BERT (Devlin et al., 2019).

Given this, the usage of BERTScore addresses the potential issue of accurately transferred sentences being scored poorly due to its low n-gram overlap. Table 6 shows an example of this where the style is accurately transferred but is scored poorly by BLEU as a result of low n-gram overlap.

Furthermore, following Malmi et al. (2020) who use a BERT-based classifier to score their outputs, we train a classifier initialized with RoBERTa-base (Liu et al., 2019). This model correctly classifies 98.2% of the YELP classification test set by Shen et al. (2017). Its accuracy is used to evaluate the output of style transfer models.

Human Evaluation We perform a robust human evaluation on all datasets, asking crowdworkers to rate 300 examples from Yelp (150 positive, 150 negative), 200 examples from Amazon (100 positive,100 negative) and 100 from Politeness. Five annotators rate each pair from 1 (strongly disagree) to 5 (strongly agree) in terms of fluency, content preservation (CP) and style transfer. We compare with our strongest baseline Tag and Generate (Madaan et al., 2020).

Dataset	Model	Fluency	CP	Style
YELP	TG	3.84±1.01	3.63±0.93	3.67±1.02
	LEWIS	**3.94**±0.99	**3.76**±0.88	**3.72**±0.98
AMAZON	TG	3.60±1.01	3.48±0.93	3.37±1.02
	LEWIS	**3.65**±0.88	**3.50**±0.88	3.37±0.90
POLITE	TG	3.83±0.84	3.76±0.90	3.48±1.04
	LEWIS	**3.93**±0.78	**3.87**±0.83	**3.63**±0.98

Table 7: Human evaluation results comparing LEWIS and Tag and Generate (TG)

	Mean	Std
# merged edit ops	1.57	0.78
# source toks	10.74	2.73
# style-agnostic template toks	10.42	2.86
# edit output toks	11.24	3.16

4 Results

Performance of LEWIS compared to other methods on YELP, AMAZON, and POLITE are respectively shown in Tables 2, 3, and 4, with human evaluation shown in Table 7. LEWIS outperforms prior methods on all datasets in terms of accuracy, BLEU, and BERTScore: LEWIS achieves more successful transfers (2.6-13.5% accuracy depending on task), has higher overlap with human annotations (4-14.4 BERTScore), and retains more source content (5.7-14.3 Self-BERTScore). Human evaluation ($p < 0.01$ for YELP and POLITE using pairwise bootstrap sampling (Koehn, 2004)) shows that LEWIS outperforms Tag and Generate on fluency, content preservation and style across datasets. These results indicate that LEWIS is an effective method for style transfer. On the AMAZON dataset — which is noisier than the YELP dataset — LEWIS underperforms Tag and Generate when evaluating using BLEU, however when evaluating using BERTScore LEWIS outperforms the latter. When we inspect the output of LEWIS, we find that it generates more diverse output as shown in Figure 4.

One reason that LEWIS generates more diverse output is that unlike previous and concurrent editing work that use single-span replacement (Malmi et al., 2019, 2020), our method concurrently edits multiple spans with a larger set of operations. This is inherently supported by the editor (Figure 5) as well as encouraged during unsupervised data synthesis (Figure 4). Table 8 shows that a large number of examples do require multiple edits, and that the coarse-to-fine editor indeed performs multiple edit operations on average.

In addition to comparing end-to-end systems, we also compare LEWIS to concurrent editing and synthesis methods by Malmi et al. (2019, 2020). Table 2 shows that training the same model (LaserTagger) on our data improves and BLEU by 9.5 (the accuracy difference is not directly comparable since Malmi et al. (2020) used a BERT classifier and did not release model output). This suggests that our data synthesis procedure produces higher quality data than Malmi et al. (2020). Furthermore, because LaserTagger only performs single-span edits (when performing insertion/replacement), it often fails to transfer the style of the text. This also accounts for its high BLEU and BERTScore but low accuracy, as we show that a model that simply copies the input also achieves high BLEU and BERTScore but low accuracy. Replacing LaserTagger with our coarse-to-fine Levenshtein editor results in a sizable 33% gain in accuracy. In Table 1 of the Appendix, we show example outputs of these models for comparison. Finally, we ablate LEWIS to investigate how the different components of LEWIS affect performance.

Editing outperforms pure generation We replace the coarse-to-fine editor with a sequence-to-sequence BART model, which we also train with synthesized data. This is a strong baseline that outperforms prior pure generation work on style transfer, as shown in Table 3. Nevertheless, Table 5 shows that LEWIS outperforms this baseline on all metrics. This confirms our hypothesis that editing is a more effective means of style transfer compared to pure generation.

Training on synthesized data improves performance. Instead of training an editor using synthesized data, given a source text during inference, we convert it to a style-agnostic template and immediately fill it using the target language model. Table 5 shows that the resulting model underperforms both the sequence-to-sequence BART and the coarse-to-fine editor on all metrics. This result may be surprising, in that one expects the performance of a model trained on data synthesized by language models to be at-most on par with the per-

formance of the language model. In this case, we observe that training on the synthesized data actually improves over just using the language models. We hypothesize that this gain is due to the editor learning correlations between the source language model and the target language model, namely how to precisely transform the output of the source language model to the output of the target language model. The gains we observe here may be related to gains from training on back-translated or pseudo-parallel data (Sennrich et al., 2016; Edunov et al., 2018; He et al., 2020a). More research is needed to investigate the problem conditions under which such gains occur.

Filtering improves performance. Here, we forgo the filtering step, which removes $\approx$ 20% of the synthesized data on Yelp. Table 5 shows that filtering improves the quality of the synthesized data and leads to consistent gains.

5 Related Work

Text style transfer Previous work on style transfer can largely be divided into two categories: (1) learning a latent space with controllable attributes such as those found in Shen et al. (2017); John et al. (2019) or (2) using unsupervised generative approaches from retrieval (Li et al., 2018), tagging using style phrases (Madaan et al., 2020), to back-translation and unsupervised machine translation techniques (Prabhumoye et al., 2018; Lample et al., 2019; He et al., 2020b).

Editing for style transfer Our work is closest to Madaan et al. (2020) and Malmi et al. (2020). Madaan et al. (2020) use a tagger to mark style phrases in the source text, then generates the target text conditioned on the tagged source text. In contrast, we do not fully generate target text and only perform small, precise edits. In concurrent work to ours, Malmi et al. (2020) train a BERT language model on each style and edits a span where the models' likelihoods disagree the most. In contrast, instead of performing single-span replacement, our editor concurrently edits multiple spans in the text, and supports a wider set of operations than replacement. We showed that this results in more effective and more diverse style transfer. This coarse-to-fine transformations of text, in which the input context is progressively refined, has also led to improvements in syntactic parsing (Charniak and Johnson, 2005), semantic parsing (Dong and Lapata, 2018), and NER (Choi et al., 2018).

Unsupervised data synthesis for style transfer Malmi et al. (2020) also generate synthetic data with which to train an editing model from Malmi et al. (2019). Our synthesis differs from Malmi et al. (2020) in how slots for generation are chosen. In their work, the highest disagreeing span is chosen for rewriting. In our work, multiple spans with words whose attention weights that exceed the average are chosen for rewriting, which allows for more flexible and diverse samples. In turn, training on our synthesized data improves the performance and diversity of the style transfer model.

6 Conclusion

We proposed LEWIS, a coarse-to-fine editor for style transfer that transforms text using Levenshtein edit operations. Unlike prior edit methods, our methods concurrently performs multi-span edits. To train this editor, we proposed an unsupervised data synthesis procedure that converts text to style-agnostic templates using style classifier attention, then fills in slots in these templates using fine-tuned pretrained language models. LEWIS outperformed existing generation and editing style transfer methods on sentiment and politeness transfer. In addition, the proposed data-synthesis procedure increased transfer performance. Given the same synthesized data, our editor outperformed prior pure generation and editing methods. In future work, we will study the application of LEWIS to general sequence to sequence problems.

Ethical Considerations

This work has impact in the field of controlled text generation, and as with much of language technology has the potential to be both used for good and used maliciously. Our work learns to generate synthetic data in an unsupervised way, and is based on a pre-trained model (BART), which is likely to capture and amplify biases found in the data. Furthermore, as with all text-style transfer models, our model is amenable to malicious use, including impersonation and mass generation of faked opposing opinion, for example, negative and positive product reviews or political statements. We refer readers to Section 8 of Hu et al. (2020) for more on this topic. Given this, further study is needed to see how text-style transfer models are affected by the bias contained in the corpora they are trained on and other aspects to avoid undesired behaviors such as those listed in the cases above.

A Evaluation

Automatic Evaluation When evaluating using BLEU we used detokenized SacreBLEU (Post, 2018). For BERTScore (Zhang et al., 2020), we use the `rescale_with_baseline` option with the following hash: `roberta-large_L17_no-idf_version=0.3.5(hug_trans=4.1.0.dev0)-rescaled`.

Human Evaluation When using Amazon Mechanical Turk, we screen our annotators for English proficiency, and require all to have a greater than 95% approval rate. We hire workers with at least 1000 HITs and pay workers 5 cents per example, amounting to USD$10-15 per hour.

B Training Infrastructure

For training models we use between 1 and 8 NVIDIA V100 16GB GPUs on a DGX-1 machine running Ubuntu 16.04 on a Dual 20-Core Intel Xeon E5-2698 v4 2.2 GHz.

C Source Code & Synthetic Data

We release source code with this work, with preprocessing scripts, training scripts for both conditional lanaguage models, editors and coarse-grain taggers, edit operations extraction scripts, and synthetic data generation scripts at `https://github.com/machelreid/lewis`.

D Synthetic Data

For synthetic data generation, we generate approximately 2.2M pairs for Yelp, 2.0M pairs for Amazon, and 1M pairs for Polite. Note that when generating synthetic data on Polite, given the longer sequence length, we threshold the amount of `SLOT` tokens to be the minimum of one-third of the total sequence length and 6.

We release our synthetic data to help facilitate further development in approaches using synthetic data for this task.

E Qualitative Analysis

We analyzed 100 examples from YELP produced by Lewis. 83% transfers were correct,6% incorrect,and 11% ambiguous (the resulting sentence expressed both styles). This is in line with automatic metrics and shows Lewis is effective in successfully transferring style. For diversity of edits, in 59% of cases, Lewis inverted key phrases (*and enjoying this → and avoiding this*, *friendly folks, delicious authentic bagels → sorry folks,not authentic bagels*), in 26%, Lewis rewrote part of the sentence in a way that is not inverting key adjectives/nouns (and he loved it → and he said it was OK). In 10%, Lewis performed purely syntactic editing (*definitely not enough room → enough room*). In contrast to other editors that rely on primarily single-phrase inversion (e.g. LaserTagger), demonstrating that Lewis provides diverse edits.

F Further Automatic Evaluation

We further evaluate our model on semantic similarity and fluency using the classifiers released by Krishna et al. (2020). Results are shown in Table 9 and 10. Lewis improves fluency by a significant margin on all, and outperforms other methods on 2/3 datasets on semantic similarity.

Dataset	Model	Fluency
Yelp	Delete and Retrieve	38.7
	TG	53.1
	DeepLatentSeq	68.1
	Lewis	84.5
	Gold	89.4
Amazon	Delete and Retrieve	49.2
	TG	54.6
	Lewis	85.6
	Gold	84.5
Polite	TG	67.5
	Lewis	93.0
	Gold (src)	92.3

Table 9: Fluency classification from Krishna et al. (2020)

G Further automatic evaluation

We also conduct further human We also evaluate Yelp using the same 300 examples, asking five annotators which system (LEWIS, Tag and Generate, or Neither) they prefer. Results can be seen in Table 11. These results show general preference for LEWIS is consistent across fluency, content preservation, and style transfer.

Dataset	**Model**	**Target sim.**	**Source sim.**
YELP	Delete and Retrieve	49.2	61.0
	Deep Latent Seq	48.8	60.5
	TG	54.0	67.3
	LEWIS	61.2	77.4
	Gold	—	65.7
AMAZON	Delete and Retrieve	64.9	81.0
	TG	59.2	76.3
	LEWIS	59.6	78.8
	Gold	—	75.7
POLITE	TG	—	84.6
	LEWIS	—	87.4

Table 10: Semantic similarity classification from Krishna et al. (2020)

Attribute	**LEWIS**	**Tag and Generate**	**Neither**
Fluency	**50.2**	39.2	10.6
Content Preservation	**53.3**	38.3	8.4
Style	**45.2**	41.0	13.7

Table 11: Human evaluation with annotators indicating their preference when comparing aligned pairs from both LEWIS and Tag and Generate

H Example Outputs

Source	the wine was very average and the food was even less .
LEWIS	the wine was very good and the food was even better .
LaserTagger	the wine was very good and the food was even less .
Reference	the wine was above average and the food was even better
Source	owner : a very rude man .
LEWIS	owner : a very nice man .
LaserTagger	owner : a very man .
Reference	The owner was such a friendly person.
Source	i love the food ... however service here is horrible .
LEWIS	i love the food and the service here is great .
LaserTagger	i love the food ... however service here is great .
Reference	i love the food ... and service here is awesome .

Table 12: Three examples from the Yelp test set comparing the LaserTagger trained on our synthetic data and LEWIS

Constructing Flow Graphs from Procedural Cybersecurity Texts

Abstract

Following procedural texts written in natural languages is challenging. We must read the whole text to identify the relevant information or identify the instruction-flow to complete a task, which is prone to failures. If such texts are structured, we can readily visualize instruction-flows, reason or infer a particular step, or even build automated systems to help novice agents achieve a goal. However, this structure recovery task is a challenge because of such texts' diverse nature. This paper proposes to identify relevant information from such texts and generate information flows between sentences. We built a large annotated procedural text dataset (CTFW) in the cybersecurity domain (3154 documents). This dataset contains valuable instructions regarding software vulnerability analysis experiences. We performed extensive experiments on CTFW with our LM-GNN model variants in multiple settings. To show the generalizability of both this task and our method, we also experimented with procedural texts from two other domains (Maintenance Manual and Cooking), which are substantially different from cybersecurity. Our experiments show that Graph Convolution Network with BERT sentence embeddings outperforms BERT in all three domains.

1 Introduction

Many texts in the real-world contain valuable instructions. These instructions define individual steps of a process and help users achieve a goal (and corresponding sub-goals). Documents including such instructions are called *procedural texts*, ranging from simple cooking recipes to complex instruction manuals. Additionally, *discussion in a shared forum or social media platform, teaching books, medical notes, sets of advice about social behavior, directions for use, do-it-yourself notices, itinerary guides can all be considered as procedural texts* (Delpech and Saint-Dizier, 2008). Most of these texts are in the form of natural languages and thus, lacking structures. We define *structure* as sentence-level dependencies that lead to a goal. These dependencies can vary based on the text-domain. Some examples of such dependencies are action traces, effects of an action, information leading to the action, and instruction order. Constructing structured flow graphs out of procedural texts is the foundation for natural language understanding and summarization, question-answering (QA) beyond factoid QA, automated workflow visualization, and the recovery of causal relationships between two statements. By flow-graph we mean both information and action flows in a text. However, the lack of structures in such texts makes them challenging to follow, visualize, extract inferences, or track states of an object or a sub-task, which ultimately makes constructing their flow graphs an insurmountable task.

Procedural texts are common in cybersecurity, where security analysts document how to discover, exploit, and mitigate security vulnerabilities in articles, blog posts, and technical reports, which are usually referred to as *security write-ups*. Practitioners in cybersecurity often use write-ups as educational and researching materials. Constructing structured flow graphs from security write-ups may help with automated vulnerability discovery and mitigation, exploit generation, and security education in general. However, automatically analyzing and extracting information from security write-ups are extremely difficult since they lack structure.

Figure 1 illustrates the core of a security write-up (broken into sentences) that carries instructions for exploiting a vulnerability in an online shopping service. S_1, S_3, and S_4 are the author's observations about the service's nature. Based on this information, S_5 and S_6 are two possible paths of actions.

---

[*] These authors contributed equally to this work.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3945–3957
August 1–6, 2021.

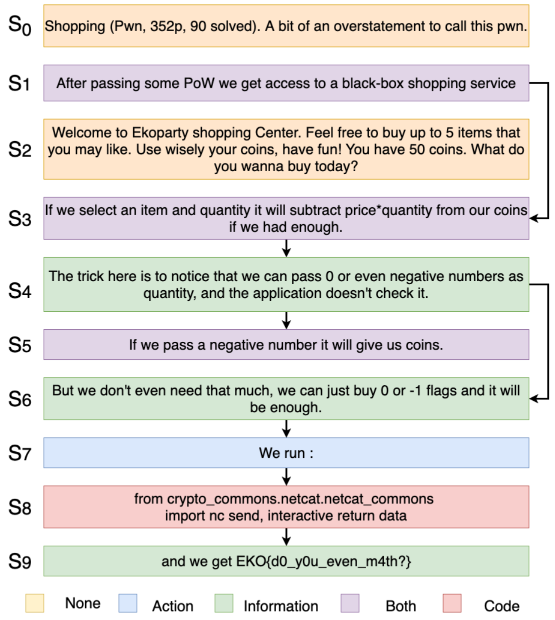

Figure 1: An example flow graph from the CTFW. Sentences in S_2 are merged into one block for clarity.

The author chose S_6 and ran the Python code in S_8 to exploit the service. S_0 and S_2 are irrelevant for the author's goal of exploiting this service.

Here we propose a novel approach to extract action paths out of structure-less, natural language texts by identifying actions and information flows embedded in and between sentences and constructing action flow graphs. Specifically, our focus is on procedural texts in the cybersecurity domain. We also show that constructing flow graphs helps extract paths of actions in domains besides cybersecurity, such as cooking and maintenance manuals.

Most previous works (Mori et al., 2014; Kiddon et al., 2015; Malmaud et al., 2014; Maeta et al., 2015; Xu et al., 2020; Mysore et al., 2019; Song et al., 2011) focus on fine-grained knowledge extraction from procedural texts in diverse domains. There are also a handful of works (Delpech and Saint-Dizier, 2008; Fontan and Saint-Dizier, 2008; Jermsurawong and Habash, 2015) that study the structure of natural language texts. Different from previous works, we extract structures and construct flow graphs from natural texts at the sentence level. This is because fine-grained domain-entity extraction tasks require a large amount of annotated data from people with specific in-depth domain knowledge, whereas text structures can be generalized.

Dataset. We built a dataset from security write-ups that are generated from past Capture The Flag competitions (CTFs). CTFs are computer security competitions that are usually open to everyone in the world. Players are expected to find and exploit security vulnerabilities in a given set of software services, and through exploiting vulnerabilities, obtain a *flag*—a unique string indicating a successful attempt—for each exploited service. Once the game is over, many players publish security write-ups that detail how they exploited services during the game. While these write-ups are a valuable educational resource for students and security professionals, they are usually unstructured and lacking in clarity. We collected 3617 CTF write-ups from the Internet, created a procedural text dataset, and invited domain experts to label each sentence for the purpose of constructing flow graphs and identifying action paths. To the best of our knowledge, this is the first attempt to use the knowledge embedded in security write-ups for automated analysis. The data and the code is publicly available [1] for future research.

This paper makes the following contributions:

- We built a new procedural text dataset, CTFW, in the cybersecurity domain. To the best of our knowledge, CTFW is the first dataset that contains valuable information regarding vulnerability analysis from CTF write-ups.
- We proposed a new NLU task of generating flow graphs from natural language procedural texts at the sentence level without identifying fine-grained named entities.
- We proposed four variations of a graph neural network-based model (LM-GNN) to learn neighbor-aware representation of each sentence in a procedural text and predict the presence of edges between any pair of sentences.
- We evaluated our models on CTFW. To the best of our knowledge, this is the first attempt in automated extraction of information from security write-ups. We also evaluated our models across three datasets in different domains and showed the generalizability of our approach.

2 Our Approach

We map each sentence of a procedural text as a node in a graph, and the action or information flows as edges. The task is then simplified into an edge prediction task: Given a pair of nodes, find if there is an edge between them. We learn feature representations of nodes using language models like BERT/RoBERTa (Devlin et al., 2018; Liu et al.,

Dataset Statistics	COR	MAM	CTFW
# Documents	297	575	3154
Avg size of document	9.52	8.12	17.11
Avg length of sentence	65.46	34.81	92.87
# Edges ($\|e^+\|$)	2670	5043	54539
$\|e^+\| : (\|e^+\| + \|e^-\|)$	0.18	0.12	0.07
Avg degree of node	1.83	1.76	1.88

Table 1: Dataset Statistics. $|e^+|$ is the total number of actual edges, and $|e^+| + |e^-|$ is the total number of edges possible. The in-degree of the starting node and out-degree of the end node are both 0.

2019). Then, to make the nodes aware of their neighboring sentences, we use Graph Neural Network (GNN) to update the node representations. We check for the edge between every pair of nodes in a graph and reduce the task to a binary classification during inference. This formulation enables us to predict any kind of structure from a document.

3 Dataset Creation

In this section, we present how we created three datasets on which we evaluated our approach. Table 1 shows the statistics for each datasets used.

3.1 CTF Write-ups Dataset (CTFW)

Each CTF competition has multiple challenges or tasks. Each task may have multiple write-ups by different authors. We crawled 3617 such write-ups from GitHub and CTFTime (CTFTime). Write-ups are unique and diverse but have common inherent principles. For each write-up, we provide two kinds of annotations: *sentence type* and *flow structure*. The writing style is informal with embedded code snippets and often contains irrelevant information.

Part of the annotations were provided as an optional, extra-credit assignment for the Information Assurance course. These CTF write-ups were directly related to the course-content, where students were required to read existing CTF write-ups and write write-ups for other security challenges they worked on during the course. Then students were given the option of voluntarily annotating CTF write-ups they read for extra credits in the course. For this task, we followed all the existing annotation guidelines and practices. We also ensured that (1) The volunteers were aware of the fact that their annotations would be used for a research project (2) They were aware that no PII was involved or would be used in the research project (3) They were aware that extra credits were entirely optional, and they could refrain from submitting at any point of time without any consequences (4) Each volunteer was assigned only 10-15 write-ups based on a pilot study we did ahead of time, annotating an average-length CTF write-up took about two minutes (maximum ten mins).

Remaining annotations were performed by the Teaching Assistants (TA) of the course. These annotations were done as part of the course preparation process, which was part of their work contract. All the TAs were paid bi-weekly compensation by the university or by research funding. It was also ensured that the TAs knew these annotations would be used for a research project, their PII was not involved and annotations were to be anonymized before using. We verified the annotations by randomly selecting write-ups from the set. Figure 1 shows a sample annotation.

Sentence Type Annotations. We split the documents into sentences using natural language rules. We then ask the volunteers to annotate the type of each statement as either Action (A), Information (I), Both (A/I), Codes (C), or irrelevant (None). *Action* sentences are those where the author specifies actions taken by them, whereas, *Information* statements mention observations of the author, the reasons and effects of their action. Sentences containing *codes* are assigned as C, and those which can be considered as both information and actions are marked as *Both* (A/I).

Flow structure Annotations. The second level of annotations is regarding the write-up structure. Each volunteer is given a csv file for each document with a set of sentence IDs and text for each write-up. They are asked to annotate the flow of information in the document by annotating the sentence id of some next possible sentences, which indicate the flow. We filter those write-ups which are irrelevant and those which did not have much detail (single line of valuable information). We call a write-up as irrelevant if it has no action-information annotations or if it has direct codes without any natural language description of steps to detect vulnerabilities. We only keep write-ups written in the English language for this work. Finally, we have 3154 write-ups with *sentence type* and *structure annotations*.

CTFTime website states that the write-ups are copyrighted by the authors who posted them and it is practically impossible to contact each author.

Such data is also allowed to use for academic research purposes(usc; euc). Thus, we follow the previous work using data from CTFTime (Švábenskỳ et al., 2021), and share only the urls of those write-ups which we use. We do not provide the scraper script since it would create a local copy of the write-up files unauthorized by the users. Interested readers can replicate the simple scraper script from the instructions in Appendix A and use it after reviewing the conditions under which it is permissible to use. We, however, share our annotations for those write-up files.

3.2 Cooking Recipe Flow Corpus (COR)

This corpus (Yamakata et al., 2020) provides 300 recipes with annotated recipe named entities and fine-grained interactions between each entity and their sequencing steps. Since we attempt to generate action flow graphs without explicitly identifying each named entity, we aggregate the fine-grained interactions between recipe named entities to generate sentence-level flows for each recipe. We reject three single-sentence recipes.

3.3 Maintenance Manuals Dataset (MAM)

This dataset (Qian et al., 2020) provides multi-grained process model extraction corpora for the task of extracting process models from texts. It has over 160 Maintenance Manuals. Each manual has fine-grained interactions between each entity and its sequencing steps. We use the annotations from sentence-level classification data and semantic recognition data for generating annotations of sentence-level flows for each process. Here also, we reject single sentence processes.

4 Model Description

Our goal is to find paths or traces of actions or information between texts. This needs an understanding of each sentence's interconnection. Hence, we modeled the problem into an edge prediction task in a graph using GNNs. We represent each sentence as a node and directed edges as information flows. Since this is procedural text (unidirectional nature) of instructions, we consider only the directed edges from one sentence S_n to any of its next sentences S_{n+i}. The node representations are learned using language models (LM) and GNNs.

4.1 Document to Sentence Pre-processing

Given a natural language document, first we split the document into sentences based on simple rules and heuristics. COR and MAM datasets already have document split into separate sentences. In the flow graph creation task, we filter out irrelevant sentences for the CTFW dataset based on the sentence type annotations. After this pre-processing task, each document (D_i) is converted into a series of sentences (S_j) where n is the number of valid sentences in a document.

$$D_i = \{S_0, S_1, S_2 ... S_{n-1}\}$$

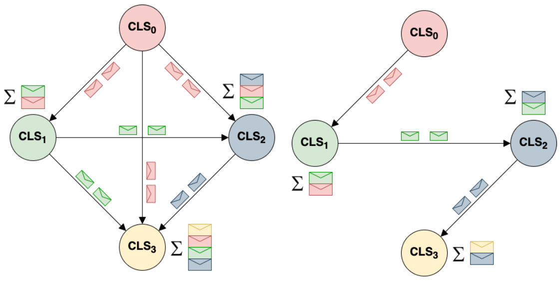

Figure 2: *Node Representation Learning for a document with four sentences in single-layer GNN.* Left: *Semi-Complete* Structure, Right: *Linear* Structure. During training, the sentence representation (CLS_i) are enriched using appropriate message passing techniques from the connected 1-hop neighbors.

4.2 Document to Graph Representation

A graph ($G = (V, E)$) is formally represented as a set of nodes ($V = \{v_0, v_1, ..\}$) connected by edges ($E = \{e_0, e_1, ..\}$ where $e_i = \{v_m, v_n\}$). We consider the sentences (S_j) of any document (D_i) as nodes of a directed graph (G_i). We experiment with two graph structure types for learning better node representation using GNN. First, we form local windows (W_N, where $N = 3, 4, 5, all$ sentences) for each sentence and allow the model to learn from all of the previous sentences in that window. We form the document graph by connecting each sentence with every other sentence in that window, with directed edges only from S_i to S_j where $i < j$. We do this since procedural languages are directional. We call this configuration *Semi-Complete*. Second, we consider connecting the nodes linearly where every S_i is connected to S_{i+1} except the last node. We call this *Linear* setting. Figure 2 shows the settings. We use LMs like BERT and RoBERTa to generate initial sentence representations. For each sentence (S_i), we extract the pooled sentence representation (CLS_{S_i}) of contextual BERT/RoBERTa embeddings (h_{S_i}).

We use CLS_{S_i} as node features for the graph (G_i).

$$h_{S_i} = BERT\,(\,[CLS]s_0s_1...s_{n-1}\,[SEP]\,)$$

4.3 Neighbor Aware Node Feature Learning

Since the LM sentence vectors are generated individually for each sentence in the document, they are not aware of other local sentences. So, through the *semi-complete* graph connection, the model can learn a global understanding of the document. However, the *linear* connection helps it learn better node representation conditioned selectively on its predecessor. We call the connected nodes as the neighbor nodes. We use Graph Convolutional Network (GCN) (Kipf and Welling, 2016) and Graph Attention Network (GAT) (Veličković et al., 2017) to aggregate the neighbor information for each node following the generic graph learning function (1)

$$\mathbf{H}^{l+1} = f(\mathbf{H}^l, \mathbf{A}) \tag{1}$$

where $\mathbf{A}$ is the adjacency matrix of the graph, $\mathbf{H}^l$ and $\mathbf{H}^{(l+1)}$ are the node representations at lth and $(l+1)$th layer of the network and f is the message aggregation function. In GCN, each node i, aggregates the representations of all of its neighbors $N(i)$ based on $\mathbf{A}$ and itself at layer l and computes the enriched representation $\mathbf{h}_i^{l+1}$ based on the weight matrix $\mathbf{\Theta}$ of the layer normalized by degrees of source $d(i)$ and its connected node $d(j)$ as per (2). In GAT, messages are aggregated based on multi-headed attention weights (α) learned from the neighbor node representations $\mathbf{h}_j^l$ following (3).

$$\mathbf{h}_i^{l+1} = \mathbf{\Theta} \sum_{j \in N(i) \cup \{i\}} \frac{1}{\sqrt{d(i)d(j)}} \mathbf{h}_j^l \tag{2}$$

$$\mathbf{h}_i^{l+1} = \alpha_{ii} \mathbf{\Theta} \mathbf{h}_i^l \; + \sum_{j \in N(i)} \alpha_{ij} \mathbf{\Theta} \mathbf{h}_j^l \tag{3}$$

4.4 Projection

We concatenate the neighbor aware node representations of each pair of nodes ($\mathbf{h}_i$;$\mathbf{h}_j$) from a graph and pass it through two projection layers with a GELU (Hendrycks and Gimpel, 2016) nonlinearity in between. We use the same non-linearity functions used by the BERT layers for consistency. We steadily decrease the parameters of each projection layer by half. During testing, given a document, we are unaware of which two sentences are connected. So, we compare each pair of nodes. This leads to an unbalanced number of existing (1) and non-existing (0) edge labels. Hence, we use weighted cross-entropy loss function as in equation (4) and (5), where L is the weighted cross-entropy loss, w_c is the weight for class c, i is the data in each mini-batch.

$$L(x,c) = w_c\Big(-x_c + log\Big(\sum_j exp(x_j)\Big)\Big) \tag{4}$$

$$L = \frac{\sum_{i=1}^{N} L(i, c_i)}{\sum_{i=1}^{N} w_{c_i}} \tag{5}$$

4.5 Training and Inference

Our training data comprises a set of sentences and the connections as an adjacency matrix for each document. Batching is done based on the number of graphs. GCN/GAT updates the sentence representations. A pair of node representations are assigned a label of 1 if there is an edge between them; otherwise, we assign them 0. Thus, we model it as a binary classification task as in equation (6) where f is the projection function, g is the softmax function, and y is the binary class output. Depending on the weighted cross-entropy loss, the node representations get updated after each epoch. During inference, the model generates node representations of each sentence in a test document, and we predict whether an edge exists between any two nodes in a given document graph.

$$y_c = \arg\max_k g(f(\mathbf{h}_i; \mathbf{h}_j), k) \quad c \in \{0, 1\} \tag{6}$$

5 Experiments

Datasets and Tasks: Each dataset is split into train, validation, and test sets in 70:10:20 ratio. The first task is identifying relevant information from raw CTF write-ups by classifying the type of each sentence. The second task is identifying information flows between sentences by predicting edges between sentence pairs, if any.

Metrics: We use *accuracy* as the evaluation metric for the Sentence Type classification task on CTFW. For the second task, because of the label imbalance we compare based on the *area under Precision-Recall curve* (PRAUC) and also report the corresponding *F1-score*. Hence do not report area under the ROC curve or accuracy.

We consider four settings for this task. The *no window* setting (W_{all}) checks whether there is an edge between any two statements in the given document. The comparisons required in this setting are directly proportional to the document's size. In CTFW, the size of each write-up is quite large. So,

	Models	CTFW		COR		MAM	
		PRAUC	F1	PRAUC	F1	PRAUC	F1
Baselines	Random	-	50.49	-	42.78	-	47.82
	Weighted Random	-	37.81	-	39.13	-	44.10
	BERT-NS	0.5751	26.12	0.5638	43.14	0.5873	29.73
	RoBERTa-NS	0.5968	32.44	0.5244	42.99	0.6236	39.65
Ours	BERT-GCN	0.7075	69.26	**0.6312**	58.13	**0.6888**	63.75
	RoBERTa-GCN	**0.7221**	69.04	0.6233	61.44	0.6802	65.73
	BERT-GAT	0.5585	61.93	0.4553	41.93	0.4568	62.18
	RoBERTa-GAT	0.5692	64.51	0.4358	24.74	0.4585	59.55

Table 2: Comparison with Baselines on Best Test Area under Precision-Recall Curve (PRAUC) and its corresponding F1 for **CTFW** (CTFwrite-up), **COR** (Cooking), **MAM** (Maintenance) datasets. NS is the next sentence based prediction approach. Our best model performance is bold, while maximum baseline performance is underlined.

to reduce unnecessary comparisons, we apply simple heuristics that instructions in procedural text, in general, does not have longer *direct* dependencies. Thus, using the windows, we can control each sentence's number of comparisons (node). To understand how the performances change we evaluate with a *sliding windows of N sentences* (W_N) where $N = 3, 4, 5$. The comparisons are only made with the next N sentences from a given sentence. For example, in case of W_5, for first sentence (S_1) we check for edges with S_2, S_3, S_4, S_5, S_6 and not S_7 on-wards. However, to have a fair comparison, we keep labeled out-of-window gold edges, if any. The ratios of existing and total edges in CTFW are 0.07 (W_{all}), 0.24 (W_5), 0.29 (W_4), 0.38 (W_3).

Training: We use Pytorch Geometric (Fey and Lenssen, 2019) for GNN and transformers (Wolf et al., 2020) for LM implementations. Training is done with AdamW (Loshchilov and Hutter, 2017) optimizer along with linear warmup scheduler on 4 Tesla V100 16GB GPUs. We use bert-base-uncased, bert-large-uncased, roberta-base and roberta-large versions as base model. We store the model with the best PRAUC score. Batch size of {4,8,16} and learning rates of {1e-5,5e-6} are used. Maximum sequence length varies between {64, 80, 128}. GNN depths are kept 128 (layer 1) and 64 (layer 2). We use a dropout of 0.4 in selected layers. For GAT, we keep four attention heads in layer 1. Details are present in Appendix C.

6 Results and Discussion

6.1 Sentence Type Classification (STC)

We use large and base versions of BERT and RoBERTa for this task to predict the type of sentences in a given text to establish a baseline for this task. This task helps to identify relevant and irrelevant sentences in a document. Each sentence is classified into any of Action, Information, Both, Code, and None. These fine-grained annotations can be used in later works for creating automated agents for vulnerability analysis. The processed data consists of 120751 samples for training, 17331 for validation, and 34263 for testing. Table 3 shows that RoBERTa-large performs better than the rest.

Model	**Val**	**Test**
BERT-Base	78.48±0.25	77.42±0.10
BERT-Large	78.19±0.48	77.13±0.20
RoBERTa-Base	78.85±0.25	77.37±0.11
RoBERTa-Large	79.02±0.16	**77.66±0.12**

Table 3: Sentence Type Classification (Mean Accuracy from three seed values). Best performance in bold.

6.2 Flow Structure Prediction

Here we present the performance results for the flow structure prediction.

Random Baseline: In the *Random* baseline, for every pair of nodes in each document we randomly select 0 (no-edge) or 1 (edge). For *Weighted Random* baseline, we choose randomly, based on the percentage of edge present in the train set. We only report F1 since there is no probability calculation.

Next Sentence-based Prediction (NS) Baseline: We use LMs like BERT and RoBERTa in a next sentence prediction setting to get the baselines. Each pair of sentences is concatenated using [SEP] token and passed through these language models. Using the pooled LM representation, we classify whether an edge exists between them or not. We show maximum PRAUC and its corresponding F1 for each dataset from the results of each of our window settings (W_3, W_4, W_5, W_{all}).

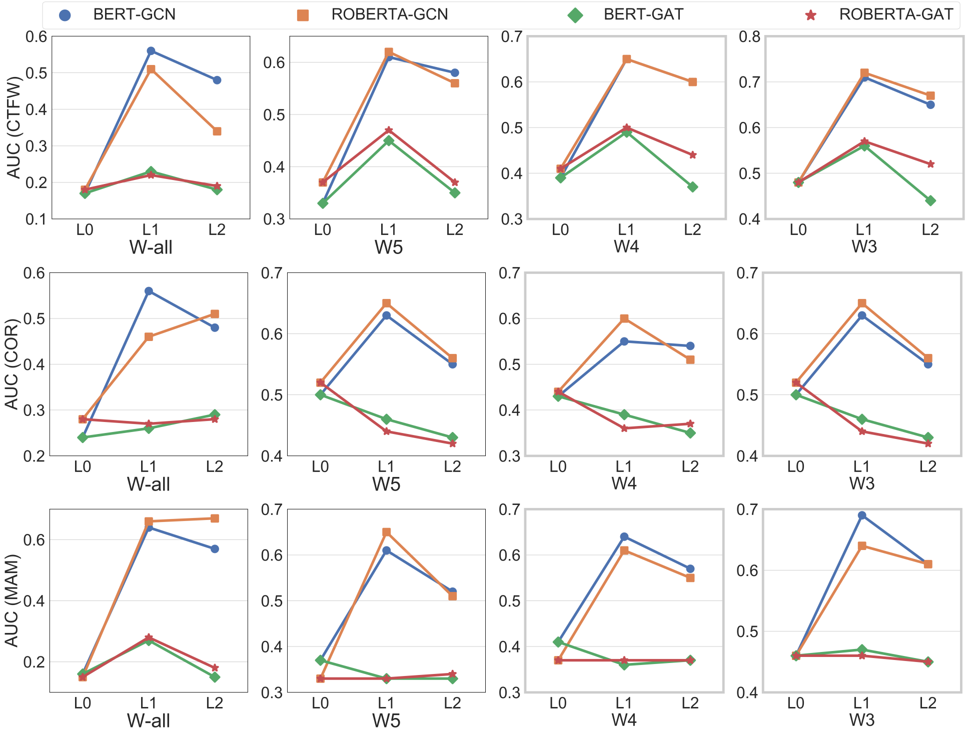

Figure 3: Effect of GNN Layers (L_0, L_1, L_2) on performance (PRAUC) of the models for W_{all}, W_5, W_4, W_3 settings on the three datasets

Models: We compare four variants of our LM-GNN models both with baseline and among each other in Table 2. The scores are overall best scores across single and double layers GNN (GCN/GAT) and LM (BERT/RoBERTa) after experiments with both base and large version, trained with pre-trained and randomly initialized weights.

We see that the best LM-GCN models outperform the best baseline model by 0.12, 0.07, 0.06 in PRAUC for CTFW, COR, and MAM datasets, respectively. However, the best LM-GAT scores falls short of the baselines indicating that the graph attentions on LM *sentence representations* cannot learn robust representation to perform this edge prediction task. Another thing to notice here is that, the best BERT-GCN models perform better than RoBERTa-GCN for COR and MAM datasets while performs poorly in the CTFW dataset. We hypothesize that this is because, the CTFW dataset has ten times more data than COR and six times more than MAM, which helps the RoBERTa model correctly predict the edges.

	W_3	W_4	W_5	W_{all}
CTFW-SC	0.6630	0.5985	0.5733	**0.5590**
CTFW-L	**0.7221**	**0.6520**	**0.6150**	0.3962
CTFW-EP	0.3700	0.2900	0.2400	0.0700
COR-SC	0.5639	0.5129	0.4731	**0.5580**
COR-L	**0.6456**	**0.6012**	**0.5274**	0.4034
COR-EP	0.3700	0.3100	0.2600	0.1700
MAM-SC	0.6528	0.6219	0.6091	**0.6718**
MAM-L	**0.6888**	**0.6362**	**0.6137**	0.4161
MAM-EP	0.4500	0.3700	0.3200	0.1500

Table 4: Effect of Semi-Complete(SC) and Linear(L) Graph Connection on 3 datasets in Area under Precision-Recall Curve (PRAUC). We also keep edge-percent (EP) in four window settings for comparison.

6.3 Analysis

Effect of Graph Connection Type: Table 4 shows how the models behave with semi-complete (SC) and linear (L) graph connection. For each dataset, we compare the PRAUC results for each window to draw more granular insight on the effect of neighbor aware representation learning. When we restrict graph learning by creating small windows (W_3, W_4, W_5), the linear model works better because of its selective learning conditioned on its predecessor. On the other hand, the semi-complete connection helps to learn a global awareness and works best in the W_{all} setting. It is important to note that each model performs better than the average PRAUC performance, which is the percentage of edges in the data indicating that the model is able to learn using the graph connections.

Effect of Graph Layers: We study how the depth of the GNNs affects the performance. We compare PRAUC across all four variations of the model in No-Window (W_{all}), W_5, W_4, W_3 settings in Figure 3. We experimented with no (L_0), single (L_1) and double (L_2) GNN layers. In all three datasets, we find the performance improves when we use a single layer and degrades beyond that for each of the windows with GCN based models. We do not go beyond two layers because of this observation and the graph connection types we use. We believe the reason for this drop (0.03-0.08 PRAUC) is that information from 2-hop neighbors might hinder the learning of the current node and confuse the model to predict wrongly. The GAT-based models mostly remain unaffected with the graph layers for both COR and MAM while showing some improvement in CTFW for one layer setting.

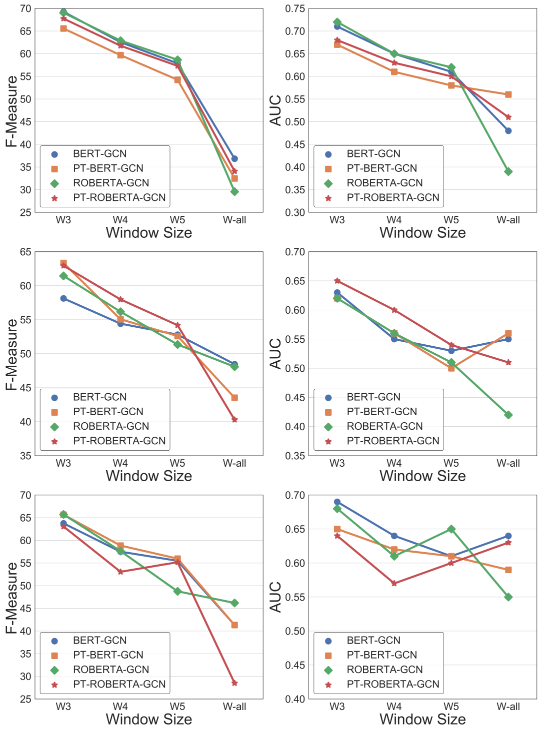

Figure 4: Performance for CTFW, COR, MAM trained from **scratch** and fine-tuned with **pre-trained weights**.

Effect of Pre-trained LM Weights: We study the impact of pre-trained weights of BERT and RoBERTa on the performance in Figure 4. We notice, for the three datasets, the performance slightly decreases when the pre-trained model weights are used. This observation may be because the texts' nature is quite different from the type of texts these LMs have been pre-trained on. The CTFW data often contains code fragments embedded in sentences, emoticons, or common conversational languages used in public forums.

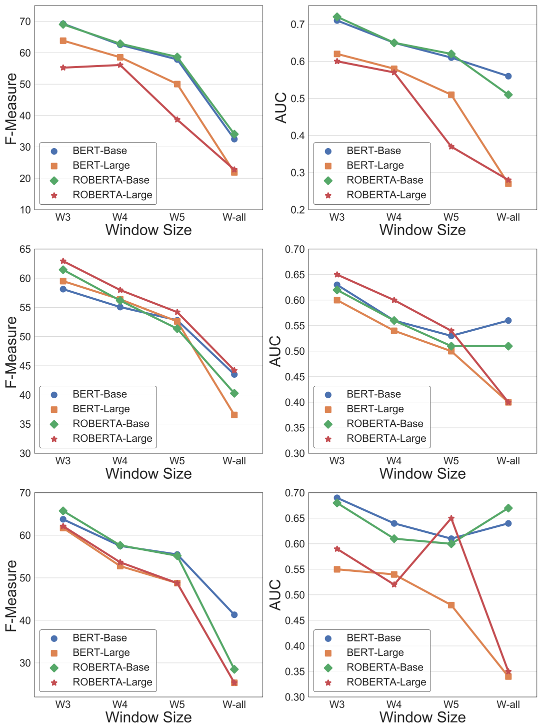

Figure 5: Performance on CTFW, COR, MAM trained with **base** and **large** version of the model.

Effect of LM Size: We also experimented with the size of sentence embeddings to see if that makes any difference to the performance. We use base and large version of BERT and RoBERTa for the experiments across three datasets. We present the impact on F1 and PRAUC in Figure 5. The performance of the larger versions of the models drop in all three datasets. This drop, we believe, is because the sentences in these texts are relatively short and help the smaller versions of the models with lesser parameters to learn better.

Other experiments: We also experimented with modifications of other parts of the models like changing the number of projection layers, projection layer sizes, the number of attention heads in the GAT model, or dropout percent in selected layers and modes of message aggregation (add, max, mean). We do not report them since they do not significantly change PRAUC values.

7 Related Work

Procedural knowledge extraction: There are attempts to extract structured knowledge from cooking instructions in the form of named entities (Malmaud et al., 2014), their sentence-level dependencies (Mori et al., 2014; Maeta et al., 2015; Xu et al., 2020), and action-verb argument flow across sentences (Jermsurawong and Habash, 2015; Kiddon et al., 2015; Pan et al., 2020). In other domains, extraction of clinical steps from medline abstracts (Song et al., 2011), extraction of material synthesis operations and its arguments in material science (Mysore et al., 2019), providing structures to how-to procedures (Park and Motahari Nezhad, 2018), and action-argument retrieval from web design tutorials (Yang et al., 2019) mostly focus on fine-grained entity extractions rather than action or information traces. The goal of our paper is constructing flow graphs from free-form, natural-language procedural texts without diverse domain knowledge. Hence, we refrain from training specialized named-entity recognizers for each domain to find specific entities. Our work is related to event or process discovery in process modeling tasks (Epure et al., 2015; Honkisz et al., 2018; Qian et al., 2020; Hanga et al., 2020), but our goal is not finding specific events or actions from procedural texts. In addition, the recent research proposed a method to create the forum structures from an unstructured forum based on the contents of each post using BERT's Next Sentence Prediction (Kashihara et al., 2020). However, we focus on building flow graphs for procedural texts using GNNs.

Graph Neural Networks: GNNs are important in reasoning with graph-structured data in three major tasks, node classification (Kipf and Welling, 2016; Hamilton et al., 2017), link prediction (Schlichtkrull et al., 2018), and graph classification (Ying et al., 2018; Pan et al., 2015, 2016; Zhang et al., 2018). GNNs help learn better node representations in each task using neural message passing (Gilmer et al., 2017) among connected neighbors. We consider two widely used GNNs, GCN (Graph Convolutional Network) (Kipf and Welling, 2016) and GAT (Graph Attention Networks) (Veličković et al., 2017) to learn sentence representation to provide a better edge prediction.

Edge Prediction Task: Edge or link prediction tasks (Li et al., 2018; Zhang and Chen, 2018; Pandey et al., 2019; Haonan et al., 2019; Bacciu et al., 2019) work mainly on pre-existing networks or social graphs as inputs and predict the existence of future edges between nodes by extracting graph-specific features. Different from existing work, we modeled the task of generating a graph-structure from a given natural-language text as an edge prediction task in a graph and learning representations of sentences considered as nodes.

Combinations of BERT and GCN: Recent works have used concatenation of BERT and GCN representations of texts or entities to improve performance of tasks like commonsense knowledge-base completion (Malaviya et al., 2019), text classification (Ye et al.; Lu et al., 2020), multi-hop reasoning (Xiao et al., 2019), citation recommendation (Jeong et al., 2019), medication recommendation (Shang et al., 2019), relation extraction (Zhao et al., 2019). Graph-BERT (Zhang et al., 2020) solely depends on attention layers of BERT without using any message aggregation techniques. However, we differ from each of the previous methods in terms of model architecture, where we use BERT to learn initial sentence representations and GCN or GAT to improve them by learning representations from its neighboring connected sentences. BERT-GAT for MRC (Zheng et al., 2020) created the graph structure from the well-structured wikipedia data whereas we explore two predefined natures of graph structures because of the free-formed text nature without such well-defined text-sections, presence of code-fragments, emoticons, and unrelated-token.

8 Conclusion and Future Work

We introduce a new procedural sentence flow extraction task from natural-language texts. This task is important for procedural texts in every domain. We create a sufficiently large procedural text dataset in the cybersecurity domain (CTFW) and construct structures from the natural form. We empirically show that this task can be generalized across multiple domains with different natures and styles of texts. In this paper, we only focus on English security write-ups. As part of future work, we plan to build automated agents in the cybersecurity domain to help and guide novices in performing software vulnerability analysis. We also plan to include non-English write-ups. We hope the CTFW dataset will facilitate other works in this research area.

Impact Statement

The dataset introduced here consists of write-ups written in public forums by students or security professionals from their personal experiences in the CTF challenges. The aggregated knowledge of such experiences is immense. This in-depth knowledge of the analysis tools and the approach to a problem is ideal for students working in software vulnerability analysis to learn from. Automated tutors built using such knowledge can reduce the efforts and time wasted in manually reading through a series of lengthy write-up documents.

CTFTime website states that the write-ups are copyrighted by the authors who posted them and it was practically impossible to contact each authors. It is also allowed to use the data for research purposes (usc; euc) Thus, we follow the previous work (Švábenskỳ et al., 2021) using data from CTFTime and share only the urls of those write-ups from the CTFTime website which we use. We do not provide the scraper script since it would create a local copy of the write-up files unauthorized by the users. Interested readers can replicate the simple scraper script from the instructions in Appendix A and use it after reviewing the conditions under which it is permissible to use. We, however, share our annotations for those write-ups files.

Part of the annotations were provided as an optional, extra-credit assignment for the Information Assurance course. These CTF write-ups were directly related to the course-content, where students were required to read existing CTF write-ups and write write-ups for other security challenges they worked on during the course. Then students were given the option of voluntarily annotating CTF write-ups they read for extra credits in the course. For this task, we followed all the existing annotation guidelines and practices. We also ensured that

- The volunteers were aware of the fact that their annotations would be used for a research project.
- They were aware that no PII was involved or would be used in the research project.
- They were aware that extra credits were entirely optional, and they could refrain from submitting at any point of time without any consequences.
- Each volunteer was assigned only 10-15 write-ups based on a pilot study we did ahead of time, annotating an average-length CTF write-up took about two minutes (maximum ten mins).

Remaining annotations were performed by the Teaching Assistants (TA) of the course. These annotations were done as part of the course preparation process, which was part of their work contract. All the TAs were paid bi-weekly compensation by the university or by research funding. It was also ensured that the TAs knew these annotations would be used for a research project, their PII was not involved and annotations were to be anonymized before using.

A Extraction and Processing of Write-ups:

The extraction of CTF Write-up involved the following three phases.

Writeup URL extraction : We loop through all the write-up pages on ctftime website from page numbers 1 to 25500). We use a simple python scraper to scrape the content of each page using python requests (Reitz) library. We look for keyword "*Original write-ups*" and extracted the href component if present. These URLs are stored for each writeup indexed with the page numbers.

Write-up Content extraction : We use these URLs and extract the contents of the write-ups using python libraries requests and BeautifulSoup (Richardson, 2007). We extract all the text lines ignoring contents in html tags like style, scripts, head, title. The contents are stored in a text file named with the same page ids of the URLs.

Processing of Write-up : We processed and filter out sentences which do not have any verb forms using spacy (spaCy, 2017) POS-Tagger. We cleaned and removed unnecessary spaces and split them into sentences. The processing script is available in the github.

B CTFW Data Statistics

In CTFW, there are write-ups for 2236 unique tasks. Only four out of those having more than 5 write-ups each. 72% of the tasks have single write-up. The write-ups are from 311 unique competitions, ranging from years 2012-2019. A task having multiple write-ups vary in contents. In CTFW, only 3% of the tasks have more than three write-ups, and 9% have more than two.

C Training Details:

The correct set of hyperparameters are found by running three trials. We run for {50, 100} epochs and store the model with the best PRAUC score. Each training with evaluation takes around 1-3 hours for base version of models and around 6 hours for larger versions depending upon the dataset used. The model parameters are directly proportional to the model parameters of language models, since the GNN only allow few more parameters as compared to the LMs.

D Baseline NS with weighted cross-entropy

Table 5 shows the PRAUC values when we use weighted cross-entropy with base version of BERT on unbalanced data during training. The results are not much different than the Next-Sentence baseline shown previously.

Dataset	W_3	W_4	W_5	W_{all}
CTFW	0.4613	0.4397	0.2546	0.3681
COR	0.4724	0.4748	0.4837	0.4761
MAM	0.5318	0.2318	0.2297	0.4724

Table 5: BERT-base-uncased performance with NS prediction when Weighted Cross-Entropy used with Unbalanced Training Data

E Number of comparisons Reduction using Windows

We can control the total number of comparisons required to predict the edges in a graph by using the windows (W_N where $N = 3, 4, 5, all$). The number of comparisons for each window is given by the equation 7. We can reduce the number of comparisons considerably for large documents using shorter windows of 3, 4, 5 sentences. The number of comparison $\mathcal{C}$ is defined by

$$\mathcal{C} = \begin{cases} max\{(n-s), 0\}s + \frac{s(s-1)}{2} & n = 3, 4, 5 \\ \binom{n}{2} & n = all \end{cases} \tag{7}$$

Abstract

Transformer has become ubiquitous in the deep learning field. One of the key ingredients that destined its success is the self-attention mechanism, which allows fully-connected contextual encoding over input tokens. However, despite its effectiveness in modeling short sequences, self-attention suffers when handling inputs with extreme long-range dependencies, as its complexity grows quadratically *w.r.t.* the sequence length. Therefore, long sequences are often encoded by Transformer in chunks using a sliding window. In this paper, we propose *Cluster-Former*, a novel clustering-based sparse Transformer to perform attention across chunked sequences. The proposed framework is pivoted on two unique types of Transformer layer: Sliding-Window Layer and Cluster-Former Layer, which encode local sequence information and global context jointly and iteratively. This new design allows information integration beyond local windows, which is especially beneficial for question answering (QA) tasks that rely on long-range dependencies. Experiments show that Cluster-Former achieves state-of-the-art performance on several major QA benchmarks.

1 Introduction

Long-range contextual understanding has proven critical in many natural language processing (NLP) tasks. For example, the relevant context for correctly answering an open-domain question can arch over thousands of words (Chen et al., 2017). Encoding long sequences via deep neural networks, however, has remained an expensive and challenging task due to high demand on training time and GPU memory. Traditional sequence modeling methods (Hochreiter and Schmidhuber, 1997) encode long sequences in a chronological order, which suffers high latency. In the place of sequential encoding, recent models such as Transformer (Vaswani et al., 2017) use simultaneous self-attention over the entire input instead, which has been successfully adopted in many NLP tasks such as textual entailment (Devlin et al., 2019), dependency parsing (Zhou and Zhao, 2019), and summarization (Lewis et al., 2019). A caveat with Transformer though is that building full connections over long sequences translates to quadratic growth on memory demand and computational complexity *w.r.t.* sequence length.

One way to efficiently encode long sequences is to first chunk a sequence into much shorter ones with a sliding window, then build connections between the shorter sequences (Figure 1(a)). For example, Child et al. (2019), Beltagy et al. (2020) and Zaheer et al. (2020) apply sparse attention to chunked sequences in hand-designed patterns in order to gather information from the chunks (Figure 1(b)). Choi et al. (2017) and Wang et al. (2019) first use a simpler model to filter chunked sequences, then process selected sequences with fully-connected self-attention. Rae et al. (2019) makes use of the shared memory of chunked sequences to build connections between them. However, these methods cannot encode long-range dependencies with as much flexibility or accuracy as fully-connected self-attention, due to their dependency on hand-designed patterns.

Recently, several studies (Kitaev et al., 2020; Tay et al., 2020a) propose to further improve the sparse attention mechanism by hashing or sorting the hidden states into different buckets (Figure 1(c)). These works mainly explore tasks with relatively short sequences, such as sentence-level machine translation, where the number of hashing vectors is relatively small (less than 16 in Kitaev et al. (2020)), allowing randomly initialized hashing vectors to hash hidden states into correct buckets. However, how to use hashing-based attention in the context of long sequences (*e.g.*,, up to

(b) builds cross-sequence attention based on sliding window over pre-selected positions (red-dotted boxes). (c) hashes the hidden states into different buckets by randomly-initialized vectors. (d) is our proposed approach to cluster the hidden states. Our final model is a combination of (a) and (d) that processes both local and global context.

thousands of words) is still an unexplored territory.

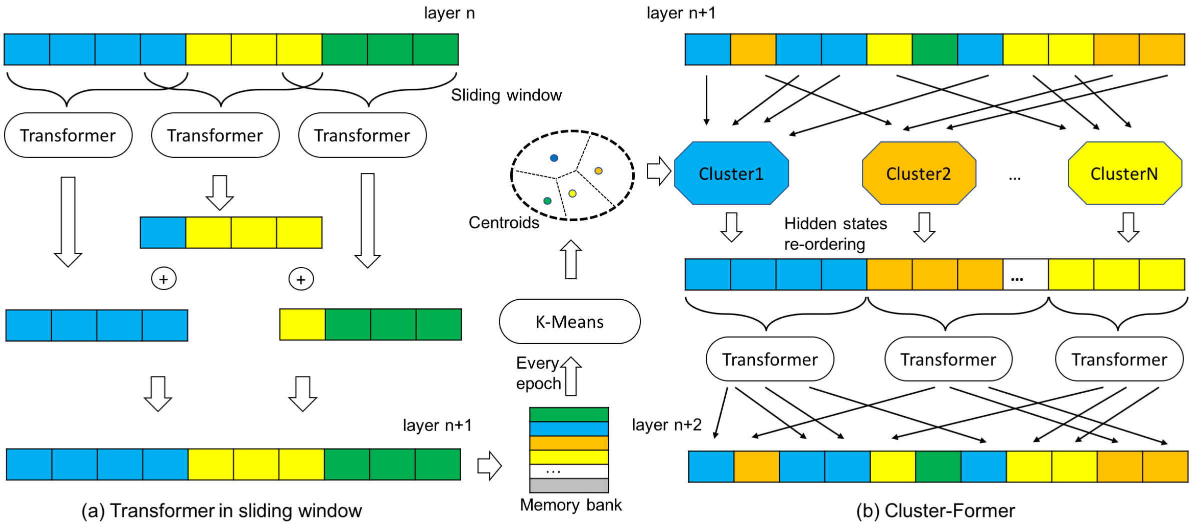
Our proposed framework for efficient long sequence encoding, *Cluster-Former*, marries both sliding-window and hashing-based methods to achieve effective local and long-range dependency encoding. Cluster-Former consists of two types of encoding layer. The first one (noted as *Sliding-Window Layer*) focuses on extracting local information within a sliding window. It applies Transformer to the hidden states of each chunked sequence independently, as shown in Figure 1(a). The other one (noted as *Cluster-Former Layer*) learns to encode global information beyond the initial chunked sequences. Specifically, we first apply clustering to the input hidden states so that similar hidden states are assigned to the same cluster, as shown in Figure 1(d). The clustered and sorted input is then divided uniformly into chunks, each encoded by a Transformer layer. Note that to make model training more efficient, the cluster centroids are not computed online but updated periodically (every epoch or a few epochs). We accumulate the hidden states from the layer prior to the Cluster-Former layer in a memory bank, and apply the K-Means algorithm to form cluster centroids during each update cycle. Compared to previously discussed sparse attention based on pre-selected positions (Figure 1(b)) or randomly-initialized hashing vectors (Figure 1(c)), experimental results show that our method can encode dependency across chunked sequences more effectively.

Our contributions can be summarized as follows. (i) We propose Cluster-Former, a novel approach to capturing long-range dependencies more effectively than locality-sensitive hashing method. (ii) We propose a new Transformer-based framework to process long sequences by combining Sliding-Window and Cluster-Former layers to extract both local and global contextual information. (iii) Our model achieves the best performance on question answering datasets of Natural Questions (long answer), SearchQA, and Quasar-T.

2 Related Work

Efficient Transformers With Transformer models growing larger and larger, how to handle longer sequences arises as a critical challenge. Many works have been proposed to improve the computational and memory efficiency of Transformers, including Sparse Transformer (Child et al., 2019), Set Transformer (Lee et al., 2019), Routing Transformer (Roy et al., 2020), Fast Transformer (Vyas et al., 2020), Reformer (Kitaev et al., 2020), Sinkhorn Transformer (Tay et al., 2020a), Longformer (Beltagy et al., 2020), ETC (Ainslie et al., 2020), Synthesizer (Tay et al., 2021), Performer (Choromanski et al., 2020), Linformer (Wang et al., 2020), Linear Transformer (Katharopoulos et al., 2020), and BigBird (Zaheer et al., 2020). Tay et al. (2020b) provided an excellent literature survey on this emerging topic. Our method falls into the setting of learnable sparse-attention patterns.

Among all these works, our method is closer to Set Transformer (Lee et al., 2019), Routing Transformer (Roy et al., 2020), and Fast Trans-



(a) Transformer in sliding window
(b) Cluster-Former

former (Vyas et al., 2020), which all use cluster centroids to learn patterns. However, we target at solving a different task, question answering. And it also leads to a significant different framework to encode a short question with a long context, other than a single long sequence, such as language modeling task. Moreover, our cluster centroids are updated in a very different way by periodical centroids update with K-Means on memory bank, other than memory-based centroids (Lee et al., 2019), exponentially moving centroids (Roy et al., 2020), or online clustering (Vyas et al., 2020).

Long Sequence in Question Answering For tasks such as open-domain question answering (Chen et al., 2017), a large volume of documents or paragraphs is usually retrieved to infer the answer, yielding extremely long context content. Despite the fact that state-of-the-art NLP models are capable of extracting answers amid complex context, they still struggle with extremely long input sequences. Recent advances that advocate the use of large-scale pre-trained models (Lewis et al., 2019; Liu et al., 2019; Lan et al., 2020) for question answering make this problem more prominent, due to tremendous memory consumption. To process long sequences, the most widely-used method is to first use a lightweight model to filter out redundant text, then use sliding-window-based approaches to encode the remaining sequences with a more sophisticated model. Chen et al. (2017) integrated bi-gram features into Information Retrieval (IR) methods to retrieve related documents more accurately. Wang et al. (2018) trained a paragraph selector using as the reward whether the entire system can obtain the correct answer or not. Asai et al. (2020) trained a recurrent retriever to select paragraphs for multi-hop question answering. Izacard and Grave (2021) proposed to fuse local encoded information into a decoder for answer generation. Besides the above methods, directly applying Efficient Transformers to process long sequences in question answering is another option. In this paper, we focus on this direction by directly training our Cluster-Former on the long context without using lightweight model for context filtering.

3 Proposed Approach

The proposed framework to handle long sequences is pivoted on two types of Transformer layer: (i) *Sliding-Window* Layer; and (ii) *Cluster-Former* Layer. The former focuses on encoding local sequence information, while the latter is on encoding global context and always built on top of the former layer. An overview of the two layers is illustrated in Figure 2.

3.1 Sliding-Window Layer

Despite that our focus is on capturing long-range dependencies for global context, local information also plays a critical role for knowledge propagation. Therefore, in the lower section of our network, we adopt the traditional sliding-window encoding mechanism. A sliding window segments a long sequence X into short, overlapping ones with window size l and stride m, as illustrated in Figure 2(a). Note that in this paper, we focus on question answering tasks, for which we concatenate the question Q with each sequence chunked from the document:

$$\mathbf{H}_k^0 = \left[\mathbf{Q}; \mathbf{X}\left[m \times k : (m \times k + l)\right]\right], \quad (1)$$

where $\mathbf{Q} \in \mathbb{R}^{q \times d}$ denotes question embeddings given a QA task, q is the number of tokens in the question, and $\mathbf{X} \in \mathbb{R}^{x \times d}$ is the embeddings for all context, x is the number of tokens in context. k is the ID of the chunked sequence, l is the window size, and m is the stride of the sliding window. $[idx_1 : idx_2]$ indicates selecting rows between the index of idx_1 and idx_2 of the matrix. $[\cdot;\cdot]$ means concatenating the matrices along the row. We first use Transformer to encode each sequence in sliding window as follows:

$$\mathbf{H}_k^{n+1} = \text{Transformer}(\mathbf{H}_k^n), \quad (2)$$

where $\mathbf{H}_k^{n+1} \in \mathbb{R}^{(q+l) \times d}$ is the output of Transformer on the k-th sequence in the n-th layer, while it is not the final output of the n-th layer. As we expect the neighbouring sequences to share useful information in hidden states as well, we always set $m < l$ to allow overlapping between sequences. We use the mean values of the Transformer hidden states at the overlapped tokens between windows as final outputs. To merge the representations from the $(k-1)$-th sequence:

$$\begin{aligned} \mathbf{H}_k^{n+1}[q : q+l-m] \quad &+= \quad \mathbf{H}_{k-1}^{n+1}[q+m : end], \\ \mathbf{H}_k^{n+1}[q : q+l-m] \quad &/= \quad 2, \end{aligned}$$

and merge representations from $(k+1)$-th sequence:

$$\begin{aligned} \mathbf{H}_k^{n+1}[q+m : end] \quad &+= \quad \mathbf{H}_{k+1}^{n+1}[q : q+l-m], \\ \mathbf{H}_k^{n+1}[q+m : end] \quad &/= \quad 2, \end{aligned} \quad (3)$$

where $+=$ is to add matrices in-place and $/=$ is to divide a matrix by a scalar value in-place. The merged hidden states $\mathbf{H}_k^{n+1} \in \mathbb{R}^{(q+l) \times d}$ are the final outputs of the n-th layer. If the next layer is Cluster-Former, the output hidden states in this layer $\mathbf{H}_k^{n+1}$ will be saved into memory bank for computing the cluster centroids.

    end for
    return Outputs
end function
```

3.2 Cluster-Former Layer

We introduce a Cluster-Former layer to add global representational power to Transformer beyond sliding windows. An in-depth visualization of the layer is illustrated in Figure 2(b).

The input of the Cluster-Former layer comes from the hidden states of the prior layer (in our case a Sliding-Window layer). After merging the overlaps between sequence chunks, the input of this layer is defined as:

$$\bar{\mathbf{H}}^n = \left[\mathbf{H}_0^n[0 : q+m]; ...; \mathbf{H}_k^n[0 : q+m]\right], \quad (4)$$

where $\bar{\mathbf{H}}^n \in \mathbb{R}^{(q\lceil x/m \rceil + x) \times d}$ is the hidden states to cluster, x is the number of tokens in the context.

As the hidden states with larger cosine similarity are more likely to have higher attention weights, we build sparse self-attention only on the hidden states in the same cluster. In this work, we use K-Means as the chosen clustering method for simplicity. More advanced clustering algorithms have the potential of yielding better performance. Since running K-Means on the fly in each training iteration is computationally expensive, we decide to re-compute the cluster centroids with low frequency (every epoch or a few epochs).

In addition, to avoid dramatic changes in the cluster centroids due to limited hidden state inputs, we maintain a memory bank for the most recent hidden states. The entire procedure is depicted in Algorithm 1. Once we compute the cluster centroids, we can directly use them for hidden state clustering as follows:

$$\mathbf{v}^n = \text{argmax}\Big(\frac{\mathbf{H}^n(\mathbf{C}^n)^T}{||\mathbf{H}^n||_2||\mathbf{C}^n||_2}\Big), \quad (5)$$

where $\mathbf{C}^n \in \mathbb{R}^{p\times d}$ are the cluster centroids for layer n, and p is the pre-defined number of clusters. The function argmax$(\cdot)$ performs on the last dimension and assigns all the input hidden states into different clusters based on the max value of cosine similarity between the hidden states and cluster centroids. $\mathbf{v}^n \in \mathbb{R}^{(q\lceil x/m\rceil+x)}$ is the assigned cluster IDs of all the input hidden states.

Since the number of hidden states in different clusters can vary substantially, padding them to the maximum length for Transformer training will significantly increase the computational time. To make the extraction of global context more efficient, we greedily pick the cluster centroids based on the nearest neighbour (measured by cosine similarity) as shown in the function GETCENTROIDS in Algorithm 1. Thus, the hidden states with similar cluster IDs are also close to each other. Then, we can directly sort the cluster IDs of hidden states and uniformly chunk the hidden states (same window size and stride m):

$$\begin{aligned}\mathbf{u}^n &= \text{argsort}(\mathbf{v}^n),\\ \mathbf{a}^n_k &= \mathbf{u}^n[mk : m(k+1)],\\ \mathbf{E}^n_k &= \mathbf{H}^n[\mathbf{a}^n_k], \end{aligned}\quad (6)$$

where the function argsort$(\cdot)$ is to obtain the indexes of input values sorted in order (same values sorted by the corresponding position of hidden states). $\mathbf{a}^n_k \in \mathbb{R}^m$ is the chunked indexes of the hidden states. $\mathbf{E}^n_k \in \mathbb{R}^{m\times d}$ is the k-th clustered hidden states, and we will run Transformer on top of it to build the connection beyond the words in the initial sliding window as follows:

$$\mathbf{E}^{n+1}_k = \text{Transformer}(\mathbf{E}^n_k). \quad (7)$$

After updating the hidden states, we map them back to the order before clustering:

$$\begin{aligned}\bar{\mathbf{H}}^{n+1} &= [\mathbf{E}^{n+1}_0; \mathbf{E}^{n+1}_1; ...; \mathbf{E}^{n+1}_K],\\ \bar{\mathbf{a}}^n &= [\mathbf{a}^n_0; \mathbf{a}^n_1; ...; \mathbf{a}^n_K], \quad (8)\\ \bar{\mathbf{H}}^{n+1}[\bar{\mathbf{a}}^n] &= \text{clone}(\bar{\mathbf{H}}^{n+1}), \quad (9)\end{aligned}$$

	#train	#test	med	max
Quasar-T	29k	3k	2.8k	8.2k

where $\bar{\mathbf{H}}^{n+1}$ is the final output hidden state of this layer and has the same word order as the input $\bar{\mathbf{H}}^n$. In experiments, we stack these two types of layer interchangeably to capture both global and local context efficiently.

4 Experiments

4.1 Datasets

We evaluate our proposed approach on multiple question answering benchmarks. The statistics of all the datasets are summarized in Table 1.

- **Quasar-T**[1] (Dhingra et al., 2017): The goal of this task is to answer open-domain questions from Trivia Challenge. All the passages harvested through information retrieval can be used to answer questions. The task requires the model to generate answers in phrases. The evaluation metric on this dataset is based on Exact Match and F1 score of the bag-of-words matching. Our evaluation tool[2] comes from the SQuAD dataset.
- **SearchQA**[3] (Dunn et al., 2017): The setting of this dataset is the same as Quasar-T, except that the questions are sourced from Jeopardy! instead.
- **Natural Questions**[4] (Kwiatkowski et al., 2019): This task aims to answer questions based on a given Wikipedia document, and has two settings. (i) Long answer: select a paragraph that can answer the question based on the Wikipedia document if any. (ii) Short answer: extract an answer phrase from the document if the document contains the answer. As the given document may not contain answer, we can either predict an answer or predict no answer. The evaluation metric on this dataset is the F1 score, where true positives are exactly correct answers, false positives are

Cluster-Former (Ours)	**78.0**	**78.5**	77.5	60.9	62.1	**59.8**

Table 3: Results on Natural Questions (NQ) leaderboard (test set). We show two published results here from over 40 submissions. Our model achieves No.1 for long answer and No.4 for short answer.

incorrect answer predictions, and false negatives are incorrect "no answer" predictions. As the test set is hidden, we split 5% of the training set for validation, and use the original validation set for testing. We use the official tool from the dataset to evaluate our models. We also submit our best model to the leaderboard.

4.2 Implementation Details

All the models are trained on 8 Nvidia V100 GPUs. For clustering, we adopt "Yinyang kmeans" (Ding et al., 2015)[5] which takes less than 5 seconds for clustering in all our experiment settings. We set the memory size for clustering $M = 100,000$ in Algorithm 1. Based on our experiments, it makes little difference for memory banks with 50k and 100k, update cycles with 1 iteration or half iteration. We use cluster centroids that perform the best on the validation set for test set experiments. As the cluster-centroid is offline computed, the inference time is the same as the sliding-window-based method. We initialize our models with RoBERTa-large (Liu et al., 2019). As the number of position embeddings of RoBERTa is limited to 512, we cannot assign different position embeddings to all tokens. Instead, we assign the same position embeddings to each chunked sequence.

The majority of our model is made up of Sliding-Window Layers, as the local information is essential for QA tasks. We adopt the proposed Cluster-Former Layer in layers 15 and 20 to further capture long-range information. We set the sliding window size l to 256, stride m to 224, and change the number of clusters in $\{64, 256, 512\}$ to analyze its impact on the final performance. We prepend a special token to the beginning of all the given/retrieved paragraphs and directly concatenate all the paragraphs as the final context sequence. Due to memory constraints, we set the max length to be 5000

Table 4: Experiments on Quasar-T dev dataset. $a \in \{3, 4, 5, 6\}$ and $b \in \{8, 12, 16, 20\}$, if the layer number $l \ \% \ a == 0$ and $l >= b$, we set it as Cluster-Former Layer, otherwise Sliding Window Layer.

during training and 10000 during inference. During dataset finetuning, we use Adam (Kingma and Ba, 2015) to optimize the model. We set warm-up updates to 2,220, maximal updates to 22,200, learning rate to 5×10^{-5}, and batch size to 160. We tune the dropout rate from $\{0.1, 0.15, 0.2\}$ for all the methods including baselines and report the best results. The model converges in one day for all the QA datasets.

For Quasar-T and SearchQA, we predict the start and end positions of the answer. For Natural Question, we first identify whether the question has short/long answers or not based on the mean values of the first hidden state of all the chunked sequences, $\frac{1}{K}\sum_{k=1}^{K} \mathbf{H}_k^N[0]$, where K is the number of chunks and N is the number of layers. If answerable, we rank all the candidates for long answer selection, and predict the start and end positions of short answers. Our model submitted to Natural Question Leaderboard ensembled 3 models with 512 clusters, and only these models are firstly trained on SQuAD2.0 and then finetuned on Natural Question dataset.

4.3 Baselines

We compare our models with several strong baselines, including:

R3 (Wang et al., 2018) proposes to use reinforcement learning to jointly train passage ranker and reader. **DS-QA** (Lin et al., 2018) proposes to first use paragraph selection to filter the noisy data and then trained model on denoised data. **Multi-passage BERT** (Wang et al., 2019) proposes to filter the passages and then merge multiple useful passages into one sequence, which can be encoded by BERT. **DrQA** (Chen et al., 2017) makes use of attention mechanism across the question and the document for answer phrase extraction. **DecAtt and DocReader** (Kwiatkowski et al., 2019) is based on a pipeline approach that first uses a simpler model to select long answers and then a reading comprehension model to extract short answers from the long answers. **BERT$_{\text{joint}}$** (Alberti et al., 2019) jointly trains short and long answer extraction in a single model rather than using a pipeline approach. **BERT$_{\text{wwm}}$+SQuAD2** (Pan et al., 2019) makes use of multi-task learning to further boost performance. **RikiNet-RoBERTa** (Liu et al., 2020) proposes a dynamic paragraph dual-attention reader and a multi-level cascaded answer predictor. **BigBird-ETC** (Zaheer et al., 2020) makes use of a sparse attention mechanism to encode long sequences.

	Wikitext ppl	Enwik8 bpc

Cluster-Former (#C=256)	20.3	1.24
Cluster-Former (#C=512)	**20.2**	**1.22**

Table 5: Results on Language Modeling. #C: number of clusters; Wikitext: Wikitext-103.

We also re-implement several strong baselines which have not been applied to process long context in question answering tasks:

- **Sliding Window**: The original method is fully made up of Sliding-Window Layers and can only attend to local information. To make a fair comparison among different methods on long-range information collection, we replace several layers of this sliding window baseline with Sparse Attention, Locality-Sensitive Hashing, and Cluster-Former.

- **Sparse Attention** (Child et al., 2019): This method replaces several layers in the previous baseline by training a Transformer layer across sequences on pre-selected positions. We run this sparse Transformer on all the hidden states in the same position across sequences, so that the output of sparse Transformer can merge the information from different sequences.

- **Locality-Sensitive Hashing** (Kitaev et al., 2020): This method hashes hidden states into different buckets determined by randomly-initialized hashing vectors. A Transformer layer is then applied across buckets to build Sparse

Attention across the whole sequence. Note that this method cannot be directly used for question answering without adding Sliding-Window layer, as our QA model is initialized by RoBERTa that only has 512 position embeddings.

4.4 Experimental Results

State-of-the-Art Results on QA Table 2 and 3 show that our proposed method outperforms several strong baselines, thanks to its ability to encode both local and global information. Cluster-Former with 512 clusters achieves new state-of-the-art results on Quasar-T, SearchQA and Natural Question (long answer).

Effect of Cluster-Former We also test the ability of Cluster-Former on modeling long-range dependencies. Note that Sparse Attention (Child et al., 2019) and Locality-Sensitive Hashing (Kitaev et al., 2020) have never been tested on question answering tasks with long context. For fair comparison, we set the layers 15 and 20 as either Sparse Attention, Locality-Sensitive Hashing or our Cluster-Former, and the left layers are Sliding Window layers.

As shown, Sparse Attention performs worse than our Cluster-Former. The loss may come from the noise introduced by pre-selected positions, the corresponding words of which may not be related. We set the number of hashing vectors in Locality-Sensitive Hashing (LSH) to 64, the same as the number of clusters in Cluster-Former. LSH outperforms the baseline slightly on QA and consistently underperforms our Cluster-Former (#C=64). Overall, our Cluster-Former performs the best.

Effect of Number of Cluster Centroids We also test the effect of different numbers of cluster centroids (C) on model performance. We observe that the model with 512 clusters works significantly better than the model with 64 clusters on most of the tasks. However, for Natural Questions Long Answer setting, the improvement is marginal. As we mainly rely on the hidden state of special tokens "<s>" for long answer selection, and the same tokens can be assigned into same chunk more easily even with a smaller number of clusters.

Selection of Cluster-Former Layers We also have an analysis on which layers are better used for Cluster-Former layer. As shown in Table 4, we conduct a hyper-parameter search. And find that it can get better performance with at least one Cluster-Former layers in the middle layer (8-16). The worst results come from only one Cluster-Former layer in the layer of 22 or 23.

Language Modeling Although we focus on QA tasks, to demonstrate the versatility of Cluster-Former, we conduct additional experiments on language modeling using the Wikitext-103 (Merity et al., 2017) and Enwik8 (Mahoney, 2011) benchmarks. All the models are trained from scratch. We set the number of layers to 16, with 8 heads per layer. Our Cluster-Former Layer is used in layers 11 and 15 as in QA models. We segment long input into short sequences of 3072 tokens, set sliding window size l to 256, and stride m to 128. SGD is used for optimizing the models. We set clip threshold of gradients to 0.1, warm-up updates to 16,000, maximal updates to 286,000, dropout rate to 0.3, learning rate to 0.1, and batch size to 16. The model will converge in 3 days for all the LM datasets. As shown in Table 5, Cluster-Former outperforms strong state-of-the-art baselines.

4.5 Qualitative Analysis

We perform qualitative analysis on how the hidden states are clustered, by visualizing the corresponding words and positions of the hidden states in Table 6. From the first row, we can see that the special tokens "<s>" tend to belong to the same cluster. Note that "<s>" is the start token of each long answer candidate, and its hidden state is used for final long answer selection. Therefore, Transformer on this cluster can compare across the candidates to make the final prediction.

We further observe that the same types of token are more likely to appear in the same cluster. For example, words from the second row to the forth row cover the topics of time, stopwords, and organization & geopolitical entities.

Finally, we randomly sample a cluster and list the positions of clustered hidden states in the last row of the table. We find that states in long distance, such as the 50-th and 6060-th states (over 6000 tokens apart), can be in one cluster, which demonstrates the ability of Cluster-Former in detecting long-range dependencies. Further, we observe that states tend to cluster in phrases. For example, we see consecutive positions such as "49, 50, 51, 52, 53, 54, 55", which likely results from the sliding-window encoding.

5 Conclusion

In this paper, we present Cluster-Former, a new method to encode global information for long sequences. We achieve new state of the art on three question answering datasets: Quasar-T, SearchQA, and Natural Questions. Further, we observe that a larger number of clusters in Cluster-Former can lead to better performance on question answering tasks. Cluster-Former is a generic approach, and we believe that it can benefit other NLP tasks that rely on long-range dependencies as well.

Abstract

With the increasing interest in low-resource languages, unsupervised morphological segmentation has become an active area of research, where approaches based on Adaptor Grammars achieve state-of-the-art results. We demonstrate the power of harnessing linguistic knowledge as priors within Adaptor Grammars in a minimally-supervised learning fashion. We introduce two types of priors: 1) grammar definition, where we design language-specific grammars; and 2) linguist-provided affixes, collected by an expert in the language and seeded into the grammars. We use Japanese and Georgian as respective case studies for the two types of priors and introduce new datasets for these languages, with gold morphological segmentation for evaluation. We show that the use of priors results in error reductions of 8.9 % and 34.2 %, respectively, over the equivalent state-of-the-art unsupervised system.

1. Introduction

Morphological segmentation is an essential subtask in many natural language processing (NLP) applications, especially in the case of morphologically complex languages. With the need to develop NLP tools for low-resource languages, unsupervised morphological segmentation has been receiving increasing interest over the last two decades (Goldsmith, 2001; Creutz and Lagus, 2007a; Poon et al., 2009; Sirts and Goldwater, 2013; Botha and Blunsom, 2013; Narasimhan et al., 2014; Eskander et al., 2016, 2018, 2019).

In this work, we show how linguistic priors effectively boost morphological-segmentation performance in a minimally-supervised manner that does not require segmented words for training. We integrate our priors within Adaptor Grammars (Johnson et al., 2007), a type of nonparametric Bayesian models that generalize Probabilistic Context-Free Grammars (PCFGs). Adaptor Grammars have proved successful for unsupervised morphological segmentation, achieving state-of-the-art results across a variety of typologically diverse languages (Eskander et al., 2020).

We introduce two types of linguistic priors: 1) grammar definition, where we design a language-specific grammar that is tailored for the language of interest by modeling specific morphological phenomena, and 2) linguist-provided affixes, where an expert in the underlying language compiles a list of carefully selected affixes and seeds it into the grammars prior to training the segmentation model. We use Japanese and Georgian as case studies for priors 1 and 2, respectively. As our goal is to develop a robust approach that benefits low-resource and/or endangered languages of high morphological complexity, we use Japanese and Georgian in a low-resource setting where we do not have access to morphologically segmented data for training but have access to linguistic information such as word structure and affixes.

We show that using linguistic priors in a minimally-supervised setting leads to a significant improvement in performance over the equivalent state-of-the-art unsupervised system. We also present two morphologically segmented datasets for Japanese and Georgian that we use as our gold standard and that can be utilized in other morphology tasks.[1]

2. Linguistic Priors

We utilize MorphAGram (Eskander et al., 2020)[2], an open-source morphological-segmentation framework that is based on Adaptor Grammars (AGs) (Johnson et al., 2007). AGs have proved successful for unsupervised and

Figure 1: Language-independent PrStSu+SM grammar (left side) vs. its Japanese cognate (right side)

minimally-supervised morphological segmentation, outperforming the competing discriminative models (Sirts and Goldwater, 2013; Eskander et al., 2019, 2020).

Adaptor Grammars are non-parametric Bayesian models that are composed of two main components: 1) a Probabilistic Context-Free Grammar (PCFG) whose definition relies on the underlying task (in the case of morphological segmentation, a PCFG models word structure); and 2) an adaptor that is based on the Pitman-Yor process (Pitman, 1995). The adaptor keeps the posterior probability of a subtree proportional to the number of times that subtree is utilized to parse the input data and manages the caching of the subtrees. The learning process is Markov Chain Monte Carlo sampling (MCMC) (Andrieu et al., 2003) that does the inference of the PCFG probabilities and the hyperparameters of the model.

Eskander et al. (2016) define a set of language-independent grammars and three learning settings for Adaptor Grammars: 1) *Standard*, fully unsupervised; 2) *Scholar-Seeded*, minimally-supervised by manually seeding affixes into the grammar prior to training the segmentation model, and 3) *Cascaded*, fully unsupervised by approximating the *Scholar-Seeded* setting using automatically generated affixes from an initial round of learning. We next present two ways of including linguistic priors in Adaptor Grammars: 1) defining a language-specific grammar; and 2) using linguist-provided affixes in the Scholar-Seeded learning setup.

2.1. Linguistic Priors as Grammar Definition

Eskander et al. (2016) define language-independent grammars that model the word as a sequence of generic morphemes or as a sequence of prefixes, stem and suffixes. We consider their *PrStSu+SM* grammar in the current study as it is the grammar that performed best on average across different languages. This language-independent definition of the grammar is depicted on the left side of Figure 1, where the word is modeled as a prefix *Pr*, a stem *St* and a suffix *Su*, and both the prefix and suffix are recursively defined in order to model compounding in affixes, while a morpheme is composed of smaller units, submorphemes *SM*, representing sequences of characters.

While this grammar is intended to be generic and to describe word structure in any language, we hypothesize that a definition that imposes language-specific constraints would be more efficient. Therefore, we define a grammar for Japanese, where we use characteristics that are specific to Japanese word structure as language priors. Our tailored grammar definition for Japanese is shown on the right side of Figure 1, where we impose the following specifications:

- A word has a maximum of one one-character or two-character prefix morphemes.
- A stem is recursively defined as a sequence of morphemes in order to allow for stem compounding.
- Characters are separated into two groups, Kana (Japanese syllabaries) and Kanji (adapted Chinese characters).
- A submorpheme represents a sequence of characters that is either in Kana or Kanji.

2.2. Linguistic Priors as Linguist-Provided Affixes

Similar to the *Scholar-Seeded* setting, we compile a list of affixes and seed it into the grammar trees before learning the segmentation model. However, unlike Eskander et al. (2016), where the affixes are collected from online resources by someone who may have never studied the language of interest, in this study we use affixes that are carefully compiled by an expert linguist who specializes in Georgian, resulting in more accurate linguistic priors. With that goal in mind, a total of 119 affixes are collected from the leading reference grammar book (Aronson, 1990).

3. Evaluation Data

We annotate two datasets with morphological segmentation that we use as the gold standard to evaluate our segmentation models for Japanese and Georgian. Both datasets are composed of 1,000 words that are randomly sampled from the most frequent 50,000 words in Wikipedia and segmented into their basic morphemes[3], similar to the data of the Morpho Challenge shared task [4]. Table 1 lists segmentation examples for both languages.

The Japanese gold segmentation was created by a native-speaker linguist. For Georgian, which has highly complex morphology, we started with the gold-standard dataset of 1000 words introduced by Eskander et al. (2020), which was built by an untrained native speaker and contained only one possible segmentation per word. An expert in Georgian then corrected 193 examples in the data and further annotated 116 words for two possible alternative segmentations. In addition, the expert coded each word based on its syntactic category: verbs (359), nouns (475), numerals (44) and other (122).

Japanese Word	Segmentation
いました	い + ま + した
勉強して	勉強 + し + て
始められません	始め + られ + ま + せん

Georgian Category	Word	Segmentation
Verb	იქნებაო	ი + ქნ + ებ + ა + ო იქნებ + ა + ო
Noun	თვითფრინავი	თვი + თ + ფრინ + ავ + ი თვითფრინავ + ი
Numeral	თოთხმეტი	თ + ოთხ + მეტ + ი თოთხმეტ + ი
Other	ვისი	ვი + ს + ი ვის + ი

Table 1: Japanese and Georgian segmentation examples

4. Evaluation and Results

4.1. Experimental Setup

We evaluate our morphological-segmentation models for Japanese in the *Standard (STD)* and *Cascaded (CAS)*[5] settings, both with generic and language-specific *(LS)* grammar definitions. For Georgian, we evaluate our morphological-segmentation models in the *Standard (STD)*, *Cascaded (CAS)* and *Scholar-Seeded (SS)* settings, in addition to the proposed *Scholar-Seeded* setting with linguist-provided affixes (*SS-Ling*).

We perform the evaluation in a transductive manner, where the unsegmented words in the gold standard are part of the training sets; this is common in evaluating unsupervised and minimally-supervised morphological segmentation (Poon et al., 2009; Sirts and Goldwater, 2013; Narasimhan et al., 2014; Eskander et al., 2016, 2019, 2020). For the metrics, we use Boundary Precision and Recall (BPR) and EMMA-2 (Virpioja et al., 2011). BPR is the classical metric for evaluating morphological segmentation; it compares the boundaries in the proposed segmentation to those in the reference. EMMA-2

---

[3] The Georgian dataset contains five non-words and three phonetic spellings of English character names.

[4] http://morpho.aalto.fi/events/morphochallenge/

[5] For the Cascaded setup, we use the high-precision grammar *PrStSu2a+SM* defined by Eskander et al. (2016) as the base grammar.

Language	Setting	BPR			EMMA-2		
		Prec.	Recall	F1-Score	Prec.	Recall	F1-Score
Japanese	*Morfessor*	81.4	77.2	79.3	91.5	80.1	85.4
	AG STD	81.7	77.4	79.5	91.0	81.8	86.1

Table 3: Category-wise morphological-segmentation performance for Georgian using the BPR and EMMA-2 metrics. *AG* = *Adaptor Grammars*. *SS* = *Scholar-Seeded*. *SS-Ling* = *Scholar-Seeded* with linguist-provided affixes.

is based on matching the morphemes in the proposed segmentation to those in the reference in a many-to-one assignment setup.

We evaluate our system versus two state-of-the-art unsupervised baselines: MorphAGram without the use of linguistic priors and Morfessor (Virpioja et al., 2013) [6]. Morfessor is a commonly-used framework for unsupervised morphological segmentation. It is based on an HMM model that relies on the Minimum Description Length (MDL) concept for deriving the optimal segmentation (Creutz and Lagus, 2007b). Since our approach does not assume access to manually annotated segmentation, it is not directly comparable to semi-supervised approaches that rely on such annotations (Ruokolainen et al., 2014; Kann et al., 2018). Finally, we report all the Adaptor-Grammar results as the average over three runs of different randomization parameters.

4.2. System Performance

Table 2 reports the overall performance of our models for both Japanese and Georgian, while Table 3 shows the results per part-of-speech category for Georgian.

For Japanese, the use of a language-specific grammar definition improves both precision and recall, resulting in BPR F1-score error reductions of 8.9 % and 7.1 % over the generic *Standard* and *Cascaded* settings, respectively, and a BPR F1-score error reduction of 9.8 % over Morfessor.

For Georgian, the use of linguist-provided seeded affixes improves both precision and recall, where the recall significantly increases by absolute 13.3 % over using an affix list of lower quality. In addition, the proposed linguistic priors result in BPR F1-score error reductions of 34.2 %, 30.0 % and 31.1 % over the *Standard*, *Cascaded* and regular *Scholar-Seeded* settings, respectively, and a BPR F1-score error reduction of 53.3 % over Morfessor. Analysing results per category, verbs and nouns receive the biggest F1-score improvements of absolute 14.3 % and 4.9 %, respectively, with the use of linguist-provided affixes.

A similar pattern of results is found with EMMA-2. Finally, all the improvements due to the use of linguistic priors are statistically significant ($P < 0.01$) on both metrics.

4.3. Error Analysis

Table 4 lists some examples of correctly and incorrectly segmented words by our Japanese and

	Word	Gold Segmentation	*STD* Segmentation	*STD-LS* Segmentation
Japanese	お電話	お + 電話	お + 電話	お + 電話
	ご親族	ご + 親 + 族	ご + 親 + 族	ご + 親 + 族
	登られませ	登 + られ + ま + せん	登ら + れ + ません	登 + られ + ません
	比べなかったら	比べ + な + かった + ら	比べ + なかった + ら	比べ + なかった + ら

	Word	Gold Segmentation	*STD* Segmentation	*SS* Segmentation	*SS-Ling* Segmentation
Georgian	ლურჯი	ლურჯ + ი	ლურჯ + ი	ლურჯ + ი	ლურჯ + ი
	რვის	რვ + ის	რ + ვის	რვ + ის	რვ + ის
	გამოვა	გა მო ვ ა	გამო ვ ა	გა მო ვ ა	გამოვ ა
	შაური	შაურ + ი	შა + ური	შა + ურ + ი	შაურ + ი

Table 4: Examples of output segmentations for Japanese and Georgian. *STD* = *Standard*. *STD-LS* = *Standard* with a language-specific grammar. *SS* = *Scholar-Seeded*. *SS-Ling* = *Scholar-Seeded* with linguist-provided affixes. Incorrect morphemes are marked in red.

Georgian segmentation models. We discuss the most prominent observations below.

Japanese: Both the *STD* and *STD-LS* models perform well on prefix segmentation, achieving F1-scores of more than 90 % in the detection of several one-character prefixes, such as お and ご. However, *STD-LS* outperforms its language-independent counterpart in the detection of stems, where compounding is explicitly modeled. For instance, *STD* and *STD-LS* achieve F1-scores of 15.8 % and 98.6 %, respectively, in the detection of the common stem られ (*be*). On the other hand, when either model consistently fails to detect a specific morpheme, the other model fails as well. For example, neither model can detect the morphemes せん and かった.

Georgian: *SS-Ling* outperforms both *STD* and *SS* at discovering the top most frequent one-letter morphemes, such as ი, ა, ს, ე, მ, ო and ვ, achieving an average F1-score of 76.0 %, compared to 57.7 % and 57.3 % by *STD* and *SS*, respectively. In addition, *SS* and *STD* suffer lower precision as they tend to oversegment the morphemes represented by a single letter. Similarly, *SS-Ling* can recognize the most frequent two-letter morphemes, namely ებ and და, with absolute increases in precision of 59.0 % and 62.0 % over *STD* and *SS*, respectively; both morphemes are explicitly seeded into the *SS-Ling* grammar prior to training the model.

5. Conclusion and Future Work

We proposed two types of linguistic priors for minimally-supervised morphological segmentation using Adaptor Grammars. The first prior is in the form of defining a language-specific grammar, while the second relies on compiling a list of linguist-provided affixes and seeding it into the grammars. Our approaches result in error reductions of 8.9 %, for Japanese, and 34.2 %, for Georgian, as compared to the state-of-the-art system. In future work, we plan to explore the use of linguistic priors that apply to a group of morphologically similar low-resource languages.

Acknowledgements

This research is based upon work supported by the Intelligence Advanced Research Projects Activity (IARPA), (contract #FA8650-17-C-9117) and the National Science Foundation (awards #1941742 and #1941733). Ethical Considerations

The Japanese annotations were done by a linguist with appropriate compensation; we thus have ownership of the Japanese dataset for open distribution. We have been granted the rights to modify and distribute the dataset for Georgian by Eskander et al. (2020), where the annotations were done in-house by a paid linguist. Finally, the quality of the annotations was examined, both manually and empirically.

Abstract

Detecting what emotions are expressed in text is a well-studied problem in natural language processing. However, research on finer-grained emotion analysis such as what causes an emotion is still in its infancy. We present solutions that tackle both emotion recognition and emotion cause detection in a joint fashion. Considering that common-sense knowledge plays an important role in understanding implicitly expressed emotions and the reasons for those emotions, we propose novel methods that combine common-sense knowledge via adapted knowledge models with multi-task learning to perform joint emotion classification and emotion cause tagging. We show performance improvement on both tasks when including common-sense reasoning and a multi-task framework. We provide a thorough analysis to gain insights into model performance.

1 Introduction

Utterance and document level emotion recognition has received significant attention from the research community (Mohammad et al., 2018; Poria et al., 2020a). Given the utterance *Sudan protests: Outrage as troops open fire on protestors* an emotion recognition system will be able to detect that *anger* is the main expressed emotion, signaled by the word "outrage". However, the semantic information associated with expressions of emotion, such as the cause (the thing that triggers the emotion) or the target (the thing toward which the emotion is directed), is important to provide a finer-grained understanding of the text that might be needed in real-world applications. In the above utterance, the cause of the anger emotion is the event "troops open fire on protestors", while the target is the entity "troops" (see Figure 1) .

Research on finer-grained emotion analysis such as detecting the cause for an emotion expressed in text is in its infancy. Most work on emotion-cause detection has utilized a Chinese dataset where the cause is always syntactically realized as a clause and thus was modeled as a classification task (Gui et al., 2016). However, recently Bostan et al. (2020) and Oberländer and Klinger (2020) argued that in English, an emotion cause can be expressed syntactically as a clause (*as troops open fire on protestors*), noun phrase (*1,000 non-perishable food donations*) or verb phrase (*jumped into an ice-cold river*), and thus we follow their approach of framing emotion cause detection as a sequence tagging task.

We propose several ways in which to approach the tasks of emotion recognition and emotion cause tagging. First, these two tasks should not be independent; because the cause is the trigger for the emotion, knowledge about what the cause is should narrow down what emotion may be expressed, and vice versa. Therefore, we present a multi-task learning framework to model them jointly. Second, considering that common-sense knowledge plays an important role in understanding implicitly expressed emotions and the reasons for those emotions, we explore the use of common-sense knowledge via adapted knowledge models (COMET, Bosselut et al. (2019)) for both tasks. A key feature of our approach is to combine these adapted knowledge models (i.e., COMET), which are specifically trained to use and express common-sense knowledge, with pre-trained language models such as BERT, (Devlin et al., 2019).

Our primary contributions are three-fold: (i) an under-studied formulation of the emotion cause detection problem as a sequence tagging problem; (ii) a set of models that perform the emotion classification and emotion cause tagging tasks jointly while

using common-sense knowledge (subsection 4.2) with improved performance (section 6); and (iii) analysis to gain insight into both model performance and the GoodNewsEveryone dataset that we use (Bostan et al., 2020) (section 7).

2 Related Work

Emotion detection is a widely studied subfield of natural language processing (Mohammad et al., 2018; Poria et al., 2020a), and has been applied to a variety of text genres such as fictional stories (Alm et al., 2005), news headlines (Strapparava and Mihalcea, 2010), and social media, especially microblogs such as Twitter (Abdul-Mageed and Ungar, 2017; Kiritchenko et al., 2014; Rosenthal et al., 2019; Mohammad et al., 2018). Earlier work, including some of the above, focused on feature-based machine learning models that could leverage emotion lexicons (Mohammad and Turney, 2013)), while recent work explores deep learning models (e.g., Bi-LSTM and BERT) and multi-task learning (Xu et al., 2018; Demszky et al., 2020).

However, comparatively few researchers have looked at the semantic roles related to emotion such as the cause, the target or the experiencer, with few exceptions for Chinese (Gui et al., 2016; Chen et al., 2018; Xia and Ding, 2019; Xia et al., 2019; Fan et al., 2020; Wei et al., 2020; Ding et al., 2020), English (Mohammad et al., 2014; Ghazi et al., 2015; Kim and Klinger, 2018; Bostan et al., 2020; Oberländer et al., 2020; Oberländer and Klinger, 2020) and Italian (Russo et al., 2011). We highlight some of these works here and draw connection to our work. Most recent work on emotion-cause detection has been carried out on a Chinese dataset compiled by Gui et al. (2016). This dataset characterizes the emotion and cause detection problems as clause-level pair extraction problem – i.e., of all the clauses in the input, one is selected to contain the expression of an emotion, and one or more (usually one) are selected to contain the cause of that emotion. Many publications have used this corpus to develop novel and effective model architectures for the clause-level classification problem (Chen et al., 2018; Xia and Ding, 2019; Xia et al., 2019; Fan et al., 2020; Wei et al., 2020; Ding et al., 2020). The key difference between this work and ours is that we perform cause detection as a sequence-tagging problem: the cause may appear anywhere in the input, and may be expressed as any grammatical construction (a noun phrase, a verb phrase, or a clause). Moreover, we use common sense knowledge for both tasks (emotion and cause tagging), through the use of adapted language models such as COMET.

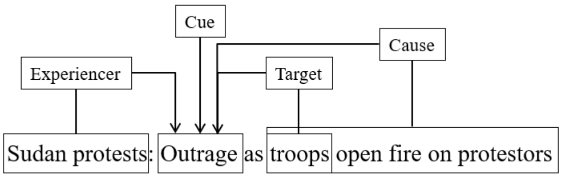

Figure 1: An example of the semantic roles annotated by Bostan et al. (2020)

For English, several datasets have been introduced (Mohammad et al., 2014; Kim and Klinger, 2018; Ghazi et al., 2015; Bostan et al., 2020; Poria et al., 2020b), and emotion cause detection has been tackled either as a classification problem (Mohammad et al., 2014), or as a sequence tagging or span detection problem (Kim and Klinger, 2018; Ghazi et al., 2015; Oberländer and Klinger, 2020; Poria et al., 2020b). We particularly note the work of Oberländer and Klinger (2020), who argue for our problem formulation of cause detection as sequence tagging rather than as a classification task supported by empirical evidence on several datasets including the GoodNewsEveryone dataset (Bostan et al., 2020) we use in this paper. One contribution we bring compared to these models is that we formulate a multi-task learning framework to jointly learn the emotion and the cause span. Another contribution is the use of common-sense knowledge through the use of adapted knowledge models such as COMET (both in the single models and the multi-task models). Ghosal et al. (2020) have very recently shown the usefulness of common-sense reasoning to the task of conversational emotion detection.

3 Data

For our experiments, we use the GoodNewsEveryone corpus (Bostan et al., 2020), which contains 5,000 news headlines labeled with emotions and semantic roles such as the target, experiencer, and cause of the emotion, as shown in Figure 1.[1] We focus on the emotion detection and cause tagging tasks in this work. To our knowledge, GoodNewsEveryone is the largest English dataset labeled for

---

[1] While the dataset labels both the most dominant emotion expressed in text and the reader's emotion, for this paper we only focus on the former.

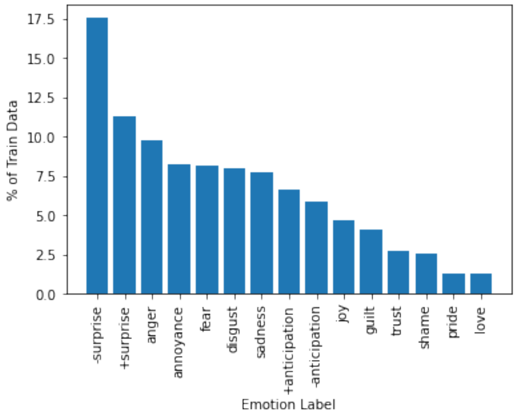

Figure 2: Distribution of adjudicated emotion labels in the GoodNewsEveryone train data, as a percentage of the data points. "Positive" and "Negative" are abbreviated as + and -.

both of these tasks.

In our experiments, we limit ourselves to the data points for which a cause span was annotated (4,798). We also note that this dataset uses a 15-way emotion classification scheme, an extended set including the eight basic Plutchik emotions as well as additional emotions like *shame* and *optimism*. While a more fine-grained label set is useful for capturing subtle nuances of emotion, many external resources focus on a smaller set of emotions. We also note that the label distribution of this dataset heavily favors the more basic emotions, as shown in Figure 2. Therefore, for our work, we choose to limit ourselves to the six Ekman emotions (*anger*, *fear*, *disgust*, *joy*, *surprise*, and *sadness*). We also choose to keep *positive surprise* and *negative surprise* separated, to avoid severely unbalancing the label distribution for our experiments. We randomly split the remaining data (2,503 data points) into 80% train, 10% development, and 10% test.

4 Models

An important feature showcased by the GoodNewsEveryone dataset is that causes of emotions can be expressed through different syntactic constituents such as clauses, verb phrases, or noun-phrases. Thus, we approach the cause detection problem as a sequence tagging problem using the IOB scheme (Ramshaw and Marcus, 1995): $\mathcal{C} = \{\text{I-cause}, \text{O}, \text{B-cause}\}$. Our approach is supported by very recent results by Oberländer and Klinger (2020) and Yuan et al. (2020) who show that modeling emotion cause detection as a sequence tagging problem is better suited than a clause classification problem, although not much current work has yet adopted this formulation. We tackle the emotion detection task as a seven-way classification task with $\mathcal{E} = \{\text{anger}, \text{disgust}, \text{fear}, \text{joy}, \text{sadness}, \text{negative surprise}, \text{positive surprise}\}$.

4.1 Single-Task Models

As a baseline, we train single-task models for each of emotion classification and cause span tagging. We use a pre-trained BERT language model[2] (Devlin et al., 2019), which we fine-tune on our data, as the basis of this model. Our preprocessing strategy for all of our models consists of the pretrained BERT vocabulary and WordPiece tokenizer[3] (Wu et al., 2016) from Huggingface (Wolf et al., 2020). Therefore, for a sequence of n WordPiece tokens, our input to the BERT model is a sequence of $n + 2$ tokens, $X = [\text{[CLS]}, x_1, x_2, ...x_n, \text{[SEP]}]$, where each x_i is from a finite WordPiece vocabulary and [CLS] and [SEP] are BERT's begin and end tokens. Passing X through BERT yields a sequence of vector hidden states $H = [h_{[CLS]}, h_1, h_2, ..., h_n, h_{[SEP]}]$ with dimension $d_{BERT} = 768$. For emotion classification, we pool these hidden states and allow hyperparameter tuning to select the best type: selecting the [CLS] token ($h_f = h_{[CLS]}$), mean pooling ($h_f = \frac{\sum_{i=1}^{n} h_i}{n}$), max pooling ($h_{f,j} = \max h_{i,j}$), or attention as formulated by Bahdanau et al. (2015):

$$h_f = \sum_{i=1}^{n} \alpha_i h_i \tag{1}$$

where $\alpha_i = \frac{\exp(W_a h_i + b_a)}{\sum_{j=1}^{n} \exp(W_a h_j + b_a)}$ for trainable weights $W_a \in \mathbb{R}^{1 \times d_{BERT}}$ and $b_a \in \mathbb{R}^1$. Then, the final distribution of emotion scores is calculated by a single dense layer and a softmax:

$$e = \text{softmax}(W_e h_f + b_e) \tag{2}$$

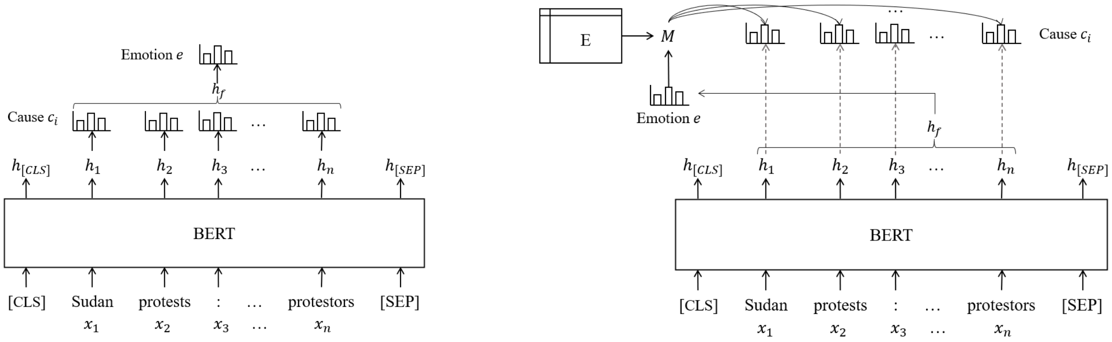
with $e \in \mathbb{R}^{|\mathcal{E}|}$ and for trainable parameters $W_e \in \mathbb{R}^{|\mathcal{E}| \times d_{BERT}}$ and $b_e \in \mathbb{R}^{|\mathcal{E}|}$. For cause tagging, a tag probability distribution is calculated directly on each hidden state:

$$c_i = \text{softmax}(W_c h_i + b_c) \tag{3}$$

---

[2] We use BERT-BASE-UNCASED. We experimented with BERT-BASE-CASED, but it underperformed as the headlines incorporated into GoodNewsEveryone come from different news sources and have different capitalization styles.

[3] In the tagging setting, we ignore all tags predicted for subword tokens and use only the tag of the first subword.



(a) The Multi$_{C\to E}$ model.

(b) The Multi$_{E\to C}$ model.

Figure 3: Our multi-task models.

with $c_i \in \mathbb{R}^{|\mathcal{C}|}$ and for trainable parameters $W_c \in \mathbb{R}^{|\mathcal{C}|\times d_{BERT}}$ and $b_c \in \mathbb{R}^{|\mathcal{C}|}$. We refer to both of these single-task models as BERT; if the task is not clear from the context, we will refer to the emotion detection model as BERT$_E$ and the cause tagging model as BERT$_C$. Our training loss for emotion classification as well as emotion cause tagging is the mean negative log-likelihood (NLL) loss per minibatch of size b:

$$\text{NLL}_{\text{emo}} = -\frac{1}{b}\sum_{j}\sum_{k} y_{jk} \log e_{jk} \tag{4}$$

$$\text{NLL}_{\text{cause}} = -\frac{1}{b}\sum_{i}\sum_{j}\sum_{k} y_{ijk} \log c_{ijk} \tag{5}$$

where j is the index of the sentence in the minibatch, k is the index of the label being considered (emotion labels for NLL$_{\text{emo}}$ and IOB tags for NLL$_{\text{cause}}$), i is the index of the i^{th} token in the j^{th} sentence in the minibatch, $y_{jk} \in \{0, 1\}$ is the gold probability of the k^{th} emotion label for the j^{th} sentence, $y_{ijk} \in \{0, 1\}$ is the gold probability of the k^{th} cause tag for the i^{th} token in the j^{th} sentence, and e_{jk} and c_{ijk} are the output probabilities of the k^{th} emotion label and of the k^{th} cause label for the i^{th} token, both for the j^{th} sentence.

4.2 Multi-Task Models

Our hypothesis is that the emotion detection and cause tagging tasks are closely related and can inform each other; therefore we propose three multi-task learning models to test this hypothesis. For all multi-task models, we use the same base architecture (BERT) as the single models. Additionally, for these models, we combine the losses of both tasks and weight them with a tunable lambda parameter: $\lambda\text{NLL}_{\text{emo}} + (1-\lambda)\text{NLL}_{\text{cause}}$, using NLL$_{\text{emo}}$ and NLL$_{\text{cause}}$ from Equation 4 and Equation 5.

Multi. The first model, Multi, is the classical multi-task learning framework with hard parameter sharing, where both tasks share the same BERT layers. Two dense layers for emotion classification and cause tagging operate at the same time from the same BERT layers, and we train both of the tasks simultaneously. That is, we simply calculate our emotion scores e and cause tag scores c from the same set of hidden states H.

We further develop two additional multi-task models with the intuition that we can design more explicit and concrete task dependencies than simple parameter sharing in the representation layer.

Multi$_{C\to E}$. We assume that if a certain text span is given as the cause of an emotion, it should be possible to classify that emotion correctly while looking only at the words of the cause span. Therefore, we propose the Multi$_{C\to E}$ model, the architecture of which is illustrated in Figure 3a. This model begins with the single-task cause detection model, $BERT_C$, which produces a probability distribution $P(y_i|x_i)$ over IOB tags for each token x_i, where $P(y_i|x_i) = c_i$ from Equation 3. Then, for each token, we calculate the probability that it is part of the cause as $P(\text{Cause}|x_i) = P(B|x_i) + P(I|x_i) = 1 - P(O|x_i)$. We feed the resulting probabilities through a softmax over the sequence and use them as an attention distribution over the input tokens in order to pool the hidden representations and perform emotion classification: attention is computed as in Equation 1, where $\alpha_i = \frac{\exp P(\text{Cause}|x_i)}{\sum_{j=1}^{n}\exp P(\text{Cause}|x_i)}$, and emotion classification as in Equation 2. For the Multi$_{C\to E}$ model, we apply teacher forcing at training time, and the gold cause spans are used to

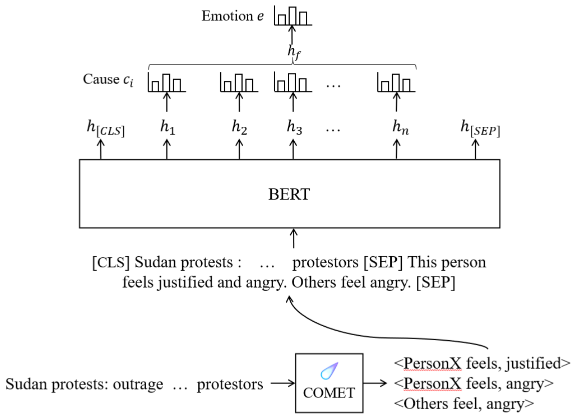


Figure 4: The architecture of our proposed $\text{Multi}_{C\rightarrow E}^{COMET}$ model.

create the attention weights before emotion classification (which means that $P(\text{Cause}|x_i) \in \{0, 1\}$). At inference time, the model uses the predicted cause span instead.

Multi$_{E\rightarrow C}$. Next, we hypothesize that knowledge of the predicted emotion should help us identify salient cause words. The Multi$_{E\rightarrow C}$ model first performs emotion classification, which results in a probability distribution over predicted emotion labels, as in the BERT$_E$ model and Equation 2. We additionally keep an emotion embedding matrix E, where $E[i]$ is a learnable representation of the i-th emotion label (see Figure 3b) with dimension d_e (in our experiments, we set $d_e = 300$). We use the predicted label probabilities e to calculate a weighted sum of the emotion embeddings, i.e., $M = \sum_i e_i \cdot E[i]$. We then concatenate M to the hidden representation of each token and perform emotion cause tagging with a final dense layer, i.e., $c_i = \text{softmax}(W_{c'}[h_i; M] + b_{c'})$, where ; is the concatenation operator and $W_{c'} \in \mathbb{R}^{|\mathcal{C}|\times(d_{BERT}+d_e)}$ and $b_{c'} \in \mathbb{R}^{|\mathcal{C}|}$ are trainable parameters. In the Multi$_{E\rightarrow C}$ model, we again do teacher forcing and use the gold emotion labels before doing the sequence tagging for cause detection (i.e., e is a one-hot vector where the gold emotion label has probability 1 and all other emotion labels have probability 0). At inference time, the model will use the predicted emotion distribution instead.

4.3 Adapted Knowledge Models

Recent work has shown that fine-tuning pre-trained language models such as GPT-2 on *knowledge graph tuples* such as ConceptNet (Li et al., 2016) or ATOMIC (Sap et al., 2018) allows these models to express their implicit knowledge directly (Bosselut et al., 2019). These adapted *knowledge models* (e.g., COMET (Bosselut et al., 2019)) can produce common-sense knowledge on-demand for any entity, relation or event. Considering that common-sense knowledge plays an important role in understanding implicitly expressed emotions and the reasons for those emotions, we explore the use of common-sense knowledge for our tasks, in particular the use of COMET adaptively pre-trained on the ATOMIC event-centric knowledge base. ATOMIC's event relations include "xReact" and "oReact", which describe the feelings of certain entities after the input event occurs. For example, ATOMIC's authors present the example of <PersonX pays PersonY a compliment, xReact, PersonX will feel good>. xReact refers to the feelings of the primary entity in the event, and oReact refers to the feelings of others (in this instance, oReact yields "PersonY will feel flattered"). For example, using the headline "Sudan protests: Outrage as troops open fire on protestors", COMET-ATOMIC outputs that PersonX feels justified, PersonX feels angry, Others feel angry, and so on (Figure 4). To use this knowledge model in our task, we modify our approach by reframing our single-sequence classification task as a sequence-pair classification task (for which BERT can be used directly). We feed our input headlines into COMET-ATOMIC (using the model weights released by the authors), collect the top two outputs for xReact and oReact using beam search decoding, and then feed them into BERT alongside the input headlines, as a second sequence using the SEP token. That is, our input to BERT is now $X = [[\text{CLS}], x_1, x_2, ..., x_n, [\text{SEP}], z_1, z_2, ..., z_m, [\text{SEP}]]$, where z_i are the m WordPiece tokens of our COMET output and are preprocessed in the same way as x_i. We hypothesize that, since pre-trained BERT is trained with a next sentence prediction objective, expressing the COMET outputs as a grammatical sentence will help BERT make better use of them, so we formulate this second sequence as complete sentences (e.g., "This person feels... Others feel...") (Figure 4).

This approach allows us incorporate information from COMET into all our single- and multi-task BERT-based models; the example shown in Figure 4 is our Multi$_{C\rightarrow E}$ model. We refer to the COMET variants of these mod-

	Emotion Macro F1	**Emotion Accuracy**	**Cause Span F1**
BERT	37.25 ± 1.30	38.50 ± 0.84	37.49 ± 1.94
BERT^{COMET}	37.74 ± 0.84	38.50 ± 1.14	39.27 ± 1.85
Multi	36.91 ± 1.48	38.34 ± 1.94	38.35 ± 3.89
Multi$_{C\rightarrow E}$	37.74 ± 2.12	38.74 ± 2.07	39.08 ± 3.73
Multi$_{E\rightarrow C}$	38.26 ± 3.28	39.69 ± 3.41	38.83 ± 1.60
Multi^{COMET}	37.06 ± 2.04	39.05 ± 0.98	**39.50** ± 2.25
Multi$^{COMET}_{C\rightarrow E}$	**39.26*** ± 1.13	**40.79** ± 2.17	38.68 ± 1.36
Multi$^{COMET}_{E\rightarrow C}$	37.44 ± 1.37	38.58 ± 1.44	36.27 ± 1.31

Table 1: The results of our models, averaged over five runs with the same five distinct random seeds. The model with the highest mean performance under each metric is bolded. Results marked with a * are statistically significant above the single-task BERT baseline by the paired t-test ($p < 0.05$).

els as: BERT^{COMET} (single-task models) and Multi^{COMET}, Multi$^{COMET}_{C\rightarrow E}$, Multi$^{COMET}_{E\rightarrow C}$ for the three multi-task models.

5 Experimental Setup

Evaluation Metrics For emotion classification, we report macro-averaged F1 and accuracy. For cause tagging, we report exact span-level F1 (which we refer to as *span F1*), as developed for named entity recognition (e.g., Tjong Kim Sang and De Meulder (2003)), where a span is marked as correct if and only if its type and span boundaries match the gold exactly[4].

Training and Hyperparameter Selection The classification layers are initialized randomly from a uniform distribution over $[-0.07, 0.07]$[5], and all the parameters are trained on our dataset for up to 20 epochs, with early stopping based on the performance on the validation data (macro F1 for emotion, span F1 for cause). All models are trained with the Adam optimizer (Kingma and Ba, 2015). We highlight again that for our Multi$_{C\rightarrow E}$ and Multi$_{E\rightarrow C}$ models, we use teacher forced during training to avoid cascading training error. Because the subset of the data we use is relatively small, we follow current best practices for dealing with neural models on small data and select hyperparameters and models using the average performance of five models with different fixed random seeds on the development set. We then base our models' performance on the average of the results from these five runs (e.g., reported emotion F1 is the average of the emotion F1 scores for each of our five runs). For our joint models, since our novel models revolve around using one task as input for the other, we separately tune two sets of hyperparameters for each model, one based on each of the single-task metrics, yielding, for example, one Multi model optimized for predicting emotion and one optimized for predicting cause. The hyperparameters we tune are dropout in our linear layers, initial learning rate of the optimizer, COMET relation type, lambda weight for our multi-task models, and the type of pooler for emotion classification (enumerated in subsection 4.1).

6 Results

We present the results of our models in Table 1[6]. We see that the overall best model for each task is a multi-task adapted knowledge model, with Multi$^{COMET}_{C\rightarrow E}$ performing best for emotion (which is a statistically significant improvement over BERT by the paired t-test, $p < 0.05$) and Multi^{COMET} performing best for cause. These results seem to support our two hypotheses: 1) emotion recognition and emotion cause detection can inform each other and 2) common-sense knowledge is helpful to infer the emotion and the cause for that emotion expressed in text. Specifically, we notice that Multi$_{C\rightarrow E}$ alone does not outperform BERT on either cause or emotion, but Multi$^{COMET}_{C\rightarrow E}$ outperforms both BERT and Multi$_{C\rightarrow E}$ on both tasks. For cause, we also see additional benefits of common-

---

[4] Our cause tagging task has only one type, "cause", as GoodNewsEveryone is aggregated such that each data point has exactly one emotion-cause pair. We note that this problem formulation leaves open the possibility of multiple emotion-cause pairs.

[5] The default initialization from the `gluon` package: `https://mxnet.apache.org/versions/1.7.0/api/python/docs/api/gluon/index.html`

[6] Oberländer and Klinger (2020) report an F1 score of 34 in this problem setting on this dataset, but on a larger subset of the data (as they do not limit themselves to the Ekman emotions) and so we cannot directly compare our work to theirs.

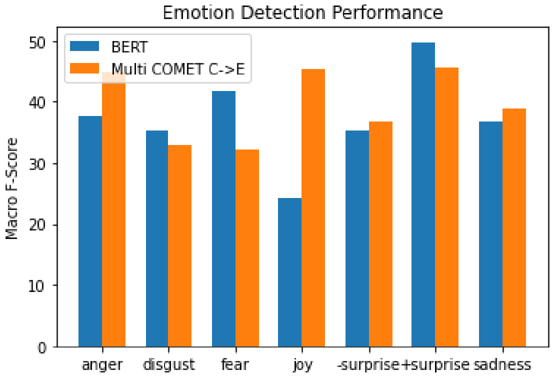

Figure 5: Performance of the BERT and Multi$^{COMET}_{C\rightarrow E}$ models on emotion classification.

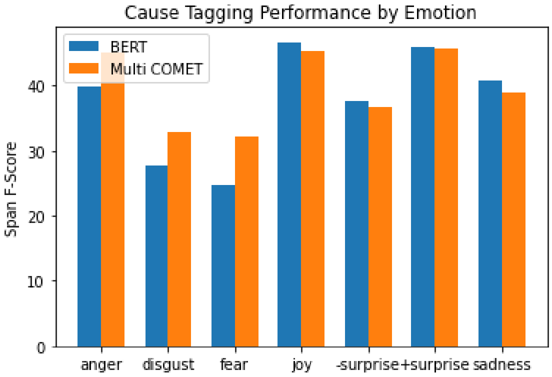

Figure 6: Performance of the BERT and Multi^{COMET} models on cause tagging, broken down by emotion.

sense reasoning alone: BERT^{COMET} outperforms BERT (multi-task modeling alone, Multi, also outperforms BERT for this task) and Multi^{COMET} outperforms Multi. These results speak to the differences between the two tasks, suggesting that common-sense reasoning, which aims to generates implicit emotions, and cause information may be complementary for emotion detection, but that for cause tagging, common-sense reasoning and given emotion information may overlap. The common-sense reasoning we have used in this task (xReact and oReact from ATOMIC) is expressed as possible emotional reactions to an input situation, so this makes intuitive sense.

Finally, we also present per-emotion results for our best model for each task (Multi$^{COMET}_{C\rightarrow E}$ for emotion and Multi^{COMET} for cause) against the single-task BERT baselines in Figure 5 and Figure 6; these per-emotion scores are again the average performance of models trained with each of our five random seeds. We see that each task improves on a different set of emotions: for emotion classification Multi$^{COMET}_{C\rightarrow E}$ consistently improves over BERT by a significant margin on joy and to a lesser extent on anger and sadness. Meanwhile, for cause tagging, Multi^{COMET} improves over BERT on anger, disgust, and fear, while yielding very similar performance on the rest of the emotions.

7 Analysis and Discussion

In order to understand the impact of common-sense reasoning and multi-task modeling for the two tasks, we provide several types of analysis in addition to our results in section 6. First, we include examples of our various models' outputs showcasing the impact of our methods (subsection 7.1). Second, we carry out an analysis of the dataset, focusing on the impact of label variation among multiple annotators on the models' performance (subsection 7.2).

7.1 Example Outputs

We provide some example outputs from our systems for both cause and emotion in Table 2; the various Multi models have been grouped together for readability and because they often produce similar outputs, but the outputs for every model are available in the appendix. In the first example, the addition of COMET to BERT informs the model enough to choose the gold emotion label; in the third and fourth, either COMET or multi-task learning is enough to help the model select key words that should be included in the cause (*return* and *triple shooting*). We also particularly note the second example, in which multi-task learning is needed both for the BERT and BERT^{COMET} models to be able to correctly predict the gold emotion. This suggests that for cause, both common-sense reasoning and emotion classification may carry overlapping useful information for cause tagging, while for emotion, different instances may be helped more by different aspects of our models.

7.2 Label Agreement

Upon inspection of the GoodNewsEveryone data, we discover significant variation in the emotion labels produced by annotators as cautioned by the authors in their original publication[7]. From our inspection of the development data, we see recur-

---

[7] While the authors selected data according to agreement on the emotion labeling task, they found that in only 75% of cases do at least 3 annotators agree, with diminishing rates of agreement for more annotators.

Table 2: Example outputs from our systems. For each example, the gold cause is highlighted in yellow and the gold emotion is given under the text; the first two examples give our models' emotion outputs; the latter two, their causes. Joined cells show that multiple models produced the same output. To make this table easier to read, "Multitask" here may refer to Multi, Multi$_{E \to C}$, or Multi$_{C \to E}$ (details on selection and results for each individual model available in appendix; most multi-task models gave similar outputs).

Metric	**BERT**	**BERT**^{COMET}	**Multi**	**Multi**$_{E\to C}$	**Multi**$_{C\to E}$	**Multi**^{COM}	**Multi**$^{COMET}_{E\to C}$	**Multi**$^{COMET}_{C\to E}$
Acc. (Gold)	38.50	38.50	38.34	39.68	38.74	39.05	38.58	40.79
Acc. (¬Gold)	23.48	23.24	22.37	21.11	22.85	21.26	22.45	20.08

Table 3: Comparison of gold accuracy and non-gold (¬gold) accuracy for our emotion classification models.

ring cases where different annotators give directly opposing labels for the same input, depending on how they interpret the headline and whose emotions they choose to focus on. For example, our development set includes the following example: *Simona Stuns Serena at Wimbledon: Game, Set and "Best Match" for Halep*. The gold adjudicated emotion label for this example is *negative surprise*, but annotators actually included multiple primary and secondary emotion labels including *joy*, *negative surprise*, *positive surprise*, *pride*, and *shame*, which can be understood as various emotions felt by the two entities participant in the event (Simona Halep and Serena Williams). For this input, COMET suggests xReact may be *happy* or *proud* and oReact may be *happy* — these reactions are likely most appropriate for tennis player Simona Halep, but not the only possible emotion that can be inferred from the headline.

Inspired by the variation in the data, we compute also models' accuracy using the human annotations that did not agree with the gold (i.e., a predicted emotion label is correct if it was suggested by a human annotator but was not part of a majority vote to be included in the gold). We denote this ¬Gold, and we compare the performance of our models with respect to Gold and ¬Gold. We present the results of this analysis in Table 3[8]. In this table, a higher ¬Gold accuracy means that the model is more likely to produce emotion labels that were not the gold but were suggested by some annotator. First of all, we note that all models have a relatively high ¬Gold accuracy (about half the magnitude of their gold accuracy); we believe this reflects the wide variety of annotations given by the annotators. We see a trade-off between the Gold and ¬Gold accuracy, and we note that generally the single-task models have higher ¬Gold accuracy and the COMET-enhanced multi-task models have higher Gold accuracy. This suggests that our language models have general knowledge about emotion already, but that applying common-sense knowledge helps pare down the space of plausible outputs to those that are most commonly selected by human annotators. Recall

---

[8] Note that we perform this analysis on just one of our five runs of the model, so the accuracy numbers do not exactly correspond to those in Table 1.

that this dataset was annotated by taking the most frequent of the annotator-provided emotion labels. Further, since the multi-task models have higher Gold accuracy and lower ¬Gold accuracy than the single-task models, this suggests that also predicting the cause of an emotion causes the model to narrow down the space of possible emotion labels to only those that are most common.

8 Conclusions and Future Work

We present a common-sense knowledge-enhanced multi-task framework for joint emotion detection and emotion cause tagging. Our inclusion of common-sense reasoning through COMET, combined with multi-task learning, yields performance gains on both tasks including significant gains on emotion classification. We highlight the fact that this work frames the cause extraction task as a span tagging task, allowing for the future possibility of including multiple emotion-cause pairs per input or multiple causes per emotion and allowing the cause to take on any grammatical role. Finally, we present an analysis of our dataset and models, showing that labeling emotion and its semantic roles is a hard task with annotator variability, but that common-sense knowledge helps language models focus on the most prominent emotions according to human annotators. In future work, we hope to explore ways to integrate common-sense knowledge more innately into our classifiers and ways to apply these models to other fine-grained emotion tasks such as detecting the experiencer or the target of an emotion.

Ethical Considerations

Our intended use for this work is as a tool to help understand emotions expressed in text. We propose that it may be useful for things like product reviews (where producers and consumers can rapidly assess reviews for aspects of their products to improve or expand), disaster relief (where those in need of help from any type of disaster can benefit if relief agents can understand what events are causing negative emotions, during and after the initial disaster), and policymaking (where constituents can benefit if policymakers can see real data about what policies are helpful or not and act in their interests). These applications do depend on the intentions of the user, and a malicious actor may certainly misuse the ability to (accurately or inaccurately) detect emotions and their causes. We do not feel it responsible to publicly list the ways in which this may happen in this paper. We also believe that regulators and operators of this technology should be aware that it is still in its nascent stages and does not represent an infallible oracle — the predictions of this and any model should be reviewed by humans in the loop, and we feel that general public awareness of the limitations and mistakes of these models may help mitigate any possible harm. If these models are inaccurate, they will output either the incorrect emotion or the incorrect cause; blindly trusting the model's predictions without examining them may lead to unfair consequences in any of the above applications (e.g., failure to help someone whose text is misclassified as positive surprise during a natural disaster or a worsened product or policy if causes are incorrectly predicted). We additionally note that in its current form, this work is intended to detect the emotions that are expressed in text (headlines), and not those of the reader.

We concede that the data used in this work consists of news headlines and may not be the most adaptable to the use cases we describe above; we caution that models trained on these data will likely require domain adaptation to perform well in other settings. Bostan et al. (2020) report that their data comes from the Media Bias Chart[9], which reports that their news sources contain a mix of political views, rated by annotators who also self-reported a mix of political views. We note that these data are all United States-based and in English. Bostan et al. (2020) do sub-select the news articles according to impact on Twitter and Reddit, which have their own user-base biases[10], typically towards young, white American men; therefore, the data is more likely to be relevant to these demographics. The language used in headlines will likely most resemble Standard American English as well, and therefore our models will be difficult to use directly on other dialects and vernaculars.

A Appendix

A.1 Hyperparameter Tuning

We include descriptions of our hyperparameter tuning setup and the selected hyperparmeters for each of our models in Table 4; we note that single-task cause models (BERT$_C$ and COMET$_C$) do not tune the `pooler`, all single-task models do not tune the lambda parameter, and all non-common-sense models do not tune `comet_relations`. The parameters selected by all of our models can be seen in Table 5, Table 6, and Table 7. All of our models are trained with minibatches of size $b = 32$.

We used Bayesian optimization as implemented by Amazon SageMaker[11] to tune these parameters, giving the learning rate a logarithmic scale and the dropout and lambda a linear one and allowing 75 iterations of parameter choice before selecting the setting with the best performance on the development set. Each individual instance of each model consisted of five different restarts with five distinct random seeds; one of these instances took approximately five minutes on a single Tesla V100 GPU, for a total of about 6.25 GPU-hours per model and thus 87.5 GPU-hours overall (since each multi-task model was trained twice: once optimized for emotion and once optimized for cause).

A.2 Model Sizes

Our models' sizes are dominated by BERT-base, which has 110 million trainable parameters (Devlin et al., 2019). We note that our trainable dense layers that interface with BERT have sizes 768 × 7 for emotion classification, 768 × 3 for cause tagging, and 1068 × 7 for our Multi$_{E \to C}$ models, while our emotion embedding matrix E has 300×7 trainable parameters. Our fine-tuning process does continue to tune all of BERT's parameters.

A.3 Extended Examples

We include the output of all models for our four selected examples in subsection 7.1 in Table 8, Table 9, Table 10, and Table 11.

The Utility and Interplay of Gazetteers and Entity Segmentation for Named Entity Recognition in English

Oshin Agarwal[1] and **Ani Nenkova**[1,2]
[1]University of Pennsylvania
[2]Adobe Research
oagarwal@seas.upenn.edu, nenkova@adobe.com

Abstract

Recent papers have introduced methods to incorporate gazetteer features and entity segmentation techniques in neural named entity recognition models. These papers rely on different resources and include features not related to the use of gazetteers, rendering impossible the comparison of the relative effectiveness of the approaches. Here, we provide a comprehensive overview of methods for incorporating gazetteers and for entity segmentation. We evaluate representative methods from each in similar settings for a fair comparison and identify the ones that are consistently better across datasets and input representations. We further show that gazetteers improve entity segmentation and not just entity typing. Hence, we explore their utility in recognizing long entities, a problem for which entity segmentation techniques were developed. Our work explains the mechanisms via which gazetteers improve the performance of neural NER models.

1 Introduction

Named Entity Recognition (NER) has the unique property of being a task appealing to researchers and at the same time being fairly robust for immediate practical applications. In many domains, it is of interest to identify segments of text conveying a concept of a given type—a person (Grishman and Sundheim, 1996), an event (Hovy et al., 2006), a disease (Doğan et al., 2014), a gene (Kim et al., 2003), a chemical (Krallinger et al., 2015), a food (Magnolini et al., 2019), an item of clothing (Putthividhya and Hu, 2011), a research technique (Augenstein et al., 2017a), etc.

Approaches to NER are typically not domain-specific, treating the problem as a sequence labelling task regardless of the categories of interest. Yet, researchers also widely agree that named entity recognition is a knowledge intensive task (Ratinov and Roth, 2009; Seyler et al., 2018): the availability of external knowledge resources in the form of lists of example entities of a given type, or *gazetteers*, improve performance almost universally. Since gazetteers are readily available, from knowledge bases, databases of products and specialized ontologies, having practical guidance on how to handle gazetteers in NER would be valuable.

In this paper, we provide a survey of how gazetteers have been used in neural approaches to NER in English and compare key approaches with the popular biLSTM-CRF architecture. To ensure that our conclusions accurately characterize the utility of gazetteers, we test the approaches on several datasets from different genres covering newswire, conversations and twitter. The extensive head-to-head comparison reveals that while certain approaches are consistently beneficial, others are variable, impressively improving results on one dataset but reducing performance on others.

Gazetteers typically contain multi-word entries. In contrast, the majority of entity mentions in text are single word, with lower performance of models on longer entities. This discrepancy highlights a potential application of gazetteers for improving NER prediction for mentions of long entities. Recent work on entity segmentation[1] as part of the named entity recognition task aims to recognize long entities better. We overview this work and compare these methods similar to the way we compare methods for incorporating gazetteers.

We find that certain ways for incorporating gazetteers show stable improvements across datasets, while segmentation approaches do not appear to be that useful overall. We further explore the interplay of gazetteers with entity segmentation and their role in recognizing long entities. We find that incorporating gazetteers improves entity

---

[1] Identifying entity spans without types

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3990–4002
August 1–6, 2021. ©2021 Association for Computational Linguistics

segmentation, not just entity typing and depending on the input representation to the model, gazetteer types may be irrelevant. We also find that incorporating gazetteers can serve as an alternate method to recognizing long entities, likely due to the abundant presence of multi-word entities in the Wikipedia-derived gazetteers we used.

Our work provides *(i)* a concise overview of methods for incorporating gazetteers and entity segmentation in NER, *(ii)* a principled comparison of representative approaches for each aspect, and *(iii)* novel findings and analyses of the interplay between gazetteers and segmentation. Our findings can inform both future researchers and practitioners interested in NER.

2 biLSTM-CRF architecture for NER

We explore variants of the now classic biLSTM-CRF architecture for NER (Huang et al., 2015). We overview how gazetteer features and segmentation can be integrated in this paradigm and carry out a comparison of several representative methods. We use two input word representations: the 300-d GloVe vectors trained on Common Crawl (Pennington et al., 2014), which is the dominant representation in NER, and the 1024-d contextual ELMo (Peters et al., 2018) representations trained on the 1B Word Benchmark (Chelba et al., 2014). In each case, character-based word representations learned with CNNs (Ma and Hovy, 2016) are also concatenated. The final concatenated representation is used as input to bidirectional LSTMs (Hochreiter and Schmidhuber, 1997), followed by a CRF (Lafferty et al., 2001) layer. We use the implementation by Lample et al. (2016) for most experiments.

3 Why Use Gazetteers?

Gazetteers are large dictionaries consisting of lists of entities of a particular type. For example, a person gazetteer may consist of full names and parts of names such as the first names of people. Before we start our discussion of methods for incorporating gazetteers, it is worth considering if we have sufficient evidence that they are needed at all.

Gazetteers are needed for better generalization through improved entity coverage, to predict the type for words that have not been encountered in training and possibly even pre-training. This means the need will be more acute for practical deployment of NER and will be less pronounced on fixed datasets in which train and test data are sampled from overlapping or adjacent time periods, with high overlap of entities across both.

The most compelling example for the need to handle unseen language comes from work on NER on Twitter. Language on Twitter changes rapidly, much more rapidly than for other types of text (Eisenstein, 2013). This change requires models to be retrained periodically to maintain optimal performance for the current time period (Rijhwani and Preotiuc-Pietro, 2020). An alternative to retraining, not yet explored in literature, is to develop methods that can make use of gazetteers that possibly could be updated more quickly and cheaply compared to continuously annotating new training data.

Even in stable domains such as newswire, the ability of models to generalize to words not seen in the training data is low (Augenstein et al., 2017b; Fu et al., 2020a,b). Both traditional models with hand-crafted features (Finkel et al., 2005; Okazaki, 2007) and more recent neural network approaches (Collobert et al., 2011; Huang et al., 2015; Peters et al., 2018; Devlin et al., 2019) achieve lower performance on entities unseen in the training data.

Methods that make use of large pretrained language representations, neural (Collobert et al., 2011) or not (Miller et al., 2004), can ameliorate the problem of coverage to some extent. We do not yet know enough about how pretraining data should be chosen (Cherry and Guo, 2015), though there is some evidence that performance on downstream tasks correlates with the vocabulary coverage in the pre-training data (Dai et al., 2019). Prior work has reported that performance is lowest for words that appear neither in the training nor the pretraining vocabulary (Ma and Hovy, 2016). Moreover, the deteriorated performance on out of vocabulary words is not necessarily a failure of the models: many contexts simply do not provide sufficient knowledge to predict the type of an entity, even for people (Agarwal et al., 2021). Models need to expand their knowledge of entities and gazetteers are a natural way for doing that.

4 Where Do Gazetteers Come From?

Existing tables, lists, directories, databases and knowledge bases are widely available and can be used to derive gazetteers. Some researchers have specifically compiled various resources to form gazetteers, while others make use of those provided in prior work. Early work collected gazetteers from the CIA factbook for geographic locations, lists of

1	**2**	**3**	**≥ 4**
15	43	18	24

Table 1: Gazetteer entities(%) by length (words).

popular person names, etc (Mikheev et al., 1999). More recently, Ratinov and Roth (2009) derived a gazetteer from the Web and Wikipedia and Chiu and Nichols (2016) used DBPedia.

In our work, we use the Ratinov and Roth (2009) wide-coverage gazetteer. It contains ∼3M entities grouped into ∼30 fine-grained categories. In some experiments, we use all categories, regardless of the entity types in the dataset. In the remaining, we identify the gazetteer category that most closely matches that types in a given dataset and disregard the rest. The mapping can be found in the appendix.

Table 1 shows the approximate percentage of entities by length in words in our gazetteer. Most entries are of length two, but unlike NER datasets (Table 3), the remaining entries are evenly distribution between length 1, 3 and ≥4. Most notably, around 24% of gazetteer entities have four or more words. In comparison, in NER datasets where entities appear in the context of a sentence that is often a part of a longer document, such long entities typically make up about 2% of all entities. This distributional difference hints at the possibility of using gazetteer to not only improve coverage but also improve performance on longer entities for which segmentation methods are developed.

Regardless of the distribution of entity lengths, the total number of entities in gazetteers is much higher than that in NER datasets so a higher percentage of longer entities does not equate to a small number of short entities.

5 Gazetteer Features for NER

Here, we overview the ways gazetteers have been integrated in NER models.

5.1 Discrete Gazetteer Lookup Features

Feature-based CRF models for NER used gazetteers to generate indicators for each word in a sentence (Bender et al., 2003; Minkov et al., 2005; Ratinov and Roth, 2009; Ritter et al., 2011; Yang et al., 2016; Seyler et al., 2018). The number of indicators equals the number of entity types in the dataset and indicate (with a binary 1/0 value) if the word is part of a gazetteer entry of the given type.

Many neural network approaches continue to incorporate gazetteers as discrete indicator features concatenated to the pre-trained word embeddings as the input (Collobert et al., 2011; Huang et al., 2015). Adding the features in later stages does not work as well (Magnolini et al., 2019). Both Collobert et al. (2011) and Huang et al. (2015) pre-process datasets to match the gazetteer entries to sentences, using both exact matches and multi-word partial matches to gazetteer entries. Chiu and Nichols (2016) perform a similar matching but use four binary values for each label, indicating whether the given word matches the gazetteer entity exactly (S), at the beginning (B), end (E) or the any of the words in between (I).

5.2 Continuous Gazetteer Features

The approach above does not use gazetteers very effectively. Gazetteers contain many more entities of each type than are available in even the largest training set (Table 3). One insight is to use the gazetteers as a additional source of training examples. A simple way is to add the gazetteer entries to the labeled data, without any context. Liu et al. (2019a) report that this data augmentation approach led to much worse overall results, presumably because of the great shift in label distributions. Another approach is to augment the training data by replacing entities in place by other entities from gazetteers. Song et al. (2020) reported no improvement with such a random entity replacement, likely due to the need for manual intervention for replacement of entities of some types to maintain coherence of text (Agarwal et al., 2020).

A much more successful alternative is to learn a separate (or sub-) module, trained to predict types for text spans, using the gazetteer entries and synthetic negative examples sampled from a NER training set or even the gazetteer. We will refer to the separate module as a *gazetteer network*. It is straightforward to integrate the label distribution scores from this model in a semi-Markov CRF for sequence labeling (Ye and Ling, 2018) that operates at the span level (which we describe in greater detail later). The resulting combination is far more effective than discrete indicator gazetteer features.

Magnolini et al. (2019) and Liu et al. (2019b) propose a similar approach. They learn a gazetteer network but instead of using the label score distribution, intermediate word representations (*gazetteer embeddings* henceforth) are incorporated in the NER model. Liu et al. (2019b) use a semi-Markov CRF operating at the span level and generate the gazetteer embeddings for each potential span. They follow the evaluation approach of Ma and Hovy (2016), breaking down results by whether an entity was seen only in training, seen only in pre-training, seen in both and seen in neither. The largest improvement was in the "seen in neither" subset, showing that this approach is particularly helpful for out-of-vocabulary words with respect to the training and pre-training data.

Magnolini et al. (2019) use the standard word-level CRF and hence do not have spans available so they input the full sentence to the gazetteer network. This makes the training and inference setup for the gazetteer network different as entity phrases are used as input during training. They reported mixed results for this approach. In our experiments, we evaluated their method on a larger number of datasets but used a different approach for negative sampling for the gazetteer network training data. We observed some improvement on almost all datasets, contingent on the input representation.

5.3 Contextual Gazetteers

Learning from just the gazetteer has the drawback that the representations do not include any clues about the context in which the entity types are used. The same entity may appear in multiple gazetteers. Given that current methods heavily rely on entity memorization and little on context, this is possibly acceptable. For completeness however, we ought to mention that the link structure of Wikipedia can be used to derive dense representations for entity types directly (Long et al., 2016; Ganea and Hofmann, 2017; Mengge et al., 2020; Ghaddar and Langlais, 2018). Comparing gazetteer representations with and without context would be a direction for exploration in future work.

6 Entity Segmentation in NER

Early work (Collins and Singer, 1999; Downey et al., 2007; Ritter et al., 2011) treated NER as two subtasks, i.e. *entity segmentation:* finding spans of text that refer to named entities, and *typing:* assigning a type to the identified span. Recent efforts have also incorporated entity segmentation explicitly in neural models, with goal of finding longer entities better (Xiao et al., 2019; Ye and Ling, 2018). Such work can be divided into two categories—Multi-task learning and semi-Markov CRFs.

6.1 Multi-task Learning

Multi-task learning (MTL) involves jointly training multiple related tasks using the same representation such that the auxiliary tasks can help with the performance of the target task. Aguilar et al. (2017) use MTL with hard parameter sharing to add two auxiliary tasks—binary classification to identify entity spans (segmentation) and multi-class classification to type them without CRF. Both tasks use the same biLSTM representation as the target task. The output of the additional tasks is not used in the NER task; they only act as regularizers for NER. Others (Stratos, 2017; Aguilar et al., 2018) also use auxiliary tasks as regularizers but instead of binary classification, the additional tasks performs multi-class classification into B (first word of entity), I (remaining entity words) and O (non-entity).

The auxiliary tasks in MTL can also be used for extra supervision by concatenating their output label distribution to the representation used by NER (Xiao et al., 2019). Unlike prior work, Xiao et al. (2019) do not use the same representation for the target and auxiliary task. Instead, they build a sub-module called similarity-based auxiliary classifier (SAC). SAC takes as input the original input representation and adds token position embeddings (Vaswani et al., 2017), followed by multiple convolution layers. It maintains two randomly initialized vectors representing entity and non-entity classes. These vectors are combined with an attention layer to get the final word representations. The attention weights are calculated with the multiplicative attention function over the word representation and each of these two vectors. The final word representation is concatenated with the biLSTM representation for NER and the attention weights are used as proxy for probabilities of the word being an entity or not. The loss of both tasks is jointly optimized, with less weight given to entity segmentation over NER. Yu et al. (2018) also add extra supervision, but with a two-step approach. They learn two character-level language models for entity and non-entity words and use their output as a binary feature in NER.

Augenstein and Søgaard (2017) use MTL for NER in scientific texts, adding five auxiliary tasks. They add syntactic chunking, hyperlink prediction, multi-word expression identification, frame target annotation, and semantic super-sense tagging; the first three target segmentation. The auxiliary tasks are used one at a time with the target task. Since the datasets for NER and the auxiliary tasks are

different, at each training step, a random task is chosen, followed by a random training instance.

6.2 Semi-Markov CRFs

Semi-Markov CRFs (Sarawagi and Cohen, 2004) are a variant of linear chain CRFs that capture dependencies between adjacent spans of text instead of adjacent words. The Markov assumption still holds across spans but not within the span. The goal is to find the best possible segmentation into spans using scores at span-level. The maximum length of spans is bound to reduce computation cost. Sarawagi and Cohen (2004) use hand-crafted features for span representations but recent work has explored other techniques to represent spans.

Gated recursive semi-markov CRF (Zhuo et al., 2016) creates a pyramid-shaped feature extractor for spans. The bottom-most layer consists of word representations and hence length one spans. Representation of adjacent words are combined to form length two spans for the next layer and so on. The top layer consists of a single span with the full sentence. Hybrid semi-Markov CRF or HSCRF (Ye and Ling, 2018) do not use an explicit span representation. Instead they consider the span-level score as sum of the word-level CRF scores of constituent words. Both the word-level and span-level CRF are jointly optimized. Sato et al. (2017) use a two step process to reduce the search space of the spans. They first generate possible spans from a separate model using a score cutoff and then find the best possible labelling over these spans instead of all spans upto a maximum specified length.

7 Datasets

We evaluate several of the above models on four datasets, to compare their performance. Table 2 shows the entity types in each dataset.

1. **CoNLL** is the English portion of the CoNLL'03 data (Tjong Kim Sang and De Meulder, 2003), extracted from the Reuters 1996 newswire corpus.
2. **ON** is the union of broadcast conversation (bc) and telephone conversation (tc) domains in the English portion of Ontonotes (Hovy et al., 2006).[2] The number of entity types is the largest in this dataset. We merge the closely related categories, *GPE* with *LOC* and *FAC* with *ORG*, to allow us to easily map gazetteer labels to dataset labels.
3. **BTC** or Broad Twitter Corpus (Derczynski et al., 2016) consists of tweets. We use the recommended train, validation and test splits.
4. **TTC** or Temporal Twitter Corpus (Rijhwani and Preotiuc-Pietro, 2020) also consists of tweets. It has multiple training splits from years ranging from 2014 to 2018 and validation and test splits from 2019. We use the 2014 training split as it overlaps less with 2019 and hence is more challenging.

Some dataset statistics are shown in Table 3. CoNLL and OntoNotes are the largest and are roughly equal in size. OntoNotes has more long entities and fewer entities that are sequences of capitalized words. Such characteristics will favor methods that perform better segmentation without relying on standard orthography. BTC and TTC are smaller and have more distinct surface forms. The entities in TTC follow capitalization conventions but BTC has many entities that consist of words that are not capitalized. BTC also exhibits a different distribution of capitalization patterns between the training and the test set. In the training set, roughly half of the entities are sequences of word with capitalized first letter but this number falls to just 28% in the test set. Most entities in all datasets consist of a single words. Only about 2% of entities have length more than three. OntoNotes contains the largest percentage of long entities, 10% of all.

We also present statistics on in/out of vocabulary words in the test data, with respect to the pretraining data, the training data and the gazetteer entries. An entity is considered *seen* in pre-training if the phrase is seen as such in the pre-training corpus or all of the constituent words are seen. For CoNLL and OntoNotes, almost all entities are seen in the pretraining data (>90%), followed by TTC (88%). For BTC, only 65-75% entities are seen in pretraining. Adding ELMo increases the entity coverage by only a small amount in all datasets.

---

[2] We also experimented with newswire, broadcast news and magazines, which had similar results to CoNLL.

Title case (%)	82.60	80.76	58.13	56.09	49.50	28.88	67.66	78.17

Table 3: Dataset Statistics. CoNLL and Ontonotes are larger but TTC and BTC have more distinct surface forms. Except Ontonotes, all datasets have very few long entities. Most entities are seen in the pre-training data. Test entities seen in the training data are generally seen with the same type at least. BTC has many lowercase entities.

The gazetteer provides a better coverage than the training data. Training data coverage is especially low in TTC, making the dataset more challenging. According to our definition of seen, entities may be seen in the training data but not necessarily with the expected types. We also check if they are seen in the training data with the same type as in the test data. There is a decrease of only 1-5% when taking the type into consideration. Overwhelming, the type in training is also that in testing.

8 Experiments

Results for models using different word representations, without any gazetteer or segmentation features, are shown in Table 4. We report micro-F1 over all entity types, averaged over three runs. On all datasets, the combination of GloVe, ELMo and character-based representations works best. Given these results, it would have been reasonable to study methods of adding gazetteers only for this representation. However, given that the GloVe along with character-based embeddings is much more commonly used in recent work on NER, we also present results for that.

We now compare one representative approach from each class of methods for adding gazetteer and segmentation features to the biLSTM-CRF architecture. For a fair comparison, we add only the core idea of the model and use the same hyperparameters, noted in the appendix, removing different peripheral features such as part-of-speech tags and word shape, used in papers that introduced the idea.

8.1 Gazetteers

We compare four gazetteer-derived features. In each case, the gazetteer representation vector is passed through a feedforward layer with 32 neurons and ReLU activation and then concatenated to the input word representation to the biLSTM-CRF.

1. **WORD_GAZ** We map gazetteer entity types to dataset types and split gazetteer entries into words using space as a delimiter, to create a vocabulary associated with each entity types, i.e. a list of words that appeared in person names etc. Each word in a sentence is associated with a binary valued vector with length equal to the number of entity types in the dataset. The dimension corresponding to a given type gets value one if the word is in the gazetteer vocabulary for that type and zero otherwise. The vector is all zeros for words that do not appear in the vocabulary for any entity types and can have multiple components with value one, when the word appeared in gazetteer entries of more than one type.

all	0.7	0.0	9.1	13.8

Table 7: Percentage of words in the vocabulary with the number of gazetteer types in which they appear.

2. **GAZ_IOBES** is similar to WORD_GAZ but instead of a single bit, there are four values for each label denoting a matching to an entity exactly (S), to the first word (B), to the last word (E) or other words in between (I).
3. **GAZ_FINE** is also similar to WORD_GAZ but instead of selecting types from the gazetteer to match the label types for a given dataset, we use all 30 gazetteer types as is. The length of the gazetteer vector equals the numbers of the original gazetteer types without any mapping.
4. **PHRASE_GAZ** Here, we perform phrase level matching between the sentence and the gazetteer. All subsequences (continuous sequence of words) in a sentence are matched to each entry in the gazetteers, retaining the gazetteer type only for the longest match. For example, only 'New York University' is matched, not the nested 'New York' entity in it. Each word in the longest match subsequence gets the bit corresponding to the matched gazetteer category switched on in the gazetteer vector representation.
5. **LRN_GAZ** Gazetteer embeddings are learned with a separate model and concatenated to the input representation for the NER model, as in Magnolini et al. (2019). Random n-grams, excluding named entities, from CoNLL'03 training data are used as negative examples for training the gazetteer network, as opposed to negative examples generated from gazetteer entries used in Magnolini et al. (2019).

Both word-level matching and learned gazetteers make it possible for the model to learn phrases beyond the exact entries in the gazetteers. For example, if the organization gazetteer contains 'GAZ High School' but the dataset contains 'TST High School', phrase-level matching would not match any of the words in 'TST High School' to a gazetteer. A word-level matching would at least mark 'High' and 'School' as organizations. Similarly, learned gazetteer embeddings may learn a similar representation for both and make it possible to recognize 'TST High School' correctly.

8.2 Segmentation

We experiment with the different multi-task learning methods of incorporating segmentation and one of the semi-Markov CRF models.

1. **SEG_REG** (Aguilar et al., 2017) is the MTL approach with two auxiliary tasks: binary classification to predict if the word is a part of entity and multi-class classification to predict the type of the word without CRF.
2. **SEG_SUP** is the same as SEG_REG, but the label distribution scores from the binary classification auxiliary task are concatenated to the final representation used for NER.
3. **SAC** is the similarity-based auxiliary classifier in Xiao et al. (2019) as described above.
4. **HSCRF** is the hybrid semi-Markov CRF in Ye and Ling (2018) as described above

9 Results

We test the gazetteer-enhanced and segmentation approaches using both GloVe+char and ELMo+GloVe+char as the input representations. Results are shown in Tables 5 and 6 respectively.

9.1 Consistency Across Datasets

We report the average and maximum improvement in F1-score over the base model across datasets. A high average improvement means that the model is consistently better across datasets spanning newswire, conversations and Twitter posts. A high maximum improvement with a low or negative average improvements means that the model can do well on some dataset but fails to perform well when tested on multiple datasets of varied genres.

The word indicator gazetteer features are the best and most consistent on average. With ELMo+GloVe, they also show the maximum improvement. WORD_GAZ combines gazetteer labels to dataset labels whereas the GAZ_FINE does not do any dataset specific mapping. Prior work has used the former but this experiment shows that we do not need to do such dataset specific modifications of gazetteer labels. We can use fine-grained labels and obtain similar gains. PHRASE_GAZ and LRN_GAZ improve performance with GloVe+char, with especially high performance on TTC, but they are not as good with ELMo+GloVe+char. Improvement with both representation by incorporating gazetteers is higher on BTC and TTC than CoNLL and OntoNotes. This is likely because the gazetteer features are more ambiguous in CoNLL and OntoNotes (Table 7), with most words appearing in two or more possible categories.

Segmentation methods can show vast improvement on specific datasets but they are unstable across datasets. The average improvement is *negative* in many cases for both representations. SEG_SUP is the only segmentation approach that is consistently beneficial across datasets for both representations. HSCRF performs well too, but only when ELMo is used as well. In comparison, including gazetteers is consistently better.

9.2 Gazetteers for Segmentation

In this section, we explore if gazetteers can be used as an alternative for segmentation, owing to their stable performance across datasets. We ask the following question:Are gazetteers recognizing new entities not previously marked as entities or are they improving the typing of spans already recognized as entities by adding entity type information? To answer this question, we report the entity segmentation F1 in Tables 8 and 9. Entity segmentation is the task of finding the correct entity span, regardless of the type. Since pre-training data covers most entities (Table 3), one would expect gazetteers to improve typing of entities through a more explicit type signal. However, segmentation results are consistent with those of NER. The models that improved performance of NER also perform well on segmentation and often by similar margins as NER. In fact, following similar trends as NER, gazetteer-enhanced models are more consistent than segmentation methods at entity segmentation as well. Since gazetteer-enhanced models induce segmentation and improve performance despite a near perfect coverage provided by the pre-training data, we expect them to improve performance of even the latest transformer-based models

System	CoNLL				Ontonotes				BTC				TTC

- gaz types	91.58	80.31	74.75	65.16	0.17	0.91

Table 11: NER F1. *avg-diff* and *max-diff* are the average and maximum increase over the base model across datasets. Removing gazetteer typ information improves performance for GloVe+char.

(Devlin et al., 2019) pre-trained on large corpora.

Next, we modify WORD_GAZ to mark the presence in any gazetteer without taking the type into consideration (Table 11). Surprisingly, removing type information results in better performance with GloVe, indicating the most benefit came from segmentation and not typing. With ELMo included, however, we do not observe the same trend. While performance is better than the baseline system, it is not better than WORD_GAZ that includes types. Though we cannot point conclusively to the reason behind such results with ELMo, we suspect it is due to the ambiguity within the pre-training data. The model may not be using the gazetteer representation if there is a strong signal from the pretrained representation that the word is not an entity. This can only be verified if all representations are trained on the same pre-training corpus.

9.3 Gazetteers for Long Entities

To further verify the effectiveness of gazetteers for segmentation, we break down performance by *entity length* in words, reporting F1 in Table 10 for the top performing gazetteer-enhanced model and segmentation model with ELMo+GloVe+char. Recall that the majority of entities in all corpora are of length one and that entities consisting of more than three words are the rare, about 2% in three of the datasets, expect in OntoNotes, where they are 10%. The highest performance is on entities of length two, followed by length one. Longer entities are recognized much more more poorly.

Typically segmentation methods have been used to improve performance on long entities. But our experiments reveal that gazetteers are better at it. With the exception of TTC, WORD_GAZ is better on long entities and HSCRF on shorter ones. This is likely due to the presence of many long entities in gazetteers (§4, Table 1).

10 Conclusion

We provided a comprehensive overview of methods for incorporating gazetteers and inducing segmentation in NER. We chose these two areas because even though they have been explored separately in prior work, we find that they are interrelated and achieve similar goals. We implemented representative models from each category for a fair comparison. We found that while segmentation methods can achieve impressive improvements on specific datasets, gazetteer-enhanced models are more stable across datasets. Moreover, the simpler methods of gazetteer enhancement (binary valued discrete feature vector with word-level gazetteer matching) and segmentation (multi-task learning with a extra supervision from and auxiliary binary classification for segmentation) performed better within their respective categories.

Furthermore, contrary to expectation, we found that gazetteer-enhanced models improve entity segmentation, not just entity typing. In fact, one need not perform a gazetteer to dataset label mapping for incorporating gazetteers; using the original gazetteer types works just as well. Even more surprisingly, gazetteer types are even unnecessary depending on the input representation. With GloVe, performance improves by removing gazetteer types altogether. This is likely a consequence of gazetteers inducing segmentation. Lastly, we showed that gazetteers are better at finding long entities, another consequence of inducing segmentation. They are an effective alternative to segmentation techniques developed to identify long entities, which we found are unstable across datasets.

B Implementation

We use the implementation in `https://github.com/guillaumegenthial/tf_ner` for most models.

SAC uses https://github.com/XiaoShiyuan/NCRF-SAC but is based off the same codebase.

HSCRF uses `https://github.com/ZhixiuYe/HSCRF-pytorch` but ELMo was added additionally by us.

C Hyperparameters

Hyperparameters used as same as the ones in `https://github.com/guillaumegenthial/tf_ner/models/chars_conv_lstm_crf`, except for number of epochs and the minimum number of steps before early stopping which depend on dataset size. Numbers of epochs used were 25, 25, 50 and 50 for CoNLL, Ontonotes, BTC and TTC respectively. Minimum steps were 8000, 15000, 2500 and 2500 for CoNLL, Ontonotes, BTC and TTC respectively.

On the Cost-Effectiveness of Stacking of Neural and Non-Neural Methods for Text Classification: Scenarios and Performance Prediction

Abstract

Neural network algorithms such as those based on transformers and attention models have excelled on Automatic Text Classification (ATC) tasks. However, such enhanced performance comes at high computational costs. Ensembles of simpler classifiers (i.e., stacking) that exploit algorithmic and representational complementarities have also been shown to produce top-notch performance in ATC, enjoying high effectiveness and potentially lower computational costs. In this context, we present the first and largest comparative study to exploit the cost-effectiveness of stacking of ATC classifiers, consisting of transformers and non-neural algorithms. In particular, we are interested in answering research questions such as: Is it possible to obtain an effective ensemble with significantly less computational cost than the best learning model for a given dataset? Disregarding the computational cost, can an ensemble improve the effectiveness of the best learning model? Besides answering such questions, another main contribution of this paper is the proposal of a low-cost oracle-based method that can predict the best ensemble in each scenario (with and without computational cost limitations) using only a fraction of the available training data.

1 Introduction

Natural Language Processing, Machine Learning and Data Mining techniques work together to automate the fundamental task of Automatic Text Classification (ATC). ATC automatically associates documents with classes, providing means to organize information, allowing better comprehension and interpretation of the data. Algorithms based on neural networks (e.g., BERT (Devlin et al., 2018), XLNet (Yang et al., 2019)) have become the highlight in the area, where they are used both to learn features for text representation and as classification algorithms. The main problem of such methods is the very high computational costs needed for learning the model parameters (Sun et al., 2019; Cunha et al., 2021).

Ensemble approaches, such as stacking, which combine the outputs of several base classification models to form an integrated output, have also been shown to excel in ATC (Džeroski and Ženko, 2004; Ding and Wu, 2020), enjoying high effectiveness and computational costs that depend on the selected learning methods of the ensemble. They are motivated by the fact that distinct learning models or text representations may complement each other, uncovering specific structures that underlie the input/output relationship of the data. Early works (Larkey and Croft, 1996) aimed at showing combinations of different classification algorithms capable of producing better effectiveness results than any single type of classifier.

However, the benefits of ensemble techniques against a strong classifier are not always clear (Yan-Shi Dong and Ke-Song Han, 2004), in part, due to the excellent generalization power of the best classifiers. In fact, previous ensemble works mostly focus on improving the overall classification effectiveness using the results of traditional classification algorithms (Campos et al., 2017; Ding and Wu, 2020), paying little or no attention to practical issues such as the execution time or which combination of efficient base algorithms can bring effective results at a lower cost.

Accordingly, our *first contribution* in this paper is a thorough study of the cost-effectiveness tradeoff of stacking techniques for text classification tasks. Rather than just evaluating the effectiveness of an ensemble of various recent and effective methods, including those based on transformers and attention models, we focus on the study of stackers capable of achieving a better compromise between low cost (or high efficiency) and high ef-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4003–4014
August 1–6, 2021.

fectiveness when compared to a single base model (i.e., the most effective single classifier in a given dataset). A wide range of comparative experiments with stacked ensemble models and state-of-the-art base algorithms are conducted on six datasets widely used in text classification. We seek answers based on empirical evidence to the following questions, considering the best learning model for each given dataset: *(RQ1): Is it possible to obtain an effective ensemble with significantly less computational time than the best learning model? (RQ2): Is it possible to improve the effectiveness of the best learning model using an ensemble without increasing the computational time? (RQ3): Disregarding the computational time, can an ensemble improve the effectiveness of the best learning model?* As far as we know, we are the first to investigate the cost-effectiveness trade-offs (Cunha et al., 2021) of stacking of neural and non-neural text classifiers from the described perspectives.

A second main contribution of our work is the proposal of a low-cost oracle-based method that can predict the best ensemble in each scenario (with and without computational cost limitations) using only a fraction of the available training data. Our **"Oracle"** first estimates the best base algorithm (which can be seen as a baseline for effectiveness) to perform an efficient greedy search of ensembles guided by both their effectiveness and efficiency concerning the best base algorithm. Particularly, the Oracle predicts effective ensembles by successively including base algorithms that improve their combined majority voting effectiveness. Moreover, our method avoids the inclusion of expensive base algorithms (concerning the best base algorithm) to guarantee the ensemble efficiency. Our proposed Oracle is the first known strategy to provide an efficient prediction of effective ensembles capable of tackling practical efficiency issues related to our research questions. In more details, our proposal aims at predicting three ensembles corresponding to the time restrictions of RQ1, RQ2 and RQ3, respectively, while avoiding the potential high computational cost of evaluating expensive base models and their ensembles, especially on large datasets.

Our experimental results show affirmative answers to our three research questions in most experiments. In most datasets, it is possible to obtain an ensemble of base algorithms that is as good as or better than the base algorithm, at a lower cost. In 5 out of 6 datasets it is possible to obtain an ensemble with statistically significant gains against the best algorithm with no increase in cost. Similarly, in 5 out of 6 datasets, our oracle provides as good as or better results than the best base algorithm with no increase in cost, providing empirical evidence to the practical benefits of the proposed oracle.

2 Background and Related Work

2.1 Text Classification Strategies

Early efforts in ATC focused on improving machine learning algorithms such as Naïve Bayes, kNN, Logistic Regression and SVM (Howard and Ruder, 2020) using a simple bag of (TFIDF weighted) words representation. Even with such simple document representation, the use of methods such as LinearSVM (Fan et al., 2008a) and XGBoost (Chen and Guestrin, 2016a) produced high effectiveness with and efficient convergence for large datasets (Fan et al., 2008a).

More recent strategies, such as metafeatures (Canuto et al., 2018) and neural networks (NNs) (Joulin et al., 2017; Tang et al., 2015a), exploit the training data to build more informative document representations. Particularly, strategies based on metafeatures (Canuto et al., 2018; Canuto et al., 2019b) extract information from more basic (bag-of-words) features to enhance the feature space by smartly exploiting a document's neighborhood. Strategies based on NNs enhance word representations (and thus documents) also exploiting the training data. FastText (Joulin et al., 2017) and PTE (Tang et al., 2015a), for instance, presented high effectiveness in comparison to (costly) deep learning approaches.

Considerable advances on deep learning for ATC were achieved by using pre-trained language models with fine-tuning (Howard and Ruder, 2018), mainly when combined with attention mechanisms (Kokkinos and Potamianos, 2017; Yang et al., 2016) and the parallelization benefits of transformers, better exemplified by BERT (Devlin et al., 2018). Following BERT's success, the recent XLNet network (Yang et al., 2019) proposes a new autoregressive formulation to improve the exploitation of contextual information. Though effective, the fine-tuning process of methods such as BERT and XLNet still takes substantial computational time, requiring powerful hardware (GPUs) (Sun et al., 2019). Such requirements might bring practical limitations for these solutions.

2.2 Stacking

Stacking (Wolpert, 1992) is a widely known ensemble technique that combines the predictions of heterogeneous algorithms (i.e., base algorithms) to improve effectiveness concerning these base algorithms. To implement stacking, we first need to train each base algorithm. With the trained models, we can make predictions in a different validation set, which was not used for training. With the saved models and the predictions in the validation set, a *metalayer* (another learning algorithm) is used to learn how to combine the predictions in the combination. Recent work reported high effectiveness with stacking for multiple ATC tasks, such as topic classification (Campos et al., 2017; Abuhaiba and Dawoud, 2017), sentiment analysis (Carvalho and Plastino, 2020; Onan et al., 2016) and multi-label classification (Xia et al., 2020; Weng et al., 2019). Particularly, stacking provided substantial effectiveness improvements on recently proposed decision-tree-based algorithms (Campos et al., 2017) and with methods trained on different representations (including word embeddings) (Carvalho and Plastino, 2020; Pelle et al., 2018; Onan et al., 2016).

A careful choice of base algorithms is necessary due to the potential degradation of the stacking effectiveness and efficiency. The literature reported low effectiveness on stacking due to overfitting issues with multiple base algorithms (Reid and Grudic, 2009; Ledezma et al., 2010). Previous works that optimize the choice of a subset of base algorithms (Ledezma et al., 2010; Gupta and Thakkar, 2014) focused on maximizing the ensemble effectiveness with no concern for efficiency. Stacking efficiency is usually attached to the most expensive method. In fact, (Hou et al., 2021) reportedly avoids the cost of using expensive deep learning methods by including gradient boosting base algorithms comparable to convolutional NNs.

In this work, we provide a thorough evaluation of the effectiveness and efficiency tradeoffs of stacking, i.e., we investigate whether there are combinations of algorithms that overcome (in both, efficiency and effectiveness) the best base ones in a given dataset. Our proposed oracle in turn is the first method to explicitly tackle a time-constrained stacking prediction goal by explicitly and efficiently exploiting the relationships between stacking and the best base algorithms.

3 Methodology

3.1 Time-Constrained Stacking

We aim to answer the following research questions: *(RQ1): Is it possible to obtain an effective ensemble with significantly less computational time than the best learning model? (RQ2): Is it possible to improve the effectiveness of the best learning model using an ensemble without increasing the computational time? (RQ3): Disregarding the computational time, can an ensemble improve the effectiveness of the best learning model?*

With RQ1 we aim to identify whether it is possible to obtain a stacking of (a subset of) base algorithms that is as effective or better than the best (i.e., most effective) base algorithm and takes strictly less computational time than the best base. Favorable evidence towards a positive answer is important to indicate the existence of cost-effective stacking solutions, especially if the best base algorithm is a costly strong/high generalization power baseline. RQ2 keeps the same effectiveness demands of RQ1, but considering the following relaxation on the time constraint: the parallel execution of the base models can take at most the same execution time as the best base algorithm. This time constraint allows the best base algorithm to be included in the stacking. With this, we intend to evaluate if effectiveness improvements are possible with the (time) cost of the best base algorithm as an upper limit. In RQ3 we remove all time constraints to obtain the best possible stacking regardless of cost. With RQ3 we want to evaluate the potential effectiveness improvements of an stacking over the best base algorithm, in exchange for additional (time) cost.

3.2 Oracle-Based Prediction of Stacking Performance

The proposed strategy is implemented as follows: (i) each base algorithm is trained with a reduced amount of the training set (e.g., 30%); (ii) we run an algorithm, called "Oracle" (Algorithm 1), which aims at finding the best combination of base algorithms with less training by a greedy strategy. First, we select the best base algorithm obtained with the reduced training to start the combination, where $\mathbb{A}$ is the set of all base algorithms executed with less training. For this, we use the $Best(\mathbb{A})$ function, which simply returns the best algorithm based on the validation set. For each iteration, the next best algorithm, as estimated in a validation set, is added and we verify whether the combined result presents a statistically significant improvement ($\alpha = 0.05$) in relation to the previous iteration. If positive, it is permanently included in the combination. The process continues until all base algorithms are considered. The strategy is greedy since it makes the best choice in the current iteration.

To perform the comparison and statistical tests in each iteration, we use a separated piece within the training set (validation) that is not contained in the smaller part used in training. Besides, as a meta-layer, we use a simple average, i.e., we simply add the probabilities of the predictions dividing it by the number of base algorithms. The meta-layer average is represented by the function $Avg(\mathbb{E})$ in the pseudocode, where $\mathbb{E} \subset \mathbb{A}$. As it is a simple meta-layer and not a learning algorithm, the cost can be considered insignificant in the choice process.

Algorithm 1 Oracle Algorithm

```
procedure ORACLE($\mathbb{A}$)
    $\mathbb{C} \leftarrow Best(\mathbb{A})$
    $\mathbb{S} \leftarrow \mathbb{A} - \mathbb{C}$
    while $\mathbb{S} \neq \emptyset$ do
        $X \leftarrow Best(\mathbb{S})$
        $\mathbb{E} \leftarrow \mathbb{C} + X$
        if $Avg(\mathbb{E}) > Avg(\mathbb{C})$ then
            $\mathbb{C} \leftarrow \mathbb{E}$
            $\mathbb{S} \leftarrow \mathbb{A} - \mathbb{C}$
        else
            $\mathbb{S} \leftarrow \mathbb{S} - X$
    return $\mathbb{C}$                                   ▷ Best combination
```

With the oracle defined, we raise the following research questions: *(ORQ1): Can we predict, using a fraction of the training data, an effective stacking that will tie or outperform the best learning model when trained with all the available training, at a smaller cost than that of the best model? (ORQ2): Can we make a similar prediction than in ORQ1, but now with cost smaller or at the maximum equal to that of the best model when trained with all training data? (ORQ3): with no constraints in time, can we predict a combination that will be better than the best learning algorithm in a dataset?*

4 Experiments

4.1 Experimental Setup

We consider the effectiveness and efficiency of the models on two large-scale ATC datasets (Zhang et al., 2015) (more than 100,000 documents) – AG's News (AGNews) and IMdB Reviews – and four mid-sized datasets very known in the ATC community – 20 Newsgroups (20NG), WebKB (WebKB), Reuters (Reut) and ACM Digital Library (ACM). Table 1 shows the datasets details.

In terms of classification (base) algorithms, we consider the LinearSVM (Fan et al., 2008b), kNN (Altman, 1992), LogisticRegression (Fan et al., 2008b), XGBoost (Chen and Guestrin, 2016b), XLNet (Yang et al., 2019) and BERT (Devlin et al., 2018). In terms of representations, beyond the traditional term-weighting alternatives (TFIDF), we consider distributional and other types of word embeddings, such as FastText (Joulin et al., 2016; Bojanowski et al., 2017) and PTE (Tang et al., 2015b), as well as recent representations based on MetaFeatures that have obtained state-of-the-art (SOTA) effectiveness in some of the experimented datasets (Canuto et al., 2019a, 2018, 2016; Cunha et al., 2020, 2021). Table 2 has a summary of the base algorithms and respective representations used in each of them.

Algorithm	Representation	ID	Algorithm	Representation	ID
LinearSVM	FastText	A	Logistic	FastText	J
	PTE	B	Regression	PTE	K
	TFIDF	C		TFIDF	L
	Metafeatures	D		Metafeatures	M
kNN	FastText	F	XGBoost	FastText	N
	PTE	G		PTE	O
	TFIDF	H		TFIDF	P
	Metafeatures	I		Metafeatures	Q
			XLNet	Raw Documents	R
			BERT	Raw Documents	S

Table 2: Base Algorithms and Representations IDs.

We run the stacking process with the following variants: all combinations of the same base algorithm with different representations, all combinations of different base algorithms with their best representations, and a combination that includes all the base algorithms. For example, we perform all possible combinations of LinearSVM with FastText, PTE, TFIDF and MetaFeatures, resulting in total of 11 combinations: $\binom{4}{2} + \binom{4}{3} + \binom{4}{4}$. This limitation of combinations has a main reason: all combinations of all algorithms and representations, 18 in our case, would result in an impractical number of possible combinations for execution: 262,125 experiments = $\binom{18}{2} + \binom{18}{3} + .. + \binom{18}{18}$.

An important observation is that we assume that the base algorithms can be run in parallel (e.g. different machines). Thus, a stacking or oracle combination has the execution time limited by the most costly base algorithm in the respective combination. Even if this assumption is not true and it is necessary to execute the base algorithms and combinations on one single machine, this would only

			Class Distribution						
Dataset	Size	# Feat.	# Classes	Minor Class	Median	Mean	Major Class	Avg Doc. Size (words)	Skewness
20NG	18,846	97,401	20	628	984	942	999	296	Balanced

Table 1: Datasets statistics.

aggravate the cost problem and allow an unfair comparison in our favor. Therefore, to avoid this unfair comparison, we maintain the assumption of parallel execution.

The experiments in the smaller datasets were executed using a 10-fold cross-validation procedure while in the larger we used 5 folds due to the cost of the procedure. The algorithms parameters were tuned using the Bayesian Optimization (Bergstra et al., 2015) approach with 10 iterations, with the 5-fold stratified strategy and the training set (nested cross-validation). In Table 14 in the Appendix, we have the values of each parameter that we optimize in the non-neural base algorithms. The parameters and pre-trained models for BERT and XLNet are also shown in the Appendix (Table 12). For the neural networks, we adopted the same parameters defined by the authors of their respective methods (Devlin et al., 2018; Yang et al., 2019). In our experiments, we adopt AWS EC2 instances to run and measure the execution time for both neural and non-neural algorithms. For the non-neural algorithms, we use the instance model *c5a.12xlarge*, which has 48 CPUs, 96GB of RAM (without GPU). For the neural algorithms, we use the instance model *p2.xlarge*, which has one NVIDIA K80 GPU (12 GB of memory), 4 CPUs and 61 GB of RAM.

We evaluate all methods, combined with different representations, with respect to classification effectiveness and training time. We assess classification effectiveness in the test partitions using MicroF1 and MacroF1 (Sokolova and Lapalme, 2009). While MicroF1 measures the classification effectiveness over all decisions, MacroF1 measures the classification effectiveness for each individual class, averaging them, being very important for skewed datasets. In addition to effectiveness, we also assess the cost of each method in terms of the training execution time aiming at analyzing the cost-effectiveness trade-offs for all methods. The metric is the overall time in seconds (average of folds). To compare the average test results on our cross-validation experiments, we assess the statistical significance employing the paired t-test with 95% confidence, which is strongly recommended over signed-rank tests for hypothesis testing on mean effectiveness and arguably robust to potential violations of the normality assumption in this context (Urbano et al., 2019; Hull, 1993).

4.2 Experimental Results

4.2.1 Stacking Results

Effectiveness and Time results for the base algorithms in each dataset are shown in Table 3. The results of these best base algorithms are considered in the next analyses. Results for RQ1, RQ2 and RQ3, in terms of MacroF1 for each dataset are shown in Tables 4, 5, and 6, respectively, while Figure 1, shows the analysis of the cost (time). For each dataset, the tables show the effectiveness (MacroF1) of the best base algorithm along with the stacking combination that best answered the respective research question (if any), the respective combination of methods (the letters refer to the index of algorithms described in Table 2), and finally, in the last column, (Most Costly) the most costly algorithm that entered in the combination, according to the constraints imposed by the question. We present only MacroF1 results due to space constraints and the fact that is it harder to improve them in the highly skewed scenario that occurs in most of the experimented datasets. However, we also consider MicroF1, whose results are summarized in Table 7.

In Table 4, which focuses on RQ1 that has a strong constraint in terms of cost (time), we can see that in 4 out of 6 datasets, it is possible to obtain a combination of classifiers (stacking) that is

Table 3: Effectiveness, based on MicroF1 and MacroF1, and efficiency, based on execution time, for all classification algorithms and datasets considered in the our experiments. The algorithms are: (A) LinearSVM + FastText; (B) LinearSVM + PTE; (C) LinearSVM + TFIDF; (D) LinearSVM + TFIDF+Mf; (F) KNN + FastTex; (G) KNN + PTE; (H) KNN + TFIDF; (I) KNN + TFIDF+Mf; (J) LogisticRegression + FastTex; (K) LogisticRegression + PTE; (L) LogisticRegression + TFIDF; (M) LogisticRegression + TFIDF+Mf; (N) XGBoost + FastTex; (O) XGBoost + PTE; (P) XGBoost + TFIDF; (Q) XGBoost + TFIDF+Mf; (R) XLNet + Raw Documents; and (S) BERT + Raw Documents. The best results are highlighted in bold. When we identified statistically ties between two or more algorithms, we chose the one with lower execution time. For example, for the 20NG, we identified statistical ties for the algorithms M (LogisticRegression + TFIDF+Mf) and Q (XGBoost + TFIDF+Mf) and choose the M that presents lower execution time.

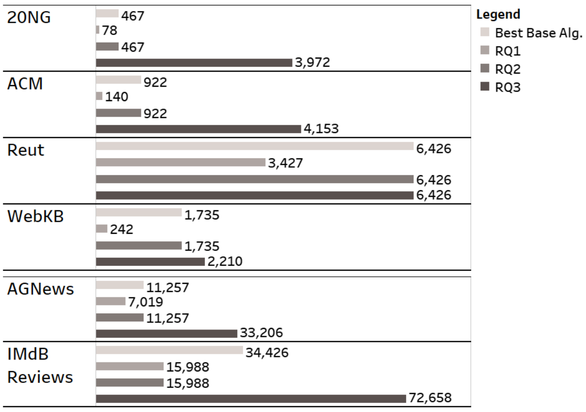

Figure 1: Stacking Times

as good as (statistical tie) or better (see the *ACM* case, with statistically significant gains of 3.1%) than the best base algorithm, at a lower cost. In fact, the gains in terms of cost (time) are very significant (see Figure 1), ranging from 1.87x speedup improvement (in Reuters) to 7.16x (in WebKB)[1]. Even if we consider the two cases in which there were some minimum effectiveness losses (0.39% in AGNews and 2.66% in IMdB), there are some significant speedups: 1.6x in AGNews and 2.15x in IMdB. Some chosen stacked combinations are interesting, such as FGHI in 20NG that contains all versions of kNN, and JLM in ACM, containing three versions of Logistic Regression. Both combinations contains classifiers with Metafeatures.

Results for RQ2 (Table 5) are also very interesting. In 5 out of 6 datasets it is possible to obtain

Dataset	Experiment	MacroF1	Combination	Most Costly
20NG	Best Base	90.58	M (Log. Reg. + MetaFeat)	
	RQ1	● 91.02	FGHI	I

	RQ1	▼ 33.18	KM	M

Table 4: RQ1.

effectiveness gains with no increase in cost (remind that in this scenario the cost is limited by that of the best base algorithm). Effectiveness gains vary from 0.4% in AGNews, 1.15% in 20NG[2], 3.1% in ACM, 5.4% in IMdB and 9% in WebKB. Reuters is only considered a tie because of the high variability of the results across folds in this dataset (due to the large number of classes and very high skewness), which generates large standard deviations/confidence intervals. In absolute terms, there was a positive variation (non-statistically significant gain) of more than 9.7%. Indeed, the MicroF1 stacking results confirms statistically significant gains in Reuters (See Table 7).

As expected, to obtain gains in this scenario it is necessary to include the best base algorithm in the combination in most datasets, inserting diversity/complementarity into the combination. Only

---

[1] Speedups in 20NG and ACM were 6x and 6.6x

[2] Notice that improvements in 20NG and AGNews are very hard to obtain given the already high effectiveness values.

Dataset	Experiment	MacroF1	Combination	Most Costly

Table 5: RQ2.

in ACM, the base algorithm is not part of the combination. Notice also that, due to the time constraints, the gains are somewhat limited due to the restricted number of classifiers that can be combined. This has some impacts on the results, for instance, in IMdB only two algorithms belong to the best combination while the combination in ACM has only three classifiers. Only in WebKB the combination includes all 18 classifiers as the base algorithm is also the most expensive one. Another interesting aspect of the combinations is that in all datasets, a classifier using Metafeatures was included (e.g., M and Q)

Finally, in the scenario with no time constraint (RQ3), further gains can be obtained with the inclusion of more costly classifiers. There are further gains in AGNews (0.94%), 20NG (2.06%), IMdB (5.8%) and ACM (6.32%). Notice that in this scenario, there is a tendency to include most algorithms in the combinations, like in ACM, WebKB and AGNews, to obtain further improvements. This means that most algorithms have complementary information that tends to contribute to the final results. Another interesting aspect to notice is that in some cases, such as in 20NG, a completely different combination than that chosen in scenario RQ2, was picked. This combination exploits the most effective and complementary algorithms, and may not even include the base classifier. In other cases, such as in IMdB, a combination of a few of the most effective (and costly) algorithms suffices to obtain larger gains. This means that the meta-layer is really doing a good job in learning about the individual performance of the algorithms and their complementarity. Finally, these additional effectiveness gains come with potential high increases in cost, clearly seen in Figure 1 for the cases of 20NG, ACM and AGNews. In those datasets, the costs have tripled (AGNews), quadrupled (ACM and IMdB) or become 8x more cost expensive. It is up to the application designer to decide whether this cost-effectiveness tradeoff is worth it.

Dataset	Experiment	MacroF1	Combination	Most Costly

	RQ3	▲ 36.06	QS	Q

Table 6: RQ3.

Table 7 summarizes the effectiveness results. For RQ1, there are 8 win/ties out of 12 possibilities (6 datasets, two metrics). Remind that in this scenario ties are considered a good result due to the reduction in costs. For RQ2 and RQ3, there are 11 wins, only 1 tie (in Macro in Reuters) no losses at all. In terms of cost (Figure 1), significant reductions in scenario 1 (RQ1) can be obtained in all 6 datasets, with almost no loss (or minimal losses) in terms of effectiveness. For scenario 2 (RQ2), effectiveness gains can be obtained in almost all cases with no additional cost when compared to the cost of the base classifier. And for scenario 3 (RQ3) additional effectiveness gains can be obtained, but sometimes with a very high increase in cost.

RQ	MicroF1			MacroF1		
	Win	Tie	Loss	Win	Tie	Loss
RQ1	2	2	2	1	3	2
RQ2	6	0	0	5	1	0
RQ3	6	0	0	5	1	0

Table 7: Win/Tie/Loss Summary.

4.2.2 Oracle Results

MacroF1 results of the Greedy Oracle predictor are shown in Tables 8, 9 and 10. These results correspond to an Oracle that uses the results of the base algorithms trained with 30% of the training data and predicting in a different training data portion in a nested folded cross-validation procedure.

We start by answering ORQ1. Table 8 shows that in half of the cases we can perform a good prediction, i.e., one that predicts a combination of methods that will tie or outperform the best base algorithm when trained with all the available training data (100%). It is very important to stress that in a real situation we do not really know what will be the best algorithm when using all the training data nor its effectiveness. Indeed, with more data, there is a tendency for some algorithms, such as the transformers, to improve their effectiveness, but their good performance may not be predicted with few training data. Remind also that this is a very strict scenario: even if we can predict which will be the best base algorithm, we cannot use it in the combination given the time constraints of ORQ1.

Dataset	Experiment	MacroF1	Combination	Most Cost
20NG	Best Base	90.58	M (Log. Reg. + MetaFeat)	
	ORQ1	▲ 91.62	ABCDIL	I

IMdB Reviews	Best Base	34.09	S (BERT)	
	ORQ1	▼ 27.79	L	L

Table 8: Oracle ORQ1.

Given all these limitations, mainly that only the algorithms with a cost lower than the best base algorithm (with 30% of training) can be considered, it is impressive that we can make a prediction that will surpass in effectiveness the best base algorithms using 100% of training in 20NG and ACM and tie with it, being cheaper, in WebKB. But even in the case in which there were losses, some were minimal, like in AGNews with a loss of only 2.5% with potential gains in training time. Only in Reuters and IMdB there were significant MacroF1 losses, mainly due to the failure of predicting which would be the best base algorithm[3] and the impossibility of including the predicted best base algorithm in the combination.

When we are allowed to include the best-predicted algorithm in the stacking (scenario for ORQ2) results are even better – we can make a good prediction in 5 out 6 cases (2 wins and 3 ties). Notice that in this scenario we consider a tie as a good result. We interpret that being able to predict a combination that will tie with the best algorithm with 100% of training in a dataset, without knowing which one will this best, at a very lost cost (Figure 2), as an excellent result. Notice that the best results in this scenario (i.e., 20NG and ACM) are obtained when we can in fact predict what will be the best base algorithm with 100% of training. But even when we cannot predict, as in the case of WebKB and AGNews[4], we can find a combination of simpler (and potentially less expensive) algorithms that can tie with the best. Again, IMdB was the only case in which we could not make a good prediction exactly by the failure in predicting, with 30% of training, that BERT would be the best algorithm when all the training data is used.

Dataset	Experiment	MacroF1	Combination	Most Cost

	ORQ2	▼ 31.11	K	K

Table 9: Oracle ORQ2.

Finally, when no time constraints are imposed the oracle's prediction results are excellent: 4 wins, 1 tie and only one loss (in IMdB). This last loss is explained by the same reasons as in the previous scenario: the failure of predicting BERT as the future best algorithm. But even in this case, the prediction for using algorithm K: LogisticRegression with PTE as the sole combination (an unusual prediction) produced minimal losses: only 1.05% at a cost much smaller than using BERT. And in the case of Reuters, we obtain an absolute increase in MacroF1 values (6% increase), though not statistically significant due to the high variability.

When looking at the costs of making the predictions in each scenario (ORQ1, ORQ2, and ORQ3), shown in Figure 2, we can see that in all cases (but 20NG for ORQ3), the oracle's predictions times are much smaller, in many cases negligible[5], when compared to the time to run the base algorithm with 100% of training. Given the time constraints imposed by ORQ1 and ORQ2 and the fact even in the scenario for ORQ3, only a portion of the 18 available algorithms needed to be stacked (in most cases) to produce effectiveness gains, the advan-

---

[3] In case of Reuters, a XGBoost with Metafeatures (Q) and in IMdB, BERT (S).

[4] In both the best base algorithms with 100% were the neural transformers XLNet and BERT

[5] Some differences are in the orders of magnitude.

Table 10: Oracle ORQ3.

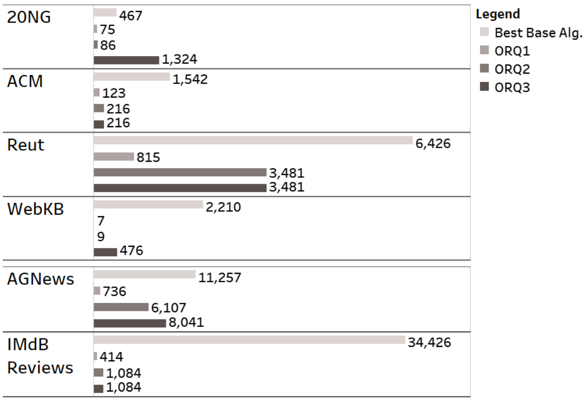

Figure 2: Oracle Times

tage's of running the oracle's predictions in terms of cost stand for themselves.

Table 11 summarizes the results in terms of Micro and MacroF1: considering all 36 results (three RQs, 6 datasets, 2 metrics) the oracle predicted 17 wins, 10 ties (most of them (8) in scenarios ORQ1 and ORQ2, which can be considered good results) and only 9 losses, six of them in a single dataset (IMdB) for the simple reason that we failed in predicting a neural network winner with fewer data. This is certainly a point to be improved in our methodology. One idea is to look not only at the absolute effectiveness values with a single training point (30%) but look also at the tendency of growing considering several points (5%, 10%, ..).

RQ	MicroF1			MacroF1		
	Win	Tie	Loss	Win	Tie	Loss
ORQ1	2	0	4	2	1	3
ORQ2	2	4	0	2	3	1
ORQ3	5	1	0	5	1	0

5 Conclusion and Future Work

We presented two important contributions to the application of Stacking in ATC: a thorough study of cost-effectiveness trade-offs and the proposal of a new oracle method to predict the best ensemble combination for a dataset at a low cost. Our extensive experiments, composed of 4 textual representation methods, 6 datasets, 4 non-neural based algorithms and 2 neural-based algorithms, provided us with answers to questions that had not yet been explored in the literature. By performing stacking with different time constraints, we showed that it was possible to obtain combinations that positively answered the posed questions regarding the time-constrained stacking and the oracle predictions in terms of both, effectiveness and efficiency.

We highlight general and practical guidelines based on our extensive experiments. First, we notice the consistent appearance of recent meta-features on the best combinations of base learners obtained for each evaluated research question (Tables 4–6). In fact, due to the focus of meta-features on summarizing relevant distance-based information from the original features, we strongly suggest their exploitation in ensemble combinations. Moreover, the largest datasets benefit from additional data to fine tune BERT for the classification task. Therefore, combinations including both of these recent and distinct paradigms (meta-features and BERT) for stacking were able to produce very effective results on most datasets (as shown in Table 10). We suggest that stacking methods should start by exploiting these two paradigms in conjunction. Finally, our experiments show the need of specific stacking solutions for different scenarios/datasets. The application of our proposed Oracle efficiently predicts effective best base models on time-constrained scenarios, allowing adaptable solutions that automatically optimize the choice of base learners for each specific dataset. We suggest to exploit the Oracle in all these situations.

In the future, we will explore different Oracle configurations, explore multi-objective feature selection in the stacking meta-layer (Viegas et al., 2018), study other types of constraints (e.g., labeling effort) and apply the Oracle in fields such as recommender systems.

Table 14: Algorithms and parameters. The implementations of LinearSVM, kNN and LogisticRegression are from scikit-learn and XGBoost is from the respective authors implementation-based package. Omitted parameters are the libraries default. This table has the **range** functions and the **uniform** and **quniform** distributions functions, which are used to define the search space of some algorithms. The range(low, high, step) function returns a number between [**low**, **high**) in a **step** interval. The uniform(low, high) function returns a value uniformly between **low** and **high**. The quniform(low, high, q) function returns a value like round(uniform (low, high) / q) * q and differs from the uniform by a smooth factor.

Unsupervised Domain Adaptation for Event Detection using Domain-specific Adapters

Abstract

Due to the multi-dimensional variation of textual data, detection of event triggers from new domains can become a lot more challenging. This prompts a need to research on domain adaptation methods for event detection task, especially for the most practical unsupervised setting. Recently, large transformer-based language models, e.g. BERT, have become essential to achieve top performance for event detection. However, their unwieldy nature also prevents effective adaptation across domains. To this end, this work proposes a **D**omain-specific **A**dapter-based **A**daptation (**DAA**) framework to improve the adaptability of BERT-based models for event detection across domains. By explicitly representing data from different domains with separate adapter modules in each layer of BERT, **DAA** introduces a novel joint representation learning mechanism and a Wasserstein distance-based technique for data selection in adversarial learning to substantially boost the performance on target domains. Extensive experiments and analysis over different datasets (i.e., LitBank, TimeBank, and ACE-05) demonstrate the effectiveness of our approach.

1 Introduction

Event detection (ED) is an important component in the overall event extraction pipeline, which plays a crucial role in any natural language understanding system. The goal of ED is to identify event triggers in a given text and classify them into one of several pre-defined types. Formally, according to the ACE-05 annotation guideline , each event trigger is a phrase (usually a single verb or nominalization), which evokes that event in the context of the associating event mention. For example, the word "*fired*" is the trigger word for an event of type *Attack* in the following sentence: *"The police* ***fired*** *tear gas and water cannons in street battles with activists."* Tackling ED problem involves both locating the event triggers and categorizing them into specific event types, therefore can be a quite challenging task due to the intricate dependency among triggers, events, and contexts in linguistic data. The complication is further amplified by domain shift problem when text are collected from multiple different domains.

The majority of prior approaches on ED relied on the basic supervised learning assumption where training and testing data follow the same distribution. Several works further evaluated their methods on cross-domain setting where their models were trained using data from one domain and tested on another, without leveraging any adaptation mechanism to alleviate the domain shift problem (Nguyen and Grishman, 2015; Yubo et al., 2015; Hong et al., 2018b). To this end, our work explores the general problem of domain adaptation for ED where data comes from two different source and target domains. In particular, we focus on the unsupervised setting that requires no annotations for target data, and the model has to learn to make use of both labeled source and unlabeled target samples to improve its performance on target domain. To our knowledge, this is the first work on unsupervised domain adaptation (UDA) for ED in the literature.

The most prominent approach for UDA is a representation learning method based on the theory of learning from different domains developed by Ben-David et al. (2010). The main result provided a way to bound the loss of a model on target domain with its performance on source domain using a domain-divergence term and an optimal joint error term (which is assumably negligible). Ganin et al. (2016) adopted this idea for deep learning architecture in their domain-adversarial neural network (DANN). They employed a domain-adversarial training procedure in which a domain classifier is learned concurrently and adversarially with the network's fea-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4015–4025
August 1–6, 2021.

ture extractor, resulting in a not only discriminative but also domain-invariant joint representation for data from both domains. While DANN and its variants are very well-studied in computer vision's domain adaption researches, their NLP counterparts are pale in comparison, especially for a newly established architecture like BERT. There have been only several works that adopted DANN to align the contextualized representations learned by BERT across domains (Lin et al., 2020; Naik and Rosé, 2020; Wright and Augenstein, 2020). Lin et al. (2020) even observed negative effect when applying adversarial training compare with simply fine-tuning BERT on in-domain data. One explanation is that the pre-training of BERT on massive corpora has already induces a somewhat general representation, thus DANN has little effect while the fine-tuning process using source dataset could cause over-fitting on the corresponding domain due to the immense capacity of the model. To this end, we propose fixing the parameters of the already universal language model while leveraging multiple adapter modules for domain-adversarial training process. More specifically, inspired by the works of Liu et al. (2017a) and Houlsby et al. (2019) on effective multi-task learning, we augment the pre-trained BERT model by adding three different adapters to create a shared-private architecture. Two source and target adapters which take as inputs data from their respective domains to capture private properties of each, and a joint adapter that encodes every sample in a subspace shared across domains through adversarial training. Orthogonality constraints together with a self-supervised auxiliary task are employed to ensure the representations of all adapters are informative while also attaining the above desired properties.

Recently, Ma et al. (2019) and Aharoni and Goldberg (2020) have shown that BERT's representations are extremely effective at clustering text to their respective domains, and a small subset of good in-domain data can already provide significant boosts in target performance while the rest only provide little to no improvement, in some cases even degrade model's out-of-domain generalization. Considering this, we explicitly find hard instances to leave out when learning to extract the domain-invariant features. Our data selection component estimates and minimizes the cost of transport between source and target marginal representation distributions based on the Wasserstein-1 distance (also refer to as Earth Mover distance). Arjovsky et al. (2017) pointed out that the relative strength of the topologies induced by this distance is much weaker than that of KL-divergence used by adversarial training. Therefore, it could serve as a good necessary condition for DANN component to achieve optimal alignment. The faraway source instances that induce the highest transportation costs are those out-of-distribution samples that may introduce noise and hurt adaptation performance. Accordingly, they are omitted from the domain-adversarial training process. The entire computation makes use of representations from source and target adapters, thus implicitly provides informative signals from domain-specific adapters to joint adapter without interrupting the joint representation learning procedure.

2 Related Work

Prior ED works have focused on the in-domain setting (Li et al., 2013; Chen et al., 2015; Nguyen et al., 2016; Yang and Mitchell, 2016; Nguyen and Grishman, 2018; Sha et al., 2018; Liu et al., 2017b; Tong et al., 2020; Nguyen et al., 2021), the cross-domain evaluation (Nguyen and Grishman, 2016; Hong et al., 2018a), the few/low-shot learning scenario (Lai et al., 2020a,b). Our work is different from those prior work as we explore a new formulation for ED with unsupervised domain adaptation where unlabeled data in the target domain is utilized to improve domain-invariant representation learning.

Recently, some efforts have been made to study the domain-related knowledge encoded in BERT's representations (Aharoni and Goldberg, 2020), and methods to leverage it to improve performances on domain-specific tasks, such as pre-training on additional data (Gururangan et al., 2020), fine-tuning using intermediate tasks (Phang et al., 2018; Garg et al., 2020), and data selection (Ma et al., 2019; Aharoni and Goldberg, 2020). Another line of research regarding multi-task learning shares a common goal of creating a universal representation space for all data with domain adaptation. Previous approaches made use of multiple encoders to set up a shared-private architecture (Bousmalis et al., 2016; Liu et al., 2017a), which usually is impractical for BERT-based models because of theirs sizes. By fixing a pre-trained BERT as the base for general representations, Houlsby et al. (2019) and Stickland and Murray (2019) proposed to adapt the model to each task by adding small task-specific layers between BERT's layers and updating only them when fine-tuning on the corresponding task.

3 Model

Throughout this work, we formulate ED task as a token-level multi-class classification problem (Nguyen and Grishman, 2015; Ngo et al., 2020). For UDA setting in particular, we have a labeled source dataset $\mathcal{D}^{\mathbf{s}}_{\mathbf{XY}} = \{(\mathbf{X}^{\mathbf{s}}_i, y^{\mathbf{s}}_i)\}_{i=1}^{N^{\mathbf{s}}}$ of $N^{\mathbf{s}}$ samples from source domain $\mathbf{s}$ and an unlabeled set of $N^{\mathbf{t}}$ samples $\mathcal{D}^{\mathbf{t}}_{\mathbf{X}} = \{\mathbf{X}^{\mathbf{t}}_i\}_{i=1}^{N^{\mathbf{t}}}$ drawn from target domain $\mathbf{t}$. Each $\mathbf{X}^{\mathbf{s}}_i$ is a pair consists and an event mention $W^{\mathbf{s}}_i = (w^{\mathbf{s}}_{i1}, w^{\mathbf{s}}_{i2}, \cdots, w^{\mathbf{s}}_{im})$ (m is the fixed number of words), and a trigger position u $(1 \leq u \leq m)$ corresponding to the word $w^{\mathbf{s}}_{iu}$. An encoder computes its latent representation $x^{\mathbf{s}}_i$, which is then used by the event classifier to predict an event of type $y^{\mathbf{s}}_i$. For target domain, parallel notations are used $x^{\mathbf{t}}_i$ and $y^{\mathbf{t}}_i$ (only accessible in target domain's test dataset)

3.1 Baseline Model

As this is the first work on UDA for ED, this section aims to establish a baseline of the task for further research. Recent works have shown a substantial boost in performance for the standard supervised setting of ED by leveraging contextual embedding of large self-attention based language models (Wang et al., 2019; Lai et al., 2020c). Accordingly, we utilize a pre-trained BERT's encoder, together with its domain-adversarial variant to create a strong baseline for the UDA setting.

Without any domain adaptation mechanism, our **BERT** baseline only follows cross-domain evaluation setting as previous works. The model is fully fine-tuned on source domain dataset while at test time, data from target domain is used to evaluate its performance.

On the other hand, the **BERT+DANN** baseline takes advantage of the availabel unlabeled target data through adversarial training. Specifically, a domain classification task is learned concurrently with the main downstream task, using unlabeled samples and their domain labels from both domains. By pushing the encoder to both minimize the event classfication loss and maximally misdirect domain predictor, the resulting representation can be indiscriminate with respect to the shift between the domains while also discriminative for the main learning task.

Finally, to demonstrate to ability of adapter-based tuning approach to retain the original's model performance, we also evaluate a **BERT+Adapter** baseline. Following recommendation from Pfeiffer et al. (2021), we augment a pre-trained BERT model by injecting a single bottleneck adapter module between the encoder's layers. Then, the fine-tuning process proceeds in the same manner as that of the **BERT** baseline, but only parameters of the adapter modules get updated in this case.

3.2 Adapter-based Domain Representation

Pre-trained BERT model was previously optimized for the task of masked language model in unsupervised manner on several extremely large corpora. The diversity of these unlabeled text also pushes the network to be a good starting point for learning domain-invariant features, which would be lost if we fully fine-tune it on source domain task. Accordingly, we make use of a fixed pre-trained BERT model as the base of our adapters.

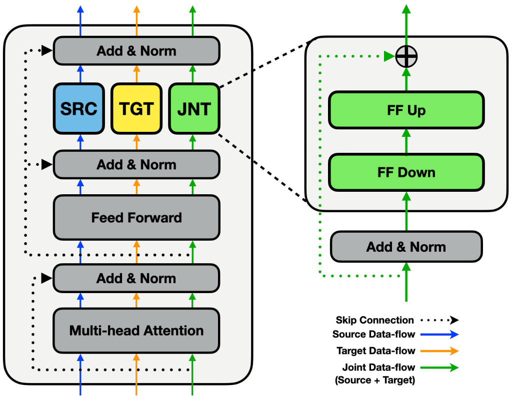

Figure 1: Domain-specific adapters inside the original BERT's layers.

An adapter for each domain To explicitly create a shared-private representation subspace of each domain, we inject three adapters into the same base encoder. Formally, adapter modules $a^{\mathbf{s}}_i$, $a^{\mathbf{t}}_i$, $a^{\mathbf{j}}_i$ are added on top of each BERT's layer. While these modules share the same architecture, they take in as inputs data only from their corresponding sources:

$$\mathbf{A}^{\mathbf{d}}(x^{\mathbf{d}}_i) = a^{\mathbf{d}}_L \circ b_{L-1} \circ \cdots \circ a^{\mathbf{d}}_1 \circ b_1(x^{\mathbf{d}}_i)$$

where b_i is the fixed layer of BERT $(1 \leq i \leq L)$, $\mathbf{d} \in \{\mathbf{s}, \mathbf{t}, \mathbf{j}\}$, and $\mathcal{D}^{\mathbf{j}}_{\mathbf{X}} = \mathcal{D}^{\mathbf{s}}_{\mathbf{X}} \cup \mathcal{D}^{\mathbf{t}}_{\mathbf{X}}$. The joint adapter $\mathbf{A}^{\mathbf{j}}$ is our main representation which will be used by event detection head h_c for source classification task:

$$\mathcal{L}_c = \frac{1}{n^{\mathbf{s}}} \sum_{i=1}^{n^{\mathbf{s}}} -y_i^{\mathbf{s}} log\left(h_c\left(\mathbf{A}^{\mathbf{j}}\left(x_i^{\mathbf{s}}\right)\right)\right)$$

On the other hand, the domain-specific adapters $\mathbf{A}^{\mathbf{s}}$ and $\mathbf{A}^{\mathbf{j}}$ will only be used to help $\mathbf{A}^{\mathbf{j}}$ find to the optimal joint-domain space while simultaneously retain good performance on downstream task.

Adapter architecture: There are a variety of ways that one can design the adapter modules' architecture. Following the observations from Pfeiffer et al. (2021), we choose ours to be the most efficient but also effective, which is a singular bottleneck neural network with skip-connection, taking features computed by BERT's feed-forward sub-layer as inputs. The adapter module in layer l can be decoupled into two parts $a_l^{\mathbf{d}} = a_l^{\mathbf{d},up} \circ a_l^{\mathbf{d},dw}$, where $a_l^{\mathbf{d},dw} : \mathbb{R}^{d_{model}} \to \mathbb{R}^c$ and $a_l^{\mathbf{d},up} : \mathbb{R}^c \to \mathbb{R}^{d_{model}}$ (as shown in figure 1). Despite tripling the added parameters from adapter modules, by setting $c \ll d_{model}$, the amount needed to be tuned is still only less than 10% that of the original network. Additionally, the factorized features enable effective adaptation by making use of the low-dimensional down-sampled representation, while also boosting classification performance by leveraging the free parameters of the up-sampling projection, as described in the next sections.

3.3 Joint Representation Learning

To learn a joint representation that is as general as possible while also maintaining its discriminative property, we propose to combined two mechanisms with complementary effects : a layer-wise domain-adversarial (LDA) component and an adapter-wise domain disentanglement (ADD) component.

3.3.1 Domain-adversarial Training

LDA apply domain-adversarial training to the representation of $\mathbf{A}^{\mathbf{j}}$. Multiple refinements to the original DANN are introduced to mitigate its flaws and learn better domain-invariant features.

Dimension Reduction It is known that discriminative features computed by high-level layers usually lie on low dimensional manifolds. As a result, naively applying adversarial training for BERT's representations, which require high dimension to capture contexts, can lead to gradient vanishing problem. We leverage the adapter's architecture to tackle this issue. Instead of the full dimension outputs of layers, we align domains based on the down-sampled version of the representations, computed by $a_i^{\mathbf{j},dw}$. In consequence, an adapter module can be viewed as a two-step adaption: a down-sampling projection step that extracts domain-invariant features and a following up-sampling projection step which transforms the extracted general features into task discriminative ones.

Layer-wise Alignment To enhance the alignment capability of our model, domain-adversarial training is applied on every layer's output. In particular, we incorporate the asymmetric relaxation of DANN (Wu et al., 2019):

$$\mathcal{L}_d^l = -\frac{1}{N}\sum_{i=1}^{N}\left[d_i\, log\left(\frac{h_d(a_l^{\mathbf{j},dw}(x_i))}{1+\beta_j}\right)\right. \\ \left. +(1-d_i)log\left(1-\frac{h_d(a_l^{\mathbf{j},dw}(x_i))}{1+\beta}\right)\right]$$

where d_i is domain label of samples x_i, $N = n^{\mathbf{s}} + n^{\mathbf{t}}$ is minibatch size, and $\beta_l \geq 0$ is a hyperparameter controlling the maximal difference of the two marginal distributions ($\beta_l = 0$ is the original formulation). This modification addresses the target shift scenario where domain-adversarial training is unable to achieve optimal solution. As outlined by Rogers et al. (2021), lower-level layers of BERT contain quite broad knowledge, thus encode more random distribution when projected into label space. In contrast, high-level ones are gradually more task-specific, effectively reducing the possible amount of label shift between the two domains. Therefore, we adopt the following relaxation annealing strategy:

$$\mathcal{L}_d = \sum_{l=1}^{L} \mathcal{L}_d^l(a_l^{\mathbf{j},dw}, \beta_l, h_{d,l}^{\mathbf{j}}), with\ \beta_l = 2^{3-l}$$

where each term on the right-hand side is a different relaxed domain classification loss computed by a separate domain classifier $h_{d,l}^{\mathbf{j}}$.

3.3.2 Adapter-wise Domain Disentanglement

The role of ADD component is to ensure the shared-private relationship among adapters. We want the joint adapter $\mathbf{A}^{\mathbf{j}}$ to encode a shared representation space containing common information between domains and no domain-specific information, while the private adapters $\mathbf{A}^{\mathbf{s}}$ and $\mathbf{A}^{\mathbf{t}}$ should only accommodate distinct knowledge that belong exclusively to their corresponding domains. Following the work of Liu et al. (2017a) and Bousmalis et al. (2016), an orthogonality constraint is imposed using the following similarity loss function:

$$\mathcal{L}_s = \|\mathbf{A}_{\mathbf{s}}^{\mathbf{j}}{}^{\top}\mathbf{A}_{\mathbf{s}}^{\mathbf{s}}\|_F^2 + \|\mathbf{A}_{\mathbf{t}}^{\mathbf{j}}{}^{\top}\mathbf{A}_{\mathbf{t}}^{\mathbf{t}}\|_F^2$$

where $\|.\|_F$ is the Frobenius norm and $\mathbf{A}_{\mathbf{d_2}}^{\mathbf{d_1}}$ is a matrix whose rows are the outputs of adapter $\mathbf{A}^{\mathbf{d_1}}$ taking inputs from domain $\mathbf{d_2}$. Minimizing $\mathcal{L}_s$ will force $\mathbf{A}^{\mathbf{j}}$ to be in a complementary subspace with $\mathbf{A}^{\mathbf{s}}$ and $\mathbf{A}^{\mathbf{t}}$, encouraging independency among adapters and removing domain-specific noises that may contaminate the joint representation. However, whereas $\mathbf{A}^{\mathbf{j}}$ is trained to be informative for the downstream classification, $\mathbf{A}^{\mathbf{s}}$ and $\mathbf{A}^{\mathbf{t}}$ are not constrained by any task, which potentially could lead to a trivial solution where the network learns to map each representation into the same orthogonal space with $\mathbf{A}^{\mathbf{j}}$ while not having any expressive capability of their corresponding domains. To address this issue, we incorporate a self-supervised component, using the popular Masked Language Modeling (MLM) as our unsupervised task. The token predictor $h_m : \mathbb{R}^{d_{model}} \rightarrow \mathbb{R}^V$ (V is the vocabulary size), is shared between source and target domains:

$$\mathcal{L}_m = \sum_{i=1}^{N_{mask}} \mathcal{L}_m^{\mathbf{s}}(x_i^{\mathbf{s}}) + \mathcal{L}_m^{\mathbf{t}}(x_i^{\mathbf{t}})$$

$$\mathcal{L}_m^{\mathbf{d}}(x_i^{\mathbf{d}}) = -w_i^{\mathbf{d}} \log h_m\left(\mathbf{A}^{\mathbf{j}}(x_i^{\mathbf{d}}) + \mathbf{A}^{\mathbf{d}}(x_i^{\mathbf{d}})\right)$$

where N_{mask} is the number of randomly masked input tokens, following the original procedure in Devlin et al. (2019). The benefit of adding the MLM component is twofold. On one hand, it serves as a constraint to learn informative representations for domain-specific adapters. On the other hand, it also help conditioning joint adapter $\mathbf{A}^{\mathbf{j}}$ on unsupervised knowledge of unlabeled target data, which can have a positive impact on target domain's performance.

3.4 Data Selection

Considering the Wasserstein-1 distance between the distributions generating source and target marginal representations $\mathbb{P}_{\mathbf{X}}^{\mathbf{s}}$ and $\mathbb{P}_{\mathbf{X}}^{\mathbf{t}}$, which can be written as:

$$W(\mathbb{P}_{\mathbf{X}}^{\mathbf{s}}, \mathbb{P}_{\mathbf{X}}^{\mathbf{t}}) = \sup_{\|f\|_L \leq 1} \mathbb{E}\left[f(x^{\mathbf{s}})\right] - \mathbb{E}\left[f(x^{\mathbf{t}})\right]$$

There are several advantages of using this distance as the proxy for data selection mechanism. First, Wasserstein distance takes into account the geometry of the actual data distributions. Thus, it is intuitive to use it to evaluate the discrepancy between marginal distributions and pick source samples that are geometrically close to samples from target distribution. Furthermore, it has been proven by Arjovsky et al. (2017) that the minimization of KL-divergence, on which LDA component based to update $\mathbf{A}^{\mathbf{j}}$, also implies the minimal Wasserstein distance between the corresponding distributions. Therefore, leaving out the most far-a-way samples based on this distance should provide a good necessary condition for LDA to achieve optimal alignment from source to target domain.

Approximate Wasserstein Distance Following the approximation from Shen et al. (2018), we employ a data selection head h_w to estimate the Wasserstein distance between two representation distributions of $\mathbf{A}^{\mathbf{s}}$ and $\mathbf{A}^{\mathbf{t}}$ by maximizing the following empirical loss with respect to θ_w:

$$\mathcal{L}_{\hat{w}} = \frac{1}{n^{\mathbf{s}}} \sum_{i=1}^{n^{\mathbf{s}}} h_w\left(\mathbf{A}^{\mathbf{s}}\left(x_i^{\mathbf{s}}\right)\right) - \frac{1}{n^{\mathbf{t}}} \sum_{i=1}^{n^{\mathbf{t}}} h_w\left(\mathbf{A}^{\mathbf{t}}\left(x_i^{\mathbf{t}}\right)\right)$$

For the above approximation to work, we need to enforce the Lipschitz constraint, which will force the hypothesis class of h_w to be 1-Lipschitz. Following Gulrajani et al. (2017), a gradient penalty $\mathcal{L}_{gr}$ is added to the loss, resulting in the overall estimation problem for the Wasserstein distance as

$$\max_{\theta_w} \mathcal{L}_w = \mathcal{L}_{\hat{w}} - \lambda_{gr}\mathcal{L}_{gr}$$

$$\mathcal{L}_{gr}(\mathbf{A}^{\mathbf{d}}) = (||\nabla_{\mathbf{A}^{\mathbf{d}}} h_w(\mathbf{A}^{\mathbf{d}})||_2 - 1)^2$$

where $\mathbf{d} \in \{\mathbf{s}, \mathbf{t}\}$ and λ_{gr} is a hyper-parameter.

Data Selection based on Wasserstein Distance To avoid negative transfer problem in case of highly dissimilar domains, we propose to use a data selection mechanism based on the estimated Wasserstein distance. By minimizing the empirical distance using $\mathbf{A}^{\mathbf{s}}$ and $\mathbf{A}^{\mathbf{t}}$, we find the representations that achieve the shortest transport distance between source and target samples. Then, a subset of $\hat{n}^{\mathbf{s}}$ source samples is selected with the lowest $h_w(.)$ scores, which corresponds to the $\hat{n}^{\mathbf{s}}$ shortest distances to target domain. These source instances will be used by the joint adapter $\mathbf{A}^{\mathbf{j}}$, together with target unlabeled data, to learn domain-invariant features in LDA.

3.5 Alternating Minimization

Taking it all together, our final training objective is given as:

$$\mathcal{L}_{total} = \mathcal{L}_c + \lambda_d \mathcal{L}_d + \lambda_w \mathcal{L}_w + \lambda_s \mathcal{L}_s + \lambda_m \mathcal{L}_m$$

where $\lambda_d, \lambda_w, \lambda_s, \lambda_m$ are hyper-parameters which help to balance the importance of the corresponding loss with the main event detection loss. Of the five terms on the right-hand side, the domain discrepancy losses ($\mathcal{L}_d$ and $\mathcal{L}_w$) require optimization of different directions with respect to the added heads and the adapters, resulting in a min-max optimization problem. Previous works that made used of domain-adversarial training usually applied gradient reversal layer to train the feature extractors. We find this approach to be unstable and cause performance degradation. Following suggestions from Goodfellow et al. (2014) and Shu et al. (2018), we design an alternating minimization process that is compatible with our learning algorithm whilst also stabilizing the domain-adversarial training. In the first stage, all parameters are fixed except for those of domain-adversarial heads and data selection head. This step corresponds to the estimation of corresponding distance functions between domains given the current representations. After repeatedly updating for k times (k is a hyper-parameter that controls the trade-off between computation and accuracy of the divergence estimations), a subset of source minibatch can be selected based on the approximated Wasserstein distance, which will be used for domain-adversarial training of joint adapter in next step. The following stage, while keeping the previously updated heads fixed, updates the rest of the model's parameters, using the standard gradient descent algorithm. All maximization problems of discrepancy losses are converted into minimization using reversed domain labels.

At test time, a new sample x_{test} will go through the trained joint adapter $\mathbf{A^j}$ to produce domain-invariant representation $\mathbf{A^j}(x_{test})$, which is then used by prediction head h_c to produce the corresponding event label.

4 Experiments

We evaluate our model on two related tasks: event identification and event detection. Given a trigger word in the context of an event mention, the former is formulated as a binary classification problem in which the goal is to determine if the trigger word expresses an event, while the latter is a multi-class classification task that requires model to assign the predicted label into one of the pre-defined 34 event types (include 1 negative type).

4.1 Datasets

TimeBank dataset (Pustejovsky et al., 2003) a fine-grained temporally annotated corpus of events and their positions and ordering in time. The text of the dataset were chosen from a wide range of sources from the news media domain. Events are annotated in a binary manner.

LitBank dataset (Sims et al., 2019) a recently introduced corpus of literary events. The dataset contains excerpts of 100 literary works from the Project Gutenberg corpus. Labels for events are binary.

Table 4: Ablation study. Performances on the ACE-05 test datasets for different domains.

Automatic Content Extraction 2005 (ACE-05) dataset (Walker et al., 2005) a densely annotated corpus collected from 6 different domains: Newswire (`nw`) - 20%, Broadcast news (`bn`) - 20%, Broadcast conversation (`bc`) - 15%, Weblog (`wl`) - 15%, Usenet Newsgroups (`un`) - 15%, Conversational Telephone Speech (`cts`) - 15%. Events of the dataset are categorized into 33 types.

4.2 Experimental Setup

4.2.1 Unsupervised Domain Adaptation Setting

To formulate the unsupervised domain adaptation setting from the origin dataset of each task, we split the target domain's documents into two parts at the ratio of 1 to 4, a training dataset without labels which models have access to when learning, and a test dataset that models are evaluated on. For event identification, transfer experiments are performed in two ways: `LitBank-to-TimeBank`, and the reserve direction, `TimeBank-to-LitBank`. In event detection experiments, we combine samples from two closely related domains, `nw` and `bn`, to create a sizeable labeled training source dataset. Then, each of the other domains is considered the target domain of a single adaptation setting.

4.2.2 Implementation and Hyper-parameters

Our model leverage the pre-trained BERT-base model as the fixed foundation for all adapters, each of which has a down-sampled dimension of 96. All of the downstream heads are implemented as feed-forward networks with activation functions between layers. We train all models using batch size of 150, which composes of 90 source samples (60 of which will be used for domain-adversarial training) and 60 target samples. Weights of the losses are chosen from a grid-search of range $[0.01, 0.05, 0.1, 0.2, 0.5, 1, 5]$ using `bc` domain as development dataset. Every experiment is run 5 times epochs with different random seeds and the performance is reported using the average result of the 5 runs.

4.2.3 Baseline

We compare the proposed model **DAA** with several other baselines. In particular, for the task of event identification, the performance of domain-adversarial models implemented in Naik and Rosé (2020) are considered. Regarding the event detection task, our baselines include adaption results of **BERT** and **BERT+Adapter** models fine-tuned using only source dataset, and finally **BERT+DANN** which making use of unlabeled target data through adversarial training.

4.3 Experimental Result

Event Identification The results of our event identification experiments are presented in tables 2 and 3. In both settings, our proposed model **DAA** outperforms naive implementation of domain-adversarial on BERT by about 10 points in F1. We also note that high precision is observed from models transferring from `LitBank-to-TimeBank`, while the other direction has high recall. This imbalance is caused by the extreme disparity between the two adaptation settings, which our model manages to address and thus significantly improves out-of-domain performance in both cases.

Event Detection Table 1 showcases the results of our event detection experiment. The main conclusions from the table include: (1) The **BERT** baseline performs decently without using any mechanism to address the discrepancy between domains. This is due to the generalization potential of large unsupervised pre-trained language model. However, naively adopting DANN for BERT has an adverse effect, notably reducing the performance of **BERT+DANN** on all target domains. This outcome is consistent with results from Lin et al. (2020), further emphasizing the need for a compatible implementation method for domain-adversarial training on BERT's representations. (2) The results of **BERT+Adapter** proves that adapter-based tuning procedure is not only able to retain performance but also prevent over-fitting through capacity reduction, therefore performing better than the

Table 5: Domain-adversarial analysis. Performance on the ACE-05 test datasets for different domains.

fully fine-tuned **BERT** in case where it follows too closely to source domain. (3) Finally, our proposed model **DAA** manages to achieves the best adaptation performance across all target domains. In settings where domains are closely related such as `bc` and `cts`, **DAA** is more robust and thus performs better on target domain. On the other hand, **DAA** significantly outperforms baselines (3 to 5 points increase in F1 score) when transferring to target domains that are highly dissimilar to source domains (`wl` and `un`).

4.4 Ablation Study

To examine the effect of each of the proposed component individually, We perform an extensive ablation analysis for our **DAA** model by measuring domain adaptation ability of each trained model, with a single main component discarded (by setting the weight of its associated loss to 0), on ACE-05. In table 4, **DAA-D**, **DAA-W**, **DAA-M**, and **DAA-S** correspond to performances of partial models with domain-adversarial training, data selection component, self-supervised task, and orthogonality constraint removed, respectively. Results from the study show that every incomplete model performs consistently worse compare to the full model. In particular, while in-domain performances are retained across settings, different domains experience varying degree of reduction in target performance depending on its relation with the source domain. Especially, data drawn from the domains of `wl` and `un` are substantially diverged from the source domain. Therefore, components that address domains' dissimilarity play important roles in improving adaptation capability, which is confirmed by the fact that models such as **DAA-W** and **DAA-D** have the lowest results.

4.5 Domain-adversarial Analysis

The central component of our architecture is undoubtedly LDA whose responsibility is to ensure joint adapter extracts domain-invariant features for classifying event triggers. From the negative results of **BERT+DANN**, finding an appropriate way to implement domain-adversarial training for BERT is an important question. This section aims to demonstrate the effectiveness of our layer-wise implementation of DANN.

We apply domain alignment to different portions of BERT. Specifically, we partitioned 12 layers of the BERT-base encoder into 3 levels - **Lower**, **Middle**, **Upper** - each corresponds to the only 4 layers whose representations are used by domain-adversarial training. In addition, we present results of **Last** and **Up-Dim**. The former is original implementation where last layer's output is aligned , while the latter is similar to our model **Full** except the representation with full dimension (768) is used instead of the down-sampled ones. Finally, **No-Rel** is the same as **Full** but no relaxation is used.

Table 5 showcases the results of our experiment. Overall, we observe performance degrades on all three partial adaptation settings However, the changes vary across domains in each situation, probably stemming from the fact that adversarial training addresses different degrees of domain shifts in each layer. Moreover, taking only the last layer's representation as input for DANN component performs worse compare to all other multi-layer counterparts. Notably, using representations with full dimension significantly reduces out-of-domain performances of model. This result confirms the benefit of the bottleneck architecture. Not only the alignment of down-sampled representations is more effective, but the free parameters of up-sampling layers also increase model's capacity for the main downstream task.

4.6 Domain Discrepancy Analysis

To verify the effect of our method on alleviating the negative impact of the domain shift problem on the learning process, we compare each model's performance on different settings with varying shift magnitudes. Specifically, for each target domain, based on the learned Wasserstein distance between the two domains, we quantify the distance of each target domain sample (in evaluation dataset) to the source dataset and group them into 2 disjoint sets: **FAR** - 25% of target samples that are farthest from the source dataset, and **CLOSE** - 25% of those closest to source dataset. The domain adaptation performances on these sets for 2 target domain `bc` and `wl`, together with the set of in-domain examples **IN-DOM** from `bnnw` domain, are provided in Table 6. When adapting to `bc` domain which has a low discrepancy to source domain, the results for each setting show little variance, but we still observe the over-fitting of **BERT** as performance of out-of-domain settings is lower compared to its in-domain score. Moreover, **BERT+DANN** is able to improve on **FAR** set, however at the cost of degradation in the other two settings. In contrast, the negative effect of high discrepancy between domains is apparent in the case of `wl` domain, as the gaps between each setting are all above 10 points. Notably, the results of **BERT+DANN** are lower than that of **BERT**, indicating that naive implementation of **DANN** is not only unable to align between source and target domains, but also causes negative transfer when trying to learn domain-invariant representation. On the other hand, in both case, **DAA** is able to address the weakness of the baseline and improves the performance on **FAR** and **CLOSE** simultaneously.

	`bc`		`wl`		`bnnw`
	FAR	CLOSE	FAR	CLOSE	IN-DOM
BERT	72.4	75.6	43.1	59.2	77.5
BERT+DANN	73.2	76.6	35.3	52.4	76.6
DAA	74.8	76.4	50.9	64.4	77.7

Table 6: Domain adaptation performances in F1 score with different domain shift settings.

5 Conclusion

We present a novel framework for ED in UDA setting that effectively leverages the generalization capability of large pre-trained language models through a shared-private adapter-based architecture. A layer-wise domain-adversarial training process combined with a Wasserstein-based data selection addresses the discrepancy between domains and produces domain-invariant representations. The proposed model achieves state-of-the-art results on several adaptation settings across multiple datasets. In the future, we plan to extend our approach in the several directions: (1) We will devise a method to incorporate target domain's private adapter to further improve model's out-of-domain performance.; (2) We will adapt our framework to more general settings such as multi-source domain adaptation and domain generalization.; and (3) We will extend our work to novel domains for ED (Trong et al., 2020).

Predicting in-hospital mortality by combining clinical notes with time-series data

Iman Deznabi, Mohit Iyyer, Madalina Fiterau
College of Information and Computer Sciences
University of Massachusetts Amherst
`{iman, miyyer, mfiterau}@cs.umass.edu`

Abstract

In intensive care units (ICUs), patient health is monitored through (1) continuous vital signals from various medical devices, and (2) clinical notes consisting of opinions and summaries from doctors which are recorded in electronic health records (EHR). It is difficult to jointly model these two sources of information because clinical notes, unlike vital signals, are collected at irregular intervals and their contents are relatively unstructured. In this paper, we present a model that combines both sources of information about ICU patients to make accurate in-hospital mortality predictions. We apply a fine-tuned BERT model to each of the patient's clinical notes. The resulting embeddings are then combined to obtain the overall embedding for the entire text part of the data. This is then combined with the output of an LSTM model that encodes patients' vital signals. Our model improves upon the state of the art for mortality prediction, attaining an AUC score of 0.9, compared to the previous 0.87, setting a new standard for mortality prediction on the MIMIC III benchmark.[1]

1 Introduction

One of the major costs in healthcare is critical care in intensive care units. A crucial aspect of critical care is mortality prevention. With advancements in healthcare, a patient's condition during an ICU visit is monitored through devices that measure many different vital signals, such as heart rate, systolic blood pressure, temperature, etc. Additionally, we have access to clinical notes written by medical professionals during the patient's stay. This data can be used to predict the condition of patients during their ICU stay, which can help in managing the expensive resources in hospitals and providing these services to patients who need them most in a more cost-effective way.

Most prior work has been focused on predicting patient health using the time-series data gathered from medical devices (Lipton et al., 2016; Che et al., 2018; Narayan Shukla and Marlin, 2020; Xu et al., 2018). More recent work also attempted to leverage clinical notes for making these predictions (Zhang et al., 2019; Ghorbani et al., 2020; Lee et al., 2020; Alsentzer et al., 2019). However, research on combining time series data with clinical notes for outcome prediction has been limited due to the irregularity of the clinical notes compared to the time series data, and the complexity of jointly modeling the two sources of information.

In this work, we propose a multimodal neural network that combines time-series data from medical devices with textual information from clinical notes to improve the prediction of in-hospital mortality. This task is defined as predicting whether a patient will die before getting discharged from hospital based on the first two days of data. Our model improves on the prior state of the art by using fine-tuned BERT-based models (Devlin et al., 2019) to encode clinical notes and integrates the resulting representations with time-series embeddings derived from a long short-term memory (LSTM) network (Hochreiter and Schmidhuber, 1997). We also show that fine-tuning clinical BERT models in isolation from other parts of the model and specifically for in-hospital prediction tasks brings additional performance improvements. Furthermore, separately modeling each clinical note and combining the resulting embeddings leads to our final model which supersedes the state-of-the-art in predicting "in-hospital mortality" in terms of AUC score.

---

2 Related work

Most of the previous work in mortality prediction in critical care is focused on utilizing patient vital signals as time-series data for making predictions. Harutyunyan et al. (2019) provided a benchmark and defined 4 tasks based on MIMIC III dataset (Johnson et al., 2016) for comparing these models. This paper used a recurrent neural network to obtain the predictions. Other models also use recurrent neural networks in different forms to predict outcomes in healthcare data (Liu and Chen, 2019; Suresh et al., 2018; Lipton et al., 2016). Furthermore, others (Che et al., 2018; Shukla and Marlin, 2019; Narayan Shukla and Marlin, 2020; Horn et al., 2020) used the irregular nature of the data over time in their models.

For clinical notes, some models used pretrained embedding models (Zhang et al., 2019; Chen et al., 2019), while some use various other machine learning techniques for outcome prediction on data collected from the ICU (Jin et al., 2018; Boag et al., 2018; Ghorbani et al., 2020).

More recently, BERT-based models have been adopted for this domain following their incredible success in Natural Language Processing (NLP). A number of studies trained and used BERT-based models for clinical applications (Lee et al., 2020; Huang et al., 2019; Darabi et al., 2020; Li et al., 2020; Alsentzer et al., 2019).

All these models only use one source of available data when predicting medical outcomes. However, Khadanga et al. (2019) showed the usefulness of combining time-series and clinical notes for ICU outcome prediction. They used a convolution neural network (CNN) on top of pretrained word embedding from (Zhang et al., 2019) for getting a representation of clinical notes and a long short-term memory network (LSTM) for embedding the time series part of the data. The two representations were then concatenated to make the predictions. Concurrently to our work, Yang et al. (2021) also showed the usefulness of combining time-series data with information from clinical notes. They used an LSTM model for the time-series part of the data and use a convolutional neural network with label-aware attention layer for the clinical notes. We will use the same intuition for combining the representation of clinical notes and the time-series part of the patients' data to improve the performance of in-hospital mortality prediction. In the next section we define the notations and our method architecture.

3 Method

In this section, we first introduce the notation for our task and then describe our proposed model. Each patient has several clinical notes collected during their stay. For a patient p with N clinical notes, we denote $C^{(p)} = \{c_{t_1}^{(p)}, c_{t_2}^{(p)}, ..., c_{t_N}^{(p)}\}$ for clinical notes collected at times $\{t_1, t_2, ..., t_N\}$. We also have time-series data collected during the patient's stay as $X_{1:T}^{(p)} = \{x_1^{(p)}, x_2^{(p)}, x_3^{(p)}, ..., x_T^{(p)}\}$ where $x_i^{(p)}$ is the data collected at index i. For simplicity, the patient index p will be dropped for the rest of the section.

Our model brings three major contributions compared to prior work in this area. First, we use a fine-tuned BERT-based model for modeling clinical notes as these new attention-based models trained on language models such as BERT have been shown to significantly outperform previous approaches in many NLP applications (Devlin et al., 2019) including clinical note prediction (Lee et al., 2020; Alsentzer et al., 2019; Huang et al., 2019). Second, we feed each clinical note of a patient separately to the text part of our model, and then combine the resulting embeddings to get the final representation of text part of the data. We argue that since the clinical notes are collected separately, and usually from different sources, this approach is preferable to concatenating the text of the clinical notes for each patient and then feeding this to the model. Finally, we also fine-tune the BERT-based models in isolation on "in-hospital mortality" task, which brings additional performance improvements.

The model architecture is shown in Figure 1. It consists of two parts. The first part obtains the embedding of clinical notes and combines them to form a final representation of all the clinical notes, for which we use the notation H_C. The other part of the model is responsible for encoding the time-series part of the data, which will be referred to as H_X. These representations will then be concatenated to form the final representation of the patient $H = H_C \oplus H_X$ where $\oplus$ is the concatenation operation. Finally, a softmax layer is applied on top of H to get the final predictions.

3.1 Clinical Notes Representations

Modeling clinical notes require capturing interactions between distant words (Huang et al., 2019)

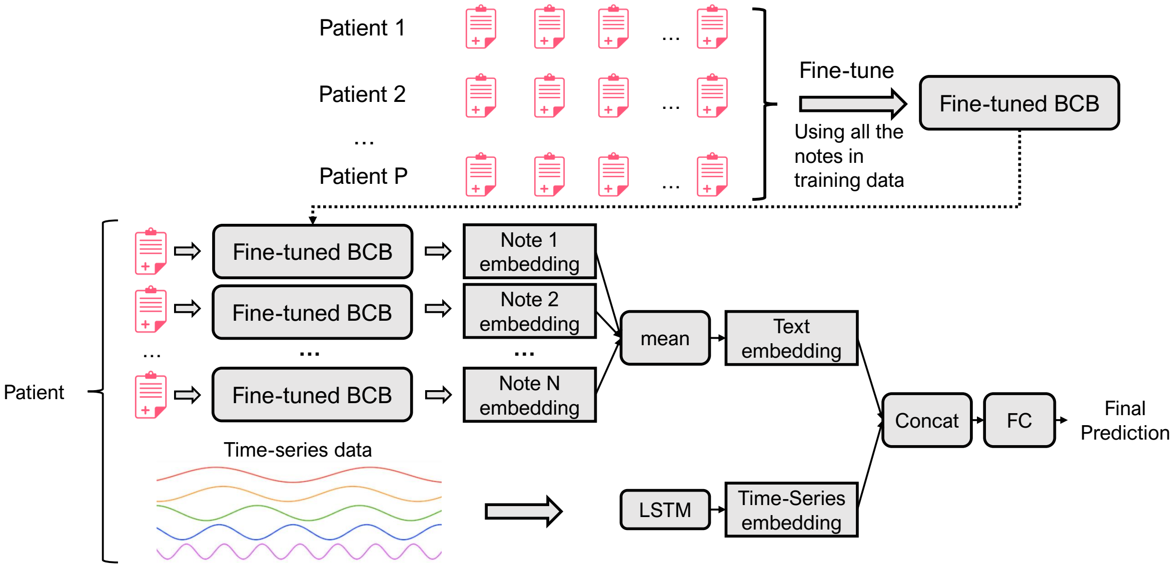

Figure 1: The model architecture. First, the Bio+Clinical BERT (BCB) (Alsentzer et al., 2019) model is fine-tuned for the in-hospital mortality prediction task using all the available notes in the training data. Then the average embedding of patient notes are combined with the time-series embedding to obtain the final patient representation. Then a fully connected layer is used to predict patient's in-hospital mortality.

and BERT-based models are designed to capture these interactions. Furthermore, Huang et al. (2019); Lee et al. (2020); Alsentzer et al. (2019) showed that these models outperform the traditional NLP models in this area. Considering this success we use a BERT-based model fine-tuned to clinical notes for getting the embedding of each clinical note of the patient. Specifically, we used the Bio+Clinical BERT model described in Alsentzer et al. (2019) which fine-tuned Bio BERT(Lee et al., 2020) on all the clinical notes in MIMIC III dataset.

After initializing our text model to Bio+Clinical BERT, we added a softmax layer on top of the classification token (CLS) output of each clinical note separately and the model is fine-tuned further on the task of predicting the in-hospital mortality of the patient. Finally, to obtain the overall text embedding of a patient, we take the average embedding of all the clinical notes available for the patient. This is shown in equation 1.

$$H_C = \frac{1}{N}\sum_{i=1}^{N} \mathrm{BCB}(c_{t_i}) \tag{1}$$

where the $\mathrm{BCB}(c_{t_i})$ function is the output of the CLS token of the fine-tuned Bio+Clinical BERT model when c_{t_i} is provided as an input to the model and H_C is the aggregated representation of all the clinical notes of the patient.

3.2 Time series

For the time-series part of the model, following the works by Harutyunyan et al. (2019) and Khadanga et al. (2019), we first limit the time-series data to first 48 hours of the patient stay, then we resample the time-series data to intervals of 1 hour. If there are any duplicate values in that hour for a variable, we use the most recent values. We use forward imputation for missing values. If no previous value is recorded we use the pre-set values for the features given in Harutyunyan et al. (2019). After pre-processing the time series data, we used an LSTM network. We input the whole time-series data of a patient ($X_{1:T}$) to the LSTM model and use the final hidden state as the representation of time-series part of the patient data.

$$H_X = \mathrm{LSTM}(X_{1:T}) \tag{2}$$

4 Results

In this section, we will show the results achieved on the in-hospital mortality prediction task on MIMIC III dataset. To ensure consistency with previous work and the benchmarks presented on Harutyunyan et al. (2019), we used the same preprocessing steps as defined by Harutyunyan et al. (2019) and split the patients into train, validation and test sets using the same splits. We also followed the preprocessing steps of Khadanga et al. (2019) to process the clinical notes and removed, from the dataset,

Type	Model	AUC
Only time-series	LSTM*	0.835
Only text	CNN*	0.831
	BERT	0.671
	BCB	0.760
	BCB FT	0.835
	BCB FT MN	**0.875**
Text + Time-series	CNN + LSTM*	0.867
	BERT + LSTM	0.840
	BCB + LSTM	0.851
	BCB FT + LSTM	0.873
	BCB FT MN + LSTM	**0.899**

Table 1: Area under the receiver operating characteristic (AUC) results on the held out data for all models including baselines. The results are averages of 5 different initializations of the models. The models indicated with a star (*) are using the same architecture as described in Khadanga et al. (2019). BCB is short for Bio+Clinical BERT (Alsentzer et al., 2019), FT means fine tuned separately for in-hospital mortality task. The baseline models only use the first available clinical note while models indicated with MN (multi-note) use all the available clinical notes in first 48 hours of a patient's ICU stay.

patients who do not have any associated medical notes. We also only used the clinical notes collected at first 48 hours of patients' stay. After these steps, our dataset consisted of 11579 records in the training set, 2570 in the validation set, and 2573 in the test set.

The time-series part of the model uses all 17 medical variables (e.g., heart rate, height, and Glucose) recorded during the first 48 hours of the patients' stay. Since in-hospital mortality prediction is a binary classification task with unbalanced classes (only around 10% of the patients suffered mortality in this dataset), the area under the receiver operating characteristic (AUC) is used for evaluating our models. The best performing model uses one layer of LSTM cells with 256 units, an Adam optimizer (Kingma and Ba, 2015) with initial learning rate of 2×10^{-5} for training and a weight decay of 0.01. The models are implemented with the Pytorch library (Paszke et al., 2019) and we run all the experiments 5 times with different initialization and report the mean of the results.

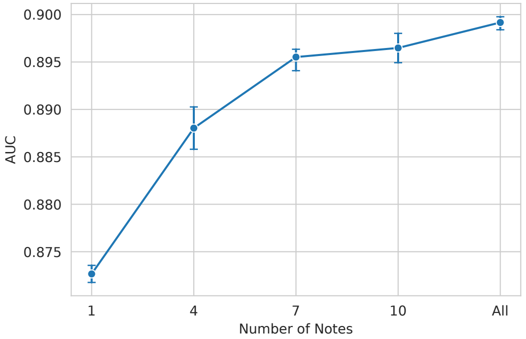

Figure 2: Increase in full model performance as more clinical notes are included in order of time for each patient. The Y axis shows the AUC score of the model on the test data and the X axis shows the number of included clinical notes. Each bar indicates 95% confidence interval over 5 different runs of the model.

Table 1 summarizes the results achieved by our models and the baseline models that use only time-series data, use a simple BERT instead of the Bio+Clinical BERT model, and the results with and without fine tuning Bio+Clinical BERT model further for the in-hospital mortality prediction task. The models which use both time-series and text data are also shown. Moreover, the results are compared with Khadanga et al. (2019) which, to the best of our knowledge, is the state-of-the-art for in-hospital prediction task in MIMIC III benchmarks. Our final model, which uses fine-tuned clinical BERT model for the text part of the data and an LSTM model for time-series part (shown in Figure 1) significantly outperforms the baseline models as well as the state-of-the-art models.

To assess the value of using multiple notes for each patient, we experimented by including various numbers of clinical notes for each patient in our final model. The AUC results are shown in Figure 2. It is apparent that the model's performance improves with more notes, and the best performance is achieved when all the notes are used.

Although we lose some information contained in the clinical notes by truncating them to fit into the maximum acceptable length of the model, using the entire text of the clinical notes by segmenting them into chunks and taking the average did not yield significant improvements in the performance of our final model. In our experiments, providing all chunks either by segmenting the concatenated text of the clinical notes or individual notes separately only improved the final AUC score from 0.899 to a maximum of 0.902 while taking approximately twice as long to train.

5 Conclusions and Future Work

Improved prediction of the admission outcome in Intensive Care Units (ICUs) can be tremendously valuable in supporting decisions in clinical diagnosis. Previous work mostly focused on using the patients' vital sign information recorded during their stay as time-series data for these predictions. However, the clinical notes written by healthcare workers include important information on both the history and current conditions of the patients in the hospital, which can be leveraged to improve these predictions significantly. In this work, we proposed a novel method for leveraging the information available both in clinical notes and time-series data. Our method consists of fine-tuning Bio+Clinical BERT model for in-hospital mortality prediction task and then combining it with the available time-series data. Finally, we showed that using all the clinical notes available significantly enhances the ability to make these kinds of predictions.

In the future, we plan to improve the performance of the model by improving the time-series part of the model from an LSTM network to a model that can leverage irregular time-series data. Furthermore, the same model architecture can be used for other tasks discussed in the literature for such medical datasets such as physiologic decompensation or forecasting length of stay.

Sequence Models for Computational Etymology of Borrowings

Abstract

We computationally model the processes of word borrowing from a donor word to an incorporated word, and vice versa, by answering two questions: (1) what does a word look like incorporated into another language, and in the opposite direction (2) where did a word come from? We employ neural sequence models, focusing on six specific borrowing relations: calques, partial calques, semantic loans, phono-semantic matches, transliterations, and generic borrowings. We experiment with several model variants, including LSTM encoder-decoders, copy attention, and Transformers. In both directions, we find that an LSTM model can beat strong baselines, with the quantity of data strongly influencing model performance.

1 Introduction

Words are borrowed into a language through various processes. For example, the English *internet* was incorporated into Welsh as *rhyngrwyd* (rhyng- 'between' + rhwyd 'net') through a calqueing process where each component is translated literally. In contrast, the English *chimpanzee* became the Welsh *tsimpansî* through a process of sound correspondences.

Borrowing is prevalent across the world's languages, and modeling how and from where words enter a language are interesting but understudied tasks under the umbrella of computational etymology (Wu and Yarowsky, 2020a). This is a relatively new field with many downstream applications. Perhaps the most salient is lexicon expansion: more comprehensive dictionaries will enable better communication between cultures as well as better training material for machine translation systems. Computational etymology is also important for historical linguistics, whose focus is on discovering the relationships between languages and their words. An accurate model of word borrowing can also be a boon for language preservation and revitalization, where models can help coin neologisms for modern terms.

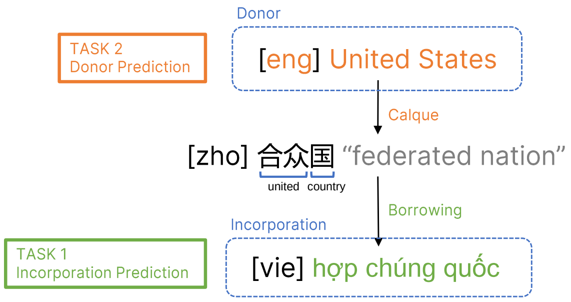

Figure 1: Two borrowing prediction tasks. The predicted output for each task is in green and orange, respectively.

Owing to recent successes of machine translation models for similar tasks (Tsvetkov and Dyer, 2015; Gorman et al., 2020; Wu and Yarowsky, 2020a,b), this paper investigates the application of neural sequence-to-sequence models for the task of etymology prediction. Specifically, we focus on word borrowings, where a word enters a language via a non-related donor language.[1] Whereas inherited words and cognates tend to follow regular sound shifts and can be modeled well with transliteration models (Beinborn et al., 2013; Wu and Yarowsky, 2018b), words borrowed from unrelated languages undergo various processes (Section 3) that may not preserve the structure or phonetics of the original word.

We propose to model borrowings in two tasks (Figure 1), motivated in Section 4. In Task 1, given a donor word and etymological relation, can we predict the form of the incorporated word in the borrowing language? In the opposite direction, in

---

[1] This is in contrast to other etymological relations, such as inheritance, where words enter through a related language, e.g. from Latin to French.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4032–4037
August 1–6, 2021.

Task 2, given the incorporated word, can we predict the donor word and language? Our experiments across several experimental scenarios on these two tasks using data from Wiktionary indicate that modeling borrowings is a challenging task with much room for future research.

2 Related Work

Though the tasks defined in this paper are new, there are several related threads of work. In the task of *cognate transliteration*, a system is trained to generate cognates in a different language (Beinborn et al., 2013; Wu and Yarowsky, 2018b). This paper uses a multilingual cognate transliteration approach applied specifically to borrowings. Similar approaches have also been applied to the task of proto-language reconstruction (Meloni et al., 2021). Related to cognate transliteration is the task of *grapheme-to-phoneme conversion*, which has a long history of research. Cognate transliteration can be viewed as G2P across languages, where the words are cognates, for example in the case of names (Waxmonsky and Reddy, 2012; Wu et al., 2018; Wu and Yarowsky, 2018a). Recently, researchers have studied massively multilingual versions of these tasks, where single (neural) models are trained on the combination of hundreds of languages (e.g. Deri and Knight, 2016; Gorman et al., 2020; Lewis et al., 2020).

3 Data

We extract etymology information from the English edition of Wiktionary using Yawipa (Wu and Yarowsky, 2020a), a recent Wiktionary parser. We focus on six specific types of borrowings (whose Wiktionary label is in monospaced font below) across a spectrum of semantic and phonetic fidelity:

- `calque`: Also called a loan translation. Components of the original word are literally translated into the target language, e.g. the English *brainwash*, from the Chinese 洗脑 *xi* ‘wash’ + *nao* ‘brain’.
- `partial calque`: A calque where not every component is translated, e.g. the English *apple strudel*, from the German *Apfelstrudel*.
- `semantic loan`: A sense extension is borrowed onto an existing word, e.g. the French *souris* ‘mouse’, which borrowed the computing sense from the English *mouse*.

Lang	Count	%
eng	23,142	0.15
lat	18,713	0.12
fra	17,556	0.11
spa	7,123	0.05
ara	6,508	0.04
san	6,393	0.04
grc	6,122	0.04
deu	5,390	0.04
rus	5,109	0.03
ita	4,660	0.03

Table 1: Distribution of top 10 languages extracted from Wiktionary.

- `psm`: Phono-semantic matching. Components of the original word are replaced with phonetically and semantically similar words, e.g. 声纳 *sheng* ‘sound’ + *na* ‘receive’, from the English *sonar*.
- `transliteration`: A deterministic process of writing script conversion that seeks to preserves a word’s orthography.
- `bor`: A generic borrowing category. The overwhelming majority of borrowings in Wiktionary are labeled as such. In this paper, we distinguish between `bor`, this relation as annotated in Wiktionary, and “borrowing”, the word formation process encompassing these six relations.

The data we extracted consists of over 150K ground-truth annotated borrowing relationships, spanning a total of 837 languages. The top 10 languages are shown in Table 1. Note that only 101 languages have more than 100 entries, and 260 languages have more than 10 entries. In this work, we are also specifically interested in the long tail of low-resource languages. The distribution of borrowing relations is shown in Figure 2. Note the log scale, and the fact that that the majority class (`bor`) comprises 96% of the entire dataset, which motivates several of our experimental variants.

4 Tasks

We first establish our terminology for borrowings: we say etymology is directed relation between a donor word and an incorporated word.[2] We experi-

---

[2] We eschew the established terms “loanword” and “borrowing” because loaning and borrowing imply an obligation to return the item being borrowed. In contrast, “borrowed” words are fully incorporated into the language.

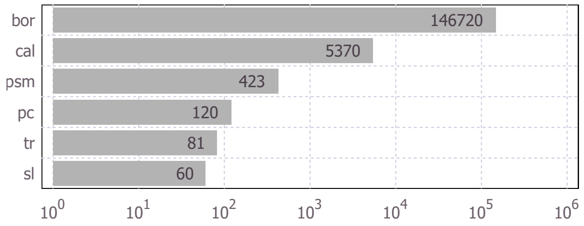

Figure 2: Distribution of borrowing relations.

ment on two tasks in etymology prediction:

4.1 Task 1: Incorporation Prediction

Given a donor word and a target language, how would the word be incorporated into that language? And by what means? This task is motivated by a real-world example: when deep learning was gaining popularity, researchers were considering how to best render the term into Japanese. Should it be a loanword and written in katakana (ディープラーニング *dīpurāningu*), or translated using a calque (深層学習 *shinsō gakushū* 'deep' + 'learning')? Besides terminology standardization, this task has applications in language revitalization and unknown word translation.

4.2 Task 2: Donor Prediction

In the opposite direction, given a word, from where and how did it come into the language? If we view Wiktionary as a directed graph, where the nodes are words and the edges are etymological relationships, there are missing edges. The task is to reconstruct these missing edges. As Wiktionary is a human-annotated resource, there is much variance in the quality and completeness of annotations, and good performance on this task can help fill in etymology even in high-resource languages like English.

5 Experiments

To tackle these two tasks, we employ character neural sequence-to-sequence models. For Task 1, predicting the incorporated word, the input is a sequence containing: the donor language, each character of the donor word, the etymological relation, and the target language. The output is the characters of the incorporated word.

In: `eng c a b b a g e bor abe`
Out: `k a b i j`

For Task 2, the input is a sequence containing the word's language and each character of the word, while the output is the donor language, donor word characters, and relation.

In: `abe k a b i j`
Out: `eng c a b b a g e bor`

For Task 1, we experiment with separate LSTM models trained for each borrowing relation (LSTM-sep), a single multi-task LSTM model trained on the combined data (LSTM), the same model trained with both the source and target data preprocessed by the unigram SentencePiece method (Kudo and Richardson, 2018) with a vocabulary size of 4000 (LSTM-spm), the same model with copy attention (See et al., 2017) (LSTM-copy), a Transformer (Vaswani et al., 2017) model (TF), and an ensembling method (Ensemble). This method is a score-based voting procedure that combines the output of the LSTM-sep, LSTM, and TF models. Each model gives 5 votes for their top prediction, 4 votes for their second place prediction, and so on (1 vote for fifth place). For each test instance, the votes are tallied up, and the prediction with the highest number of votes is the prediction of the ensemble. Ties are broken by picking the prediction with the highest model decoder score among all the models.

For Task 2, we experiment with a baseline LSTM model and the same model with copy attention.

All models were trained using the OpenNMT-py framework (Klein et al., 2020). The LSTM models are two-layer encoder-decoders with 500-dimension hidden state, trained with the ADAM optimizer. The Transformer model has a 6-layer encoder and decoder with 8 heads, trained with ADAM with learning rate scheduling. For reproducibility, we provide the training scripts which include the full model details. Accounting for the extreme imbalance in our dataset, we performed a stratified split of the dataset into a 80-10-10 train-dev-test split, where each split contains the same proportion of languages and borrowing relations.

6 Results and Analysis

6.1 Task 1

We evaluate each model on a held-out 15,288 example test set. Table 2 presents character BLEU (computed with SacreBLEU Post (2018)) as well as accuracy and character edit distance from the gold (CED). We also report 5-best results for accuracy (was the correct answer in the top 5 results?) and CED (within the top 5 results, what is the minimum edit distance to the correct answer?)

At a cursory glance, the single models trained on all the data performs slightly better compared to the separate relation-specific models, following a

Model	BLEU	Acc	CED	5Acc	5CED
LSTM-sep	53.77	20.00	2.42	33.51	1.82
LSTM	55.83	21.43	2.31	34.98	1.71
LSTM-copy	55.90	19.92	2.32	34.46	1.69
LSTM-spm	45.62	10.68	2.85	20.31	2.13
Transformer	61.30	22.19	2.06	41.54	1.43
Ensemble	60.32	25.67	2.05	49.24	1.18

Table 2: Results for Task 1. Acc is accuracy (higher is better), CED is average character edit distance (lower is better). 5 indicates 5-best results.

trend of multi-task training performing better than models trained on a single task. The Transformer model performs the best, likely due to its innovative attention mechanism that has proven successful in other tasks. However, by examining the results for each borrowing relation, we see that the successes of the models are largely on the `bor` relations. All the models perform poorly in correctly predicting any non-`bor` relations, though we find that the calque-specific model performs slightly better than the jointly trained LSTM on calques. For example, the separate calque model correctly predicted the German *vollschlank* borrowed into Dutch as *volslank*, which the LSTM model could not do. And even when it generates incorrect answers, often the predictions look like "good attempts" at calqueing. For example, the French *Pays d'en Haut* gets translated as *Land of the Roud* (correct is *upcountry*), whereas the jointly trained models often do character substitutions instead.

Copy attention (LSTM-copy), which allows the model the option to copy characters from the source, was intended to help the model with similarly spelled borrowings, but overall it did not perform as well as a simple LSTM model. The subword model (LSTM-spm) also unexpectedly did not perform well. The goal of using subwords was to encourage the model to translate larger character sequences, the idea being that translational relations such as calques would consist of two subwords rather than several individual characters. Indeed, the LSTM-spm model treats most words as calques, often translating when it should instead perform character substitutions or sound shifts. Ensembling of three models' outputs is a simple but effective method resulting in a large increase in prediction performance. The score-based voting effectively combines the strengths of individual models, especially when all models have the same word in their n-best predictions.

Error Analysis Due to the small quantities of available training data for partial calques, semantic loans, phonosemantic matches, and transliterations, the models cannot accurately learn to predict words incorporated by the aforementioned processes. This data shortage is exacerbated for the separately trained systems. Models largely treat these translational borrowings as generic `bor`s and perform character substitutions and sound shifts. This approach, exemplified by cognate transliteration systems, works for the majority of test examples, because `bor`s are essentially cognates with small edit distance. All phonosemantic matches are Chinese, so models will output Chinese characters, but due to the sparsity of the characters, the model cannot produce the correct answer. For the remainder of this analysis, we will focus on `bor` and `cal` as the main two borrowing relations. We find all the models show similar patterns of prediction, so the following examples are from the multi-task LSTM model.

In many cases, the incorporated word is similar to the donor, so the model can correctly predict the borrowing. For example, for the Latin *vanitas* borrowed into French, the model predicts *vanita*; the correct *vanité* is its second choice. The model can also handle different writing scripts. For example, it correctly predicts the Greek πυριτις borrowed into Latin as *pyritis*. Unfortunately, sound shifts do not work for the other borrowing relations, like calques, that require translation of morphemes. In many cases, the model does not seem to distinguish between non-`bor` relations and merely performs sound shifting. For example, our model predicts that the English *shopping center* calqued into Afrikaans is *schoppingsentre* (correct is *winkelsentrum*).

When encountering calques, the model sometimes recognizes that it should translate rather than transliterate. However, the lack of sufficient training data prevents the model from learning to accurately translate component morphemes. For example, our model predicts the English *download* calqued into German is *Dunnleut* (correct is *herunterladen*). Here, we see that the model picks up on the fact that German words tend to start with a capital letter, though in this case the word in question is a verb which does not need capitalization. We also find that the model cannot get the word order correct when languages have different adjective-noun ordering. For example, our model incorrectly predicts that the French *mariage blanc* borrowed into English is *marriage mank* (correct is *white marriage*).

Broken down by language, our data contains numerous low-resource languages, many of which have just 1-10 words. Training a single model on such data for a single language would yield low performance, but our massively multilingual borrowing models can successfully handle many of these low-resource languages.

6.2 Task 2

For Task 2, we follow Wu and Yarowsky (2020a), who used an LSTM model to predict both the language and formation mechanism of a word. While they attempted to predict broader categories of inheritance vs borrowing, we focus on six specific borrowing relations. Because many borrowings have small edit distance, we also employed an LSTM model with copy attention. This model's performance was slightly worse than the baseline LSTM, a trend we also observed in Task 1. This indicates that borrowings are fundamentally different from inherited and cognate words, where copy attention models have seen good performance. Results grouped by word, language, and relation are presented in Table 3.

The models for Task 2 are inherently multi-task: they must predict the donor language, donor word, as well as the relation. As such, prediction of donor language and relation can be evaluated as classification tasks. We found that our models were able to generate valid languages and relations in 98% cases, showing that sequence-to-sequence models can also be successful in classification tasks.

We briefly analyze the errors of the LSTM model. Perhaps unsurprisingly, the model gets over 96% accuracy on predicting the relation by always guessing `bor`, the majority class. Yet it is able to beat a strong majority baseline (always predicting `bor`, the majority class). Our model is also able to successfully predict the language of the borrowing in almost half of the test instances (guessing the majority donor language, English, would only achieve 14.8% accuracy). Thus a word's language and spelling provide sufficient information for identifying how and from where it entered the language. In terms of errors, we find some instances where the model predicts a donor language that is actually related to the correct language. For example, the Dutch *tabak* is borrowed from Spanish *tabaco*, rather than our model's French *tabac*, and many Dutch words originally from English were predicted to come from German, and vice versa. We also see several words like English *specify* were predicted to come from French, but are actually from Old French. Future work can address a custom loss function that gives "partial credit" to such predictions rather than marking them as completely incorrect.

Model	Rel	Lang	Word	CED
Majority	96.0	14.8	–	–
LSTM	96.1	47.9	23.2	2.9
LSTM-Copy	96.1	47.7	20.8	3.0

Table 3: Results for Task 2: 1-best accuracy grouped by Relation, Language, and Word. CED is average character edit distance for Word prediction.

In terms of word prediction, the seemingly low accuracy of the model is not discouraging. Supported by the low character edit distance, we see many examples where the model's prediction is close enough to be recognized by a human. For example, the Chinese 阿卡拉 is borrowed from English *a cappella*, but our model predicts *acapara*, and the Jersey French *thiâtre* was predicted to be borrowed from Latin *thiatrum* (correct is *theātrum*). When providing new entries to an impoverished etymology dictionary, our prediction model can suggest possible etymology and even plausible unknown word forms, which can then be verified by a human lexicographer.

7 Conclusion

We model word borrowings from a donor to an incorporated word, and vice versa, using neural sequence models in a variety of experimental scenarios. We find that a single model trained to predict multiple types of borrowings performs better than separate models trained for each borrowing. A Transformer model performs better than an LSTM model, and a simple ensembling method results in superior performance, though the amount of training data is a limiting factor in the performance of these models. Predicting the donor language and word is a slightly easier task, where our LSTM model is able to beat a strong majority baseline. Source code for reproducing our experiments is available at `https://github.com/wswu/borrowings`.

Abstract

Recently, knowledge graph (KG) augmented models have achieved noteworthy success on various commonsense reasoning tasks. However, KG edge (fact) sparsity and noisy edge extraction/generation often hinder models from obtaining useful knowledge to reason over. To address these issues, we propose a new KG-augmented model: Hybrid Graph Network (HGN). Unlike prior methods, HGN learns to jointly contextualize extracted and generated knowledge by reasoning over both within a unified graph structure. Given the task input context and an extracted KG subgraph, HGN is trained to generate embeddings for the subgraph's missing edges to form a "hybrid" graph, then reason over the hybrid graph while filtering out context-irrelevant edges. We demonstrate HGN's effectiveness through considerable performance gains across four commonsense reasoning benchmarks, plus a user study on edge validness and helpfulness.[1]

1 Introduction

Commonsense reasoning (CSR) is essential for natural language understanding (NLU) systems to function effectively in the real world (Apperly, 2010). For example, to answer the question in Figure 1, one must already know that *printing requires using paper*. Yet, since commonsense knowledge is self-evident to humans, it is rarely stated in natural language (Gunning, 2018). This makes it hard for neural pre-trained language models (PLMs) (Devlin et al., 2019) to learn commonsense knowledge from corpora alone (Marcus, 2018).

Unlike raw text corpora, knowledge graphs (KGs) can provide structured commonsense facts (edges) of the form `(concept1, relation, concept2)` (Speer et al., 2017). Hence, many recent CSR models augment the PLM with a KG, allowing such *KG-augmented models* to make predictions via multi-hop reasoning over the KG (Lin et al., 2019; Bosselut and Choi, 2019).

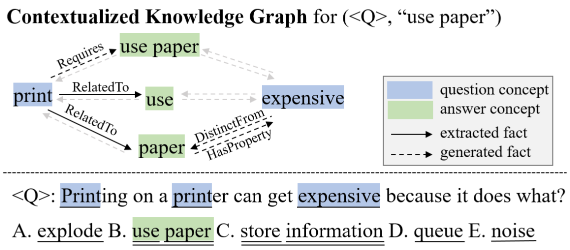

Figure 1: **KG-Augmented Commonsense QA.** Predicting the correct answer ("use paper") requires commonsense facts like `(print, Requires, paper)` and `(paper, HasProperty, expensive)`, which are not given in the question and candidate answers. HGN uses facts extracted from the KG, *e.g.*, `(print, RelatedTo, use)`, but also generates new facts, eventually upweighting relevant ones, *e.g.*, `(print, Requires, use paper)` and `(paper, HasProperty, expensive)`, while downweighting irrelevant ones, e.g., `(use, ?, expensive)`.

Despite the growing success of KG-augmented models, obtaining helpful KG facts for a given task instance remains challenging. Existing models assume using either KG-extracted edges (Lin et al., 2019; Ma et al., 2019; Feng et al., 2020; Yasunaga et al., 2021), PLM-generated edges (to address KG edge sparsity) (Bosselut and Choi, 2019), or a late fusion of both (Wang et al., 2020) is sufficient. Both extraction and generation can produce unhelpful edges, so the model must decide which edges to focus on during reasoning. Since extracted and generated edges are derived from the same set of concepts (nodes), modeling the interactions between extracted and generated edges jointly within a shared KG structure could provide stronger signal for identifying contextually relevant edges. However, current models do not leverage this information.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4038–4051
August 1–6, 2021.

In response, we propose a new KG-augmented model: **Hybrid Graph Network (HGN)**. Unlike prior models, HGN learns to jointly contextualize extracted and generated knowledge by reasoning over *both* within a unified graph structure. Given the task input (i.e., context) and an extracted KG subgraph, HGN is trained to generate embeddings for the subgraph's missing edges to form a "hybrid" graph, then reason over the graph (to update model parameters) while filtering out context-irrelevant edges. HGN achieves this primarily through edge reweighting, which downweights irrelevant edges, and edge-weighted message passing, which attenuates irrelevant edges' impact on reasoning.

Our extensive experiments demonstrate that HGN improves performance over all baselines across four CSR benchmarks. In particular, among comparable methods, HGN ranks first on the CommonsenseQA (Talmor et al., 2019) and OpenbookQA (Mihaylov et al., 2018) leaderboards. Plus, our user studies show that humans find HGN-filtered edges to be more valid and helpful than the heuristically extracted edges used in prior work.

2 Problem Statement

We consider CSR tasks, like question answering (QA), which can benefit from commonsense KGs. To solve CSR tasks, we focus on KG-augmented models, where a PLM is augmented with a commonsense KG. Given a CSR task, let x be the task's text input, f be the model, and $f(x)$ be the model output. We denote a KG as $\mathcal{G} = (\mathcal{V}, \mathcal{R}, \mathcal{E})$. $\mathcal{V}$, $\mathcal{R}$, and $\mathcal{E}$ are the sets of nodes (concepts), relations, and edges (facts), respectively, in the KG. An edge is a directed triple of the form $e = (h, r, t) \in \mathcal{E}$, where $h \in \mathcal{V}$ is the head node, $t \in \mathcal{V}$ is the tail node, and $r \in \mathcal{R}$ is the relation between h and t. Let $[\cdot, \cdot]$ denote concatenation of text or vectors.

As illustrated in Figure 2, a KG-augmented model f has three main components: text encoder f_{text}, graph encoder f_{graph}, and scoring function f_{score}. First, $\mathbf{s} = f_{\text{text}}(x; \theta_{\text{text}})$ is the encoding of x, where f_{text} is usually a Transformer PLM. Second, as supporting evidence, a x-specific graph $\mathcal{G}' = (\mathcal{V}', \mathcal{R}', \mathcal{E}')$ is constructed from $\mathcal{G}$ (Figure 1). Typically, this is done via heuristic extraction by selecting $\mathcal{V}' \subseteq \mathcal{V}$ as the concepts mentioned in x, $\mathcal{R}' \subseteq \mathcal{R}$ as the relations between concepts in $\mathcal{V}'$, and $\mathcal{E}' \subseteq \mathcal{E}$ as the edges involving $\mathcal{V}'$ and $\mathcal{R}'$. If $\mathcal{G}$ does not provide enough knowledge to build a good $\mathcal{G}'$, then new edges are sometimes added to $\mathcal{G}'$ using a PLM-based generator (Wang et al., 2020). We call $\mathcal{G}'$ the contextualized KG. $\mathbf{g} = f_{\text{graph}}(\mathcal{G}', \mathbf{s}; \theta_{\text{graph}})$ is then the joint encoding of $\mathcal{G}'$ and $\mathbf{s}$. Third, the model output is computed as $f(x) = f_{\text{score}}([\mathbf{s}, \mathbf{g}]; \theta_{\text{score}})$, where f_{score} is usually a multilayer perceptron (MLP). Existing KG-augmented models mainly differ in their design of f_{graph}, reasoning over the KG through message passing (Schlichtkrull et al., 2018a; Feng et al., 2020; Yasunaga et al., 2021) or edge/path aggregation (Lin et al., 2019; Bosselut and Choi, 2019; Ma et al., 2019).

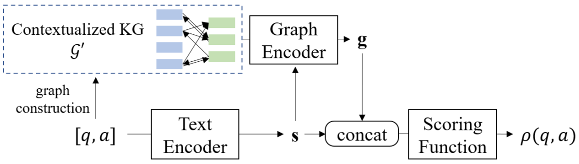

Figure 2: **High-level schematic of a typical KG-augmented model for CSR.** In KG-augmented models, text encoder f_{text} tends to be a Transformer PLM, and scoring function f_{score} is usually an MLP. Meanwhile, KG-augmented models generally vary more in their graph encoder f_{graph} and graph construction.

While KG-augmented models can be applied to any CSR task involving KGs (e.g., natural language inference), we consider multi-choice QA in this work. Given a question q and set of candidate answers $\{a_i\}$, the QA model's goal is to predict a plausibility score $\rho(q, a)$ for each $a \in \{a_i\}$, so that the highest score is predicted for the correct answer. To use KG-augmented models for commonsense QA, we set $x = [q, a]$ and $\rho(q, a) = f(x)$.

3 Hybrid Graph Network (HGN)

3.1 Overview

As illustrated in §2 and Figure 2, given question-answer pair (q, a) for an instance of the multi-choice QA task, the KG-augmented QA model first obtains a (q, a)-contextualized KG $\mathcal{G}'$ via the full KG $\mathcal{G}$. Edges in $\mathcal{G}'$ can be extracted directly from $\mathcal{G}$ or generated using a PLM-based generator (Wang et al., 2020; Bosselut et al., 2019). Then, the model transforms (q, a) and $\mathcal{G}'$ into text encoding $\mathbf{s}$ and graph encoding $\mathbf{g}$, respectively. Finally, $\mathbf{s}$ and $\mathbf{g}$ are used to predict (q, a)'s plausibility.

However, a contextualized KG may have low knowledge recall or precision, hindering the QA model's access to relevant knowledge. Low recall can stem from missing edges in $\mathcal{G}$, low precision can be the result of bad annotations in $\mathcal{G}$,

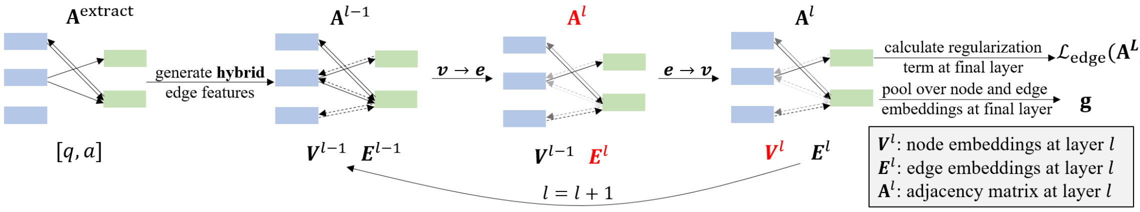

Figure 3: **Overview of HGN.** After building a hybrid graph of extracted and generated edges (§3.2), HGN reasons over the hybrid graph by updating the node embeddings $\mathbf{V}$, hybrid edge embeddings $\mathbf{E}$, and adjacency matrix $\mathbf{A}$ at each layer ℓ (§3.3). **Darker** edges indicate higher weights. **Red** variables are updated in the previous step.

and both can be caused by noisy edge extraction or generation when building $\mathcal{G}'$. HGN addresses these issues by reasoning over both extracted and generated edges within a unified graph structure. To improve recall, HGN generates new edges via a PLM-based generator, then initializes a hybrid contextualized KG containing both extracted and generated edges. Note that edge generation is generally (q, a)-agnostic and may produce irrelevant edges that hurt knowledge precision. To improve precision, HGN learns to reweight edges in the hybrid graph and reason over the hybrid graph via edge-weighted message passing. This is akin to learning the hybrid graph's structure and reduces the impact of irrelevant edges on reasoning. Additionally, to further encourage downweighting of noisy edges during reasoning, HGN is trained with entropy regularization on the learned edge weights.

The overall learning objective of HGN is defined as $\mathcal{L} = \mathcal{L}_{\text{task}} + \beta\mathcal{L}_{\text{edge}}$, where $\mathcal{L}_{\text{task}}$ is the loss for the downstream task (in our work, QA), $\mathcal{L}_{\text{edge}}$ is the entropy regularization term for edge weights, and $\beta \geq 0$ is a loss weight hyperparameter. In the following subsections, we first explain how the contextualized KG $\mathcal{G}'$ is constructed as a hybrid graph, including its node embeddings $\mathbf{V}$, hybrid edge embeddings $\mathbf{E}$, and adjacency matrix $\mathbf{A}^0$ (§3.2). Next, we show how HGN uses edge-weighted message passing to update $\mathbf{V}$, $\mathbf{E}$, and $\mathbf{A}^0$ for L layers (Figure 3), yielding a refined adjacency matrix $\mathbf{A}^L$ of learned edge weights (§3.3). Finally, we describe how $\mathcal{L}_{\text{task}}$ is computed using $\mathbf{s}$ and $\mathbf{g}$, while $\mathcal{L}_{\text{edge}}$ is calculated using $\mathbf{A}^L$ (§3.4).

3.2 Hybrid Graph Construction

Node Embeddings. The first step of retrieving knowledge from $\mathcal{G}$ is concept grounding, which involves identifying text spans in (q, a) that match nodes in $\mathcal{V}$. We define $\mathcal{V}'$ as the set of all concepts mentioned in (q, a), where $\mathcal{V}'_q = \{v_i\}_{i=1}^{n_q}$ and $\mathcal{V}'_a = \{v_i\}_{i=1}^{n_a}$ are the question and answer concepts, respectively. Each node $v_i \in \mathcal{V}'$ is represented by an embedding $\mathbf{v}_i \in \mathbf{V}$, which can be initialized using BERT (Devlin et al., 2019) or TransE (Bordes et al., 2013).

Hybrid Edge Embeddings. In $\mathcal{G}'$, we loosen the definition of an edge to be $e_{(i,j)} = (v_i, v_j) \in \mathcal{E}'$. We build fully-connected edges between question and answer nodes in $\mathcal{G}'$. The set of edges in $\mathcal{G}'$ is thus defined as $\mathcal{E}' = (\mathcal{V}'_q \times \mathcal{V}'_a) \cup (\mathcal{V}'_a \times \mathcal{V}'_q)$. After concept grounding, we need an edge embedding $\mathbf{e}_{(i,j)} \in \mathbf{E}$ for each edge $e_{(i,j)}$. Let $\mathbf{R}$ be the relation embeddings for all relations in $\mathcal{R}$, obtained using TransE. Each extracted edge $(v_i, r, v_j) \in \mathcal{E}$ is thus initialized in $\mathcal{G}'$ as $\mathbf{e}_{(i,j)} = \mathbf{r} \in \mathbf{R}$. However, due to edge sparsity, many edges do not have labeled relations and cannot be initialized this way.

Meanwhile, despite PLMs' limitations in commonsense, they have shown some ability to encode commonsense knowledge (Davison et al., 2019; Petroni et al., 2019) and aid KG completion (Malaviya et al., 2019; Bosselut et al., 2019; Wang et al., 2020). Hence, we generate edge embeddings for all unlabeled edges by feeding each unlabeled edge into a GPT-2 (Radford et al., 2019) based generator $f_{\text{gen}}(\cdot, \cdot)$. This is further explained in the "Edge Embedding Generation" paragraph.

In summary, edge embeddings are computed in a hybrid way: **(1)** If there exists $r \in \mathcal{R}$ such that $(v_i, r, v_j) \in \mathcal{E}$, then $\mathbf{e}_{(i,j)} = \mathbf{r} \in \mathbf{R}$. **(2)** Otherwise, $\mathbf{e}_{(i,j)} = f_{\text{adapt}}(f_{\text{gen}}(v_i, v_j))$, where $f_{\text{adapt}}(\cdot)$ is an MLP used to transform $f_{\text{gen}}(v_i, v_j)$ into the same space as $\mathbf{r}$.

Edge Embedding Generation. Inspired by recent work in PLM-based commonsense KG completion (Bosselut et al., 2019; Malaviya et al., 2019; Wang et al., 2020), we frame edge generation as text generation. First, for each extracted edge $(h, r, t) \in \mathcal{E}$, we first tokenize its node pair (h, t) and relation label r. Let $\tilde{h}$, $\tilde{r}$, and $\tilde{t}$ be the respective token sequences of h, r, and t. Also, let \$ be the special separator token. Next, for each tokenized extracted edge, we train a GPT-2 model (Radford et al., 2019) to autoregressively generate the concatenated sequence $[\tilde{h}, \$, \tilde{t}, \$, \tilde{h}, \tilde{r}, \tilde{t}]$.

During inference, we only have unlabeled edges $(v_i, v_j) \in \mathcal{E}'$, with no r. Thus, for each (v_i, v_j), GPT-2 is given $s_{\text{input}} = [\tilde{v_i}, \$, \tilde{v_j}, \$]$ and asked to generate the missing tokens $s_{\text{pred}} = [\tilde{v_i}, \tilde{r}, \tilde{v_j}]$. Let $[x_1, x_2, ..., x_T] = [s_{\text{input}}, s_{\text{pred}}]$. The edge embedding for (v_i, v_j) is then computed as $f_{\text{gen}}(v_i, v_j) = \frac{1}{T}\sum_{i=1}^{T} \mathbf{h}_i$, where $\mathbf{h}_i$ is the GPT-2 hidden state for x_i. See Appendix §A for more details.

Alternatively, we consider another edge generation approach proposed by Wang et al. (2020). Here, $f_{\text{gen}}(\cdot, \cdot)$ is trained to generate a relational path connecting v_i to v_j, then pool the path into an edge embedding. The rationale for this approach is that such paths have been shown to contain useful semantic information about the relation between v_i and v_j (Neelakantan et al., 2015; Das et al., 2017; Wang et al., 2020).

Adjacency Matrix. Before edge generation, $\mathcal{G}'$ has binary adjacency matrix $\mathbf{A}^{\text{extract}}$, where $\mathbf{A}_{(i,j)} = 1 \Leftrightarrow \exists r, \text{s.t. } (v_i, r, v_j) \in \mathcal{E}$. After getting embeddings for all edges $(v_i, v_j) \in \mathcal{E}'$, $\mathbf{A}^{\text{extract}}$ becomes $\mathbf{A}^0$, a denser binary adjacency matrix in which $\mathbf{A}^0_{(i,j)} = 1 \Leftrightarrow (v_i, v_j) \in \mathcal{E}'$.

3.3 Hybrid Graph Reasoning

The procedure described in §3.2 yields a hybrid graph, containing unweighted edges between all question-answer node pairs. Constructing this hybrid graph may improve edge recall, but does not address precision. Some edges in the initial hybrid graph may be irrelevant to the question-answer pair, either due to noisy edge extraction or generation. HGN is thus designed to downweight irrelevant edges by converting the unweighted graph into a weighted one, then learning to reweight all hybrid edges during reasoning (Figure 3).

Learnable Adjacency Matrix. Although $\mathbf{A}^0$ is a binary adjacency matrix, HGN populates it with learned edge attention weights and iteratively updates them over L layers of reasoning. We denote the adjacency matrix at layer ℓ as $\mathbf{A}^\ell$, where $0 \leq \mathbf{A}^\ell_{(i,j)} \leq 1$. Updating $\mathbf{A}^\ell$ can be viewed as softly contextualizing the hybrid graph's structure with respect to (q, a).

Edge-Weighted Message Passing. Following the general Graph Network (GN) formulation proposed by Battaglia et al. (2018), HGN's graph reasoning module consists of layer-wise node-to-edge ($v \rightarrow e$) and edge-to-node ($e \rightarrow v$) message passing functions. However, we equip HGN with a modified version of GN's edge-to-node message passing function, in which each edge's weight is used to rescale information flow on that edge. Intuitively, an edge's weight signifies the edge's relevance for reasoning about the given task instance. We also use text encoding $\mathbf{s}$ as global context throughout message passing.

Formally, HGN's update rule at layer ℓ is:

$$
\begin{aligned}
v \rightarrow e : \mathbf{h}^\ell_{(i,j)} &= f^\ell_{v \rightarrow e}\left(\left[\mathbf{h}^{\ell-1}_i, \mathbf{h}^{\ell-1}_j, \mathbf{h}^{\ell-1}_{(i,j)}, \mathbf{s}\right]\right); \\
w^\ell_{(i,j)} &= f^\ell_w\left(\left[\mathbf{h}^{\ell-1}_{(i,j)}, \mathbf{s}\right]\right); \\
\mathbf{A}^\ell_{(i,j)} &= \frac{e^{w^\ell_{(i,j)}}}{\sum_{(s,t)\in\mathcal{E}'} e^{w^\ell_{(s,t)}}}, \\
e \rightarrow v : \mathbf{u}^\ell_{(i,j)} &= f^\ell_u\left(\left[\mathbf{h}^{\ell-1}_i, \mathbf{h}^\ell_{(i,j)}\right]\right); \\
\mathbf{h}^\ell_j &= f^\ell_{e \rightarrow v}\left(\sum_{i\in\mathcal{N}_j} \mathbf{A}^\ell_{(i,j)} \mathbf{u}^\ell_{(i,j)}\right).
\end{aligned} \tag{1}
$$

N_j is the set of v_j's incoming neighbors; $f^\ell_{v\rightarrow e}$, f^ℓ_w, f^ℓ_u and $f^\ell_{e\rightarrow v}$ are MLPs; $\mathbf{h}^0_{(i,j)} = \mathbf{e}_{(i,j)}$ is the initial embedding for edge (v_i, v_j); and $\mathbf{h}^0_i = \mathbf{v}_i$ is the initial embedding for node v_i.

In node-to-edge message passing, the embedding of each edge $(v_i, v_j) \in \mathcal{E}'$ is updated as $\mathbf{h}^\ell_{(i,j)}$, a function of (v_i, v_j)'s constituent nodes and the given context $\mathbf{s}$. Through $\mathbf{s}$, the hybrid graph is strongly contextualized with respect to (q, a). Then, $\mathbf{h}^\ell_{(i,j)}$ is used to compute edge score $w^\ell_{(i,j)}$, which measures the edge's relevance to $\mathbf{s}$. Each edge score is globally normalized across all edges in the graph to produce edge attention weight $\mathbf{A}^\ell_{(i,j)}$, so that low-scoring edges are softly pruned by receiving close-to-zero weight.

We use global edge attention (i.e., normalizing across $\mathcal{E}'$) instead of local edge attention (i.e., normalizing across N_j) because local edge attention assumes at least one edge in N_j is relevant, which may not be true. For example, given an irrelevant or incorrectly grounded concept, none of its edges will be helpful, and so all nodes in its neighborhood should be excluded from influencing the reasoning process. To demonstrate the advantage of global edge attention, we empirically compare our default HGN architecture to an HGN variant based on Graph Attention Network (GAT) (Velickovic et al., 2018), which uses local edge attention, in our experiments.

In edge-to-node message passing, the embedding of each node $v_j \in \mathcal{V}'$ is updated as $\mathbf{h}_j^\ell$, a function of v_j's neighboring edges. For each edge neighbor, edge weight $\mathbf{A}_{(i,j)}^\ell$ is used to rescale the edge's influence on v_j's embedding update.

3.4 Learning Objective

Task Loss. After L layers of message passing, we obtain node embeddings $\{\mathbf{h}_i^L \mid i : v_i \in \mathcal{V}'\}$ and edge embeddings $\{\mathbf{h}_{(i,j)}^L \mid (i,j) : (v_i, v_j) \in \mathcal{E}'\}$. Node embeddings are aggregated into $\mathbf{v}_{\text{agg}}$ via attentive pooling with $\mathbf{s}$ as the query vector. Edge embeddings are aggregated into $\mathbf{e}_{\text{agg}}$ via edge-weighted sum pooling. The final graph encoding is then given as $\mathbf{g} = [\mathbf{v}_{\text{agg}}, \mathbf{e}_{\text{agg}}]$. The probability of a being the answer to q is calculated as $\hat{\rho}(q,a) \propto \exp(\rho(q,a))$, where $\rho(q,a) = f_{\text{score}}([\mathbf{s}, \mathbf{g}]; \boldsymbol{\theta}_{\text{score}})$. We use cross-entropy loss for the QA classification task, so the loss for each (q,a) with label y is:

$$\mathcal{L}_{\text{task}}\left(\hat{\rho}(q,a;\boldsymbol{\theta})), y\right) = -y \log \hat{\rho}(q,a;\boldsymbol{\theta}). \tag{2}$$

Entropy Regularization. To encourage the model to be decisive during edge reweighting, we use a regularization term to penalize non-discriminative edge weights. In an extreme case, a blind model will assign the same weight to all edges, degenerating $\mathcal{G}'$ into an unweighted graph. This is a failure mode, since $\mathcal{G}'$ is likely to contain mostly irrelevant edges, and we want the model to focus on the helpful edges. Therefore, via $\mathcal{L}_{\text{edge}}$, we train the model to minimize the entropy of the edge weight distribution (i.e., make the distribution more skewed), in order to maximize the informativeness of the predicted edge weights. Lower entropy means the model has higher certainty about edges' relevance to the given task instance, such that the model will discriminatively judge some edges as being much more relevant than others. $\mathcal{L}_{\text{edge}}$ is computed as:

$$\mathcal{L}_{\text{edge}}(\mathbf{A}^L(q,a)) = -\sum_{(i,j):(v_i,v_j)\in\mathcal{E}'} \mathbf{A}_{(i,j)}^L \log \mathbf{A}_{(i,j)}^L. \tag{3}$$

Joint Learning. We jointly optimize $\mathcal{L}_{\text{task}}$ and $\mathcal{L}_{\text{edge}}$, so graph reasoning and structure can be jointly learned. The full learning objective is:

$$\mathcal{L}(\boldsymbol{\theta}) = \sum_{(q,a,y)\sim X_{\text{train}}} \left[\mathcal{L}_{\text{task}}\left(\hat{\rho}(q,a)), y\right) + \beta \cdot \mathcal{L}_{\text{edge}}(\mathbf{A}^L(q,a))\right], \tag{4}$$

where $\boldsymbol{\theta} = \{\boldsymbol{\theta}_{\text{text}}, \boldsymbol{\theta}_{\text{graph}}, \boldsymbol{\theta}_{\text{score}}\}$ is the set of all learnable parameters, and X_{train} is the training set. We train our model end-to-end by minimizing $\mathcal{L}(\boldsymbol{\theta})$ with the RAdam (Liu et al., 2020) optimizer.

4 Experiments

4.1 Experimental Setup

We evaluate our proposed model on four multiple-choice commonsense QA datasets: **CommonsenseQA** (Talmor et al., 2019), **CODAH** (Chen et al., 2019), **OpenBookQA** (Mihaylov et al., 2018) and **QASC** (Khot et al., 2020) (details in Appendix §B). We use ConceptNet (Speer et al., 2017), a commonsensense knowledge graph, as $\mathcal{G}$. For text encoder f_{text}, we experiment with BERT-Base, BERT-Large (Devlin et al., 2019) and RoBERTa(-Large) (Liu et al., 2019) to validate our model's effectiveness over different text encoders. For OpenbookQA and QASC, retrieving related facts from the provided corpus plays an important role in boosting the model's performance. Therefore, we build our graph reasoning model on top of retrieval-augmented methods on the leaderboard: "AristoRoBERTa"[2] for OpenBookQA and "RoBERTa (2-step IR)"[3] for QASC. In this way, we can study if strong retrieval-augmented methods can still benefit from KG knowledge and our HGN framework.

4.2 Compared Methods

We compare our model with a series of KG-augmented methods and different graph encoders:

Models Using Extracted Facts. We consider seven models that only use extracted facts. **RN** (Santoro et al., 2017) builds the graph with the same node set as our method but extracted edges only. The graph vector is calculated as $\mathbf{g} = \text{Pool}(\{\text{MLP}([\mathbf{v}_i, \mathbf{e}_{(i,j)}, \mathbf{v}_j]) \mid (v_i, v_j) \in \mathcal{E}'\})$. **GN** (Battaglia et al., 2018) presents a general formulation of GNNs. We instantiate it with the layerwise propagation rule defined in Equation 1. It differs from our HGN in that: (1) it only considers extracted edges; (2) all edge weights are fixed to 1. **MHGRN** (Feng et al., 2020) generalizes GNNs with multi-hop message passing. **GAT** (Velickovic et al., 2018) adopts attention mechanism to

Table 1: **Accuracy on CommonsenseQA inhouse test set.** Both our model variants significantly improve over all baselines. We use the same inhouse split as Lin et al. (2019). For baselines with *, we use the reported numbers from Feng et al. (2020) and Wang et al. (2020) if available. Mean and standard deviation of four seeds are presented for all models except KagNet.

reweight edges locally in each node's neighborhood. We implement it by replacing the graph edge attention with local edge attention and only considering $\mathcal{L}_{\text{task}}$ during training. **RGCN** (Schlichtkrull et al., 2018a) extends Graph Convolutional Networks (GCNs) (Kipf and Welling, 2017) with relation-specific transition matrices during message passing. It operates on the same graph as RN. The graph vector is calculated as $\mathbf{g} = \text{Pool}(\{\mathbf{h}_i^L \mid v_i \in V\})$. **GconAttn** (Wang et al., 2019b) softly aligns the nodes in question and answer and do pooling over all matching nodes to get $\mathbf{g}$. **KagNet** (Lin et al., 2019) uses an LSTM to encode relational paths between question and answer concepts and pool over the path embeddings for graph encoding.

Models Using Extracted and Generated Facts. We consider two models that use both extracted facts and generated facts. **RN + Link Prediction** differs from RN by only considering the generated relation (predicted using TransE (Bordes et al., 2013)) between question and answer concepts. **PathGenerator** (Wang et al., 2020) learns a path generator from paths collected through random walks on the KG. The learned generator is used to generate paths connecting question and answer concepts. $\mathbf{g}$ is calculated as the concatenation of the pooled vector over the generated paths and the pooled vector over the extracted paths.

Our Model's Variants. As described in §3.2, the edge embedding can be computed either as a relation embedding or a path embedding. We name these two variants as **HGN (w/ RelGen edges)** and **HGN (w/ PathGen edges)** respectively.

4.3 Results

Performance Comparisons. Tables 1, 3, 4 show performance comparisons between our models and baseline models on CommonsenseQA, CODAH, OpenBookQA and QASC. We clearly find that models with stronger text encoders perform better (i.e. RoBERTa > BERT-Large > BERT-Base). For all text encoders, our HGN shows consistent improvement over baseline models on all datasets. The improvement over all baselines are tested to be statistically significant under most settings, demonstrating the effectiveness of HGN both with and without retrieved evidence.

We also submit our best model to leaderboards for CommonsenseQA and OpenBookQA. For CommonsenseQA (Table 2), our HGN ranks first among comparable approaches and shows remarkable improvement over PathGenerator (Wang et al., 2020) and the LM Finetuning approach (ALBERT (Lan et al., 2020)). Higher-ranking

RGCN (Schlichtkrull et al., 2018b)	65.56	82.42
GAT (Velickovic et al., 2018)	65.88	82.78
GN (Battaglia et al., 2018)	65.52	82.06
GconAttn (Wang et al., 2019a)	65.17	82.35
MHGRN (Feng et al., 2020)	65.92	83.07
PathGenerator (Wang et al., 2020)	64.67	82.27
HGN (w/ PathGen edges)	66.21	**84.32**
HGN (w/ RelGen edges)	**66.75**	84.08

Table 3: **Test accuracy on CODAH.** Both our model variants consistently improve over all baselines. We use the official split for 5-fold cross validation. Mean accuracy on 5 folds are presented.

models either use stronger text encoders or leverage additional data resources. Specifically, UnifiedQA (Khashabi et al., 2020) and T5-3B (Raffel et al., 2020) are based on T5. They have 11B and 3B parameters respectively, making them impractical to be finetuned in an academic setting. ALBERT+DESC-KCR (Xu et al., 2020) and ALBERT+KD additionally use concept definitions from dictionaries. ALBERT+DESC-KCR and ALBERT+KCR leverage "question_concept" annotations, which are used during the construction of the CommmonsenseQA dataset and allow the model to learn shortcuts that don't generalize to other datasets. ALBERT+KRD retrieve sentences from OMCS corpus (Liu and Singh, 2004) as input. These methods are therefore not comparable with our model. For OpenBookQA (Table 5), our model ranks first among all models using AristoRoBERTa as the text encoder.

Datasets	**OpenBookQA**	**QASC**
Base Models	**AristoRoBERTa**	**RoBERTa (2-step IR)**
LM Finetuning*	77.40 (±1.64)	73.34 (±0.71)
RN* (Santoro et al., 2017)	78.05 (±0.77)	72.77 (±1.50)
RN + Link Prediction*	77.25 (±1.11)	-
RGCN* (Schlichtkrull et al., 2018b)	74.60 (±2.53)	72.23 (±1.36)
GAT (Velickovic et al., 2018)	78.20 (±1.22)	72.61 (±0.93)
GN (Battaglia et al., 2018)	77.25 (±0.91)	72.53 (±0.70)
GconAttn* (Wang et al., 2019a)	71.80 (±1.21)	72.72 (±1.66)
MHGRN (Feng et al., 2020)	77.75 (±0.38)	73.24 (±0.45)
PathGenerator* (Wang et al., 2020)	79.15 (±0.78)	72.96 (±0.68)
HGN (w/ PathGen edges)	80.05 (±0.54)	74.10 (±0.42)
HGN (w/ RelGen edges)	**80.15** (±0.38)	**74.27** (±0.31)

Table 4: **Test accuracy on OpenBookQA and QASC with retrieval-augmented methods as base models.** Both our model variants greatly improve over all baselines except HGN (w/ PathGen edges) over MHGRN. For OpenbookQA baselines with *, we use reported numbers from Wang et al. (2020). Mean and standard deviation of four seeds are presented.

Training with Less Labeled Data. Figure 4 (a)(b) show the results of our model and baselines when trained with different portions of the training data on CommonsenseQA and OpenBookQA. Our model gets better test accuracy under all settings. On CommonsenseQA without retrieved evidence, the improvement over the knowledge-agnostic baseline (LM Finetuning) is generally more significant with less training data, which suggests that incorporating external knowledge is helpful in the low-resource setting.

Study on More Model Variants. To better understand the model design, we experiment with three variants of HGN (w/ RelGen edges) on CommonsenseQA and OpenBookQA. **HGN w/o statement vector** doesn't consider s in Equation 1, which isolates the graph encoder from the text encoder. **HGN w/o $\mathcal{L}_{\text{edge}}$** does not consider the entropy regularization term and thus does not penalize non-discriminative edge weights. **HGN w/o edge weights** reasons over an unweighted graph with hybrid features, which means edge weights are all fixed to 1 during training. Figure 4 (c) shows the results of the ablation study. "HGN" outperforms "HGN w/o $\mathcal{L}_{\text{edge}}$", suggesting the usefulness

Methods	**Text Encoder**	**Test Acc**
UnifiedQA (Khashabi et al., 2020)	T5-11B	87.2
T5-11B + KB	T5-11B	85.4
T5-3B (Raffel et al., 2020)	T5-3B	83.2
PathGenerator (Wang et al., 2020)	ALBERT	81.8
HGN (w/ RelGen edges)	**AristoRoBERTa**	**81.4**
AristoRoBERTa + KB	AristoRoBERTa	81.0
MHGRN (Feng et al., 2020)	AristoRoBERTa	80.6
PathGenerator (Wang et al., 2020)	AristoRoBERTa	80.2
KF + SIR (Banerjee and Baral, 2020)	RoBERTa	80.2
AristoRoBERTa	AristoRoBERTa	80.2

Table 5: **Leaderboard of OpenBookQA.** Our HGN ranks first among all submissions using AristoRoBERTa as the text encoder.

Contextualized Graph	**GN** ($\mathbf{A}^{\text{extract}}$)	**HGN** ($\mathbf{A}^L$)
Number of Edges	3.65 ($\pm$2.73)	4.38 ($\pm$3.24)
Number of Valid Edges	2.67 ($\pm$1.95)	3.15 ($\pm$1.98)
Percentage of Valid Edges	71.64%	78.51%
Average Helpfulness Score of Edges	0.90 ($\pm$0.50)	1.16 ($\pm$0.51)
Prune Rate	-	22.84%

Table 6: **User studies on learned graph structures.** 30 pairs of contextualized graphs output by GN and HGN are evaluated by 5 annotators.

of our proposed entropy regularization. Comparing "HGN w/o statement vector" with "HGN", we find that accessing context information is also important for graph reasoning, which means information propagation and edge weight prediction should be conducted in a context-aware manner. HGN also improves over "HGN (w/o edge weights)", indicating the effectiveness of conducting context-dependent pruning.

4.4 User Study on Learned Structures

To assess HGN's ability to refine graph structure, we compare the graph structure before and after being processed by HGN. Specifically, we sample 30 questions with its answer from CommonsenseQA's development set and ask 5 human annotators to evaluate the graph output by GN (with adjacency matrix $\mathbf{A}^{\text{extract}}$ and extracted facts only) and by HGN (with adjacency matrix $\mathbf{A}^L$). We manually binarize $\mathbf{A}^L$ by removing edges with weight lower than 0.01.

Given a graph, for each edge (fact), annotators are asked to rate its **validness** and **helpfulness**. The validness score is rated as a binary value in a context-agnostic way: 0 (the fact does not make sense), 1 (the fact is generally true). The helpfulness score measures if the fact is helpful for solving the question and is rated on a 0 to 2 scale: 0 (the fact is unrelated to the question and answer), 1 (the fact is related but doesn't directly lead to the answer), 2 (the fact directly leads to the answer). Note that the percentage of valid edges can be understood as the precision of graph edges. For a given instance, the number of valid edges is proportional to the recall of the edges. We also include another metric named "prune rate" calculated as: $1 - \frac{\text{\# edges in binarized } \mathbf{A}^L}{\text{\# edges in } \mathbf{A}^0}$, which measures the portion of edges assigned very low weights (softly pruned) during training and is only applicable to HGN.

The mean ratings for 30 pairs of (GN, HGN) graphs by 5 annotators are reported in Table 6. The Fleiss' Kappa (Fleiss, 1971) is 0.51 (moderate agreement) for validness and 0.36 (fair agreement) for helpfulness. The graph refined by HGN has both more edges and denser valid edges compared to the extracted one. The refined graph also achieves a higher average helpfulness score. These all indicate that our HGN learns a superior graph structure with more helpful edges and fewer noisy edges, which improves over previous works that rely on extracted and static graphs. Detailed cases can be found in Appendix §C.

5 Related Work

Commonsense QA. Commonsense QA is challenging because the required commonsense knowledge is seldom given in the question-answer context or encoded in the PLM's parameters. Thus, many works obtain this knowledge from external sources (e.g., KGs, corpora). While Lv et al. (2020) show that KGs and corpora can provide complementary knowledge, our paper focuses on improving the use of KG knowledge. KG knowledge can be acquired in different ways, either from KG-extracted edges (Lin et al., 2019; Ma et al., 2019; Feng et al., 2020; Yasunaga et al., 2021), PLM-generated edges (Bosselut and Choi, 2019), or both (Wang et al., 2020). KG-augmented models mainly differ in how they encode KG knowledge, using message passing (Schlichtkrull et al., 2018a; Feng et al., 2020) or edge/path aggregation (Lin et al., 2019; Bosselut and Choi, 2019; Ma et al., 2019; Wang et al., 2020). The most relevant work to ours is Wang et al. (2020). The main difference is that they coarsely combine extracted and generated knowledge via late fusion, while HGN encodes both types of knowledge within a unified graph. Besides, they use RN to pool over a set of paths for graph encoding, while HGN reasons over the graph via message passing and edge reweighting.

Graph Structure Learning. Instead of assuming a fixed graph structure, a number of graph models learn the graph structure with respect to the downstream task. Some models learn to discretely select edges for the graph (i.e., hard pruning). Kipf et al. (2018) and Franceschi et al. (2019) sample the graph structure from a predicted probabilistic distribution with differentiable approximations. Norcliffe-Brown et al. (2018) calculate the relatedness between any pair of nodes and only keep the top-k strongest connections for each node to construct the edge set. Sun et al. (2019) start with a small graph and iteratively expand it with retrieving operations. Others learn to reweight edges in a fully connected graph (i.e., soft pruning). Jiang et al. (2019) and Yu et al. (2019) propose heuristics for regularizing edge weights. Hu et al. (2019) use the question embedding to help predict edge weights. Unlike other edge reweighting models, HGN operates over a hybrid graph of both extracted and generated edges, while updating edge weights with respect to node, edge, and text features.

6 Conclusion

In this paper, we propose HGN, a KG-augmented model for CSR. To address KG edge sparsity and noisy edge extraction/generation, HGN learns to jointly contextualize extracted and generated knowledge by reasoning over both within a unified graph structure. We justify HGN's design by showing that HGN improves performance on various CSR benchmarks and user studies. In future work, we plan to increase the graph's relation expressiveness by incorporating open relations, plus make the edge extraction/generation process more dependent on the reasoning context.

A Implementation Details of Edge Embedding Generator (RelGen)

Here, we give a more detailed explanation of the PLM-based edge embedding generator f_{gen}, introduced in the "Edge Embedding Generation" paragraph of §3.2.

To implement f_{gen}, we adopt GPT-2 (Radford et al., 2019), which is pretrained on large corpora and achieves great success on a wide range of tasks involving sentence generation, as a generator to generalize the facts from the knowledge graph. We first convert each fact $(h, r, t) \in \mathcal{E}$ into a word sequence with a "prompt-generation" format: $\left[\tilde{h}, \$, \tilde{t}, \$, \tilde{h}, \tilde{r}, \tilde{t}\right]$, where $\tilde{h}, \tilde{r}, \tilde{t}$ are the word sequence of h, r, t respectively, $\$$ denotes the delimiter token used by GPT-2, and $[\cdot, \cdot]$ denotes word sequence concatenation. We adopt this format because $\left[\tilde{h}, \tilde{r}, \tilde{t}\right]$ is similar to a natural language fact. Generating facts in a natural format helps induce commonsense knowledge stored in GPT-2 (Bosselut et al., 2019). We denote the synthetic sentence as $s_{(h,r,t)} = \left[x_1^{(h,r,t)}, \ldots, x_{n_{(h,r,t)}}^{(h,r,t)}\right]$ and finetune GPT-2 on all synthetic sentences created from $\mathcal{E}$ with the language modeling objective:

$$\mathcal{L}_{\text{gen}}(\mathcal{E}) = \sum_{(h,r,t) \in \mathcal{E}} \sum_{i=1}^{n_{(h,r,t)}} \log P\left(x_i^{(h,r,t)} \mid x_1^{(h,r,t)}, \ldots, x_{i-1}^{(h,r,t)}\right).$$

After that, given any two concepts (v_i, v_j), we build a prompt as $[\tilde{v_i}, \$, \tilde{v_j}, \$]$ and let the model to generate the following word sequence. We denote the whole sentence (both prompt and generation) as $s_{(v_i,v_j)}$, and the hidden states of each word during generation as $\mathbf{h}_1, \ldots, \mathbf{h}_T$ where T is the sentence length. We average hidden states of all words in the sentence to get the relational feature: $f_{\text{gen}}(v_i, v_j) = \frac{1}{T} \sum_{i=1}^{T} \mathbf{h}_i$.

B Details of Datasets

Below are descriptions of the four datasets used for the experiments presented in §4.

CommonsenseQA (Talmor et al., 2019) is a multiple-choice QA dataset targeting commonsense. It's constructed based on the knowledge in ConceptNet. Since the test set of the official split (9741/1221/1140 for OFtrain/OFdev/OFtest) is not publicly available, we compare our models with baseline models on the inhouse split (8500/1221/1241 for IHtrain/IHdev/IHtest)[4] used by previous works (Lin et al., 2019; Feng et al., 2020; Wang et al., 2020).

CODAH (Chen et al., 2019) contains 2801 sentence completion questions testing commonsense reasoning skills. We perform 5-fold cross validation using the official split.

OpenBookQA (Mihaylov et al., 2018) is a multiple-choice QA dataset modeled after openbook exams. Besides 5957 elementary-level science questions (4957/500/500 for train/dev/test), it also provides an open book with 1326 core science facts. Solving the dataset requires combining facts from open book with commonsense knowledge.

QASC (Khot et al., 2020) is a QA dataset with questions about grade-school science. It has 9980 8-way multiple-choice questions (8134/926/920 train/dev/test), and comes with a corpus of 17M sentences. Since the official test set does not have labels, we create an in-house test split by moving a randomly sampled set of 920 questions from the training set to the test set. Solving questions in QASC requires retrieving facts from the corpus and composing them to produce an answer.

C Case Study

In addition to the experiments in §4, we present a case study here, which compares a HGN-generated graph with a KG-extracted graph used by GN. On the development set of CommonsenseQA, there are two dominating cases and we show the representative instance of each one. Figure 5 (a) shows the first case, where HGN prunes edges from the extracted graph. Our HGN assigns the highest weights to the most helpful facts (`book`, `AtLocation`, `house`), (`telephone book`, `AtLocation`, `house`). It also downweight unhelpful fact (`place`, `IsA`, `house`) and invalid fact (`usually`, `RelatedTo`, `house`). Figure 5 (b) shows the second case, where new generated facts are incorporated into reasoning. All generated facts that are kept by the model make sense in the context and help identify the answer. Both cases suggest that our model improve the quality of the contextualized knowledge graph compared to the current methods that only rely on extracted facts.

Question: What is a place that usually does not have an elevator and that sometimes has a telephone book?

Answer: house

Triples:

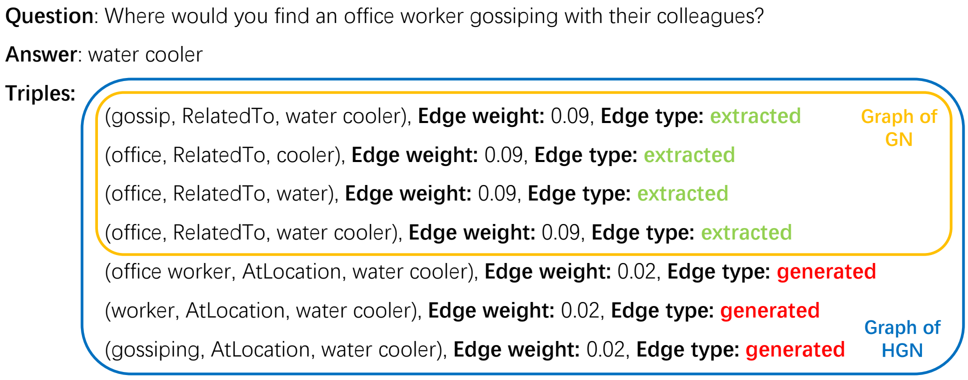
(book, AtLocation, house), **Edge weight:** 0.48, **Edge type:** extracted

(telephone book, AtLocation, house), **Edge weight:** 0.48, **Edge type:** extracted

(place, IsA, house), **Edge weight:** 0.01, **Edge type:** extracted

(usually, RelatedTo, house), **Edge weight:** 0.01, **Edge type:** extracted

(a) **Case I: Unrelated extracted facts are filtered out.**



Question: Where would you find an office worker gossiping with their colleagues?

Answer: water cooler

Triples:

(gossip, RelatedTo, water cooler), **Edge weight:** 0.09, **Edge type:** extracted

(office, RelatedTo, cooler), **Edge weight:** 0.09, **Edge type:** extracted

(office, RelatedTo, water), **Edge weight:** 0.09, **Edge type:** extracted

(office, RelatedTo, water cooler), **Edge weight:** 0.09, **Edge type:** extracted

(office worker, AtLocation, water cooler), **Edge weight:** 0.02, **Edge type:** generated

(worker, AtLocation, water cooler), **Edge weight:** 0.02, **Edge type:** generated

(gossiping, AtLocation, water cooler), **Edge weight:** 0.02, **Edge type:** generated

(b) **Case II: Helpful generated facts are incorporated.**

Abstract

Stereotypes are inferences drawn about people based on their demographic attributes, which may result in harms to users when a system is deployed. In generative language-inference tasks, given a premise, a model produces plausible hypotheses that follow either logically (natural language inference) or commonsensically (commonsense inference). Such tasks are therefore a fruitful setting in which to explore the degree to which NLP systems encode stereotypes. In our work, we study how stereotypes manifest when the potential targets of stereotypes are situated in real-life, neutral contexts. We collect human judgments on the presence of stereotypes in generated inferences, and compare how perceptions of stereotypes vary due to annotator positionality.

1 Introduction

Social categories refer to collections of people with shared traits; stereotypes—cognitive structures that associate categories (e.g., man, Black, poor, professor) with both roles (e.g., doctor) and traits (e.g., absent-minded)—are central to how people construe social meaning (Levon, 2014; Macrae and Bodenhausen, 2001; Greenwald et al., 1998). Social psychology has studied how stereotypes, as a cognitive process, are entwined with the production of human affects of prejudice and in-group favoritism, as well as behaviors like discrimination (Stangor, 2014; Jackson, 2011). Linguistic anthropology and sociolinguistic studies argue that language—as the predominant way of naming categories and transmitting knowledge—is the only (or at least the primary) mechanism by which social stereotypes are shared as part of cultural knowledge (Fishman, 1956; Stangor and Schaller, 2012; Maass and Arcuri, 1996).

premise	A Cuban person needs help.	
↳ **hypothesis**	Then PERSONX gets a job.	
Question	**Annotator 1**	**Annotator 2**
correct?	yes	yes
plausible?	yes	yes
identity?	maybe yes	no
situation?	maybe no	not sure
sentiment?	maybe negative	positive
stereotype?	yes	no
description?	problems with jobs	n/a

Table 1: Annotation example; the hypothesis is automatically generated from the premise. Both annotators found the hypothesis grammatically correct and plausible. One annotator viewed this hypothesis as negative stereotypical towards Cuban people, assuming that they have problems with jobs. The other annotator had the opposite opinion. Annotators differ in their backgrounds and social groups they belong to.

In this paper, we study ways in which categories implicate inferences around stereotypical roles and traits computationally.[1] Approaching stereotyping through the lens of *inference* allows us to focus on what models learn as *implications* rather than simply associations (e.g., that lexical semantics models typically find antonyms like “hot” and “cold” to be highly related). Specifically, we train models for English textual inference—including both logical- (NLI) and commonsense-inference (CI)—and investigate how stereotypes are reproduced by these models. The models we train *generate* hypothesis text given a fixed premise text (e.g., “PERSONX lights up candles”, where PERSONX is substituted with the target category label), and by varying the target category label, we are able to investigate what and how much stereotypical information the model produces in its generated hypotheses (see Table 1).

To perform this analysis, we collect human judgments on the generated hypotheses, given explic-

Domain	Target Categories
Gender	man, woman, non-binary person, trans man, trans woman, cis man, cis woman
Race	African American, African-American, Black, White, White-American, White American, Hispanic, Latino, Latina, Latin American, Arab, American Indian, Native American, Alaska Native, Asian American, Native Hawaiian, Pacific Islander
Nationality	Mexican, Chinese, Russian, Indian, Irish, Cuban, Italian, Japanese, German, French, British, Jamaican, American, Filipino
Religion	Jewish, Muslim, Catholic, Christian, Buddhist, Mormon, Amish, Protestant, Atheist, Hindu
Politics	Democrat, Republican, Communist, Socialist, Fascist, Libertarian, Liberal, Capitalist, Conservative
Socio	Rich, Wealthy, Poor, Immigrant, Refugee, Homeless, Aristocrat, Lower class, Middle class, Working class, Upper class, Formerly incarcerated, First generation, Bourgeoisie

Table 2: Stereotype domains and corresponding target categories.

itly stated target categories in an otherwise neutral premise, such as that in Table 1. We focus on 71 target categories drawn from six stereotype domains that are particularly salient in the United States[2], listed in Table 2. With the collected human judgments, we first investigate which models and categories lead to stereotyped inferences, and the degree to which the invoked stereotypes are negative. It is well established that stereotypes are both an individual phenomenon—something that resides in the heads of individual people—as well as a cultural phenomenon—that "[sterotypes] exist also in 'the fabric of society' itself" (Stangor and Schaller, 2012), and as such *who* the annotators are matters (Hovy and Spruit, 2016; Jørgensen et al., 2015; Hazen et al., 2020). In view of this, part of our analysis specifically considers how individual annotators' perceptions of stereotypes may vary.

Overall, we find that socioeconomic status and politics are the domains most likely to yield stereotyped inferences. This is notable, as most existing work in this space has focused on the domains of gender and race (see § 2). We also discover that within these domains, certain target categories are more likely to yield negatively stereotyped inferences; specifically, the categories of *poor*, *working class*, and *formerly incarcerated* people. For human judgements, we observe that annotators disagree the most on the questions about whether an inference is based on the identity mentioned in the premise, as well as whether it reflects a stereotype or not. This appears especially true when the hypotheses include less well-known stereotypes, or stereotypes toward groups that are not typically stereotyped in US culture.

Significant limitations. The most significant limitation is our focus on English and US culture, as discussed above; this means that while we may recognize negative stereotypes of (for instance) *Latin Americans* in the US, we will likely miss negative stereotyping of *Roma* in Spain. Our work is also limited to just six stereotype domains, and we do not explicitly account for intersectionality. While our annotators are of diverse cultural backgrounds, another limitation is that there are only four, limiting the breadth of our analysis of annotator positionality.

2 Related Work

Our work builds on a growing body of recent computational literature on stereotypes (often termed "bias"). A major focus of past work has been on the domains of gender and race, across a variety of tasks including language modeling, coreference resolution, natural language inference, machine translation, and sentiment analysis (Sheng et al., 2019; Rudinger et al., 2018; Lu et al., 2018; Dinan et al., 2019; Rudinger et al., 2017; Kiritchenko and Mohammad, 2018); Blodgett et al. (2020) provide a review. There has simultaneously been a range of work aimed to mitigate problems of stereotyping in NLP systems, including many in the space of text generation (Sheng et al., 2020; He et al., 2019; Clark et al., 2019; Huang et al., 2020). In comparison to this line of work, our main extensions are (a) a broader range of domains considered, and (b) a specific focus on the generation of entailed text.

Several very recent papers have also explored other stereotype domains, including disabilities (Hutchinson et al., 2020), and larger collections of domains similar to ours. For instance, two recently released datasets by Nadeem et al. (2020) and Nangia et al. (2020) provide example texts and measurements to determine if a language generation system exhibits stereotyping toward the domains of nationality, race, religion, profession, orientation, disability, age, appearance, socioeconomic status, and gender. Li et al. (2020) probes transformer-

---

[2] Although we focus on the US, many of these categories are salient globally, especially gender, sex and class (Fiske, 2017). Other domains may also be globally relevant due the US's export of stereotypes through media (Crane, 2014).

based question answering models on stereotypes towards gender, nationality, religion, ethnicity domains. Here, question/answer pairs are constructed where a particular answer either does or does not contain a known stereotype. Our analysis is similar to these, with a slightly broader set of domains, a focus on inference rather than question answering, and a post-hoc analysis of what a model actually produces, rather than a predefined dataset of potentially expected stereotypes. An advantage of the dataset approach is re-usability, while an advantage of the post-hoc analysis approach is that it may capture stereotypes we had not thought of a priori.

3 Data Generation & Annotation

We conduct experiments to study stereotypes with a focus on generative text inference tasks. To do that, we construct a list of stereotype domains and a list of target categories for each of the domains. We also manually create a list of underspecified, real-life context situations for instantiated premises. Using these constructed premises, we conditionally generate hypotheses from three models. The resulting premise-hypothesis pairs are then judged for stereotypes by four humans annotators.

3.1 Background on Text Inference Tasks

We consider two text inference tasks: natural language inference (NLI; also *textual entailment*) and commonsense inference (CI); both are typically framed as classification tasks (Dagan and Glickman, 2004; Bowman et al., 2015; Williams et al., 2018). Namely, given a text *premise* p and a text *hypothesis* h, determine the relationship r between the two. For NLI, the typical set of relationships are $r = \text{ENTAILED}$ if p logically entails h, CONTRADICTED if h contradicts p, and NEUTRAL otherwise.

While CI tasks are less standardized than NLI, here we follow the *if-then* formulation used in ATOMIC (Sap et al., 2018) and COMET (Bosselut et al., 2019). There, a premise is a short sentence describing a scenario involving a generic participant ("PersonX"). Associated with each premise is a multiplicity of hypotheses, capturing likely or plausible inferences belonging to one of several predefined relation types, e.g., X-INTENT (inferences about PersonX's intent) or X-EFFECT (inferences about the scenario's effect on PersonX). See appendix Table A1 for the full list of relations.

Following Bosselut et al. (2019), we consider text inference from a generative perspective: given a premise p and relation type r, generate a hypothesis h that bears that relation to p. This framing enables us to explore what trained models have learned about inference, without providing explicit hypothesis prompts. For NLI, we focus on two finetuned GPT-2 models using the SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018) datasets. For CI, we use the COMET model (Bosselut et al., 2019), which is trained on the ATOMIC (Sap et al., 2018) dataset.[3] More details are in Appendix A.

3.2 Experimental Setup

Our goal is to construct hypotheses like "The [TARGETCATEGORY] person is cutting up fish for dinner." To this end, we define a set of domains and target categories, and a set of context situations.

Stereotype Domains. Certain social categories are more likely to be referenced in stereotyped inferences. As discussed in § 2, previous works have mostly focused on two domains: gender (typically *men* vs. *women*) and race (typically *Black* vs. *White*). To broaden the space of consideration, we mostly follow Nangia et al.'s (2020) taxonomy of stereotype domains, which is a narrowed version of US Equal Employment Opportunities Commission's list of protected categories; to this set, we also add the *political stance* domain. Overall, the six stereotype domains we choose to focus on are: race/color/ethnicity/ancestry (henceforth, *race*, *gender*, *religion*, *nationality*), socioeconomic status (henceforth, *socio*), and political stance (henceforth, *politics*).

Target Categories. Within each stereotype domain, our goal is to select target categories that are (a) common and (b) most likely to be the target of stereotypes in the United States; we rely on authoritative sources to assembled these lists. For *religion*, *nationality*, *race*, *socio*, and *politics*, we mostly follow the lists from outside resources (such as Pew, the World Atlas, and Wikipedia; see Appendix C); for *gender*, we manually create the list. Note that many categories have multiple possible labels; we attempt to use ones that are currently generally benign and affirming, to avoid triggering stereotypical inferences based on an explicitly negative represen-

---

[3] We note that even when CI is not framed as a generative task, CI datasets have been *created* using generative textual inference models (Zhang et al., 2017; Zellers et al., 2018).

tation of the target category[4]. For instance, we use *formerly incarcerated person* instead of *felon* and *Black* or *African American* instead of older and/or related derogatory terms.[5] This choice, however, means that our results do not capture the full extent of stereotypes, as more derogatory terms often come with stronger stereotypical inferences, even for the same category (Devine and Baker, 1991). Table 2 is the list of our 71 target categories, which also includes spelling variations for some categories (e.g., presence or absence of a hyphen). In our analysis, we merge multiple terms under one category into a single label (e.g., *Latino*, *Latina*, and *Latin American* are analyzed as *Latin*). The table of substitutions is provided in the supplement.

Context Situations. For our experiments, we manually construct a list of 102 real-life contexts into which the target categories will be inserted. Our aim here is to create premises that describe situations that are unlikely themselves to lead to the production of stereotypes in hypotheses, independently of the target category. When we construct the list we follow two strategies, thus creating two types of contexts. The first type, DAILY ACTIVITIES are neutral contexts in which it is difficult to imagine a direct extension to a stereotype. These are situations that do not beg for any particular continuation, such as "PERSONX holds a cup" or "PERSONX goes for a walk". The second type, TRIGGERS, are situations that are neutral, but which may trigger some stereotypical output for different target categories. For instance, with the premise: "PERSONX is holding a knife", plausible hypotheses include "PERSONX is cooking", "PERSONX is being attacked", and "PERSONX is attacking somebody." See the supplement for the full list.[6] One limitation of using these context templates is that the resulting premise can be somewhat unnatural. However, in order to control triggers other than the tested target category, we opted for simple, if sometimes stilted, over more complex.

3.3 Data Generation

We are interested in model behavior for different target categories in our constructed contexts. We generate around $130k$ example premises for later human annotation from the cross-product of:

(a) target category (71 total),
(b) context situation (103 total),
(c) model (3: SNLI, MNLI, COMET), and
(d) entailment relation (1 for NLI and 3 for CI[7]),

and generating three hypotheses for each.

To get an initial sense of the outputs generated, we ran the Hugging Face sentiment analysis system on the generated hypotheses[8]; details are in Appendix B. For each example, it gives a label "negative" or "positive" with an associated probability. For instance, "African Americans participate in demonstrations" gets a negative label, with probability near chance: 54%. Overall, the hypotheses generated from three models have around half negative hypotheses and half positive. In general, CI (COMET) tends to produce on average slightly more negative inferences (56%) than NLI (51% for both MNLI and SNLI).

3.4 Human Annotation

The annotation is done by the four authors of this paper.[9] For annotation, we sample a subset of examples from the generated dataset. In total, we annotate 1281 examples, which are generated with 21 situations (out of 102) and 61 categories.[10] Among the 1281 examples, 255 examples (which consists of 3 situations with all categories and 4 categories with all situations) are annotated by all four annotators in order to measure annotator agreement. The remaining 1026 examples are randomly divided to be annotated by only one of the annotators.[11]

Annotation guidelines. To examine how model behaviors and human judgments vary for different

---

[4] Some target categories might be ambiguous. For instance, *Indian* can mean Native American, *conservative* can mean just a conservative person and not a political affiliation, and *fascist* is mostly a historical category (now is used more as an insult).

[5] In some cases this is difficult. For instance, different people who may generally be referred to as Indigenous, Native American, or American Indian may identify with one of those terms, or may rather prefer to be referred to by the name of their tribe (Blackhorse, 2017).

[6] We adjusted the target terms accordingly for the premise to sound more natural (e.g. we use "A poor person" and "An atheist person" rather than "A poor" and "An atheist").

[7] For NLI, we only consider the *neutral* relation, because with other relations we observe structurally limited hypotheses (e.g., CONTRADICTION tends to produce hypotheses which say the opposite of the premise). For CI, we pick three relations: X-ATTR, X-WANT, and X-EFFECT; see §3.1

[8] https://huggingface.co/transformers/examples.html

[9] Annotators consist of one Russian cis woman, one Chinese cis woman, one white American cis man, and one white American cis woman. All annotators hold advanced degrees.

[10] Out of 71 target category terms, we merge terms that are spelling variations of one category, which results in 61 target categories in total. When generating examples for each category, we use these terms rotationally.

[11] Annotated data available at: https://github.com/AnnaSou/stereotypes_generative_inferences.

Label	Annotation Question
VALID?	Does the hypothesis include more information than the premise? Is it grammatically correct? (If not, skip the remaining questions)
PLAUS?	Is the hypothesis plausible given the premise? (If not, skip the remaining questions).
IDEN?	The hypothesis appears to be based on the target category identity.
SITU?	The hypothesis appears to be based on the context situation.
SENTI?	What types of inferences does the hypothesis have about the target category?
STEREO?	Does the hypothesis contain known (to you) stereotypes of the target category?
WHAT?	What is the evoked association of the target category based on the hypothesis?

Table 3: Annotation questions.

target categories in our neutral contexts, we have annotators answer the questions in Table 3.

▶ **VALID?**: annotators decide whether the hypothesis is grammatically correct and includes more information than the premise. Possible answers are *yes* or *no*. For instance, given "A Catholic person saw dust on the floor.", an *invalid* hypothesis is "The dust on the floor PERSONX."

▶ **PLAUS?**: annotators decide whether the hypothesis is plausible given the premise. The possible answers are *yes* or *no*. A plausible hypothesis means the hypothesis is logically consistent with the premise. For instance, given "A Catholic person saw dust on the floor.", an *implausible* hypothesis is "The dust on the floor was the same as tan."

▶ **IDEN?**: annotators choose whether the hypothesis appears to be based on the target category's identity to one of the following degrees: *yes*, *maybe yes*, *not sure*, *maybe no*, *no*. For example, given the same premise "A Buddhist person is sleeping.", the hypothesis "The person is poor." is likely based on the target category identity.

▶ **SITU?**: annotators choose whether the hypothesis appears to be based on the situation: *yes*, *maybe yes*, *not sure*, *maybe no*, *no*. For instance, given the premise "A Buddhist person is sleeping.", the hypothesis "The person is having a happy dream." is based on the situation. It is possible for an inference to be based on both situation and identity, as in the same premise with hypothesis "The poor person is having a happy dream."

▶ **SENTI?**: annotators identify if the hypothesis expresses ppositive or negative sentiment toward the target person on a five item Likert scale: from *negative*, *maybe negative*, *neutral* to *maybe positive*, *positive*. For example, "The American person is rude and entitled" is a negative inference, whereas "The woman makes sure her family is happy" is a maybe positive inference.

▶ **STEREO?**: annotators choose whether the hypothesis conforms to stereotypes they know; options are *yes*, *no*, or *maybe*. People's perceptions on whether a hypothesis is stereotypical or problematical are highly subjective (Hazen et al., 2020), and one research question we seek to answer is how annotators' levels of agreement may vary for different target categories (see §4.2). Overall, stereotypes can harmful even when positive; the *nurturing* stereotype of women is used to justify exclusion from professional settings (Tinsley et al., 2009), and, for women who do not conform to the stereotype, can lead to increased sexual harassment (Leskinen et al., 2015).

▶ **WHAT?**: annotators write the possible associations evoked from the hypothesis as free text.[12]

4 Findings & Analysis

We analyze our results from two perspectives: model behavior and human judgment. We first discuss the models' behaviors for different stereotype domains, target categories, and situations. We then explore how human judgments deviate depending on target categories and domains, and provide annotator agreement analysis. We are also interested throughout in evidence of *defaulting* (Rosch, 1975)—the observation that some target categories often go unremarked (e.g., "woman" may often be used to mean "cis woman", and "American" may often be used to mean "white American")—in the generations, for instance because the models are unused to seeing language with explicit defaults.

In analyzing our results, we start from the normative position that identical model behavior across target categories is *insufficient*, despite being a prevalent goal in past literature (Blodgett et al., 2020, *inter alia*). We take this position for two reasons. First, because if a person of some category sees an offensive stereotype about themselves in a downstream system, they are harmed even if the same output is generated for other categories. Second, because social hierarchies enable members of some groups to more easily subjugate members of other groups, the same oppressive stereotypes are

---

[12] We left open the possibility that some generated text may contains *anti*-stereotypes, and had annotators mark these. However, they were exceedingly rare and had very low agreement, and so we exclude this question from the remainder of our analysis.

more likely to harm people in categories lower on the social hierarchy than those higher.

For example, for the premise "PERSONX has a child", the generated hypothesis from MNLI is "PERSONX is not allowed to have a child" for *African American*, *Asian American*, and *Amish*. This evokes historically forced sterilization of African American women (Prather et al., 2018), the recently canceled Chinese one-child policy (Xie et al., 2018), and stereotypes of Amish families having many children[13]. These stereotypes are harmful for each of these groups, even though it is also generated for others. The degree of harm also varies by category; for instance, if the same hypothesis were generated for *white American*, it is unclear that would cause much harm. More examples from COMET are in appendix Table A2 and supplement for SNLI and MNLI.

4.1 Model Behavior

With the collected human annotations, we seek to answer the following research questions:

1. Which models and domains are more prone to invalid and implausible hypotheses?
2. What target categories have more hypotheses based on identity?
3. Which models and domains are more likely to lead to stereotyped hypotheses? Which target categories are more prone to negative inferences?
4. What are the commonly evoked associations?

We address each question in turn, expanding on the question, motivating it, and presenting the results.

1. Which models and domains are more prone to invalid and implausible hypotheses? We aim to reveal model's capability of generating plausible hypotheses. It is harmful if models fail to do so for some particular target categories, because then any downstream system will not be able to rely on such inference model. Additionally, we use this question as a filtering step.

For each of the stereotype domains (and models), we wish to know what percentages of generated hypotheses are *illegitimate*. By illegitimate, we mean hypotheses that are grammatically incorrect, do not contain any additional information to the premise, or are implausible. We compare the results across models and find that the MNLI model is more prone to generate illegitimate hypotheses than SNLI and COMET models (21.9% versus 7.4% and 8.1% for SNLI and COMET respectively.)

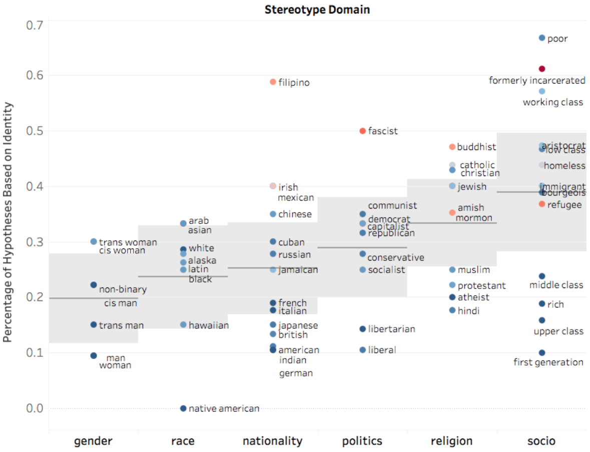

Figure 1: Annotation results for the question of what portion of models' generations are based on identities across target categories. The y-axis is the fraction of hypotheses which are based on identities. For each stereotype domain on the x-axis, the grey line and the shaded box represent the average percentage in that domain and its 95% confidence interval. Inferences based solely on target categories' identities are color-coded. The redder the more inferences are based solely on identity. The darkest blue corresponds to zero percentage of inferences based exclusively on identity.

We then compare the percentage across stereotype domains to see for which domain the inference systems are more likely to fail in generating legitimate hypotheses. The results are shown in appendix Figure A3. We find that the inference models generate more illegitimate hypotheses for target categories of *religion*, *socioeconomic status*, *race*, and *nationality* ($\sim 13\%$) than for target categories of *gender* and *politics* ($\sim 7\%$). We also find that the percentage of illegitimate hypotheses is extremely high for *British*, *Asian*, *low class*, *poor*, and *atheist*. We can also see some effect of *defaults*: *cis woman* (4.8%) generates more implausible outputs than *woman* (0%), possibly because in the training data for these models, "cis woman" is rarely seen.

2. What target categories have more hypotheses based on identity? When target categories are embedded in real-life, neutral situations, we prefer a model that generates outputs more keyed to the situation than to the identity of the person mentioned. If a model frequently makes inferences based on the identities and ignores the situations for some target categories, this can lead to harms related to those categories.

To perform this analysis, we first filter out invalid

---

[13] https://amishamerica.com/how-many-children-do-amish-have/

and implausible hypotheses (**VALID?**, **PLAUS?**). Then among the remaining 1144 annotations, we check how many hypotheses are based on identity by looking into **IDEN?**. For this analysis, annotations of *yes* and *maybe yes* are counted as based on identity. Figure 1 shows for each target category the percentage of hypotheses (post-filtering) that are based on identity.

We find that across models, around 29% of generated hypotheses are based on identities, and that the target categories of *socioeconomic status* and *religion* focus more on identities, in comparison to *politics*, *nationality*, *race* and *gender* (39% and 33% vs. 29%, 25%, 23%, and 19% respectively). In general, we find that, on average, more vulnerable target categories have a higher percentage of hypotheses generated based on identities. (This is not universal: the target category of *aristocratic* has generations with the same level of dependency on identity as the *low class* category, despite the asymmetry in social position here.)

We are particularly interested in cases where a hypothesis is based *only* on identity and not at all on situation: this means that the model has essentially focused exclusively on a person's identity and ignored everything else. Therefore, we explore **SITU?** and check how many hypotheses are not based on situation for each target category and stereotype domain. Annotations of *no* or *maybe no* for **SITU?** are counted as not based on situation. In the results, we see that hypotheses generated about *formerly incarcerated*, *poor*, *working class*, and *Filipino* turn out to be highly dependent on identities. However, among these categories, *formerly incarcerated* and *Filipino* have 38.9% and 23.5% of hypotheses exclusively based on identities (and not situation), while *poor* and *working class* categories only have 6.7% and 14.3% of such inferences. (These percentages are color-coded in Figure 1: higher percentages in red, lower in blue.) Overall, the highest percentage of inferences based exclusively on identities is for *religion* domain 14.2% and the lowest is for *gender* domain 4.4%. Similar to our observation on **IDEN?**, we find vulnerable target categories tend to have more hypotheses that completely ignore the situation. Categories like *formerly incarcerated*, *Asian*, *Filipino*, *refugee*, *Amish*, and *fascist* have a high percentage of hypotheses generated independent of situation. On the other hand, categories such as *white*, *woman*, *man*, *trans man*, *French*, and *American* have no hypotheses in which the situation is ignored.

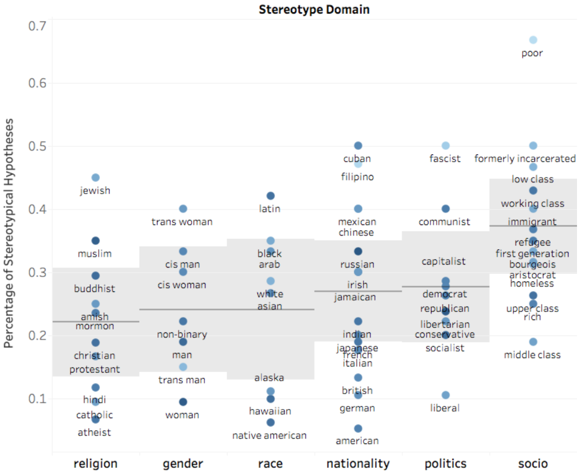

Figure 2: Annotation results for the question which target categories and stereotype domains are more likely to have stereotyped hypotheses. The y-axis represents the fraction of stereotyped hypotheses for each target category. The color of the circle encodes the overall percentage of negative inferences for each target category (The darker the color the more negative inferences such target category has. The lightest color corresponds to 33.3% of negative inferences while the darkest color corresponds to 77.8%. Note: not all negative inferences are stereotyped inferences and vise versa.). For each stereotype domain, the grey line and the shaded box represent the average percentage and its 95% confidence interval.

3. Which models and domains are more likely to lead to stereotyped hypotheses? Which target categories are more prone to negative inferences? Although the previous question reflects how much the models' generations depend on identity information, we still want to see directly how frequently explicitly stereotypical hypotheses are generated across different models and stereotype domains. If some model consistently generates hypotheses with stereotypes of some target categories, then it can cause representational harms to people in those target categories.

To answer this question, we delve into annotations for **STEREO?**. For **STEREO?**, votes for *yes* and *maybe* are categorized as containing stereotypes, while *no* is categorized as do *not* contain stereotypes. For **SENTI?**, we count *positive* and *maybe positive* as positive inferences, and *negative* and *maybe negative* as negative, and *neutral* as neither positive nor negative. We find the percentages of stereotyped hypotheses and negative hypotheses

Category	Association
Immigrant	poor, illegal, criminals, farmers, desperate
Trans man	avoided, sinful, sick, sex work
Muslim	religious, aggressive
Jewish	religious, wealthy, unpleasant
Mormon	immoral, selling drugs, sinful
capitalist	greedy, rich, mean
Asian	gangs, smart, not respected, Chinese
poor	sad, needy, drugs, avoided, weak
Cuban	alcoholics, tacos, friendly, criminals
Russian	violent, alcoholics, rude, intellectual
American	pro-war, proud, selfless

Table 4: The keywords from evoked associations for some target categories.

are similar across all three models: around 28% contain known stereotypes and 59% are with negative sentiment. Detailed results across stereotype domain comparison are shown in Figure 2. Overall, these models generate more stereotyped hypotheses for domains of *socioeconomic status*, *politics*, and *nationality*, compared to domains of *race*, *gender*, and *religion*. The most stereotyped categories from each domains are *trans woman*, *Cuban*, *Latin American*, *Fascist*, *Jewish*, and *poor*. In terms of percentage of negative inferences, *socioeconomic status* has the least negative inferences of 54% and *religion* has the highest of 63%.

Moreover, we find that the target categories that are more affected by stereotypes are not necessarily prone to have negative inferences. For instance, *poor* has 67% or stereotyped inferences, while only 33% of those are negative. On the other hand, *woman* have less than 10% of stereotyped inferences, but 76% are negative. Overall, all models produce negative inferences even for categories with a low level of stereotyping: models achieve some parity in distributing negative generations across domains, but, as discussed in the conclusion, this does not necessarily make the models fair.

4. What are the evoked associations? In Table 4, we provide keywords that are associated by annotators with the target categories. The full list is in supplementary materials. Some of these associations relate to the existing stereotypes, some do not. For instance, *democrat* based on the generated hypotheses are associated with "rude", "causing trouble", and "making deals." Even though there might be no related stereotypes, such hypotheses still might be harmful to the target category.

4.2 Human Perceptions of Stereotypes

We explore human perceptions of stereotypes. It is known that people's perceptions on whether a hypothesis is stereotypical or not can be subjective (McGarty et al., 2002). Overall, we find that annotators highly agree **VALID?** on **PLAUS?** with 91.8% and 85.8% agreements respectively, and highly disagree on **IDEN?**, **SENTI?**, and **STEREO?** with 39.2%, 37%, and 21.8% scores respectively.

To calculate annotator agreement, we use the 255 examples that were annotated by all four annotators. Throughout this section, we calculate *agreement* as the fraction of times all annotators give the same answer.[14] We filter out examples that have fewer than three annotations. This may happen because, for example, some annotators mark the example as invalid or implausible and thus skip the rest of the questions. Then for examples that have four annotations, we randomly pick three of them to calculate agreement.

Agreement on Hypotheses Origins. Annotators agree more on the situation question (66.5% agreement) than the identity question (39.2%), likely because the situation question is defined purely on the bases of the stated hypothesis, while the identity question depends on annotators' perceptions of that identity.

We observe zero agreement on whether situation is based on identity or not for several target categories such as *white*, *Asian*, *Mormon*, *liberal*. On the other hand, categories of *Jewish*, *communist*, and *atheist* have complete agreement (100%). In general, we see that annotators have more disagreements on the questions that involve target categories' identities, most likely because these rely more on cultural context.

Agreement on Stereotyped Hypotheses. Overall, for **STEREO?** annotators agree on only 21.8% of the examples. We observe that annotators have complete agreement on categories that are either highly stereotyped such as *homeless*, *trans man*, *communist* or have very little widely known stereotypes such as *atheist* and *Native American*. In addition, both categories of *atheist* and *Native American* have a very low level (around 6%) of stereotyped hypotheses. We suspect that it is simply eas-

---

[14] We choose to report the percentage of agreements rather than an inter-annotator agreement statistic (e.g., Fleiss's kappa or Krippendorff's alpha) because it is more easily interpretable than coefficients and we *expect* annotations to be skewed to some choices for questions like **VALID?** and **PLAUS?**.

ier for annotators to detect stereotypes for typically stereotyped categories.

There are also some exceptions like *cis woman*, which has a high percentage of stereotyped hypotheses (33.3%) but has low annotator agreement (0%). We suspect the reason is that the stereotypes towards *cis woman* in our dataset are not well-known existing stereotypes, which tends to lead to more disagreements. As an example of annotator disagreement for **STEREO?**, given the premise "A Latin American person has a child," annotators disagreed about whether the hypothesis "The person then gets pregnant" represents a stereotype or not; those who annotated it as stereotype did so because it evokes a fertility threat stereotype (Gutiérrez, 2009), a stereotype not known by all annotators. Overall, we find that annotators' perception and ability to detect stereotypes varies based on their knowledge of the target categories, arguing that a large—and diverse—set of annotators is important for problems around stereotyping.

Because of the subjective nature of these annotations, we further consider agreement at two levels: (1) how often do all annotators agree, and (2) how often do a randomly chosen pair of annotators agree. High percentages for (1) indicate that a question is not particularly subjective (or that all annotators have the same subjective opinion), while a small value of (1) but large value of (2) indicates that a strong degree of subjectivity exists, but that even among four annotators some of them frequently agree. For (1), agreement on the more objective questions such as hypotheses correctness, plausibility, and relatedness to situations have 91.0%, 82.9%, and 66.7% agreement. On the other hand, we observe zero agreement for stereotypes, 24.9% for identity agreement, and 26.6% for sentiment agreement. This suggests—especially for the 0% for stereotypes—that getting more annotators is needed in order to feel confident about coverage. For (2), we observe overall a high level of agreement for correctness, plausibility, and relatedness to situations with 95.3%, 88.0%, and 82.5% agreement respectively. We additionally observe a reasonable level of agreement for sentiment and stereotypes: 57.1% and 61.2% respectively. Agreement regarding whether a hypothesis is based on identity is the lowest at 50.1%. This suggests that while annotators *can* agree on these questions, there is sufficient subjectivity that all four rarely do.

5 Conclusion & Discussion

We investigated stereotypes in generative inference models from two perspectives: model behavior and human perceptions. We find that the most stereotyped domains by our NLI and CI models are *religion* and *socioeconomic status*, rather than *gender* and *race*, which are the focus of many previous studies. On the other hand, the stereotype domains and target categories we studied is not exhaustive either; even in a US context, most obviously we are missing domains related to disability, beauty/body type, sexuality, age, pregnancy, and so on.

Moreover, since we investigated inference tasks, instead of focusing on models generating "fair" hypotheses over target categories, we are much more concerned with how each hypothesis is perceived by a human reader. We observe some cases in which the models generate similar outputs across several target categories, but for which the generated text is highly stereotyped and thus may cause representational harms.

Finally, from human judgments, though our work is limited to US culture and the backgrounds of our four annotators, we find that people's different backgrounds influence their perceptions of stereotypes. Even though this might result in lower agreement scores, such diversity can be actually useful (Pavlick and Kwiatkowski, 2019) in helping to explore the problem space. Overall, when deploying a system, it is important to make a wise consideration on annotators' backgrounds. Considering annotators of different age, professions, education, and culture might give a multiplicity of valuable perspective on stereotypes.

Acknowledgments

The authors are grateful to all the reviewers who have provided helpful suggestions to improve this work. We also thank the CLIP lab at the University of Maryland for comments on previous drafts.

A Implementation Details

Text Inference Datasets. For training our generative inference models, we use three datasets: two of them cover natural language inference, and one is for commonsense inference.

The **Stanford Natural Language Inference (SNLI)** corpus was created by Bowman et al. (2015).It contains about 570k examples. Each example has a premise, relation (entails, contradicts, neutral), and related hypotheses. Premises were taken from captions for the Flickr30k corpus (Plummer et al., 2015). Hypotheses are written by crowd workers as independent image captions.

The **MultiGenre Natural Language Inference (MNLI)** corpus by Williams et al. (2018) was built following the SNLI structure. It has 433k examples. MNLI, being much broader than SNLI, covers ten different domains. It has a range of styles, degrees of formalities, and topics.

The **Atlas of Machine Commonsense (Atomic)** corpus was introduced by Sap et al. (2018). The corpus has about 300k events associated with 877k textual descriptions of inferential knowledge. Such knowledge is collected and organized as if-then relations for hypotheses specifically about a person in a premise named *PersonX*. There are 4 groups of relations (see Table A1), each group has several if-then relations. In total, there are 9 if-then relations. For instance, given the *premise* = “PersonX drops a glass”, the *relation* = “Causes for PersonX - because PersonX wanted”, then the *hypothesis* = “to get a glass”.

Type of Relations	**Inference dimension**
If-Event-Then-Mental-State	xIntent, xReact, oReact
If-Event-Then-Event	oEffect, oWant, xNeed, xEffect, xWant
If-Event-Then-Persona	xAttr

Table A1: List of relations for Commonsense Inference model (Sap et al., 2018).

Models. For our experiments, we build three models – two for NLI and one for CI. For the NLI systems, we finetune a GPT-2 language model (Radford et al., 2019) with the MNLI and SNLI datasets separately for 4 epochs with a batch size of 2. This process takes about 3 hours on a single GPU. We adapt Hugging Face transformers Wolf et al. (2020) for both finetuning and generation. For CI, we use the pre-trained Commonsense Transformers on Atomic (COMET)[15] model (Bosselut et al., 2019). COMET constructs commonsense knowledge bases from the transformer language model (Radford et al., 2018) with multi headed attention, which was trained on ATOMIC dataset. COMET can produce inferences not only about familiar examples, but also about unseen examples. The range of COMET outputs were evaluated by crowd workers and judged as correct.

B Sentiment analysis

Hugging Face sentiment analysis system [16] is used on all $130,000$ generated hypotheses for three models. For CI (COMET), averaged all target categories, 56% of inferences has negative sentiment. The domain with the most negative generations is *politics*, with average 67% negative inferences, and the most affected target category is *fascists* with 85% negative. The two next most negative domains are *socioeconomic status* and *religion* with about 61% negative. The most negative categories in these are *protestants* and *formerly incarcerated*, which are 87% and 79% negative, respectively.

For MNLI, the results have less variance: the overall average level of negative sentiment is about 51%. The most negative domain is *politics* (54%) and category *fascists* (80%). The domain with the highest variance is *socioeconomic status*, ranging from 89% negative hypotheses for *poor* to 24% for *wealthy* (with an overall average of 30%). The SNLI model has even more uniform distribution within stereotype domains and all target categories have narrow distribution within 45%-52% with the only most extreme case for *fascists*: 64%.

[16] https://huggingface.co/transformers/examples.html

Target Category	Hypothesis
African American	The person then gets called racist.
Black	The person is seen as loving.
Latin American	The person then gets pregnant.
Arab	The person is seen as loving.
Pacific Islander	The person then has to buy food.
Latina	The person is seen as caring.
White American	The person is seen as caring.
Native Hawaiian	The person then gets a lot of respect from people.
Asian American	As a result, others want to go to a restaurant.
Hispanic	The person is seen as untrustworthy.
American Indian	Then child is protected.
Formerly incarcerated	The person then gets arrested.
Filipino	As a result, others want cry.
American	The person is seen as a parent.
British	Then child cries.
Jamaican	The person then gets pregnant.
Mexican	The person then is asked to stop by a counselor.
German	As a result, others want cry.
Italian	The person then is asked questions.
Cuban	As a result, others want to have a good life.
Russian	The person then gets pregnant.
cis woman	The person is seen as loving.
woman	As a result, others want to get a new baby.
man	The person is seen as responsible.
trans man	The person is seen as responsible.
trans woman	The person then is a father.
Buddhist	The person is seen as a parent.
Catholic	The person is seen as pious.
Jewish	As a result, others want cry.
Japanese	The person then gets called a father.
Amish	As a result, others want go to church.
Muslim	Others then are protected by personx.
Mormon	The person is seen as a sinner.
Protestant	Others then cry in sadness.
communist	The person is seen as racist.
capitalist	The person then gets a raise.
conservative	Others then are loved.
republican	The person is seen as racist.
fascist	Then child is abused.
socialist	Others then get a new home.
libertarian	Others then are taken care of.
liberal	The person then gets a raise.
democrat	The person is seen as a racist.
bourgeoisie	The person then gets pregnant.
homeless	The person then gets a new home.
immigrant	Others then they learn about Personx 's culture.
formerly incarcerated	The person is seen as unintelligent.
upper class	The child is taken care of.
rich	The person then gets gifts.
wealthy	As a result, others want have a good life.
refugee	The person is seen as caring.
lower class	The child is taken care of.
middle class	Others then learn.
aristocrat	Then child cries from sadness.

Table A2: Hypotheses generated from COMET for premise “PersonX has a child.” across target categories.

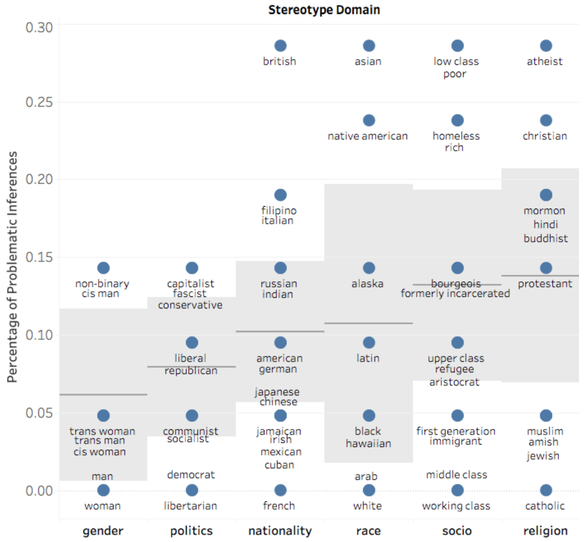

Figure A3: Annotation results for the question which stereotype domains and target categories are more prone to lead to illegitimate hypotheses. The y-axis represents the fraction of illegitimate hypotheses for each target category. For each stereotype domain on the x-axis, the grey line and the shaded box represent the average percentage and its 95% confidence interval for this domain.

HySPA: Hybrid Span Generation for Scalable Text-to-Graph Extraction

Liliang Ren, Chenkai Sun, Heng Ji, Julia Hockenmaier
University of Illinois, Urbana Champaign
Department of Computer Science
`{liliang3,chenkai5,hengji,juliahmr}@illinois.edu`

Abstract

Text-to-Graph extraction aims to automatically extract information graphs consisting of mentions and types from natural language texts. Existing approaches, such as table filling and pairwise scoring, have shown impressive performance on various information extraction tasks, but they are difficult to scale to datasets with longer input texts because of their second-order space/time complexities with respect to the input length. In this work, we propose a **Hy**brid **SP**an Gener**A**tor (**HySPA**) that invertibly maps the information graph to an alternating sequence of nodes and edge types, and directly generates such sequences via a hybrid span decoder which can decode both the spans and the types recurrently in linear time and space complexities. Extensive experiments on the ACE05 dataset show that our approach also significantly outperforms state-of-the-art on the joint entity and relation extraction task.[1]

1 Introduction

Information Extraction (IE) can be viewed as a Text-to-Graph extraction task that aims to extract an information graph (Li et al., 2014; Shi et al., 2017) consisting of mentions and types from unstructured texts, where the nodes of the graph are mentions or entity types and the edges are relation types that indicate the relations between the nodes. A typical approach towards graph extraction is to break the extraction process into sub-tasks, such as Named Entity Recognition (NER) (Florian et al., 2006, 2010) and Relation Extraction (RE) (Sun et al., 2011; Jiang and Zhai, 2007), and either perform them separately (Chan and Roth, 2011) or jointly (Li and Ji, 2014; Eberts and Ulges, 2019).

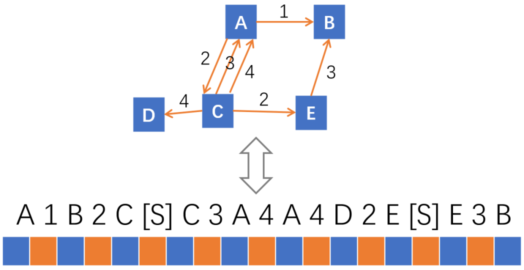

Figure 1: We represent directed multigraphs as *alternating* sequences of nodes (blue) and edges (orange). Here, the graph is traversed by Breadth First Search (BFS) with an ascending ordering of nodes and edge types. "[s]" or [SEP] is a virtual edge type, representing the end of each BFS level.

Recent joint IE models (Wadden et al., 2019; Wang and Lu, 2020; Lin et al., 2020) have shown impressive performance on various IE tasks, since they can mitigate error propagation and leverage inter-dependencies between the tasks. Previous work often uses pairwise scoring techniques to identify relation types between entities. However, this approach is computationally inefficient because it needs to enumerate all possible entity pairs in a document, and the relation type is a *null* value for most of the cases due to the sparsity of relations between entities. Also, pairwise scoring techniques evaluate each relation type independently and thus fail to capture interrelations between relation types for different pairs of mentions.

Another approach is to treat the joint information extraction task as a table filling problem (Zhang et al., 2017; Wang and Lu, 2020), and generate two-dimensional tables with a Multi-Dimensional Recurrent Neural Network (Graves et al., 2007). This can capture interrelations among entities and relations, but the space complexity grows quadratically with respect to the length of the input text, making this approach impractical for long sequences.

Some attempts, such as Seq2RDF (Liu et al., 2018) and IMoJIE (Kolluru et al., 2020), leverage the power of Seq2seq models (Cho et al., 2014)

to capture the interrelations among mentions and types with first-order complexity, but they all use a pre-defined vocabulary for mention prediction, which largely depends on the distribution of the target words and will not be able to handle unseen out-of-vocabulary words.

To solve these problems, we propose a first-order approach that invertibly maps the target graph to an alternating sequence of nodes and edges, and applies a hybrid span generator that directly learns to generate such alternating sequences. Our main contributions are three-fold:

- We propose a general technique to invertibly map between an information graph and an alternating sequence (assuming a given graph traversal algorithm). Generating an alternating sequence is equivalent to generating the original information graph.
- We propose a novel neural decoder that is enforced to only generate alternating sequences by decoding spans and types in a hybrid manner. For each decoding step, our decoder only has linear space and time complexity with respect to the length of the input sequence, and it can capture inter-dependencies among mentions and types due to its nature as a sequential decision process.
- We conduct extensive experiments on the Automatic Content Extraction (ACE) dataset which show that our model achieves state-of-the-art performance on the joint entity and relation extraction task which aims to extract a knowledge graph from a piece of unstructured text.

2 Modeling Information Graphs as Alternating Sequences

An **information graph** can be viewed as a heterogeneous multigraph (Li et al., 2014; Shi et al., 2017) $G = (V, E)$, where V is a set of nodes (typically representing spans (t_s, t_e) in the input document) and E is a multiset of edges with a node type mapping function $\phi : V \to Q$ and an edge type mapping function $\psi : E \to R$. Node and edge types are assumed to be drawn from a finite vocabulary. Node types can be used e.g. to represent entity types (PER, ORG, etc.), while edge types may represent relations (PHYS, ORG-AFF, etc.) between the nodes. In this work, we represent node types as separate nodes that are connected to their node v by a special edge type, [TYPE]. [2]

Representing information graphs as sequences Instead of directly modeling the space of heterogeneous multigraphs, $\mathcal{G}$, we build a mapping $s^\pi = f_s(G, \pi)$ from $\mathcal{G}$, to a sequence space S^π. f_s depends on a (given) ordering π of nodes and their edges in G, constructed by a graph traversal algorithm like Breadth First Search (BFS) or Depth First Search (DFS), and an internal ordering of nodes and edge types. We assume that the elements s^π_i of the resultant sequences s^π are drawn from finite sets of node representations V (defined below), node types Q, edge types R (incl. [TYPE]), and "virtual" edge types U: $\forall\, s^\pi_i \in s^\pi,\ s^\pi_i \in V \cup Q \cup R \cup U$. Virtual edge types $U = \{[\text{SOS}], [\text{EOS}], [\text{SEP}]\}$ do not represent edges in G, but serve to control the generation of the sequence, indicating the start/end of sequences and the separation of levels in the graph.

We furthermore assume that $s^\pi = s^\pi_0, ..., s^\pi_n$ that represent graphs have an **alternating** structure, where $s^\pi_0, s^\pi_2, s^\pi_4, ...$ represent nodes V, and $s^\pi_1, s^\pi_3, ...$ represent actual or virtual edges. In the case of BFS, we exploit the fact that it visits nodes level by level, *i.e.*, in the order $\mathrm{p}_i, \mathrm{c}_{i1}, ..., \mathrm{c}_{ik}, \mathrm{p}_j$ (where c_{ik} is the k-th child of parent p_i, connected by edge e_{ik}, and p_j may or may not be equal to one of the children of p_i), which we turn into a sequence,

$$s^\pi = \mathrm{p}_i, \psi(\mathrm{e}_{i1}), \mathrm{c}_{i1}, ..., \psi(\mathrm{e}_{ik}), \mathrm{c}_{ik}, [\text{SEP}], \mathrm{p}_j, ...$$

where we use the special edge type [SEP] to delineate the levels in the graph. This representation allows us to unambiguously recover the original graph, if we know which type of graph traversal is assumed (BFS or DFS).[3] Algorithm 1 (which we use to translate graphs in the training data to sequences) shows how an alternating sequence for a given graph can be constructed with BFS traversal. Figure 1 shows the alternating sequence for an information multigraph. The length $|s^\pi|$ is bounded linearly by the size of the graph $O(|s^\pi|) = O(|V| + |E|)$ (which is also the complexity of typical graph traversal algorithms like BFS/DFS).

---

[2] Q includes a [NULL] node type for the case when the input text does not have an information graph.

[3] In the case of DFS, [SEP] tokens appear after leaf nodes. Parents appear once for each child.

Algorithm 1 Alternating sequence construction algorithm with BFS

```
Input  : Ordered adjacency dictionary of an information graph $G$, positions of nodes in the
         input text $p_q$, frequency of edge types in the training set $p_r$
Output : An alternating sequence $y^\pi$
Sort the nodes in $G$ according to $p_q$
For each node $v$ in $G$, sort the neighbors and the edges of $v$ according to $p_q$ and $p_r$ respectively
Instantiate $y^\pi$ as an empty list
for $u$ in $G$ do
    if $u$ is not visited then
        Initialize an empty queue $q$
        Mark $u$ as visited and enqueue $u$ to $q$
        while $q$ is not empty do
            Dequeue the a node $w$ from $q$
            if $w$ in $G$ then
                Append $w$ and all the neighbors of $w$ with their edge types to $y^\pi$
                Append the separation edge type, [SEP], to $y^\pi$
                Mark all unvisited neighbors of $w$ as visited and enqueue them to $q$
            end
        end
    end
end
Return $y^\pi$
```

Node and Edge Representations Our node and edge representations (explained below) rely on the observation that there are only two kinds of objects in an information graph: spans (as addresses to pieces of input texts) and types (as representations of abstract concepts). Since we can view types as special spans of length 1 grounded on the vocabulary of all types, $Q \cup R \cup U$, we only need $O(nm + |Q \cup R \cup U|)$ number of indices to unambiguously represent the spans grounded on a concatenated representation of the type vocabulary and the input text, where n is the maximum input length, m is the maximum span length, and $m \ll n$. We denote these indices as *hybrid spans* because they consist of both the spans of texts and the length-1 spans of types. These indices can be invertibly mapped back to types or text spans depending on their magnitudes (details of this mapping are explained in Section 3.2). With this joint indexing of spans and types, the task of generating an information graph is thus converted to generating an alternating sequence of *hybrid spans*.

Generating sequences We model the distribution $p(s^\pi)$ by a sequence generator h with parameters θ ($|s^\pi|$ is the length of the s^π):

$$p(s^\pi_i | s^\pi_0, ..., s^\pi_{i-1}) = h(s^\pi_0, ..., s^\pi_{i-1}, \theta),$$
$$p(s^\pi) = \prod_{i=1}^{|s^\pi|} p(s^\pi_i | s^\pi_0, ..., s^\pi_{i-1}),$$

We will address in the following sections how to enforce the sequence generator, h, to only generate sequences in the space S^π, since we do not want h to assign non-zero probabilities to arbitrary sequences that do not have a corresponding graph.

3 HySPA: Hybrid Span Generation for Alternating Sequences

In order to directly generate a target sequence that alternates between nodes that represent spans in the input and a set of node/edge types that depend on our extraction task, we first build a hybrid representation H that is a concatenation of the hidden representations from edge types, node types and the input text. This representation functions as both the context space and the output space for our decoder. Then we invertibly map both the spans of input text and the indices of the types to the *hybrid spans* grounded on the representation H. Finally, hybrid spans are generated auto-regressively through a hybrid span decoder to form the alternating sequence $y^\pi \in S^\pi$. By translating the graph extraction task to a sequence generation task, we can easily use beam-search decoding to reduce possible exposure bias (Wiseman and Rush, 2016) of the sequential decision process and thus find globally better graph representation.

High-level overview of HySPA: The HySPA model takes a piece of text (e.g. a sentence or passage), and the pre-defined node and edge types as input, and outputs an alternating sequence representation of an information graph. We enforce the generation of this sequence to be alternated by applying an alternating mask to the output probabilities. The detailed architecture is described in the following subsections.

3.1 Text and Types Encoder

Figure 2 shows the encoder architecture of our proposed model. For the set of node types, Q, and the set of edge types, R, and the virtual edge types, U,

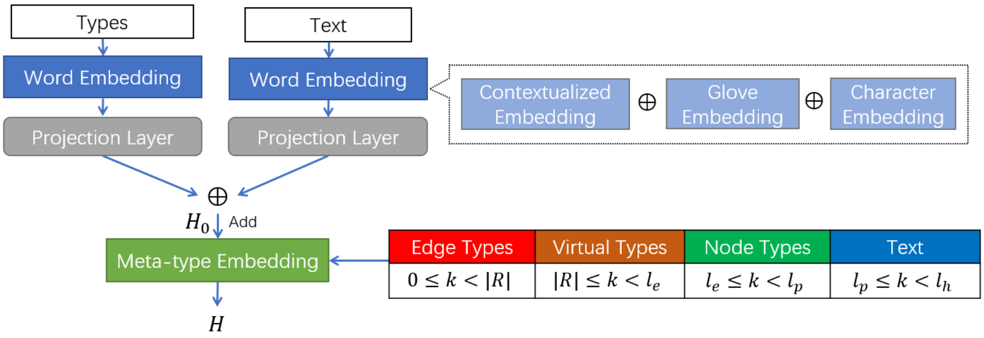

Figure 2: The encoder architecture of our model, where the $\oplus$ symbol is the concatenation operator, k is the index of the word vectors in H_0, and $l_e = |R| + |U|$. The colored table on the right indicates the assignment of the meta-types for different blocks of the concatenated word vectors from H_0.

we arrange the type list, $\mathbf{v}$ as a concatenation of the label names of the edge types, virtual edge types and node types, *i.e.*,

$$\begin{aligned}\mathbf{v} &= \hat{R} \oplus \hat{U} \oplus \hat{Q}\\ \hat{R} &= [R_1, ..., R_{|R|}]\\ \hat{U} &= [U_1, ..., U_{|U|}]\\ \hat{Q} &= [Q_1, ..., Q_{|Q|}]\end{aligned}$$

where $\oplus$ means the concatenation operator between two lists, and $\hat{R}, \hat{U}, \hat{Q}$ are the lists of the type names in the sets R, U, Q, respectively (e.g. $\hat{Q} = [$“Geopolitics”, “Person”, ...$]$). Note that the concatenation order between the lists of type names can be arbitrary as long as it is kept consistent throughout the whole model. Then, as in the embedding part of the table-sequence encoder (Wang and Lu, 2020), for each type, v_i, we embed the label tokens of the types with the contextualized word embedding from a pre-trained language model, the GloVe embedding (Pennington et al., 2014) and the character embedding,

$$\begin{aligned}E_1 &= \text{ContextualizedEmbed}(\mathbf{v}), \in R^{\,l_p \times d_c}\\ E_2 &= \text{GloveEmbed}(\mathbf{v}), \in R^{\,l_p \times d_g}\\ E_3 &= \text{CharacterEmbed}(\mathbf{v}), \in R^{\,l_p \times d_k}\\ E_4 &= E_1 \oplus E_2 \oplus E_3 \in R^{\,l_p \times d_e},\\ E_v &= E_4 W_0^T \in R^{\,l_p \times d_m},\end{aligned}$$

where $l_p = |R| + |U| + |Q|$ is the number of all kinds of types, $W_0 \in R^{\,d_e \times d_m}$ is the weight matrix of the linear projection layer, $d_e = d_c + d_g + d_k$ is the total embedding dimension and d_m is the hidden size of our model. After we obtain the contextualized embedding of the tokens of each type $v_i \in \mathbf{v}$, we take the average of these token vectors as the representation of v_i and freeze its update during training. More details of the embedding pipeline can be found in Appendix A.

This embedding pipeline is also used to embed the words in the input text, $\mathbf{x}$. Unlike the pipeline for the type embedding, we represent the word as the contextualized embedding of its first sub-token from the pre-trained Language Model (LM, e.g. BERT (Devlin et al., 2018)), and finetune the LM in an end-to-end fashion.

After obtaining the type embedding E_v, and the text embedding E_x respectively, we concatenate them along the sequence length dimension to form the hybrid representation H_0. Since H_0 is a concatenation of word vectors from four different types of tokens, *i.e.*, edge types, virtual edge types, node types and text, a meta-type embedding is applied to indicate this type difference between the blocks of vectors from the representation H_0, as shown in Figure 2. The final context representation H is obtained by element-wise addition of the meta-type embedding and H_0,

$$\begin{aligned}H_0 &= E_v \oplus E_x \in R^{l_h \times d_m},\\ H_s &= \text{MetaTypeEmbed}(H_0) \in R^{l_h \times d_m},\\ H &= H_0 + H_s \in R^{l_h \times d_m},\end{aligned}$$

where $l_h = l_p + |x|$ is the height of our hybrid representation matrix H.

3.2 Invertible Mapping between Spans & Types and Hybrid Spans

Given a span in the text, $t = (t_s, t_e) \in \mathbb{N}^2, t_s < t_e$, we convert the span t to an index k, $k \ge l_p$, in the representation H via the mapping g_k,

$$k = g_k(t_s, t_e) = t_s m + t_e - t_s - 1 + l_p \in \mathbb{N},$$

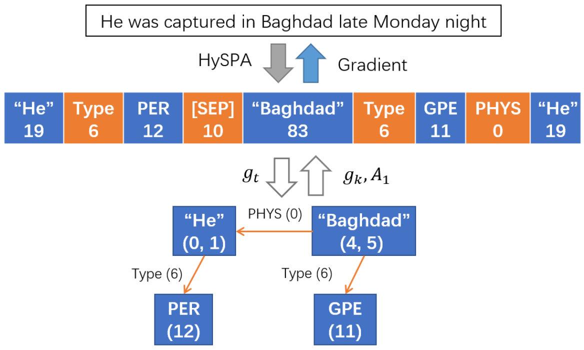

Figure 3: An example of the alternating sequence representation (in the middle) of a knowledge graph (at bottom) from the ACE05 training set, where A_1 means the Algorithm 1. We take $m = 16$ and $l_p = 19$ for this example. "19" in the alternating sequence is the index for the span (0,1) of "He", "83" is the index for the span (4,5) of "Baghdad", and "10" is the index of the virtual edge type, [SEP]. The input text (on top) for this graph is "He was captured in Baghdad late Monday night".

where m is the maximum length of spans, and $l_p = |R| + |U| + |Q|$. We keep the type indices in the graph unchanged because they are smaller than l_p and $k \geq l_p$. Since, for an information graph, the maximum span length, m, of a mention is often far smaller than the length of the text, *i.e.*, $m \ll n$, we can then reduce the bound of the maximum magnitude of k from $O(n^2)$ to $O(nm)$ by only considering spans of length smaller than m, and thus maintain linear space complexity for our decoder with respect to the length of the input text, n. Figure 3 shows a concrete example of our alternating sequence for a knowledge graph in the ACE05 dataset.

Since t_s, t_e, k are all natural numbers, we can construct an inverse mapping g_t that converts the index k in H back to $t = (t_s, t_e)$,

$$\begin{aligned} t_s = g_{t_s}(k) = &-\max(0, -k + l_p) + \\ &\lfloor \max(0, k - l_p)/m \rfloor + l_p, \\ t_e = g_{t_e}(k) = &\, g_{t_s}(k) + \max(0, k - l_p) \bmod m, \end{aligned}$$

where $\lfloor \cdot \rfloor$ is the integer floor function and $\bmod$ is the modulus operator. Note that $g_t(k)$ can be directly applied to the indices from the types segment of H and remain their values unchanged, *i.e.*,

$$g_t(k) = (k, k), \forall k < l_p, k \in \mathbb{N}.$$

With this property, we can easily incorporate the mapping g_t into our decoder to map the alternating sequence y^π back to the spans in the hybrid representation H.

3.3 Hybrid Span Decoder

Figure 4 shows the general model architecture of our hybrid span decoder. Our decoder takes the context representation H as input, and recurrently decodes the alternating sequence y^π given a start-of-sequence token.

Hybrid Span Encoding via Attention Given the alternating sequence y^π, and the mapping g_t (section 3.2), our decoder first maps each index in y^π to a span, $(t_{s_i}, t_{e_i}) = g_t(y_i^\pi)$, grounded on the representation H and then converts the span to an attention mask, M_0, to allow the model to learn to represent a span as a weighted sum of a segment of the contextualized word representations referred by the span,

$$\begin{aligned} Q &= W_1^T H_{[CLS]} + \mathbf{b}_1 \quad \in R^{|y^\pi| \times d_m}, \\ K &= W_2^T H + \mathbf{b}_2 \quad \in R^{l_h \times d_m}, \\ H_y &= \text{softmax}\left(\frac{QK^T}{\sqrt{d_m}} + M_0\right) H \quad \in R^{|y^\pi| \times d_m}, \\ M_0(i,j) &= \begin{cases} 0, & t_{s_i} \leq j \leq t_{e_i} \\ -\infty, & \text{otherwise} \end{cases} \end{aligned}$$

where $H_{[CLS]} \in R^{|y^\pi| \times d_m}$ is the $|y^\pi|$-times repeated hidden representation of the start of the sequence token, [CLS], from the text segment of H, and H_y is our final representation of the hybrid spans in y^π. $W_1, W_2, \mathbf{b}_1, \mathbf{b}_2$ are learnable parameters, and t_{s_i}, t_{e_i} are the start and the end position of the span thatwe are encoding. Note that for the type spans whose length is 1, the result of the *softmax* calculation will always be 1, which leads to its span representation to be exactly its embedding vector as we desired.

Traversal Embedding In order to distinguish the hybrid spans at different position in y^π, a naive way is to add a sinusoidal position embedding (Vaswani et al., 2017) to H_y. However, this approach treats the alternating sequence as an ordinary sequence and ignores the underlying graph structure it encodes. To alleviate this issue, we propose a novel traversal embedding approach which captures the traversal level information, the parent-child information and the intra-level connection information as a substitution of the naive position embedding. Our traversal embedding can either encode the BFS or DFS traversal pattern. As an example, we assume BFS traversal here and leave the details of DFS traversal embedding in Appendix D.

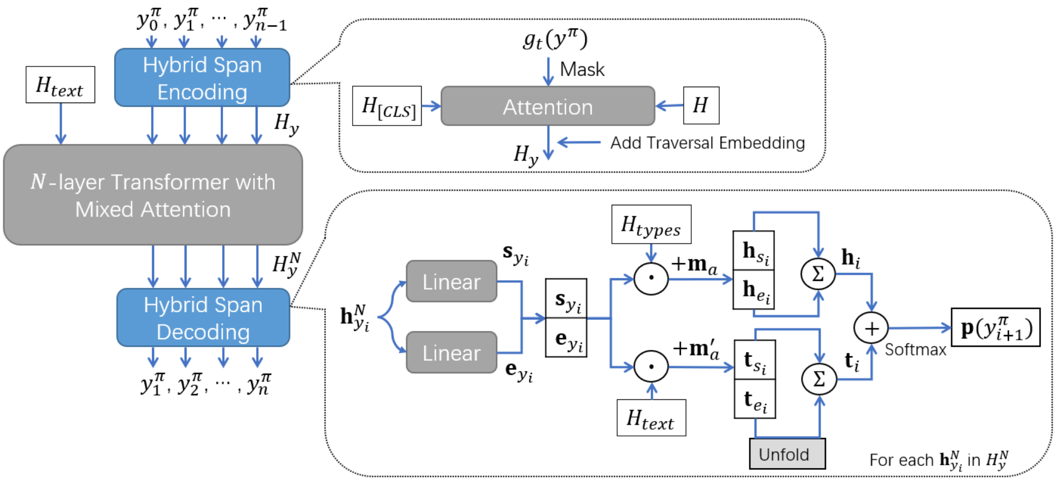

Figure 4: The architecture of our hybrid span decoder. N is the number of the decoder layers. $\oplus$ before the softmax function means the concatenation operator. H_y^N is the hidden representation of the sequence y^π from the last decoder layer. Our hybrid span decoder can be understood as an auto-regressive model that operates in a closed context space and output space defined by H.

	"He"	Type	PER	[SEP]	"Baghdad"	Type	GPE	PHYS	"He"
	+								
Level Embedding	L_1	L_1	L_1	L_2	L_2	L_2	L_2	L_2	L_2
	+

	+								
Tree Embedding	T_1	T_2	T_3	T_0	T_1	T_2	T_3	T_4	T_5

Figure 5: An example of BFS traversal embedding for an alternating sequence, ["He", Type, PER, [SEP], "Baghdad", Type, GPE, PHYS, "He"]. Our traversal embedding is the sum of the level embedding, the parent-child embedding and the tree embedding.

Our BFS traversal embedding is a pointwise sum of the level embedding, L, the parent-child embedding, P, and the tree embedding, T of a given alternating sequence, y,

$$\text{TravEmbed}(y) = L(y)+P(y)+T(y) \in R^{|y|\times d_m}$$

where the level embedding assigns the same embedding vector L_i for each position at the BFS traversal level i, and the value of the embedding vector is filled according to the non-parametric sinusoidal position embedding since we want our embedding to extrapolate to the sequence that is longer than any sequences in the training set. The parent-child embedding assigns different random initialized embedding vectors at the positions of the parent nodes and the child nodes in the BFS traversal levels to help model distinguish between these two kinds of nodes. For encoding the intra-level connection information, our insight is that the connection between each nodes in a BFS level can be viewed as a depth-3 tree, where the first depth takes the parent node, the second depth is filled with the edge types and the third depth consists of the corresponding child nodes for each of the edge types. Our tree embedding is then formed by encoding the position information of the depth-3 tree with a tree positional embedding (Shiv and Quirk, 2019) for each BFS level. Figure 5 shows a concrete example of how these embeddings function for a given alternating sequence. The obtained traversal embedding is then pointwisely added to the hidden representation of the alternating sequence H_y for injecting the traversal information of the graph structure.

Inner blocks With the input text representation H_{text} sliced from the hybrid representation H and the target sequence representation H_y, we apply an N-layer transformer structure with mixed-attention (He et al., 2018) to allow our model to utilize features from different attention layers when decoding the edges or the nodes of an alternating sequence. Note that our hybrid span decoder is perpendicular to the actual choice of the neural structures of the inner blocks, and we choose the design of mixed-attention transformer (He et al., 2018) because its layerwise coordination property is empirically more suitable for our heterogeneous decoding of two different kinds of sequence elements. The detailed structure of the inner blocks is explained in Appendix E.

Hybrid span decoding For the hybrid span decoding module, we first slice off the hidden representation of the alternating sequence y^{π} from the output of the N-layer inner blocks and denote it as H_y^N. Then for each hidden representation $\mathbf{h}_{y_i}^N \in H_y^N, 0 \leq i < |y^{\pi}|$, we apply two different linear layers to obtain the start position representation, $\mathbf{s}_{y_i}$, and the end position representation, $\mathbf{e}_{y_i}$,

$$\begin{aligned}
\mathbf{s}_{y_i} &= W_5^T \mathbf{h}_{y_i} + \mathbf{b}_5 \quad \in R^{\,d_m}, \\
\mathbf{e}_{y_i} &= W_6^T \mathbf{h}_{y_i} + \mathbf{b}_6 \quad \in R^{\,d_m},
\end{aligned}$$

where $W_5, W_6 \in R^{\,d_m \times d_m}$ and $\mathbf{b}_5, \mathbf{b}_6 \in R^{\,d_m}$ are learnable parameters. Then we calculate the scores of the target spans separately for the types segment and the text segment of H, and concatenate them together before the final softmax operator for a joint estimation of the probabilities of text spans and type spans,

$$\begin{aligned}
\mathbf{h}_{s_i} &= H_{\text{types}}\, \mathbf{s}_{y_i} + \mathbf{m}_a & &\in R^{l_p}, \\
\mathbf{h}_{e_i} &= H_{\text{types}}\, \mathbf{e}_{y_i} + \mathbf{m}_a & &\in R^{l_p}, \\
\mathbf{h}_i &= \mathbf{h}_{s_i} + \mathbf{h}_{e_i} & &\in R^{l_p}, \\
\mathbf{t}_{s_i} &= H_{\text{text}}\, \mathbf{s}_{y_i} + \mathbf{m}_a' & &\in R^{n}, \\
\mathbf{t}_{e_i} &= H_{\text{text}}\, \mathbf{e}_{y_i} + \mathbf{m}_a' & &\in R^{n}, \\
\mathbf{t}_i &= \text{unfold}(\mathbf{t}_{e_i}, m) + \mathbf{t}_{s_i} & &\in R^{nm}, \\
\mathbf{p}(y_{i+1}^{\pi}) &= \text{softmax}(\mathbf{h}_i \oplus \mathbf{t}_i) & &\in R^{nm+l_p},
\end{aligned}$$

where $\mathbf{h}_i$ is the score vector of possible spans in the type segment of H, and $\mathbf{t}_i$ is the score vector of possible spans in the text segment of H. Since the type spans always have a span length 1, we only need an element-wise addition between the start position scores, $\mathbf{h}_{s_i}$ and the end position scores $\mathbf{h}_{e_i}$ to calculate $\mathbf{h}_i$. The entries of $\mathbf{t}_i$ contain the scores for the text spans, $t_{s_i,j} + t_{e_i,k}, \forall j \leq k, k - j < m$, which are calculated with the help of an *unfold* function which converts the vector $\mathbf{t}_{e_i} \in R^n$ to a stack of n sliding windows of size m, the maximum span length, with stride 1. The alternating masks $\mathbf{m}_a \in R^{l_p}, \mathbf{m}_a' \in R^n$ are defined as:

$$\mathbf{m}_a(j) = \begin{cases} 0, & y_i^{\pi} > l_e \cap j < l_e \\ -\infty, & \text{otherwise} \end{cases}$$

$$\mathbf{m}_a'(j) = \begin{cases} -\infty, & y_i^{\pi} > l_e \\ 0, & \text{otherwise} \end{cases}$$

where $l_e = |R| + |U|$ is the total number of edge types. In this way, while we have a joint model of nodes and edge types, the output distribution is enforced by the alternating masks to produce an alternating decoding of nodes and edge types, and this is the main reason why we call this decoder a hybrid span decoder.

4 Experiments

4.1 Experimental Setting

We test our model on the ACE 2005 dataset distributed by LDC[4], which includes 14.5k sentences, 38.3k entities (with 7 types), and 7.1k relations (with 6 types), derived from the general news domain. More details can be found in Appendix C.

Following previous work, we use F1 as an evaluation metric for both NER and RE. For the NER task, a prediction is marked correct when both the type and the boundary span match those of the gold entity. For the RE task, a prediction is correct when both the relation type and the boundaries of the two entities are correct.

4.2 Implementation Details

When training our model, we apply the cross-entropy loss with a label smoothing factor of 0.1. The model is trained with 2048 tokens per batch (roughly a batch size of 28) for 25000 steps using an AdamW optimizer (Loshchilov and Hutter, 2018) with a learning rate of $2e^{-4}$, a weight decay of 0.01, and an inverse square root scheduler with 2000 warm-up steps. Following the TabSeq model (Wang and Lu, 2020), we use RoBERTa-large (Liu et al.) or ALBERT-xxlarge-v1 (Lan et al., 2020) for the pretrained language model and slow its learning rate by a factor of 0.1 during training. A hidden state dropout rate of 0.2 is applied to RoBERTa-large while the rate of 0.1 for ALBERT-xxlarge-v1. A dropout rate of 0.1 is also applied to our hybrid span decoder during training. We set the maximum span length, $m = 16$, the hidden size of our model, $d_m = 256$, and the number of the decoder blocks, $N = 12$. Even though theoretically the beam-search should help us reduce the exposure bias, we do not observe any performance gain during grid search of the beam size and the length penalty on the validation set (detailed grid search setting is in Appendix A). Thus we set a vanilla beam size of 1 and the length penalty of 1, and leave this theory-experiment contradiction for future research. Our model is built with the FAIRSEQ toolkit (Ott et al., 2019) for efficient distributed training and all the experiments are conducted on two NVIDIA TITAN X GPUs.

– Span-attention	88.5	66.1

Table 2: Ablation study on the ACE05 test set. "– Traversal-embedding": we remove the traversal embedding and instead use sinusoidal position embedding, and the following ablations are based on the model after this ablation. "– Masking": we remove the alternating mask from the hybrid span decoder. "– BFS": we use DFS instead of BFS as traversal. "– Mixed-attention": we remove the mixed-attention layer and use a standard transformer encoder decoder structure. "– Span-attention": we remove the span attention in the span encoding module and instead average the words in the span.

4.3 Results

Table 1 compares our model with the previous state-of-the-art results on the ACE05 test set. Compared with the previous SOTA, TabSeq (Wang and Lu, 2020) with ALBERT pretrained language model, our model with ALBERT has significantly better performance for both NER score and RE score, while maintaining a linear space complexity which is an order smaller than TabSeq. Our model is the first joint model that has both linear space and time complexities compared with all previous joint IE models, and thus has the best scalability for large-scale real world applications.

4.4 Ablation Study

To prove the effectiveness of our approach, we conduct ablation experiments on the ACE05 dataset.

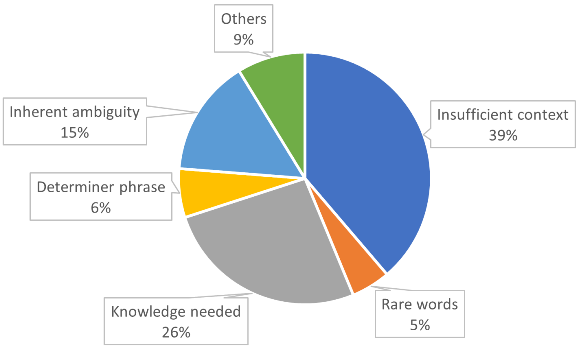

Figure 6: Distribution of remaining errors on the ACE05 test set.

As shown in Table 2, after we remove the traversal embedding the RE F1 scores drop significantly, which indicates that our traversal embedding can help encode the graph structure and improve relation predictions. Also if the alternating masking is dropped, the NER F1 and RE F1 scores both drop significantly, which proves the importance of enforcing the alternating pattern. We can observe that the mixed-attention layer contributes significantly for relation extraction. This is because the layer-wise coordination can help the decoder to disentangle the source features and utilize different layer features between the entity and the relation prediction. We can also observe that the DFS traversal has worse performance than BFS. We suspect that this is because the resultant alternating sequence from DFS is often longer than the one from BFS due to the nature of the knowledge graphs, and thus increases the learning difficulty.

4.5 Error Analysis

After analyzing 80 remaining errors, we categorize and discuss common cases below (Figure 6 plots the distribution of error types). These may require additional features and strategies to address.

Insufficient context. In many examples, the answer entity is a pronoun that cannot be accurately typed given the limited context: in *"We notice they said they did not want to use the word destroyed, in fact, they said let others do that"*, it's difficult to correctly classify *We* as an organization. This could be mitigated by using entire documents as input, leveraging cross-sentence context.

Rare words. The rare word issue is when the word in test set rarely appeared in the training set and often not termed in the dictionary. In the sentence *"There are also Marine FA-18s and Marine Heriers at this base"*, the term *Heriers* (a vehicle incorrectly classified as person by the model) neither appeared in the training set, nor understood well by pre-trained language model; the model, in this case, can only rely on subword-level representation.

Background knowledge required Often the sentence mentions entities that are difficult to infer from the context, but are easily identified by consulting a knowledge base: in *"but critics say Airbus should have sounded a stronger alarm after a similar incident occurred in 1997"*, our model incorrectly predicts the *Airbus* to be a vehicle while the *Airbus* here refers to the European aerospace corporation. Our system also separated *United Nations Security Council* into two entities *United Nations* and *Security Council*, generating a non-existing relation triple (*Security Council* part-of *United Nations*). Such mistakes could be avoided by consulting a knowledge base such as DBpedia (Bizer et al., 2009) or by performing entity linking.

Inherent ambiguity Many examples have inherent ambiguity, e.g. *European Union* can be typed as organization or political entity, while some entities (e.g., military bases) can be both locations and organizations, or facilities.

5 Related Work

NER is often done jointly with RE in order to mitigate error propagation and learn inter-relation between tasks. One line of approaches is to treat the joint task as a squared table filling problem (Miwa and Sasaki, 2014; Gupta et al., 2016; Wang and Lu, 2020), where the i-th column or row represents the i-th token. The table has diagonals indicating sequential tags for entities and other entries as relations between pairs of tokens. Another line of work is by performing RE after NER. In the work by Miwa and Bansal (2016), the authors used BiLSTM (Graves et al., 2013) for NER and consequently a Tree-LSTM (Tai et al., 2015) based on dependency graph for RE. Wadden et al. (2019) and Luan et al. (2019), on the other hand, takes the approach of constructing dynamic text span graphs to detect entities and relations. Extending on Wadden et al. (2019), Lin et al. (2020) introduced ONEIE, which further incorporates global features based on cross subtask and instance constraints, aiming to extract IE results as a graph. Note that our model differs from ONEIE (Lin et al., 2020) in that our model captures global relationships automatically through autoregressive generation while ONEIE uses feature engineered templates; Moreover, ONEIE needs to do pairwise classification for relation extraction, while our method efficiently generates existing relations and entities.

While several Seq2Seq-based models (Zhang et al., 2020; Zeng et al., 2018, 2020; Wei et al., 2019; Zhang et al., 2019) have been proposed to generate triples (i.e., node-edge-node), our model is fundamentally different from them in that: (1) it is generating a BFS/DFS traversal of the target graph, which captures dependencies between nodes and edges and has a shorter target sequence, (2) we model the nodes as the spans in the text, which is independent of the vocabulary, so even if the tokens of the nodes are rare or unseen words, we can still generate spans on them based on the context information.

6 Conclusion

In this work, we propose the Hybrid Span Generation (HySPA) model, the first end-to-end text-to-graph extraction model that has a linear space and time complexity at the graph decoding stage. Besides its scalability, the model also achieves state-of-the-art performance on the ACE05 joint entity and relation extraction task. Given the flexibility of the structure of our hybrid span generator, abundant future research directions remain, e.g. incorporating the external knowledge for hybrid span generation, applying more efficient sparse self-attention, and developing better search methods to find more globally plausible graphs represented by the alternating sequence.

A Hyperparameters

We use 100-dimensional GloVe word embeddings trained on 6B tokens as intialization [5], and freeze its update during training. The character embedding has 30-dimension with LSTM encoding [6] and the Glove Embeddings for the out of vocabulary tokens are replaced with randomly initialized vectors following Wang and Lu (2020). We use gradient clipping of 0.25 during training. The number of heads for our mixed attention is set to 8. The beam size and length penalty is decided by a grid-search on the validation set of the ACE05 dataset, and the range for the beam size is from 1 to 7 with a step size of 1 and the length penalty is from 0.7 to 1.2 with a step size of 0.1. We choose the best beam size and length penalty based on the metric of relation extraction F1 score.

B Training Details

Our model has 236 million parameters with the ALBERT-xxlarge pretrained language model. On average, our best performing model with ALBERT-xxlarge can be trained distributedly on two NVIDIA TITAN X GPUs for 20 hours.

C Data

The Automatic Content Extraction (ACE) 2005 [7] dataset contains English, Arabic and Chinese training data for the 2005 Automatic Content Extraction (ACE) technology evaluation, providing entity, relation, and event annotations. We follow Wadden et al. (2019) [8] for preprocessing and data splits. The preprocessed data contains 7.1k relations, 38k entities, and 14.5k sentences. The split contains 10051 samples for training, 2424 samples for development, and 2050 for testing.

D DFS Traversal Embedding

Since the parent-child information is already contained in the intra-level connections of DFS traversal, we only have the sum of the level embedding and the connection embedding for DFS traversal embedding. Similar to BFS embedding, the DFS level embedding assigns the same embedding vector L_i for each position at the DFS traversal level i, but the value of the embedding vector is randomly initialized instead of filled with the non-parametric sinusoidal position embedding, since the proximity information does not exist between the traversal levels of DFS. However, we do have clear distance information for the elements in a DFS level, *i.e.*, for a DFS level $D =$ [A, B, C, ..., [sep]], the distance from A to the elements [A, B, C, ..., [sep]] is $[0, 1, 2, 3, ..., |D| - 1]$. We encode this distance information with the sinusoidal position embedding which becomes our connection embedding that captures the intra-level connection information.

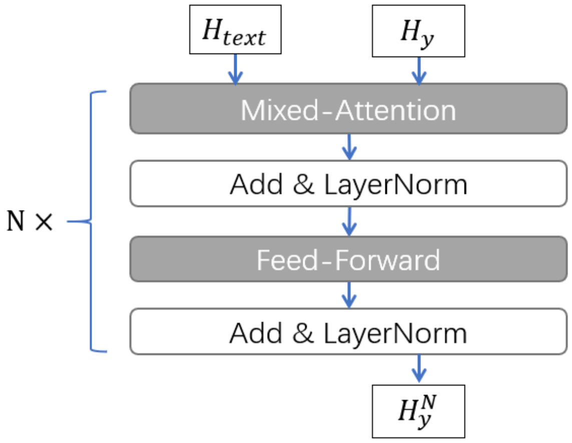

Figure 7: The general model architecture of the mixed-attention transformer.

E Transformer with Mixed-attention

We first slice off the hidden representation of the input text from the hybrid representation H, and denote it as H_{text}, then the input text representation H_{text} and the output from the Hybrid Span Encoding H_y gets fed into a stack of N mixed-attention/feedforward blocks that have the following structure (as shown in Figure 7):

Since generating the node and edge types may need features from different layers, we use mixed attention (He et al., 2018), which allows our model to utilize the features from different attention layers when encoding the text segment, H_{text}, and the

target features, H_y,

$$\text{MixedAtt}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_m}} + M_1\right)V \\ \in R^{\,l_m \times d_m},$$

$$M_1(i, j) = \begin{cases} 0, & j < n \cup j \leq i + n \\ -\infty, & \text{otherwise} \end{cases}$$

where $n = |x|$ is the length of the input text, $l_m = |x| + |y^\pi|$ is the total length of the source and the target features. Denoting the concatenation of the source features, H_{text}, and the target features, H_y, as H_0, a source/target embedding (He et al., 2018) is also added to H_0 before the first layer of the mixed attention to allow the model to distinguish the features from the source and the target sequences. The mixed-attention layer is combined with a feed-forward layer to form a decoder block:

$$\begin{aligned} \text{FFN}(x) &= \max(0, xW_3 + b_3)W_4 + b_4, \\ Q &= W_q^T H_0 + \mathbf{b}_q, \\ K &= W_k^T H_0 + \mathbf{b}_k, \\ V &= W_v^T H_0 + \mathbf{b}_v, \\ H_0' &= \text{LayerNorm}(\text{MixedAtt}(Q, K, V) + H_0), \\ H_1 &= \text{LayerNorm}(\text{FFN}(H_0') + H_0'), \end{aligned}$$

where $W_{q,k,v}, \mathbf{b}_{q,k,v}, W_3 \in R^{\,d_m \times 4d_m}, W_4 \in R^{\,4d_m \times d_m}, \mathbf{b}_3, \mathbf{b}_4$ are the learnable parameters, and LayerNorm is the Layer Normalization layer (Ba et al., 2016). The decoder block is stacked N times to obtain the final hidden representation H_N, and output the final representation of the target sequence, H_y^N. The mixed-attention has a time complexity of $O(n^2)$ when encoding the source features, but we can cache the hidden representation of this part when generating the target tokens due to the causal masking of the target features, and thus maintain a time complexity of $O(n)$ for each decoding step.

Improving Automated Evaluation of Open Domain Dialog via Diverse Reference Augmentation

Abstract

Multiple different responses are often plausible for a given open domain dialog context. Prior work has shown the importance of having multiple valid reference responses for meaningful and robust automated evaluations. In such cases, common practice has been to collect more human written references. However, such collection can be expensive, time consuming, and not easily scalable. Instead, we propose a novel technique for *automatically* expanding a human generated reference to a set of candidate references. We fetch plausible references from knowledge sources, and adapt them so that they are more fluent in context of the dialog instance in question. More specifically, we use (1) a commonsense knowledge base to elicit a large number of plausible reactions given the dialog history (2) relevant instances retrieved from dialog corpus, using similar past as well as future contexts. We demonstrate that our automatically expanded reference sets lead to large improvements in correlations of automated metrics with human ratings of system outputs for DailyDialog dataset. [1]

1 Introduction

Evaluation by human annotators perhaps give the best insights into quality of machine generated natural language outputs. However, they can be expensive and time consuming. Much focus has therefore been on automated evaluation methods which correlate with human evaluations. Automated metrics such as BLEU (Papineni et al., 2002) work well for tasks such as machine translation, but often correlate poorly with human ratings in tasks such as open domain dialog which admit a wide variety of valid response for given context, often due to small number of human written references (Zhao et al., 2017; Sai et al., 2020b). Prior work (Sugiyama et al., 2019; Gupta et al., 2019) has demonstrated that having multiple valid references for the same context leads to automated metrics being better correlated to human judgements for appropriateness. However, collecting human written responses is difficult to scale, can be costly, and may find it difficult to cover a large variety of correct responses (Celikyilmaz et al., 2020).

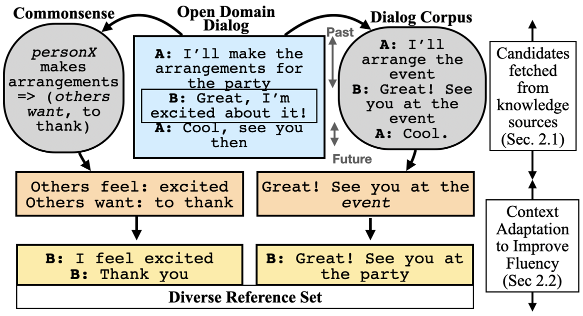

Figure 1: We propose automatic ways to collect references sans any crowd-sourcing, through two types of knowledge sources: commonsense and retrieved instance knowledge, followed by automated adaptation to make them more fluent in the target contexts.

In this work, we automatically extract a large number of diverse references to be used with such reference-based metrics, without resorting to expensive crowd-sourcing. Intuitively, since open-domain dialog pertains to everyday life, its utterance text tends to re-instantiate from a large but limited pool of situations (Schank, 1972) e.g friends debating politics etc, with variation only on some details e.g country discussed. Hence, knowledge encapsulating a wide scope of situations can serve as one starting point to automatically seed a set of diverse references. We first fetch plausible candidates from two types of knowledge sources (Figure 1). Such knowledge sources provide ready and easy access to a large number of potentially appropri-

ate and diverse references. However, all retrieved instances may not be directly useful. As such, to achieve more fluent references, we propose techniques to adapt the candidate references based on the context (e.g change country being discussed). Note that since we are interested in creating references for only evaluating appropriateness of system outputs, our techniques can rely on broader data sources compared to dialog models. For example, we use future context and human written reference for retrieval, while a dialog model cannot.

Our contributions are as follows: (1) We propose a method for automated reference set augmentation for automated dialog evaluation. Compared to collecting more human-written responses, our approach is inexpensive and scalable, and fetches a diverse set of references. (2) We observe high correlations of various automated metrics with human ratings when proposed reference augmentation is applied to the test split of DailyDialog dataset (Li et al., 2017). We additionally observe that paraphrasing, a popular data augmentation technique, performs much worse. (3) We employ novel use of commonsense knowledge and dialog corpus instances, and unsupervised techniques for adapting retrieved references into more fluent forms.

2 Method

Figure 1 shows an overview of our proposed methodology. We first fetch plausible candidates from two types of knowledge sources. Thereafter, the retrieved candidate references are adapted so that they are fluent in the target context. We refer to our proposed method as SCARCE (**SC**alable **A**utomated **R**eference **C**onstruction for **E**valuation).

2.1 Knowledge Sources

Pre-trained Commonsense Model Much open domain dialog is based on everyday matters. We posit that extracting inferences about a situation using a commonsense knowledge base could be useful in identifying a wide variety of plausible reactions for a given dialog context. For example, a person making arrangements for an event might receive thanks from others (Figure 1). We utilize COMET (Bosselut et al., 2019) an off-the-shelf commonsense knowledge model built on ATOMIC (Sap et al., 2019a) or ConceptNet (Speer et al., 2017) corpus. It can be used to elicit commonsense inferences.

COMET-ATOMIC provides inferences on cause-effect interrelations between events pertaining to nine relation types such as *oReact* (effect on others due to the event), and *oWant* (inferences about wants of the receiver of event). Given an utterance from the previous speaker, we draw up to 5 inferences pertaining to each of oEffect, oReact, and oWant relation types to construct plausible references for the target response. For example, for an utterance 'I will make the arrangements. It will be great.', one of the inferences corresponding to oEffect is 'feel excited', depicting a plausible state of the next dialog speaker. However, such outputs are typically phrases, and we discuss transformation to fluent sentences in Section 2.2. Similarly, we use inferences pertaining to 'CausesDesire' and 'HasFirstSubevent' relation types from COMET-ConceptNet.

Dialog Corpus Retrieval For a test dialog context under consideration, one is likely to find similar contexts occurring in some of the training dialogues, given a sufficient number of them. Using retrieval, we can identify such contexts and use their responses as pseudo-references for the test-time response. Specifically, for retrieval, we use the BM25 function $S_{bm25}(x, y)$ (Robertson et al., 1995) to compare each element $\{d_t^{past}, d_t^{resp}, d_t^{future}\}$ of the turn under evaluation d_t (the query) with those of the candidate turn $x_{t'}$, $\{x_{t'}^{past}, x_{t'}^{resp}, x_{t'}^{future}\}$. Here, d_t^{past} and d_t^{future} are the windows of turn sequences before and after response d_t^{resp}.

Our approach is related to Galley et al. (2015), who propose Δ-BLEU measure which uses retrieval to produce pseudo-references. However, unlike here, they require annotator quality scores to weigh them during evaluation. Moreover, though we utilize retrieval for evaluation, methods of this kind have found success in many generation setups (Li et al., 2018; Peng et al., 2019; Khandelwal et al., 2019). Besides being automatic, our method differs from the above ones in that it explores the added utility of future information for retrieval. For instance, for the dialog shown in Figure 1, besides matching "Great!" in the response, our retrieval benefits from matching "cool" in the future.

2.2 Context Adaptation

We note that commonsense knowledge outputs are incomplete sentences, and we use simple templates to convert them to fluent sentences e.g. 'feels excited' gets transformed to 'i feel excited'. (Detailed templates in Appendix B) Further, we note that references from knowledge sources are often not fluent for the target context. For example, 'event' in the retrieved reference shown in Figure 1 can be updated to 'party' to construct a more apt reference. To adapt the retrieved text to better fit the target context we use employ an unsupervised decoding procedure, based on the approach of Qin et al. (2020), that uses gradient ascent to search for output text that maximizes (1) fluency with the left context (approximated by the likelihood of the output text under a pretrained GPT-2 model) and (2) similarity to the original text from the knowledge source (approximated by the likelihood of the original text under the output text's token-level word distributions). The method utilizes a heuristic update procedure to iteratively refine a differentiable proxy for the output text (a sequence token-level word distributions), while keeping the model parameters fixed. More details can be found in Qin et al. (2020) and in Appendix B.

3 Experiments

We investigate the extent to which automated metrics on an evaluation dataset correlate with human ratings of system outputs. We use the human ratings collected by Gupta et al. (2019), who collected utterance level human ratings using Amazon Mechanical Turk (AMT). They used a collection of 100 dialogue contexts that are randomly selected from the DailyDialog dataset. The generated response from various methods are rated in terms of appropriateness (from 1-5, with 5 denoting the best) by 5 different AMT workers. They collected and considered outputs from following methods: CVAE (Zhao et al., 2017), HRED (Serban et al., 2016), Seq2Seq (Vinyals and Le, 2015), Dual-encoder (Lowe et al., 2015), and Human-written responses. We report Spearman rank correlation (Spearman, 1961) and Kendall Tau rank correlation (Kendall, 1938) of human ratings against ngram overlap metrics such as BLEU (2002), METEOR (Banerjee and Lavie, 2005), ROUGE-L (Lin, 2004), and embedding based metrics like cosine similarity of average word embedding (EmbeddingAvg) (Wieting et al., 2016) or Skip Thought Embedding (Kiros et al., 2015), and precision (BERT-Prec) and recall (BERT-Rec) components of BertScore (Zhang et al., 2020).

We compare the correlations across following setups: **SINGLE** (Li et al., 2017): Original DailyDialog dataset which had one reference per context; **SCARCE-SINGLE**: Proposed method along with SINGLE reference; **MULTI** (Gupta et al., 2019): 4 human written references. **SCARCE-MULTI**: Reference responses from the proposed method along with MULTI references. Additionally, we report the results when using PARAPHRASE instead of SCARCE: **PARAPHRASE-SINGLE** and **PARAPHRASE-MULTI**. Paraphrasing is a popular approach for automated data augmentation. Paraphrasing via backtranslation (BT) (Sennrich et al., 2016) is known to be an effective, domain-independent way to generate good quality paraphrases (Wieting and Gimpel, 2017). We use the BT model from (Xie et al., 2020) with its default hyperparameters to sample 5 paraphrases per human written reference

Results: We observe that most of the metrics show large improvements in correlations to human ratings for appropriateness when used along with SINGLE or MULTI (Table 1). In fact, rank correlations across most of the metrics are better for SCARCE-SINGLE compared to MULTI, even though former uses only single human written reference while latter uses upto 5 human written references[2]. Additionally, we observe that PARAPHRASE produces little or no improvements in correlations with human ratings (Table 1). We posit that for a given response, alternate responses constitute a strictly richer subspace than that of response paraphrases, which tend to be lexico-syntactically variant but semantically invariant.

Analyzing the impact of various components: To understand the impact of various components, we report Spearman rank correlation scores for BLEU-4 and BERT-Prec metrics with some variants of SCARCE-SINGLE (Table 2). We note that considering only one knowledge source (COMMONSENSE-only, RETRIEVAL-only) leads to good Spearman rank correlations of automated metrics to human ratings. Thus, the additive effect (SCARCE-SINGLE) shows rather small incremental benefit. Moreover, RETRIEVAL by itself does better than COMMONSENSE, though at smaller

---

[2] Rank correlations for SINGLE and MULTI deviate from the values in Gupta et al. (2019), who (in private communication with us), confirmed that the final dataset and code available on their repo does lead to the numbers we report.

Spearman Rank Correlation / Kendall Tau Rank Correlation

Setup	1 human written reference			4 human written references		
Dataset	Single (Li et al., 2017)	Paraphrase -Single	Scarce -Single(Ours)	Multi (Gupta et al., 2019)	Paraphrase -Multi	Scarce -Multi(Ours)
BLEU-4	0.09 / 0.07	0.13 / 0.09	0.30 / 0.21	0.28 / 0.20	0.27 / 0.19	**0.36** / 0.25
BLEU-3	0.06 / 0.04	0.11 / 0.07	0.29 / 0.20	0.24 / 0.17	0.24 / 0.17	0.35 / 0.24
BLEU-2	0.04 / 0.03	0.08 / 0.06	0.28 / 0.19	0.20 / 0.14	0.21 / 0.14	0.33 / 0.23

Max. value	0.27 / 0.19	0.28 / 0.19	0.38 / 0.26	0.32 / 0.22	0.32 / 0.22	0.41 / 0.28

Table 1: Utterance level Spearman Rank Correlation (1961) and Kendall Tau Rank Correlations (1938). (1) Scarce-Single augments the original single human written response (Single) in DailyDialog dataset (Li et al., 2017) using proposed method. It leads to large improvements in correlations across most of the metrics, when compared to Single. (2) Scarce-Multi augments the Multi dataset, again leading to improvements in correlations to human ratings, especially for BLEU and BERT-Prec metrics.

Method	BLEU-4	BERT-Prec
Scarce-Single	0.30	0.38
Scarce-Single variants:		
CommonSense only	0.24	0.31
Retrieval only	0.29	0.36
Retrieval only (5% corpus)	0.17	0.28
w/o context-adapt	0.26	0.37

Table 2: Analyzing the impact of various components

corpus availability (e.g. 5%), CommonSense performs better. Finally, not using context adaptation (w/o context-adapt) leads to significant performance drop.

Qualitative Examples To illustrate our approach, we present a couple of examples in Table 3. (A wider selection of examples can be found in Appendix Table 6.)

Quality of Auto-generated References: We check the quality of Scarce references by recruiting human annotators, showing them the reference along with the dialog context, and requesting them to tag each reference as appropriate, neutral, or not-appropriate, with respect to the dialog context. We randomly select 150 responses each from Scarce and Multi for this purpose. We observe that in about 29% of the references from Scarce (fully automatically generated) were annotated as not appropriate, compared to 7% for Multi, demonstrating fair quality of augmented responses from Scarce (Additional details and results in Appendix). We do note that the ones marked as not relevant/appropriate can often be tweaked easily by a human to transform them into valid responses – demonstrating the possibility of exploring human-in-the-loop setups along with Scarce to collect even better references.

4 Discussion

Transferability to more languages: Transferability of our approach to more languages is one aspect that merits discussion. While commonsense resources aren't readily available in all languages, a workaround can be to use off-the-shelf MT to translate before querying into English versions of the commonsense resources, and then translate back retrieved information. Furthermore, we note that while commonsense knowledge was useful, removing the CommonSense method and relying on retrieval alone causes only relatively modest drop in performance (see Table 2). Thus, for languages lacking commonsense resources, one may still attain good gains in reference based evaluation by retrieving and adapting from dialog corpus alone.

Reference-less metrics: We note that while comparisons of using proposed approach against using reference-free metrics (Lowe et al., 2017; Tao et al., 2017) would be interesting, the focus of the current work is on improving reference-based evaluation via unsupervised reference augmentation. While reference-less metrics offer convenience to work with zero or a very small number of references,

Type	Text
CONTEXT	A: How may I help you ?
SINGLE	B: I'm having a problem.
MULTI	B: You can help me with this problem. ‖ B: You can tell me how to get to customer service.
RETRIEVAL	B: I have a problem. ‖ B: There is a problem with my check.
COMMONSENSE	B: I want to find information. ‖ B: I want to ask question. ‖ B: I want to make appointment.
CONTEXT	B: It can be solved by drawing a draft on us at 90 days sight. A: What about a draft at 120 days sight ?
SINGLE	B: All right. But we demand the draft be accepted by a bank acceptable to us.
MULTI	B: We'd like the matter resolved sooner. ‖ B: We can do that, but there will be a higher interest rate.
RETRIEVAL	B: Well, that's a lot of time to wait for the draft to be drawn.
COMMONSENSE	B: I want to sign the contract. ‖ B: I will look at the draft sheet.

Table 3: Example showing the automated responses returned by different sub-components of SCARCE. Multiple responses from the same sub-component are separated by '‖'.

reference-based metrics can be advantageous on several fronts. Reference-based evaluation can be more interpretable under certain situations by identifying the reference which matches the most with a given system output. Reference-based evaluations allow for easy incorporation of additional references – in contrast, many learned model-based metrics will require retraining if additional annotations become available.

5 Related Work

Prior work explores many ways to improve over single-reference evaluation without collecting multiple ones. Fomicheva et al. (2020) obviate need for multiple references in MT by generating many "alt-hypotheses" via test-time dropout from the same model. Sai et al. (2020a) and Gupta et al. (2019) collect additional manually annotated responses for dialog contexts. Compare to them, our method of automatically collecting additional references automatically is more scalable.

Automatic data augmentation in NLP has largely been used for increasing training data (Feng et al., 2020; Wei and Zou, 2019; Feng et al., 2021). In this work, we use retrieved dialog instances and commonsense knowledge base to augment reference set for a given dialog context. Δ-Bleu (Galley et al., 2015) and uBLEU (Yuma et al., 2020) also use retrieval to produce pseudo-references for dialog response evaluation. Compared to Δ-Bleu and uBLEU, our work is different since we utilize commonsense knowledge base and perform contextual adaptation. Prior work in dialog response generation has explored the use of commonsense knowledge base (Majumder et al., 2020) as well as retrieval (Song et al., 2016; Majumder et al., 2021) – in contrast, our focus is on augmenting reference set for improving evaluation.

Automatic model-based metrics like ADEM (Lowe et al., 2017) and RUBER (Tao et al., 2017), which incorporate context while scoring for evaluation, at first glance seem to reduce the need for multiple references. However, these metrics have been found to suffer from several peculiar problems. For instance, ADEM can't discriminate between gold responses and certain classes of adversarial negatives e.g reversed gold responses and repeating the context as the response (Sai et al., 2019). Sato et al. (2020) evaluate dialog systems through their ability at selecting valid responses from a semi-automatically curated candidate list. Mehri and Eskenazi (2020b) introduce the unsupervised, reference-free USR metric, which leverages a suite of RoBERTa (Liu et al., 2019) models, each fine-tuned to score one of five dialog aspects e.g *Natural* and *Uses Knowledge*. Mehri and Eskenazi (2020a) further expand their USR metric to eighteen aspects from the initial five.

6 Conclusion

In this work, we demonstrate how existing knowledge sources can be used to construct a diverse set of references in an automated and scalable manner. The resulting reference set demonstrates high correlation with human ratings of system outputs.

In future, we plan to incorporate other commonsense types into SCARCE, such as social (Sap et al., 2019b) and moral (Forbes et al., 2020). We also hope to explore human-in-the-loop setups which build on SCARCE to collect even better references.

Acknowledgements

We thank anonymous ACL reviewers for insightful comments and feedback. We thank Prakhar Gupta (Gupta et al., 2019) for useful discussions.

Ethics Statement

Our preference ratings are collected over source content from an already existing, publicly available and widely used dataset i.e DailyDialog (Li et al., 2017) We neither solicit, record or request any kind of personal or identity information while collecting our ratings. Our work primarily performs experiments on dialog in English (Bender and Friedman, 2018). Dialog models are known to suffer from biases learnable from dialog training data, such as gender bias (Dinan et al., 2019). However, our work and contribution does not present or release any new models or model checkpoints, and is primarily focussed on making existing evaluation setups better through automated collection of larger reference sets.

A Additional Results

A.1 Additional Correlation Results

Table 4 shows Spearman rank correlation scores with p-values.

A.2 Quality Assessment based on RUBER

As a second, automated way of ascertaining response quality, we use the unreferenced part of the RUBER metric (Tao et al., 2017), which uses a pretrained model to score quality of responses based on context alone. Here, we use the RUBER checkpoint[3] from (Sai et al., 2020a), which first pretrains on a large Reddit dataset, followed by finetuning on DailyDialog. SINGLE and MULTI have a quality of $\approx$ 0.72, while for RETRIEVAL the values is 0.63 . COMMONSENSE is found to have the most superior quality at 0.82, surpassing even MULTI.

A.3 Diversity of References

We investigate the diversity of the references by computing self-BLEU scores (Zhu et al., 2018) among references from PARAPHRASE vs SCARCE. For fair comparison, we randomly chose 4 references from corresponding method. We observe self-BLEU4 scores of 0.36 for PARAPHRASE compared to only 0.13[4] for SCARCE.

B Additional Details on Context Adaptation

B.1 Templates to convert Knowledge Base Outputs to Full Sentences

Table 5 lists the set of templates and rules used to transform semi-structured COMET outputs to surface natural language forms.

B.2 Unsupervised Decoding Procedure For Context Adaptation

We use the author's own implementation[5] of their DELOREAN decoding algorithm from (Qin et al., 2020). We use default hyperparameters from their implementation, which use the non-finetuned *gpt2-medium* checkpoint as the LM atop which the unsupervised, gradient-based decoding procedure is run. Note that the model parameters are not updated in any way - the gradient computation and updates here are happening w.r.t the states, or more specifically, the state activation. More specifically, authors propose an iterature procedure wherein they alternatively perform forward and backward passes. In the forward pass, the current output Y is updated as per the likelihood of the underlying decoder. In the backward pass, the output is updated to be as similar as possible to the sentence Z from the knowledge source using back-propagation. However, since $Y$is discrete, we maintain a soft representation $\widetilde{Y}$ of the output Y wherein $\widetilde{Y_i}$ represents the logits at the i^{th} position as per the underlying decoder. Next, we shall describe the backward and forward passes of the iterative procedure:

1: In backward pass, we update logits based on the gradients of a content-matching loss function $\nabla_{\widetilde{Y}} L(\widetilde{Y}_{t-1}, Z)$ giving backward logits $\widetilde{y}_t^b$

2: Next, we perform forward pass using the underlying decoder for steps 1 to N. During forward pass at step t, we compute the logits $\widetilde{y}_t^f$ based on left context i.e. X and $Y_{<t}$. Next we perform weighted averaging of the forward and backward logits at step t to arrive at the final logits to be used for the next time step in forward pass.

$\widetilde{Y_i}$ is initialized by performing a forward pass conditioned only on X as per greedy decoding. We alternatively perform backward and forward passes till convergence. Final response is obtained via the resulting logit outputs $\widetilde{Y}$.

Specifically, we use their "counterfactual" setup, where an ending e_{old} is adapted from its old context c_{old} to an altered, new context c_{new}, generating a new, predicted ending $\hat{e}_{new}$. In our case, c_{new} is the dialog context for the turn under evaluation d_t^{past}. In the RETRIEVAL case, c_{old} is the context of the retrieved candidate turn $x_{t'}^{past}$. For the COMMONSENSE case, c_{old} is also our current context, i.e the same as c_{new} - we're simply attuning the already drawn inference better to the current context.

C Retrieval Similarity Function - Details

Consider a dialog d , broken up by turns as $\{C_1 \ldots C_t, C_{t+1}{=}d_t^{resp}, C_{t+2} \ldots C_T\}$, where $t+1$ denotes the turn currently under evaluation. For the context-response $C_t^1, \hat{r}_t$ pair to be evaluated, we retrieve pseudo-references based on a combination of of a) Past $d_t^{past} = C_t^{t-L_b}$ b) Gold response d_t^{resp} c) Future $d_t^{future} = C_{t+2+L_f}^{t+2}$. L_b and L_f are past and future context windows. Our retrieval similarity function is a sum of the log scores between each corresponding element of the turn under evaluation with the candidate turn.

Table 4: Utterance level Spearman Rank Correlation (Spearman, 1961) with p-values. (1) SCARCE-SINGLE augments the original single human written response (SINGLE) in DailyDialog dataset (Li et al., 2017) using proposed method. It leads to large improvements in correlations across most of the metrics, when compared to SINGLE. (2) SCARCE-MULTI augments the MULTI dataset, again leading to improvements in correlations to human ratings, especially for BLEU and BERT-Prec metrics. Additionally, we note that almost all of the correlation values with SCARCE-MULTI are statistically significant with $p < 0.05$.

Condition	Action
Type is OEFFECT Example: OEFFECT (excited)	Prepend 'I feel' => 'I feel excited.'
Type is OWANT Example: OWANT (to thank personx)	Prepend 'I' => 'I want to thank personx.'
Type is OREACT Example: OREACT (have a party)	Prepend 'I will' => 'I will have a party.'
Word PERSONX Example: i thank PERSONX.	Replace with 'you' => 'I thank *you*.'

Table 5: Templates and rules to transform semi-structured COMET outputs to surface NL forms.

$$Sim(d_t, x_{t'}) = \log S_{bm25}(d_t^{past}, x_{t'}^{past}) + \log S_{bm25}(d_t^{resp}, x_{t'}^{resp}) \\ + \log S_{bm25}(d_t^{future}, x_{t'}^{future})$$

We set $L_b = L_f = 2$ without specific tuning, as an intuitive tradeoff between enough specificity and enough possibility of relevant candidates.

BM25 (Robertson et al., 1995) or "Best Match 25" is a tfidf like similarity. Its specific form is:

$$S_{BM25}(q, d) = \sum_{w_i \in q} \log(\frac{N}{df_i}) \frac{(k_1 + 1)tf_i}{k_1((1 - b) + b\frac{dl}{avdl}) + tf_i}$$

Here, tf_i and df_i are the term frequency in the current document and the document frequency (in the corpus). N is corpus size, while dl and $avdl$ are current and average document lengths. b controls extent of document length normalization, while k_1 controls effect of term frequency. With $b = 0$ and $k_1 \to \infty$, this reduces to simple tfidf . Here, we use default gensim values, $b = 0.7$, $k_1 = 0.5$

D Qualitative Examples

In Tables 6, we list some examples, each illustrating a turn of a test dialog with its immediate past, future, the four additional human references from (Gupta et al., 2019) (shown under MULTI 2,3 and MULTI 4,5), followed by automated response sets from different sub-components of SCARCE.

D.1 Before/After CONTEXTADAPT

In Example *4-4* of Table 6, we can observe how *"Yes , I'm young , and unmarried . It's no problem for me to travel frequently ."* gets context-adapted (shown as +CA, short for CONTEXTADAPT) to *"Yes , I'm able to understand English. It 's not that I don't understand English ."* which indeed does match the preceding dialog better. Similarly, in Example *50-2* of Table 6, we can see how *"Well, that might be acceptable if you handle insurance fees"* is modulated stronger to the context which asks about duration, getting adapted to *"Well, that's a lot of time to wait for the draft to be drawn."*. Note that we omit this row for the examples where it simply leaves the input unchanged, or produces outputs which are noticeably unfaithful or ill-formed.

D.2 Complementarity of Components

Sometimes, a component may suffer from example specific issues e.g In Example *35-2*, the COMMONSENSE approaches misinterpret what is a driving ticket in the context of the dialog as an event ticket, drawing inferences accordingly. However, even in such cases, the other component salvages the situation and ensures overall response set remains healthy - e.g, here, RETRIEVAL produces pertinent responses like *Could you tell me how you dealt with it this time?*, *No I haven't. What about you ?* etc. In Example *10-3*, we see the opposite situation, where the responses from RETRIEVAL are somewhat less relevant, but COMMONSENSE produces very pertinent responses such as *"i decline the date"* and *"I go on another date"*

E Human Evaluation Details

E.1 Quality of References

The quality of references were judged by two graduate students from a university where the medium of instruction is English. The annotators were requested to ignore minor grammar issues, and focus more on the content of the response.

F Computing Details

The GPUs used for COMMONSENSE and CONTEXTADAPT experiments were a Geforce Rtx 2080 and TitanX Pascal respectively.

No	Type	Text
0-5	Context	A: I also have blow if you prefer to do a few lines.
	Future	A: come on man ! i even got dope and acid ! try some !.
	Single	B: No, I am ok, really.
	Multi 2,3	B: what is your price ? ; B: no thanks, I’m out of cash
	Multi 4,5	B: yeah , what have you go got ?; B: maybe tomorrow , i ’m running late .
	Retrieval	B: Well , I guess Zina figured you couldn’t blow it if you were in the hotel room .
	Retrieval w CA	B: I have a few lines of blow , but it is not necessary in the way of the rest of the script .
	Commonsense	B: i want to go to bathroom; B: i want to play game; B: i want to have rest; B: i want to sleep
1-1	Context	B: The taxi drivers are on strike again A: What for?
	Future	A: it is really a hot potato .
	Single	B: They want the government to reduce the price of gasoline .
	Multi 2,3	B: they want more pay for their time .; B: they are not happy with their permit related expenses .
	Multi 4,5	B: they want healthcare and benefits .; B: i don’t know . i just know there are no cabs in the city
	Retrieval	B: Well . Don’t worry about it , I will be happy to share the taxi with you .
		B: I think the price is a little high , can’t you reduce it?
	Retrieval w CA	B: Well , they are not going to be able to get their fares back .
		B: I think the reason is a little more complicated than that .
4-4	Context	A: Do you think you can make yourself easily understood in English ?
	Single	B: yes , in most circumstances .
	Multi 2,3	B: my english is fine . my keyboard sometimes just acts up . ; B: yes, and i’m constantly trying to improve my communication.
	Multi 4,5	B: i do n’t know . i may be to nervous and then i ’ll mess up . ; B: yes , i believe so . i ’ve been speaking english since birth .
	Retrieval	B: Yes , I’m young , and unmarried . It’s no problem for me to travel frequently .
	Retrieval w CA	B: Yes , I’m able to understand English . It ’s not that I don’t understand English .
10-3	Context	B: Hold on , please . Let me check it for you . Yes , you’re right . You will keep it for 3 days .
		A: Well , now I want to change the date from 24th to 28th .
	Single	B: ok , that shall be arranged .
	Multi 2,3	B: we can easily do that for you . ; B: i ’m sorry but someone’s reserved the room for 28th . i can offer you a different room ?
	Multi 4,5	B: i can extend your stay time but it may cost more since it is going into the holiday . ;
		B: i can give you a different double room for the 28th at a discounted price .
	Retrieval	B: All right . May I have your name ? ; B: Apparently there is only $ 57 left in your account . ;
		B: Here you are . What is the rate ?; B: I prefer not to move first .
	Commonsense	B: i decline the date ; B: i go on another date; B: i go on a date;
		B: i get nervous; B: i get rejected; B: i get dumped; B: i feel sad
23-10	Context	B: I mainly eat baked chicken , because there’s not a lot of fat . A: that does sound pretty good .
	Single	B: i know it does , and that ’s because it is .
	Multi 2,3	B: yes , it is very good and pretty healthy .; B: it is good , you should come over and i will make you dinner .
	Multi 4,5	B: thanks , it ’s been a struggle , but i am starting to see results . ;
		B: i appreciate your kind words , i am getting used to eating more healthy .
	Retrieval	B: You should try it . You won’t be disappointed .; B: Do you have any plans for tomorrow ? ; B: That’s it ? ;
		B: Just about . ; B: I like fish . Please bring me an order of that .
	Commonsense	B: i want to cook dinner; B: i want to go to movie; B: i want to write letter ;
		B: i will open your mouth; B: i will think about what you want; B: i will drink some water;
35-2	Context	B: I’ve never gotten one . Have you ? A: I got a ticket yesterday .
	Future	A: i parked in the red zone .
	Single	B: really ? what did you get one for ?
	Multi 2,3	B: what was it for ? ; B: how much is it ?
	Multi 4,5	B: do you resent you got a ticket ? ; B: are you going to appeal the ticket ?
	Retrieval	B: I’ve gotten a few .; B: No , I haven’t . What about you ? ;
		B: Could you tell me how you dealt with it this time ? ;
		B: I will explain it in detail in the next class , could you preview it ?
	Commonsense	B: i give ticket to you; B: i give ticket to the cashier; B: i give ticket to the clerk.;
		B: i feel happy .; B: I feel excited .; B: i feel annoyed . ; B: I feel disappointed .;
		B: i see what else they can do .; B: i see what else they can do to get the ticket; i go to the event

Table 6: Example context-response pairs from the test split of DailyDialog, showing the automated responses returned by different sub-components of Scarce. ContextAdapt is shortened to CA for brevity.

Who Blames or Endorses Whom?
Entity-to-Entity Directed Sentiment Extraction in News Text

Abstract

Understanding who blames or supports whom in news text is a critical research question in computational social science. Traditional methods and datasets for sentiment analysis are, however, not suitable for the domain of political text as they do not consider the direction of sentiments expressed between entities. In this paper, we propose a novel NLP task of identifying directed sentiment relationship between political entities from a given news document, which we call *directed sentiment extraction*. From a million-scale news corpus, we construct a dataset of news sentences where sentiment relations of political entities are manually annotated. We present a simple but effective approach for utilizing a pretrained transformer, which infers the target class by predicting multiple question-answering tasks and combining the outcomes. We demonstrate the utility of our proposed method for social science research questions by analyzing positive and negative opinions between political entities in two major events: 2016 U.S. presidential election and COVID-19. The newly proposed problem, data, and method will facilitate future studies on interdisciplinary NLP methods and applications.[1]

1 Introduction

Sentiment analysis is a useful technique for opinion mining from text data. Most existing work either focuses on sentence-level classification (Van Hee et al., 2018; Zampieri et al., 2019), or aims to detect the sentiment polarity towards specific targets (Pontiki et al., 2016; Cortis et al., 2017). These approaches typically do not distinguish sources and targets of the sentiment. They mainly use user-generated content (UGC), such as tweets or restaurant reviews from Yelp, which assumes each user (account holder) is the source of the sentiment, and that the target is also clearly defined or easily identifiable (e.g., the restaurant).

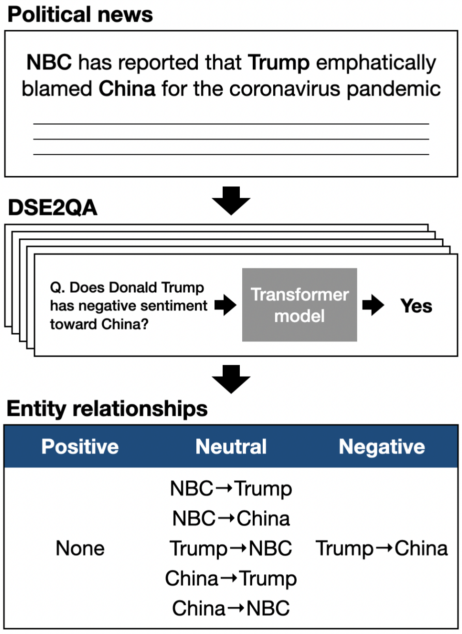

Figure 1: Overview of the directed sentiment extraction

This assumption does not hold for political news analysis where a large number of political actors blame or support each other in news articles. The key interest for political sentiment analysis is to identify "who" blame or support "whom" (Balahur and Steinberger, 2009) rather than simply assigning a global sentiment polarity to a given document or sentence. For example, from a sentence like "X supported Y for criticizing Z," we can infer X is positive toward Y and both X and Y are negative toward Z. However, existing sentiment analysis methods are not suitable to detect such sentiment relationships between entities.

This paper proposes a new NLP task of identifying directed sentiment relationships from a political entity to another in news articles: *directed sentiment extraction*. For this task, we introduce a newly annotated corpus from a million-scale news

dataset. As demonstrated in Figure 1, we transform directed sentiment extraction to multiple question-answering tasks (**DSE2QA**) and combine their predictions for making a final prediction. Evaluation results show it outperforms state-of-the-art classification approaches, such as a fine-tuned RoBERT classification model. Going further, we demonstrate the utility of our method through two case studies on how news media in the U.S. portrayed relationships between political entities differently amid the US election and COVID-19 pandemic. The analysis reveals that the left-leaning media present Donald Trump more as the target of blame while the right-leaning media present news stories blaming other entities. This study not only makes a contribution to the NLP community by defining a new problem and approach but also adds the empirical understanding of media bias to the social science community.

2 Related Work

2.1 Sentiment Analysis in Media

Sentiment analysis or polarity detection aims at deciding whether a given text contains positive or negative sentiment (Liu, 2012) or quantifying the degree of sentiments embedded in a text (Gilbert and Hutto, 2014). Previous studies have tackled the problem as a classification task (Maas et al., 2011) and applied the trained model to infer sentiments embedded in various web and social data (Park et al., 2018). Recently, transformer-based models have shown high performance in sentiment classification (Devlin et al., 2019) and aspect-based sentiment analysis (Sun et al., 2019).

Measuring sentiment or tone of political text in news media is a widely used method in computational social science (Young and Soroka, 2012). A stream of work has used social media posts to estimate public opinions about political actors and predict the outcomes of future events by large scale sentiment analysis (O'Connor et al., 2010; Ceron et al., 2014; Wang et al., 2012), while some studies further extend to nonverbal or multimodal dimensions (Joo et al., 2014; Won et al., 2017; Chen et al., 2020a).

2.2 Stance Detection

Stance detection is a relevant NLP problem that aims to predict a claim's stance on reference text (Augenstein et al., 2016) or to infer social media users' view toward an issue (Darwish et al., 2020). Many studies tried to advance the deep learning-based models (Mohtarami et al., 2018), for example, by modeling text with a hierarchical architecture (Sun et al., 2018; Yoon et al., 2019). Unlike stance detection, this study aims at understanding an entity's sentiment toward another entity, both of which appear in the same sentence.

2.3 Relation Extraction

Our target problem is also relevant to relation extraction, which is a task of extracting structured relationships between entities from unstructured text. While the early literature relied on feature-based methods (Zelenko et al., 2003), recent methods actively utilize neural methods (Lin et al., 2016); for example, a study proposed a neural model that jointly learns to perform entity recognition and relation extraction (Bekoulis et al., 2018). Most recently, a study tested the use of the pretrained transformer-based language model for relation extraction (Zhang et al., 2020).

Despite its similarity to directed sentiment extraction, most of the existing datasets only consider *explicit* entity relationships such as EMPLOYEE_OF and CITY_OF_RESIDENCE (Zhang et al., 2017). Understanding sentiment relationships between political entities is more challenging as their sentiment is usually hidden in text.

3 Problem and Dataset

In this section, we introduce our problem formulation and explain the process of our dataset construction and annotation.

3.1 Target Problem

Given a sentence s that contains two entities p and q, the *directed sentiment extraction* problem aims to detect the sentiment relation from p to q among five classes: neutral, p holds a positive or negative opinion towards q, and the reverse direction. For example, in the given sentence in Figure 1, the model should infer that Trump is the source of the negative sentiment toward China, the target. Existing approaches for sentiment analysis cannot be easily adapted to the task, as existing methods aim to detect polarity embedded in a text (sentiment classification), for a specific target (targeted), or with regard to an aspect (aspect-based). These problem setups do not consider the source and target of the sentiment at a time, which cannot identify directed sentiment relationships between political entities.

Class	Count
Neutral	10,604
Positive ($p \rightarrow q$)	1,656
Positive ($p \leftarrow q$)	327
Negative ($p \rightarrow q$)	3,163
Negative ($p \leftarrow q$)	478
Total	16,228

Table 1: Dataset statistics

In the following, we introduce a new annotated corpus for the problem.

3.2 Data Collection

To construct our dataset, we used news articles from the Real News corpus (Zellers et al., 2019), which consists of 32,797,763 real news stories in English published by various outlets over multiple years. Among them, we used 7,127,692 news articles shared by news media that are verified as trustworthy by Media Bias/Fact Check (Media Bias Fact Check, 2015). After splitting each article into multiple sentences, we only took sentences with two or more entities using the named entity recognition tool in Spacy[2]. To focus on the relationships between political entities, we considered named entities identified as people, countries/political groups, organizations, or cities/states[3].

Since most entity relationships in regular sentences are presumably neutral, we took two approaches for sampling sentences that cover diverse relationships: (i) dictionary-based and (ii) random selection approaches. The dictionary-based approach filters in sentences containing positive or negative keywords from a pre-defined dictionary. Starting from the blame-related keywords (Liang et al., 2019), we extended the dictionary by adding their synonyms and antonyms. While this method is effective in sampling from an unbalanced dataset, it excludes sentences that do not explicitly mention a blame or support keyword. Thus, we also randomly drew sentences to improve the dataset coverage.

3.3 Crowdsourced Annotation

We used Amazon Mechanical Turk (AMT) to annotate each sentence. The annotation task asked workers to identify what sentiment does an entity holds toward another in a given sentence. We instructed them to annotate a sentence based only on the sentiment expressed within the sentence, without relying on prior knowledge. There are five options to choose from, neutral, positive ($p \rightarrow q$), positive ($q \rightarrow p$), negative ($p \rightarrow q$), and negative ($q \rightarrow p$). p is the preceding entity of q, and the arrow indicates sentiment direction between the two entities. The detailed instruction used for educating annotator is presented in Table A1 in Appendix.

We hired five workers to annotate each sentence. For ensuring high-quality responses, we only allowed workers to participate in the task when they had at least a 70% acceptance rate for more than 1,000 previous annotations. After completing the initial round of annotation, we filtered out unreliable responses completed within one second or responses by workers who did not pass test questions. We designated workers with at least one unreliable response as untrustworthy and discarded all the other responses submitted by the untrustworthy workers. We repeated the annotation task for the discarded answers until we have five annotations for every sentence. The final set of annotations indicates a Fleiss' kappa value of 0.26, indicating an acceptable level of agreement among annotators. The level of reliability is comparable to studies using subjective text annotations such as hate speech annotation (Ross et al., 2017), subjectivity (Abdul-Mageed and Diab, 2011), and sentiment analysis (Park et al., 2018). By aggregating five responses for each sentence by a majority vote, we obtained the final dataset of 16,228 sentences of which sentiment direction is annotated, as shown in Table 1. While keeping the label distribution almost identical, we split the dataset into 13144, 1461, and 1623 instances for train, validation, and test set, respectively.

4 Methods

This section presents methods for addressing the problem of directed sentiment extraction. We propose a novel approach for solving it by employing augmented inputs in BERT-like transformer models and compare it with classification approaches.

4.1 Classification Approaches

Following the standard in using classification setups for (undirected) sentiment detection (Liu, 2012; Devlin et al., 2019), we construct classification models that predict scores of each sentiment for the directed sentiment extraction.

---

[2] https://spacy.io

[3] https://spacy.io/api/annotation#named-entities

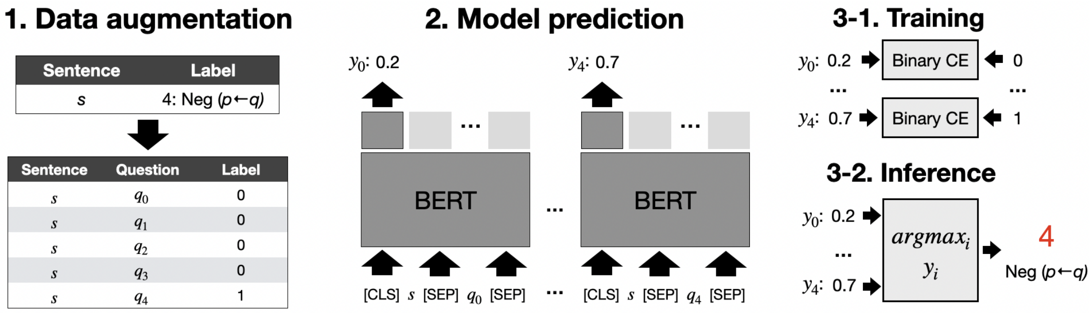

Figure 2: Detailed illustration of the DSE2QA approach

4.1.1 Existing Methods

We first construct previous approaches proposed for blame relationship detection. Liang et al. (2019) proposed three neural models that predict the classes of blame relationships in a given text: $p \rightarrow q$, $p \leftarrow q$, and no relationship. We extend their approaches to the five classes of directed sentiment in our dataset.

Entity prior model exploits the prior knowledge on political entities by using the representation of two entities using a pre-trained word embedding: $\mathbf{e}_p$ and $\mathbf{e}_q$. After concatenation, the two vectors are fed into a fully-connected network with a ReLU hidden layer to make a final prediction. *Context* model utilizes the context of the target sentence where two entities appear. After replacing p and q with special tokens ([ENT1] and [ENT2]) respectively, the model encodes the input text through a bidirectional LSTM and extracts the representation corresponding to the two entities: $\mathbf{lstm}_p$ and $\mathbf{lstm}_q$. The representation gets fed into a fully-connected network. *Combined* model utilizes the concatenated representation of the outputs of the entity prior and context model: $\mathbf{e}_p$, $\mathbf{e}_q$, $\mathbf{lstm}_p$, and $\mathbf{lstm}_q$. Then, the vector is fed into a fully-connected network. We train the existing models by minimizing the cross-entropy loss.

4.1.2 Fine-Tuning a Pretrained Transformer

Fine-tuning a BERT-like pretrained transformer has shown significant performance in many downstream tasks (Devlin et al., 2019). We also evaluate the performance of a fine-tuned transformer. In particular, after replacing the tokens corresponding to p and q with [ENT1] and [ENT2], we train a classification model that predicts the five-class output based on the representation of [CLS][4]. We use the RoBERTa base model (Liu et al., 2019) as backbone, and we refer to the classification model as *RoBERTa* in evaluation experiments. The model is trained to minimize the cross-entropy loss.

4.2 Proposed Approach: Directed Sentiment Extraction to Question-Answering

BERT-like transformer models are pretrained using two inputs including a separator token[5] with varying training objectives. The input configuration allows the model to be successfully transferred to the tasks using an auxiliary input, such as sentence pair classification (sentence 1 and sentence 2) and question answering (reference and question). Inspired by the recent achievements using auxiliary inputs (Sun et al., 2019; Cohen et al., 2020), we propose a simple but effective approach of tackling the directed sentiment extraction problem, which we call **DSE2QA**; we transform the sentiment extraction task into the sub-tasks aiming for answering yes/no questions on whether a target sentiment is embedded in the text. The basic idea is we inquire an intelligent machine who can answer yes/no questions on whether a target sentiment exists and then combine the answers corresponding to the each sentiment class for making a final guess. Figure 2 presents the overall framework, which we elaborate on each step in the following. Technically, taking auxiliary input in BERT-like transformers enables implementing the intelligent machine by making a different prediction with the same sentence input, according to the question fed as additional input. We hypothesize that a large-scale pretrained transformer model on a massive corpus can understand the meaning of the augmented question and thus successfully answer whether a directed sentiment exists in a text.

Note that our question-answering setup is different from standard question-answering tasks in NLP, as represented by well-known benchmark data such as SQuAD (Rajpurkar et al., 2016) and

---

[4] <S> in RoBERTa

[5] [CLS] in BERT, </S></S> in RoBERTa

Index	Complete questions	Pseudo questions
q_0	Do [Ent1] and [Ent2] have neutral sentiment toward each other?	[Ent1] - [Ent2] - neutral
q_1	Does [Ent1] has positive sentiment toward [Ent2]?	[Ent1] - [Ent2] - positive
q_2	Does [Ent2] has positive sentiment toward [Ent1]?	[Ent2] - [Ent1] - positive
q_3	Does [Ent1] has negative sentiment toward [Ent2]?	[Ent1] - [Ent2] - negative
q_4	Does [Ent2] has negative sentiment toward [Ent1]?	[Ent2] - [Ent1] - negative

Table 2: Auxiliary questions according to the target label

WikiQA (Yang et al., 2015). Given a question and reference text, the standard task aims at generating answers in a natural language form. In contrast, the question-answering process in DSE2QA requires a binary answer, which can be seen as a special type of question-answering.

4.2.1 Data Augmentation for DSE2QA

For each pair of label l and sentence s where the two target entities p and q are masked as [ENT1] and [ENT2] respectively, we augment the training data by transforming the original input into the five tuples using the same sentence and different questions: t_i: (s, q_i, l_i) where i is the index of the target relation class: neutral (0), $p \rightarrow q$ with positive sentiment (1), $p \leftarrow q$ with positive sentiment (2), $p \rightarrow q$ with negative sentiment (3), and $p \leftarrow q$ with negative sentiment (4). l_i becomes 1 if l is i; otherwise l_i is 0.

We design the auxiliary question q_i asking whether the given sentence s is classified as the target sentiment i. The list of questions are presented in Table 2. For example, q_1 asks a model whether a given sentence s contains positive sentiment from p to q. Here, we define two types of questions: complete and pseudo. Complete questions are written in a natural language, and pseudo questions only contain keywords that is sufficient to characterize a sentiment class i while ignoring the syntactic structure.

4.2.2 Model Prediction

We utilize the BERT-like transformer model (Devlin et al., 2019), which can take sentence pairs as input, for making a binary prediction on a given sentence s and question q_i. In particular, the model takes

$$[\text{CLS}]\ s\ [\text{SEP}]\ q_i\ [\text{SEP}]$$

as input[6] and predicts a value y_i from 0 to 1 that indicates the confidence on the target label i.

4.2.3 Training and Inference

For the augmented input of t_i, a pretrained BERT-like transformer is trained to predict 1 for t_l and 0 for $t_{i \neq l}$ through the [CLS] representation at the last layer of the transformer model followed by a classification layer. For inference, we made a prediction corresponding to s by $\text{argmax}_i\, y_i$ where y_i is the prediction outcome of t_i. The y_i indicates the confidence on each sentiment i, and therefore we take the class of which the value is maximum.

In the experiments, we utilize the RoBERTa base model for the backbone of DSE2QA and train the model to minimize the binary cross-entropy loss. This approach is different from the RoBERTa classification model that only employs a single sentence input.

5 Performance Evaluation

We evaluate the performance of the proposed DSE2QA approach using our annotated corpus. We compare our method with the current state-of-the-art methods for directional blame detection proposed by Liang et al. (2019) (LNZ) as well as a classification model fine-tuned on a pretrained transformer (RoBERTa).

5.1 Experiment Setups

For the LNZ models (Liang et al., 2019), we set the vocabulary size as 10000. We set the word embedding size, LSTM hidden dimension, and the fully connected layer dimension as 256, 512, and 1024. The search space for the dropout rate is $[0.1, 0.5]$. We train the LNZ models using Adam optimizer with a learning rate of 1e-3 (Kingma and Ba, 2014). We adopt an early stopping strategy with the patience of 5. For training RoBERTa and DSE2QA, we followed the procedure of Liu et al. (2019) using AdamW (Loshchilov and Hutter, 2017). We optimize hyperparameters by randomly choosing ten sets for each model and selecting the model with the best performance on the validation set. The learning rate is set to 2e-5 with the epsilon as

Table 4: F1-score per class measured on the test set. Top performance for each metric is marked as bold.

1e-6. The weight decay is set to 0.1. We apply random oversampling to the training set to make a balanced dataset against the label. We run the experiment five times with different random seeds and report the average scores.

5.2 Evaluation Results

We utilize three measures for evaluation: micro-f1, macro-f1, and mean average precision (mAP). Micro-f1 is calculated by (#correct)/(#total), which corresponds to the multi-class classification accuracy. Macro-f1 measures an f1-score for each class and averages them with equal importance; therefore, macro-f1 is a more robust measure to a skewed class distribution, such as our annotation data (see Table 1). Similarly, mAP measures the unweighted average of average precision (AP) on each class; AP summarizes a precision-recall curve varying prediction threshold for a target class.

In Table 3, we make three observations. First, among classification approaches (the bottom four rows), RoBERTa outperforms the other approaches across the three measures (0.7486/0.6409/0.7319). The LNZ combined model achieves a fair micro-f1 score of 0.7055 but low scores of macro-f1 (0.5358) and mAP(0.5295). This difference is because the combined model (and other non-transformer models) is poor at classifying non-neutral sentiment, which we will further investigate in Table 4. Second, DSE2QA with complete questions outperforms RoBERTa with a margin of 0.024 by micro F1. The proposed approach also achieves better performance in macro F1 and mAP. Third, the performance of DSE2QA gets further increased with the usage of pseudo questions, up to the micro-f1 score of 0.7973. This observation implies that a BERT-like transformer model may not need a full sentence to utilize the auxiliary input because it also performs well using fewer keywords for the detection task with an augmented input.

Table 4 presents the f1-score measured for each class: neutral (0), positive from the left entity to the right (1), positive from the right to the left (2), negative from the left to the right (3), and negative from the right to the left (4). Here, we make three observations. First, all models perform the best at identifying neutral sentiment (0) compared to the other sentiment classes. Second, non-transformer models (the bottom three rows) are poor at extracting non-neutral sentiment regardless of their direction, which contributes to the decreased macro F1 in Table 3. Third, among the sentiment classes from the left entity to the right entity (1, 3), transformer models better detect negative sentiment than positive sentiment. The finding suggests that positive entity relationships are more difficult to be captured in news articles, which calls for future studies for a better understanding and model improvement. AP per each class also shows a similar trend, as presented in Table A3.

In summary, the proposed approach of solving the directed sentiment extraction task by multiple question-answering tasks outperforms the state-of-the-art classification approaches. The high performance suggests that the model can understand the meaning of augmented questions to some extent, which may build on the language understanding ability of the pretrained RoBERTa.

6 Analyzing Entity Relationships in News Articles

To demonstrate the utility of the proposed dataset and model, we conduct two case studies to analyze entity-to-entity sentiment relationships presented in recent news articles on political issues: the 2016 U.S. presidential election and the COVID-19 pandemic. For the analyses, we utilize the DSE2QA model with pseudo questions trained on the annotated corpus, and we confirm that the target news articles are not overlapped with the whole set.

6.1 Case Study 1: 2016 U.S. election

We study how news media covered the entity relation during the 2016 United States presidential election using a public dataset on news articles between Feb. 2016 to Feb. 2017[7]. This dataset consists of about 140K news articles in English from fifteen media companies, including CNN, New York Times, and Guardian. We randomly select 3K articles from each month, 39K articles in total. Then we apply the proposed model to all sentences that contain at least two entities from the top-30 most frequent entities, including Donald Trump and Hillary Clinton.

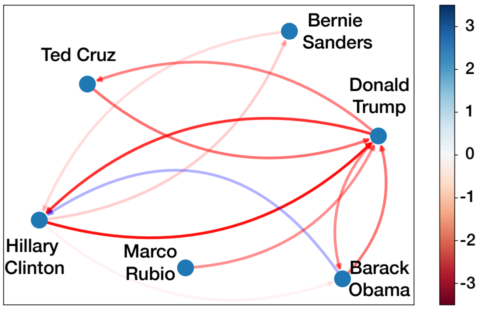

Figure 3: Log ratios of positive (blue) and negative (red) sentiments in directed political relationships in the news articles.

Figure 3 presents the frequently mentioned pairs of politicians. The red color indicates an entity pair tends to contain negative sentiment more than positive, and blue indicates the pairs with the negative sentiment more. The opacity represents the strength of the opinion measured by the log ratio of inferred pairs of positive and negative sentiment. For brevity, we present relations that appear at least 20 times in any sentiment. Overall, there are 4.68 times more negative sentiments found than positive ones, which may be explained due to the negative nature of political media (Soroka, 2014). An interesting observation is the asymmetric relation between Hillary Clinton and Barack Obama. Clinton holds a generally slightly negative opinion towards Obama, while Obama holds a stronger positive opinion towards Clinton. Note that our model does not just memorize the entity relationship in the training dataset and apply it to the target dataset as we replace detected entities with tokens in input sentences.

Washington Post		

Table 5: The list target media outlets sorted by alphabetical order.

6.2 Case Study 2: the COVID-19 pandemic

In the second study, we investigate how news media portray political entities and their relationships differently according to their political orientations. For example, a right-leaning news outlet may show more negative opinions expressed toward Democrats. To that end, we focused on the recent issue of the COVID-19 pandemic to examine the media bias. We expect the general sentiment about COVID-19 is negative but would like to investigate who blames whom because the messages will have very different meanings according to the sources and targets, differentiated by our data and method.

To collect a recent news article set, we first compiled a list of 35 popular news media outlets that cover American politics in English. We also ensure the list of news outlets was balanced against political bias, according to the media bias ratings in `allsides.com`. For brevity, we consolidate 'Lean

Entity	Rank (Left)	Rank (Center)	Rank (Right)
Donald Trump	1	2	1
Republican	2	6	6
U.S.	3	1	3
Democrat	4	5	4
Russia	5	6	9
American	6	15	10
China	7	4	5
Obama	8	10	7
Chinese	9	3	2
Joe Biden	9	8	7

Table 6: Frequency rank of top-10 frequent entities targeted with a negative sentiment through an entity-to-entity relationship in the COVID-19 news dataset. The order is sorted by the overall rank in the dataset.

left' and 'Left' into 'Left' and 'Lean right' and 'Right' into 'Right.' Table 5 presents the list of the target media.

For each of the target media outlets, we collected news articles shared throughout 2020 until September from the Common Crawl corpus, which has been collecting web data since 2008[8]. The total number of retrieved news pages are is 256,081; on average, we have 7,113 published news articles for each outlet.

Next, we selected documents containing at least one of the keywords relevant to COVID-19 by following similar practices used for collecting a Twitter dataset (Chen et al., 2020b): *coronavirus*, *covid-19*, *COVID19*, and *corona virus*. We consider sentences containing two or more entities for the target of inference, and every relationship pair is inferred when there are more than two entities in a sentence. The final set consists of 6,180 articles involving 1,078,377 entity pairs for COVID-19.

Table 6 presents the list of 10 frequent entities that are manifested through entity-to-entity relationships with a negative sentiment. While Donald Trump was the most frequent target of blames in the total data, the results show that the right-leaning media tend to express a negative sentiment toward China (#5) and Chinese people (#2) more frequently. To examine the difference systematically, we measure the spearman rank correlation coefficient for the whole list of entities that appeared in the dataset. The rank in the left-leaning media and that in right-leaning media exhibits a highly negative correlation of -0.5722 (p<0.001), which suggests that the list of political entities presented with a negative sentiment significantly varies across news media according to their political orientation. Such a high level of negative correlation is also observed in the ranks for the source entity in negative relationships (-0.4129 with p<0.001) and the source/target entities in positive relationships (-0.5605/-0.7929 with p<0.001).

Going further, we analyze the differences between frequently presented entity pairs with negative sentiment by the left and right-leaning media, respectively. Table 7 presents the rank of each entity pair in the media groups according to their political orientation. In the left-leaning media of our dataset, Donald Trump appears as either source or target in the top-10 frequent negative pairs except for the pair of Republican→Democrat and vice versa. On the contrary, the top-10 pairs in the right-leaning media include the international relationships of Donald Trump to the other countries. In other words, the left-leaning media may try to frame COVID-19 as a **domestic event** focusing on how the President handles it and how people respond to his crisis management, and the right-leaning media focus more on **foreign policies and international relationship** especially between the U.S. and China. For the whole set of entity pairs, the rank correlation between the left and right media is -0.4847 (p<0.001) for negative sentiment and -0.7929 (p<0.001) for positive sentiment. These negative correlations imply that the news media has a bias in selecting issues to cover (selection bias) and presenting relationships of political entities (presentation bias).

7 Conclusion

Detecting who blames or endorses whom in news articles is a critical ability in understanding opinions and relationship between political actors in news media. This paper provides a computational tool based on natural language processing for facilitating interdisciplinary studies using text in news and social media.

We introduced a new problem of identifying directed sentiment relationships between political entities, called directed sentiment extraction. We constructed a training corpus of which entity relationship is manually annotated for each sentence. This dataset can serve as a benchmark for future studies. A potential future direction is to build an improved version of the dataset where sentiment re-

House→Donald Trump	12	67	10

Table 7: Frequency rank of entity pairs presented with a negative sentiment in the COVID-19 news dataset

lationships between political entities appear across multiple sentences in news articles.

To tackle the problem, we proposed DSE2QA (Directed Sentiment Extraction to Question-Answering), which is a simple yet effective method of utilizing BERT-like pretrained transformers by predicting answers for binary questions on whether a sentiment relationship exists in a given text. Answers for each sentiment class are aggregated to make a final guess. Evaluation experiments show the approach outperforms state-of-the-art classification models, such as the fine-tuned RoBERTa classification model. We hypothesize the language understanding ability of the BERT-like pretrained transformer may contribute to the high performance, combined with its facility of taking auxiliary input. Furthermore, the performance increase with the pseudo questions implies that a few keywords may suffice to make an inquiry. Future research could investigate which kind of pretrained transformer is the most effective for understanding the meaning of the augmented question, as DSE2QA's backbone can be replaced with any BERT-like transformer. Also, this study calls for future studies on advanced methods for directed sentiment extraction. A potential approach could jointly learn entity recognition and directed sentiment extraction as similarly tackled by a study on information extraction (Bekoulis et al., 2018).

As the last step, we conducted case studies by analyzing directed sentiments in news text for the US election and COVID-19 pandemic. The observations not only add empirical understandings to the social science research but also highlight the utility of the proposed problem, dataset, and model for political news analysis. We believe the proposed method can therefore further the current interdisciplinary efforts of the NLP, machine learning, and the social science communities (Grimmer and Stewart, 2013; Roberts et al., 2014; Joo and Steinert-Threlkeld, 2018).

Ethics and Impact Statement

In online news and social media, people express diverse sentiment toward a target through text, such as blame, support, endorsement, to list a few. Quantifying and understanding the patterns is of significant interest in social science, but the lack of automated methods makes it difficult to handle large-scale data, which can reveal patterns in a comprehensive view. In this light, this study aims to develop automated methods of identifying directed sentiment between entities by defining a new NLP problem: directed sentiment extraction. The newly annotated dataset will facilitate future development of the NLP methods, and the DSE2QA approach will serve as a strong baseline.

The development of an automated method will have a broader impact by tackling real-world challenges such as bias in news reporting against political orientation, with potential collaboration with social science. Moreover, it will enable the discovery of hidden biases with regard to sentiment in online text, which can be mistakenly learned through data-driven methods. A fine-grained understanding of sentiment relationships will broadly contribute to building a fair machine learning model, which is of significant interest in AI ethics.

Instruction:
Based the given sentence, please identify if one entity (person, organization, or country) holds a positive or negative opinion towards another entity. There will be two entities in total. One is in red and the other is in blue.

It is also possible neither positive nor negative opinion exists in the sentence.
Please annotate such cases as neutral.

Please classify the sentence based on what people say instead of what they do.
For example, if a sentence only states the police arrest someone, this sentence should be classified as neutral.
Instead, if the police accuses someone of commiting a crime, this sentence should be classified as police holds a negative opinion towards the person.

Examples:
- Earlier on Tuesday, Mr. Trump criticized General Motors for making cars in Mexico.
(Negative: Trump holds a negative opinion towards General Motors)
- Hugo Ras has been accused of killing other people's rhino, and for that South Africans condemn him.
(Negative: South Africans holds a negative opinion towards Hugo Ras)
- DAVID Cameron's accused the Conservatives of failing to devolve essential welfare powers to, as agreed by the cross-party Smith Commission which considered further powers for the Scottish parliament last year.
(Neutral: There is no direct opinions between these two entities.)
- Prime Minister Stephen Harper shakes hands with Petty Harbour, N.L., during a campaign event in Toronto on Sept. 18, 2015. (Neutral: They shake hands just for politeness. No opinions exist.)
- Obama pulled Clinton into his administration after he defeated her in 2008 primary and has effusively praised her tenure as secretary of state. (Positive. Obama holds a positive opinion towards Clinton.)
- Earlier on Tuesday, Mr. Trump has not comments on General Motors making cars in Mexico. (Neutral.)

Note:
There are multiple annotators for each sentence. Your response will be judged as failed when it is different with other annotators. If the percentage of failed response from one annotator is above a threshold, the annotator will NOT get paid for ALL responses. Thanks for your participation.

Abstract

Motivated by recent advancements in grammatical error correction in English and existing issues in the field, we describe a new resource, an annotated learner corpus of Russian, extracted from the Lang-8 language learning website. This new dataset is benchmarked against two grammatical error correction models that use state-of-the-art neural architectures. Results are provided on the newly-created corpus and are compared against performance on another, existing resource. We also evaluate the contribution of the Lang-8 training data to the grammatical error correction of Russian and perform type-based analysis of the models. The expert annotations are available for research purposes.

1 Introduction

The task of Grammatical Error Correction (GEC) is concerned with correcting various grammatical and usage errors in text. Recently, much progress has been made, especially in English GEC, within the framework of neural machine translation (NMT) approaches. In spite of the progress, the issue of building *robust* models in GEC has been emphasized: Mita et al. (2019) showed that the performance of the models varies significantly across corpora and that single-corpus evaluation may be unreliable. While in English more efforts are being made in this direction, in other languages, due to lack of benchmark corpora and other resources, very little work has been done. More importantly, as learner data in other language is very hard to come by and expensive to annotate, few benchmark corpora exist in other languages.

We develop a benchmark corpus for Russian learner data, by providing expert quality annotations for a subset of the Russian subcorpus of Lang-8, henceforth *RU-Lang8* dataset. Lang-8 (Mizumoto et al., 2012) is a dataset collected from a language learning website and partially corrected by native language volunteers. In Russian GEC, Rozovskaya and Roth (2019) recently released an annotated learner corpus, RULEC. The expert annotations that we provide will allow researchers to use the created corpus as another evaluation benchmark corpus for non-English GEC. As we show, RU-Lang8 is more diverse than RULEC in terms of the first language backgrounds, and the genre of writing. We benchmark two state-of-the-art neural machine translation models on the new corpus: a convolutional neural network (CNN) and a Transformer model.

The paper makes the following contributions: (1) We generate gold annotations for Lang-8 data to create an additional evaluation dataset for Russian GEC, which is more diverse linguistically and contains data of different genre of writing, compared to the existing resource RULEC. We make the resource available for research purposes;[1] (2) We provide benchmark results on this new corpus, using state-of-the-art models that are trained on synthetic data and learner data; (3) We provide an error analysis showing that most of the grammar errors are still challenging for the current systems.

2 Related Work

Progress in English GEC There has been a lot of work on grammatical error correction, but most of the research has been done on English (Rozovskaya and Roth, 2011; Susanto et al., 2014; Yuan and Briscoe, 2016; Hoang et al., 2016; Chollampatt et al., 2016; Junczys-Dowmunt and Grundkiewicz, 2016; Mizumoto and Matsumoto, 2016; Rozovskaya and Roth, 2016; Jianshu et al., 2017; Chollampatt and Ng, 2018; Kaneko et al., 2020).

Recently, state-of-the-art results were obtained using statistical and neural machine translation approaches. The systems are typically trained on a combination of native data with synthetic er-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4103–4111
August 1–6, 2021.

rors and naturally-occurring learner data from NUCLE (Dahlmeier et al., 2013) and the English part of the Lang-8 corpus (Mizumoto et al., 2012), even though the latter is only partially corrected and is known to contain a lot of noise.

Motivated by the issue of robustness, a recent shared task on English GEC (Bryant et al., 2019) released new evaluation data, both from learners of English and native speakers. Napoles et al. (2019) further addressed the issue of robustness of GEC models, by proposing novel evaluation metrics, and also released a diverse GEC dataset.

GEC on Other Languages Two most prominent attempts at GEC in other languages include shared tasks on Arabic and Chinese text correction. In Arabic, a large-scale corpus (2M words) was collected and annotated as part of the QALB project (Zaghouani et al., 2014). There have also been three shared tasks on Chinese grammatical error diagnosis (Lee et al., 2016; Rao et al., 2017, 2018). In other languages, attempts at automatic grammar detection and correction have been limited to identifying specific types of misuse (grammar or spelling) (Imamura et al., 2012; Israel et al., 2013; de Ilarraza et al., 2008; Vincze et al., 2014).

The most relevant to us is the work of Rozovskaya and Roth (2019) that made available an annotated corpus of Russian learner essays. The data released in Rozovskaya and Roth (2019) is relatively uniform, as it is all produced by native English speakers, whereas the RU-Lang8 data comes from a diverse set of speakers.

3 The RU-Lang8 Dataset

RU-Lang8 was created using data collected as part of the Lang-8 corpus (Mizumoto et al., 2012). The Lang-8 learner corpus is a dataset compiled from a language learning website.[2] It contains data from learners of a variety of foreign languages and is weakly annotated (partial corrections are provided by volunteers, but these are quite noisy). The Lang-8 corpus consists of pairs of sentence (source, target), where the *source* denotes the original sentence, and the *target* refers to the modified version that may contain partial corrections and volunteer commentaries. While the English subcorpus contains over 30 million tokens, the Russian learner subcorpus is small, containing about 633,000 tokens. We created a subset of 54,000 tokens and had it manually corrected by expert annotators. This newly-created resource with expert annotations is comparable in size to existing GEC datasets, and should be a valuable addition to multi-lingual resources in GEC. The RU-Lang8 corpus differs from RULEC: the latter consists of essays written in a University setting in a controlled environment, while the Lang-8 data was collected online; the majority of texts in RU-Lang8 are short paragraphs or questions posed by learners.

First language (%)	**First language (%)**
Japanese (37.9)	Portuguese (7.5)
English (14.0)	German (4.2)
Korean (11.8)	Polish (3.0)
Trad. Chinese (8.1)	Spanish (1.0)
Mandarin (7.6)	Mongolian (0.7)

Table 1: 10 most common first language backgrounds for data from Russian learners in the Lang-8 corpus.

Partition	**Sentences**	**Tokens in the source side**
Train	43,848	578,383
Dev	1,968	23,138
Test	2,444	31,603

Table 2: Statistics on the Russian data from Lang-8. The development and the test partitions are manually re-annotated. The training partition includes original noisy corrections.

RU-Lang8 Preprocessing From the Lang-8 corpus, we extract all sentence pairs, where the source and the target sentences are in Russian, using the tool which we modified for Russian (Chollampatt and Ng, 2018). The Lang-8 corpus also contains information about the author's first language. Overall, there are 34 first languages in the Russian subcorpus. Table 1 shows the distribution of the most common first languages in the dataset. The most common first language is Japanese (37% of all writers). Other common first languages are English, Korean, Traditional Chinese, and Mandarin.

The extracted sentence pairs are then tokenized using an in-house tokenizer and further cleaned up, by removing sentence pairs where the target side includes corrector's comments. As a result, 51,575 sentence pairs are kept. These sentence pairs are randomized and split up into training, development, and test partitions. The development and test partitions are manually re-annotated, as described below. The sentence pairs from the training partition are not re-annotated but contain the original noisy Lang-8 corrections. The sizes of the subcorpora are shown in Table 2.

---

Error type	**Example**
Lexical choice	предлагает "proposes" → утверждает "claims"
Extra word (open-class)	был "was" → ∅
Prep. (ins.,del.,repl.)	в "in" → из "from, out of"
Word form	вдохновленным "inspired" → вдохновенной "inspiring"
Noun:case	специалисты "experts" (pl.,nom) → специалистам "experts" (pl.,dat.)
Adj.:case	главная "main" (sg., fem., nom.) → главную "main" (sg., fem., acc.)
Verb:number/gender	живут "live" (3rd person pl.) → живет "lives" (3rd person sg.)
Verb:aspect	чувствовала "was feeling" (past, imperf.) → почувствовала "felt" (past, perf.)
Verb:voice	продолжала "continued" (past, active) → продолжалась "continued" (past, reflexive)

Table 3: **Some common grammatical error types in Russian learner data.** A complete set of errors with examples is shown in Appendix Table 11.

	Repl. (%)	**Ins.** (%)	**Del.** (%)	**Punc.** (%)	**Word order**(%)	**Total**
Dev	71.3	7.9	7.1	12.4	1.4	3,434
Test	74.2	8.4	8.4	7.7	1.3	3,354

Table 4: Statistics on corrections in RU-Lang8.

Correction of the RU-Lang8 Data The development and the test partitions of the RU-Lang8 corpus were manually annotated by a native Russian speaker, with a Master's degree and with prior annotation experience. To estimate the quality of the annotations, a second expert annotator with a similar background and native proficiency was used (see next section). In contrast to Rozovskaya and Roth (2019), where the errors are also tagged with error type at the level of syntax, morphology, lexical usage, and orthography, the annotation of RU-Lang8 is performed at the level of four operations: *Replace*, *Insert*, *Delete*, and *Word Order*. This new annotation framework speeds up the annotation process significantly and allows the annotator to focus on providing the appropriate correction, without having to think also about the linguistic error type. This approach was also used in the annotation of other GEC corpora (Reznicek et al., 2012; Boyd et al., 2014; Mohit et al., 2014).

The annotation was performed with a publicly-available tool used in other annotation efforts (Rozovskaya and Roth, 2010). Table 4 shows the distribution of errors in terms of edit operations.

A subset of the test data was also marked with error type, using the error classification schema of RULEC. This was done to allow for a comparison of the error distributions between RULEC and RU-Lang8. Table 3 shows examples of some common Russian learner errors in the RU-Lang8 dataset. The complete set of error categories is shown in Appendix Table 11. The error distributions in the two corpora are shown in Appendix Table 12. Because RULEC contains data from two groups of learners – foreign language learners of Russian and heritage speakers[3] – we show statistics for each RULEC group separately. The distribution of errors in RU-Lang8 is very similar to that of the foreign group in the RULEC corpus, even though in RULEC the learners come from the English-speaking language background, while in RU-Lang8, there is a lot of diversity with respect to the first language background. As for error rates,[4] the RU-Lang8 data has significantly higher error rates than both foreign and heritage parts of RULEC (Table 5). We attribute this to the overall higher proficiency level of the RULEC corpus writers. Finally, note that, as shown in Table 5, the error rates in development and test partitions of RU-Lang8 vary substantially: the error rates are 15.6% and 11.3% in the development and test sets, respectively. Since the sentences were selected uniformly at random, we do not have an explanation for the reason why the error distribution is different in the two subsets. We do believe that the varying error distributions might be useful, as they would reflect realistic scenarios where the test data may not have exactly the same distribution as the development/training data.

Inter-Annotator Agreement Computing inter-rater agreement in grammatical error correction

---

[3] The heritage group in RULEC includes native Russian speakers who grew up in the United States; these speakers have a different error distribution from that of foreign learners of Russian, with the majority of errors being of type punctuation and spelling.

[4] Error rate denotes the percentage of the tokens that have been modified by the annotator.

Corpus	Total words	Incorr. words	Error rate (%)
RULEC (Foreign)	164,071	11,343	6.9
RULEC (Herit.)	42,187	1,705	4.0
RU-Lang8 (dev)	23,138	3,605	15.6
RU-Lang8 (test)	31,603	3,558	11.3

Table 5: Error rates in RULEC (foreign and heritage speakers shown separately) and in RU-Lang8. *Error rates* throughout the paper refer to the percentage of tokens that have been modified.

Second pass	Error rate (%)	Judged correct (%)
Annotator A	1.55	90.0
Annotator B	1.02	97.4

Table 6: Inter-annotator agreement. *Error rates* based on the corrections on the second pass. *Judged correct* denotes the percentage of sentences in the agreement set that the second rater did not change.

is not trivial, as the space of possible corrections for a sentence is extremely large (Choshen and Abend, 2018; Bryant and Ng, 2015; Rozovskaya and Roth, 2021). To estimate the quality of the annotation, we have a second annotator independently re-annotate a subset of the data, 120 sentences. We compute inter-annotator agreement in two ways. First, we follow the method used for RULEC (Rozovskaya and Roth, 2019) where the texts corrected by one annotator were given to the second annotator. Agreement is computed as the percentage of sentences that did not have additional corrections on the second pass, as our goal is to make the sentence well-formed. 120 sentences from each annotator were given to the other annotator for the second pass. Table 6 shows that the error rate of the sentences corrected by annotator A (original annotator) on the second pass was 1.55%, with 90% of the sentences remaining unchanged. The sentences corrected by annotator B (second annotator) on the second pass had an error rate of less than 1.02%, and over 97% of the sentences did not have additional corrections. These agreement numbers are comparable to and even slightly higher than in RULEC (68.5% and 91% of unchanged sentences). The error rates are also in the same ballpark (0.67%-2.4% for RULEC).

We also measure agreement by treating reference corrections made by one annotator as gold and scoring the second annotator against them. .Results are shown in Table 7. The scores of 66.7 and 69.9 are higher than those reported on English CoNLL-14 (score of 45.91, Bryant and Ng (2015)).

Gold annotator	P	R	$F_{0.5}$
Annotator A as gold	66.0	69.6	66.7
Annotator B as gold	72.2	61.9	69.9

Table 7: Scoring one annotator against another.

4 Experiments

GEC Models We benchmark two state-of-the-art neural machine translation models: a Convolutional Encoder-Decoder Neural Network model (*CNN*) (Chollampatt and Ng, 2018) and a *Transformer* model (Naplava and Straka, 2019).[5] The Transformer model achieved the highest F-score on RULEC. Both models make use of the RULEC training and dev data (about 5K sentences) and native data with synthetic errors. The CNN model is trained jointly on RULEC and synthetic data, while the Transformer is pre-trained on synthetic data and finetuned on RULEC data.

The models make use of the two approaches of generating synthetic data that showed state-of-the-art performance on English GEC. The Transformer model makes use of the Aspell confusion sets method (Grundkiewicz et al., 2019) to generate synthetic errors in native data. In line with Grundkiewicz and Junczys-Dowmunt (2019), the word error rate used is that of 15%, where on average 15% of the tokens are perturbed, and, on top of these Aspell-generated confusions, characters are perturbed in 10% of the word tokens to account for spelling mistakes. We refer the reader to Naplava and Straka (2019) for details about the model implementation. The CNN models are trained on synthetic data that use part-of-speech (POS)-based confusion sets (Choe et al., 2019) (which we re-implemented for Russian). In all cases, results of single models are compared.

The models are trained on similar amounts of synthetic data: the CNN model uses 13 million sentences from the Web (Borisov and Galinskaya, 2014), while the Transformer model uses 10 million sentences from the Web (Bojar et al., 2017). Although we did not directly compare the two data sources, we assume the native data used by both models is of similar quality as the data comes from the Web in both cases. Since the synthetic data used in the CNN model is not focused on spelling errors, we run an off-the-shelf spellchecker for Russian,

---

[5] We thank Jakub Náplava for kindly agreeing to run the Transformer model on the RU-Lang8 data.

Model	**RULEC**			**RU-Lang8**		
	P	**R**	$F_{0.5}$	**P**	**R**	$F_{0.5}$
CNN	55.8	26.6	45.7	57.9	26.8	**47.0**
Transf.	59.1	26.1	**47.2**	-	-	-
Transf. (+dev)	63.3	27.5	***50.2***	55.3	28.5	46.5

Table 9: Results on RULEC and RU-Lang8 of the CNN models trained jointly on synthetic and learner data. RU stands for RULEC, and L8 stands for RU-Lang8.

developed following Flor (2012) for English.

Evaluation The models are evaluated on the test partitions of RULEC and RU-Lang8. Comparing system output against human-generated reference is a standard practice in GEC. Several measures have been proposed, such as M^2 scorer (Dahlmeier and Ng, 2012), GLEU (Napoles et al., 2015), ERRANT (Bryant and Ng, 2015), and I-measure (Felice and Briscoe, 2015). M^2 computes precision, recall, and F-score and has been widely used in evaluating GEC systems, and we use it here to compare with previous results on RULEC. M^2 has been used with different beta parameter values, the default is $beta = 0.5$, weighing precision twice as high as recall, which we use here.

Overall Performance We show results for the two models in Table 8.[6] The Transformer finetuned on RULEC train data outperforms the CNN on RULEC *by 1.5 points*, and by almost 5 points when finetuned on the union of training and dev RULEC data. However, on RU-Lang8, the CNN model outperforms the transformer slightly.

Contribution of Lang8 Training Data This is shown in Table 9. Interestingly, performance on RULEC does not improve, while performance on RU-Lang8 improves by 2 points. The latter is not surprising since the data comes from the same domain, however, it is surprising that there is no effect on the RULEC corpus.

Performance Analysis by Error Type We also evaluate the best models shown in Table 8 per error type. Evaluating the precision requires classifying the edits proposed by the system, however, recall can be computed, using the types of the gold edits. In Table 10 in the Appendix, we show the recall on the most common error types. The type-based performance analysis reveals which errors are more challenging for the systems. The highest recall by far (ranging between 52.0% and 70.5%) on both datasets is achieved on spelling errors by both models. The Transformer also achieves a recall of 60% on verb agreement errors on both datasets. The following error categories are more challenging for both models: noun case, preposition, adjective case errors, and punctuation. Finally, the most challenging errors are lexical choice errors, where the recall is below 5% for both models and on both datasets. This supports the observation that current models perform best on spelling errors and currently struggle with other phenomena, which is further exacerbated by the morphological complexity of Russian: the performance on Russian falls behind that on English and German (Grundkiewicz and Junczys-Dowmunt, 2019). Our error-type-based analysis is also in line with the findings in the study on two English corpora, as well as RULEC and RU-Lang8 Rozovskaya and Roth (2021). Specifically, while lexical errors are some of the most common learner mistakes, only a small fraction of system edits are of lexical type.

5 Conclusion

This paper presents an annotated Russian learner corpus based on data from the Lang-8 website. The dataset is more diverse than the existing resource RULEC from the point of view of the first language backgrounds, and also differs in the genre of writing. We benchmark two state-of-the-art models that are trained on learner data and synthetic data, using two competitive noisification techniques.

We believe that the RU-Lang8 corpus with expert annotations is a valuable contribution to the GEC field, where a lot of progress has been made in English, due to a large number of resources and benchmark corpora, but where very few works focus on non-English GEC.

Acknowledgments

We are grateful to Jakub Náplava for the help running his system on the RU-Lang8 data. We thank the anonymous reviewers for their comments.

A *Formidable* Ability: Detecting Adjectival Extremeness with DSMs

Abstract

While distributional semantic models (DSMs) can successfully capture the similarity structure *within* a semantic domain, less is known about their ability to represent abstract semantic properties that hold *across* domains. Such properties can form the basis for abstract semantic classes that are a crucial aspect of human semantic knowledge. For example, the abstract class of extreme adjectives (such as *brilliant* and *freezing*) spans a wide range of domains (here, INTELLIGENCE and TEMPERATURE). Using a model that compares query items to an aggregate DSM representation of a set of extreme adjectives, we show that novel adjectives can be classified accurately, supporting the insight that a cross-domain property like extremeness can be captured in a word's DSM representation. We then use the extremeness classifier to model the emergence of intensifier meaning in adverbs, demonstrating, in a separate task, the effectiveness of detecting this abstract semantic property.

1 Distributional Models and Abstract Semantic Classes

Distributional semantic models (DSMs) are widely used as representations of word-level semantics. However, open questions remain as to precisely which aspects of human semantic knowledge DSMs effectively capture (e.g., Baroni et al., 2014; Hollis and Westbury, 2016; Schnabel et al., 2015; Utsumi, 2020). For example, popular DSMs such as word2vec and GloVe have been shown to predict human ratings of semantic features of objects (Rubinstein et al., 2015; Grand et al., 2018). However, performance is variable across features and object categories (Grand et al., 2018), and in particular, is better for taxonomic properties ('is an animal', 'is a weapon') than for general attributive properties ('is yellow', 'is dangerous') (Rubinstein et al., 2015).

While people may or may not have semantic categories such as "all yellow things", abstract semantic classes are an important part of human linguistic knowledge that should be captured in a computational system. Note that by *abstract* we mean the schematic properties of word meaning, rather than the content-related classes;[1] such properties abstract over commonalities of meaning that may *cross* traditional semantic domains. Consider, e.g., a semantic verb class such as change-of-state (Levin, 1993; Kipper et al., 2008), with members such as *melt* (the TEMPERATURE domain) and *quicken* (SPEED), or relational adjectives (Boleda et al., 2012), including, e.g., *Chinese* (NATIONALITY) or *pulmonary* (BODY-PART).

Much work shows the ability of DSMs to match human knowledge of semantic properties *within* a domain (e.g., Baroni et al., 2014; Pereira et al., 2016; An et al., 2018; Grand et al., 2018), but there is little work, to our knowledge, on whether the similarity structure of a DSM is sensitive to commonalities of abstract properties that hold *across* a variety of semantic domains.[2] Research on vector-based representations of analogy suggests that DSMs may be limited in their ability to represent cross-domain word relations: Rogers et al. (2017) show that cross-domain analogical relations like hypernymy (e.g., *turtle:reptile::salmon:fish*) are significantly harder to solve than within-domain ones (e.g., *Paris:France::Ottawa:Canada*). Lu et al. (2019) make significant progress towards representing such relations, showing that a DSM can form the basis for detecting the cross-domain word

---

[1] The same distinction between *schematic* and *content* is applied in Paradis (2001); Cruse and Togia (1996). It is also worth noting explicitly that our use of the term 'abstract' in this sense is not to be interpreted as 'not concrete'.

[2] DSMs may, e.g., encode concreteness and valence/arousal/dominance (e.g., Hollis and Westbury, 2016; Hollis et al., 2017), but the former can be viewed as a taxonomic property, and the latter as within the EMOTION domain.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4112–4125

relations, such as antonymy (*love–hate* in the EMOTION domain, *rich–poor* in FINANCE); however, to achieve this, their method requires additional learning of a relation-specific warping of the distributional semantic space. Our goal here is to see whether the similarity structure of the (original) DSM itself directly captures such cross-domain knowledge.

We focus as a test case on the abstract class of *extreme adjectives*: scalar adjectives that express an extreme value of their scale, such as *brilliant* and *freezing*. Previous computational work on scalar adjectives has focused on assessing their relative ranking within a domain (e.g., learning that *smart* < *brilliant* on the INTELLIGENCE scale) (e.g., Ruppenhofer et al., 2014; Cocos et al., 2018). However, as work in linguistics shows (Cruse, 1986; Paradis, 2001; Morzycki, 2012), extreme adjectives do not simply behave as if they are further along their scale, but rather (as a class) have distinguishing semantic properties. Our goal is to see whether DSMs can capture this cross-domain property of "extremeness". In our first experiment, we demonstrate that we can successfully identify extreme adjectives, across a wide range of domains, on the basis of the information contained in their DSM representations alone.

Our next goal was to show that this ability to detect the abstract property of extremeness would be useful in further tasks. We begin with the novel hypothesis that an adjective's extremeness is a strong predictor of its future use in an intensifier adverb – i.e., in phrases like *staggeringly easy* and *monumentally wrong*. Our second experiment then shows that our classification of extreme adjectives can improve over an existing computational approach (Luo et al., 2019) in a historical prediction task of emerging intensifier meanings.

2 Our Case Study: Extreme Adjectives

Extreme adjectives are a subclass of scalar adjectives that includes words such as *awesome*, *brilliant*, and *freezing*. Like all scalar adjectives, their semantics includes the specification of a scale, such as (for these) DESIRABILITY, INTELLIGENCE, and TEMPERATURE, respectively, along with some position or range on that scale. The distinguishing aspect of extreme adjectives is that they represent an extreme value at one end or the other of the scale (e.g., Cruse, 1986; Morzycki, 2012; Paradis, 2001), a value that is so high/low as to possibly even be considered "off the scale" (Morzycki, 2012). This makes extreme adjectives a good case study for us: their abstract property of "extremeness" holds across a wide variety of semantic scales, and thus crosses individual semantic domains, such as INTELLIGENCE or TEMPERATURE.[3]

Category (example)	**Intensification (*very* X)**	**Endpoint-oriented (*almost* X)**	**Extreme degree (*absolutely* X)**
Non-gradable (*civic*)	?	?	?
Open-scale (*big*)	✓	?	?
Closed-scale (*full*)	✓	✓	✓
Extreme (*huge*)	?	?	✓

Table 1: Examples showing differences in types of modifiers usable across categories of adjectives.

Our goal is to assess whether a DSM can directly capture the similarity among members of this kind of abstract class. We address this question in two ways: with a direct evaluation, testing whether we can classify adjectives as extreme or not, and with an indirect evaluation, which uses our extremeness classifier in a separate task, to show its value in NLP applications.

Our first experiment uses similarity within a DSM as the basis for classification of extreme adjectives. Linguists have long noted that distributional tests can distinguish extreme adjectives from other classes (e.g. Cruse, 1986), as in the following examples (elaborated in Table 1).[4]

1. Martha is ?very/?almost/absolutely **ecstatic**. [Extreme]
2. Martha is very/?almost/?absolutely **grateful**. [Not Extreme]

Here, we propose an approach that replaces similarity along manual distributional tests with similarity within a general DSM. Note that such an approach is not a priori guaranteed to succeed. First, the manually-identified probes are specifically chosen to highlight the distinguishing properties; looking at representations derived from all of a word's contexts may mean that the useful signal about what makes an adjective extreme is drowned in "noise"

---

[3] The difference between a semantic domain and a semantic scale is not crucial here; the important point is that "extremeness" is a property that crosses what are typically thought of as more narrowly-defined semantic areas.

[4] Note that the versions with "?" in (1), (2), and Table 1 are less felicitous and require additional facilitating context, rather than being outright ungrammatical; this is not unusual for distributional tests of semantic classes.

(with respect to the property of extremeness). Second, we're looking for an abstract property that crosses semantic domains – i.e., we're not asking if EMOTION adjectives are more similar to each other than to INTELLIGENCE adjectives; we're asking whether extremes in both domains (*ecstatic* and *brilliant*) are more similar to each other than to non-extreme adjectives.

In our second experiment, we perform a downstream task that uses our classification of an adjective as extreme or not. Here we study the historical emergence of intensifier meanings of adverbs (e.g., *monumentally* coming to mean 'very', as in *monumentally wrong*), for which in-domain similarities in DSMs have previously been found to model the phenomenon with some accuracy (Luo et al., 2019). Using our cross-domain model of extremeness, we operationalize our novel linguistic insight that adjectival extremeness (*monumental*) is inextricably linked to the emergence of intensifier senses (*monumentally wrong*).

To preview our results, we find that our method of using a DSM to classify adjectives as extreme or not substantially improves over a statistical method drawing on linguistically-devised distributional tests. That is, we see that the general similarity space of a DSM can be used as an effective replacement for similarity with respect to manually-identified probes in the detection of an abstract semantic class. Moreover, in our experiments on intensifier emergence, we find that our identification of the cross-domain property of extremeness also shows improvement over a more standard application of DSMs that assesses in-domain similarities. This pair of experiments thus provides evidence that a DSM can successfully capture an abstract class defined by cross-domain similarity.[5]

3 Classifying Extreme Adjectives

Here we propose an approach for identifying extreme adjectives using a DSM. Other work in computational linguistics has considered automatic means for placing scalar adjectives in the appropriate relative position along their scale (e.g. Sheinman et al., 2013), including approaches using DSMs to do so (e.g. Kim and de Marneffe, 2013; Sharma et al., 2017). Such methods do not distinguish extreme adjectives as a special set across semantic domains, but rather assess them as expressing a higher/lower level compared to other adjectives within the domain – e.g., *brilliant* is a higher degree of INTELLIGENCE than *smart*. Our approach instead focuses on extremeness as a categorical property of adjectives that is independent of any particular scale (following Cruse, 1986; Paradis, 2001; Morzycki, 2012, among others).

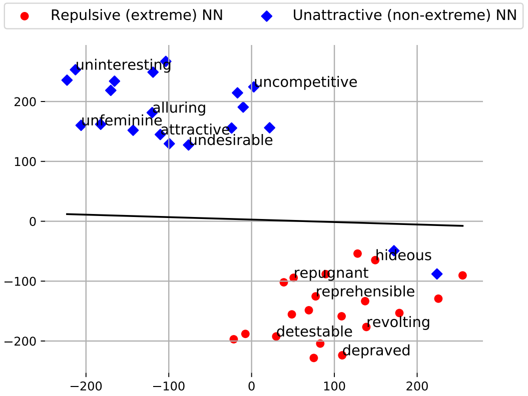

Figure 1: Nearest neighbours of *repulsive* (extreme) and *unattractive* (non-extreme), visualized with t-SNE (Maaten and Hinton, 2008) on word2vec embeddings (Mikolov et al., 2013).

As set out earlier, our hypothesis is that the similarity space of a DSM can capture the (cross-domain) similarity of the members of an abstract semantic class. Fig. 1 illustrates this intuition: the nearest neighbors of the extreme adjective *repulsive* are other extreme adjectives (*detestable*, *revolting*); conversely, the non-extreme counterpart *unattractive* has other non-extreme nearest neighbours (*undesirable*, *uninteresting*). Importantly, the two sets of nearest neighbours show a clear separability of the extreme adjectives and non-extreme adjectives, suggesting that the contextual distribution of an adjective, as represented in its word embedding, contains useful information for classifying whether it is extreme.

Reflecting this intuition, we propose to identify extremeness of adjectives using a prototype approach, in which we classify each adjective by comparing its vector to the average vector (a "prototype") of a set of extreme adjectives within a DSM. While such an approach has been used previously to characterize words *within* a semantic domain (e.g., EMOTION in the case of Xu et al. (2020), and each of a variety of domains in An et al. (2018)), here we test whether such a prototype vector can abstract over the individual semantic domains to

---

[5] All code and data are available at `https://github.com/smfsamir/detect-adjectival-extremeness`.

capture the cross-domain property of extremeness. Classification will be successful to the extent that vectors of adjectives that share the abstract property of extremeness are sufficiently similar to serve as an informative prototype.

3.1 Dataset

We collect a dataset of extreme and non-extreme adjectives in English for training and evaluating a supervised classifier. We started with a set of 54 adjectives identified as extreme (Morzycki, 2012; Paradis, 2001; Huttenlocher et al., 1971; Cruse, 1986; Lassiter, 2017). We then added extreme adjectives from human-annotated datasets of adjectival intensity (Cocos et al., 2018; Wilkinson and Tim, 2016; de Melo and Bansal, 2013; Ruppenhofer et al., 2014). For each adjective, these datasets specify its scale and its human-rated range of intensity values. For each of the scales of the 54 previously-identified extreme adjectives, we gathered all further adjectives tied with or ranked above extreme adjectives in their intensity value ($N = 17$). After filtering out 3 adjectives with frequency less than 0.5 per million, we obtained a total of $N = 68$ extreme adjectives that cover a diverse set of adjectival scales, such as DESIRABILITY (*sensational*), INTELLIGENCE (*moronic*), and SIZE (*gigantic*). We then match each extreme adjective in our dataset with a non-extreme adjective matched for frequency in COCA (Corpus of Contemporary American English; 1B words; Davies, 2009). (Since word embeddings have been shown to encode frequency (e.g., Mu and Viswanath, 2018), it is important to control for this.) To avoid including extreme adjectives, we exclude any words that appear as the most intense adjective in the above datasets. Our non-extreme set includes 68 adjectives, both scalar and non-scalar; see data in the GitHub repository.

3.2 Methods to predict extremeness

Our goal is to see whether DSMs can support the classification of an abstract class that has been previously identified through manually-selected distributional tests. Thus we compare two approaches to identifying extreme adjectives: one implements a corpus-based measure to capture manually-identified distributional tests developed by semanticists (cf. Table 1), while the other uses a DSM to capture the cross-domain similarity of extreme adjectives. For both, we propose a method for deriving the probability $p(c|a)$ of the class $c \in \{\text{Extreme}, \text{Non-extreme}\}$ for an adjective a.

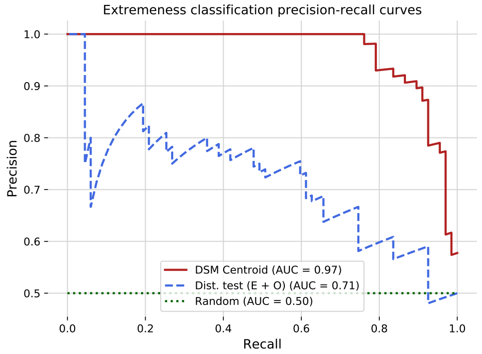

Figure 2: Results for classifying extreme adjectives.

3.2.1 The DISTRIBUTIONAL TEST method

Here we define a method based on the "probe" words specified in distributional tests of extremeness. Specifically, our approach looks at patterns of extreme adjectives that are readily assessed in a corpus: (1) frequent modification by extreme degree modifiers (Cruse, 1986); and (2) resistance to modification by endpoint-oriented modifiers and *very* (Morzycki, 2012).[6] The extreme degree modifiers we consider are E = {*absolutely*, *totally*, *simply*, *positively*, *downright*, *outright* }, while the other modifiers are O = { *almost*, *slightly*, *very* }. Formally, we measure the association with each of these sets of probes using normalized pointwise mutual information (NPMI).[7] For example, we assess the NPMI_E between an adjective a and (all) extreme degree modifiers e that immediately precede it in a sentence, as:

$$\text{NPMI}_E(e, a) = \log\left(\frac{p(e, a)}{p(e)p(a)}\right) \cdot \frac{1}{\log p(e, a)}$$

where e stands for any extreme degree modifier in E (i.e., we derive the probabilities above from pooled counts in COCA over a co-occurring with any $e \in E$). We compute the association NPMI_O with all $o \in O$ analogously. Using NPMI_E and NPMI_O as features, we train a logistic regression classifier with L2 regularization to obtain an estimation of $p(c|a)$, where $c \in \{\text{Extreme}, \text{Non-extreme}\}$. Combined with a probability threshold, the estimation of $p(c|a)$ allows us to predict whether an adjective is extreme.

---

[6] Other tests (such as prosodic cues or hyperbole, Morzycki, 2012), are difficult to identify in a written corpus.

[7] Normalizing mitigates the frequency bias known to impact PMI (Bouma, 2009; Jurafsky and Martin, 2014).

Classifier	Prec.	Recall	F$_1$
DISTRIB. TEST	0.76	0.66	0.71
DSM CENTROID	**0.90**	**0.91**	**0.90**

Table 2: Classification using a 0.5 threshold.

3.2.2 The DSM CENTROID method

To use a DSM to classify an adjective as extreme, we need to abstract away from the information about the particular scale or semantic domain that is captured in a word vector. That is: we want the model to recognize that *exquisite* is more like *huge*, *destitute*, and *repulsive* than like *big*, *poor*, and *unattractive*. As noted above, we draw on prototype approaches by classifying a novel adjective on the basis of how similar it is to the aggregate representation of a set of extreme adjectives. Analogously to the approach above, we use this similarity as a single feature in a logistic regression classifier to obtain an estimate of the probability of extremeness $p(c|a)$. For our experiments, we use the 300-dimensional pretrained word2vec embeddings of Mikolov et al. (2013).

3.3 Results

Because of the small size of our dataset ($N = 136$), we use a leave-one-out cross-validation procedure to evaluate the two methods. We evaluate performance in two ways: using precision-recall curves (shown in Fig. 2) and as Precision, Recall, and F_1 scores for the Extreme class using a classification threshold of 0.5 (shown in Table 2).

Both DSM CENTROID (AUC = .97) and DISTRIBUTIONAL TEST (AUC = .78) perform better than chance (AUC = .50). The DSM CENTROID method furthermore substantially outperforms the DISTRIBUTIONAL TEST method (AUC = .97 vs. AUC = .78; F_1 = .90 vs. F_1 = .71). This result provides strong evidence for our hypothesis that the similarity structure of a DSM can effectively capture an abstract, cross-domain property such as extremeness; in fact, at least in this case, it can do so better than a statistical corpus-based model based on manually-identified linguistic tests.

One concern with the leave-one-out approach is that there may be items in the training set (e.g., *massive*) that share semantic properties other than extremeness with the held-out item (e.g., *huge* – in this case, both are SIZE adjectives). To control for this confound, we conduct a variant of a k-fold cross-validation procedure, in which the folds consist of clusters of semantically similar adjectives, with the aim that the training data does not include adjectives from the same domain as the test items. Even in this controlled analysis, we find that the DSM CENTROID method robustly outperforms the DISTRIBUTIONAL TEST method. See Appendix A for details.

Classifier	Errors
DSM CENTROID	destitute, freezing, terrified; *runaway, memorable*
DISTRIB. TEST	gigantic, colossal, mammoth, gargantuan, immense; *identical, inconvenient, conventional, opposite*
Both	major, obese, microscopic; *creepy*

Table 3: Sample of errors made by each method, and both. False negatives; *false positives*.

3.4 Discussion

Given that the DSM CENTROID method uses information from all of a word's contexts (as captured by the DSM), in contrast to the DISTRIBUTIONAL TEST approach that uses hand-picked tests to reveal behavior relevant to extremeness, it is worth exploring why the former method performs so much better. Here we study the errors made by the two methods when using a 0.5 probability threshold for the classifiers. We focus on the sets of errors that are exclusive to each model, as shown in Table 3; a complete list of errors is available in the data provided in the GitHub repository.

One possibility is that distributional tests will fail to identify extreme adjectives when they only infrequently co-occur with the distributional probes; the fact that an extreme adjective *can* be modified by, e.g., *absolutely* does not entail that these will actually co-occur in the corpus. The false negatives for the DISTRIBUTIONAL TEST method reflect this: it misses out on extreme adjectives that do not frequently co-occur with extreme degree modifiers. We see, for instance, that many extreme adjectives in the domain of SIZE are misclassified due to a low NPMI$_E$ score – a significant error since extreme adjectives of SIZE are often presented as typical members of the class (Cruse, 1986; Morzycki, 2012). The DISTRIBUTIONAL TEST method also produces a considerable number of false positives. This reflects another shortcoming of distributional tests, as it has been noted that extreme degree modifiers can be used with adjectives that are *not* extreme (cf. *absolutely inconvenient*, *totally identical*; Paradis, 2001; Morzycki, 2012).

The cases where DSM CENTROID fails – false negatives and false positives – are mostly of a different nature. Among its errors are many words that have *both* extreme and non-extreme senses (*freezing*, *destitute*, *microscopic*, *obese*, *runaway*, and *major*). For example, *destitute* can mean 'devoid of', and *freezing* can refer to the actual transitioning from liquid to solid, resulting in a non-extreme classification. Conversely, *runaway* is misidentified as extreme due to extreme uses such as *runaway success*. Such polysemies highlight an issue for any method that draws on data from a corpus that is not sense-annotated – recognizing an adjective as extreme depends on the word being predominantly used in the expected sense.

Despite this challenge, our results align with the analysis of extreme adjectives as a distinct adjectival class (Cruse, 1986; Paradis, 2001; Morzycki, 2012). Members of this category can be automatically identified using similarity to an aggregate vector of (known) extreme adjectives, even when those exemplars cross a wide range of semantic domains. Importantly, while Morzycki (2012) argued that extreme adjectives are always felicitous with extreme degree modifiers such as *absolutely*, this does not entail that the association will necessarily manifest, even in a large corpus. Instead, we leverage the broad distributional tendencies captured by DSMs to determine semantic class membership probabilistically.

Our good performance in this task required only a single centroid representation of our semantic class of interest – importantly, it did not require an opposing negative centroid (as in, e.g., An et al., 2018) nor a relation-specific warping of semantic space as in Lu et al. (2019). In future work, we hope to use recent developments in applying influence functions for NLP (e.g., Brunet et al., 2019) to discover the contexts that enable DSMs to represent such abstract properties effectively.

4 Predicting novel intensifiers

Having shown that extremeness can be classified on the basis of similarity within a DSM, we now show that this method is sufficiently informative to guide a separate task – that of modeling the emergence of novel intensifiers. Intensifiers are adverbs such as *staggeringly* in *staggeringly easy*, or *monumentally* in *monumentally wrong*, that give force to the modified adjective without conveying their manner meaning – i.e., saying some task is *staggeringly easy* means that it is extremely easy, not that it is easy in a staggering way. Manner adverbs can gain such an intensifying sense through a continual, and frequent, process of semantic change (Bolinger, 1972; Bennett and Goodman, 2018; Luo et al., 2019). However, it is an open question why certain manner adverbs are more likely to do so than others.

Our hypothesis is that it is the abstract property of extremeness that facilitates this meaning shift – intuitively, *staggeringly easy* and *monumentally wrong* can readily be paraphrased as *off-the-scale easy* and *off-the-scale wrong* because the underlying adjectives (*staggering* and *monumental*) denote extreme values. Thus, an ability to detect extremeness should support an approach to prediction of emergence of intensifier senses: i.e., the adverbs derived from extreme adjectives should be those that are likely to become intensifiers.

We contrast our hypothesis with that of Luo et al. (2019), who propose that intensifier usage can arise with any adverb through a more general process of semantic bleaching (Traugott and Dasher, 2001). Specifically, Luo et al. (2019) argue that when adverbs modify semantically similar adjectives (*conspicuously evident*), the redundancy of the modifying adverb leads to its interpretation as intensifying the content of the adjective, and the actual manner component of the adverb is bleached over time. Luo et al. (2019) capture this insight with a measure (described below) of the within-domain similarity of adverbs to the adjectives that they are found to modify frequently.[8]

We follow Luo et al. (2019) in adopting a semantic bleaching account, but instead propose that it is the abstract property of extremeness that is the focus of the bleaching process: On our account, intensification arises when the particular scale (EMOTION or INTELLIGENCE) of an extreme adverb (an adverb derived from an extreme adjective) is backgrounded, and eventually lost, while the abstract property of extremeness remains the key part of the meaning.

Our approach is compatible with that of Luo et al. (2019), but moreover *explains* why certain adverbs are more likely to modify similar adjec-

---

[8] By "within-domain" we mean a standard topical/domain-level similarity of meaning, such as *conspicuously* and *evident* conveying 'ease of observation'.

Semantic category	Entries
The world > Relative properties > Quantity > Greatness of quantity/ amount/ degree > hugely	**colossally**, **monumentally**, hugeously, thumpingly, pyramidically
In respect of quantity > Greatly/very much > extremely/exceedingly > remarkably/ extraordinarily	**markedly**, **exceptionally**, **noticeably**, **pronouncedly**, **prominently**
Consciously, knowingly > In accordance with truth, truly > in fact, actually	**literally**, **absolutely**, **objectively**, essentially, factually

Table 4: HTE categories with a sample of entries. Bolded words are attested after 1800.

tives in the first place: Adverbs that are derived from an extreme adjective are likely to modify similar adjectives precisely because they are *not* redundant – they contribute the salient meaning of 'extremeness' over and above the expression of the scale already expressed in the modified adjective. Thus we suggest that it is primarily the abstract, cross-domain property of scalar extremeness that drives the emergence of intensifying meanings of adverbs, rather than their patterns of co-occurrence with adjectives that are semantically similar. In this section, we support our claim with a modelling experiment that contrasts the within-domain similarity measure of Luo et al. (2019), with our cross-domain similarity measure for identifying extremeness.

4.1 Methods and materials

To compare these hypotheses, we perform a historical prediction task: predicting the emergence of an intensifier sense of an adverb based on data in the decades prior to the sense's attestation date. Note that this differs from Luo et al. (2019), who performed statistical analyses over time, including both before and after emergence of the intensifying senses. Consequently, we cannot adopt the full dataset of Luo et al. (2019) since it includes adverbs whose intensifier sense emerged prior to 1800 – where historical corpus data is scarce.

Intensifiers. We start with a set of 69 intensifiers R that have their first date of attestation of an intensifier sense after 1800 according to the Historical Thesaurus of English (HTE; Kay et al., 2017). (These include 45 from Luo et al. (2019) that meet this criterion.) These adverbs come from a wide variety of semantic categories, as illustrated in Table 4. We restrict the attestation date to post-1800 so that we can draw on a large historical corpus with sufficient data and robust word embeddings.

Prediction timeframe. Because we aim to predict the *emergence* of novel intensifiers, rather than classify existing ones, the model should not use data that contains the target adverb in its intensifier meaning. In order to use the same time span for all adverbs and include a reasonable quantity of data, we take data for each adverb from the 3 decades prior to its use as an intensifier. That is, for each adverb r attested within decade $d_A(r)$, we use corpus data from the 3 decades $T_r = \{d_A(r) - 3, d_A(r) - 2, d_A(r) - 1\}$.

Matched control adverbs. Luo et al. (2019) presented a set of 178 control adverbs C that did not develop an intensifying meaning. We match each $r \in R$ with the $c \in C$ that has the most similar frequency to r in the time period T_r, and use data for c from the same timeframe T_r.

Historical corpus data. With smaller corpora being too sparse, we use historical data (years 1800–1999) from the Google N-grams corpus (English, version 2, Michel et al., 2011), drawing on the diachronic skip-gram word embeddings of Hamilton et al. (2016), and syntactic annotations from Goldberg and Orwant (2013). Note that the embeddings are formed per-decade, to allow for sufficient training data. In our primary analyses, we use the embeddings of the adjectival bases of the adverbs, due to sparsity of the adverb embeddings themselves. Due to missing embeddings for some of the items, we had to remove 28 items, leaving us with 52 intensifiers and 58 control adverbs.

4.2 Features predicting intensifier emergence

Here we describe the two features we are investigating as predictive of the development of adverbs into intensifiers, our EXTREMENESS feature and the SIMADJMOD feature of Luo et al. (2019).

EXTREMENESS. To test our hypothesis that extreme adverbs are likely to gain an intensifying sense, we adapt the DSM CENTROID measure from Section 3. For each adverb q to be classified, we first find its adjectival basis a_q (e.g., *insane* for *insanely*), and then obtain the embedding $\mathbf{a_q}$ as the average of the diachronic embeddings $\mathbf{a_q(t)}$ for each decade $t \in T_q$. We then obtain the likelihood that a_q is in class c – where $c \in \{\text{Extreme}, \text{Non-extreme}\}$ – based on its proximity to the extremeness centroid. We obtain the extremeness centroid using the extreme adjectives in Section 3, averaging their diachronic embeddings

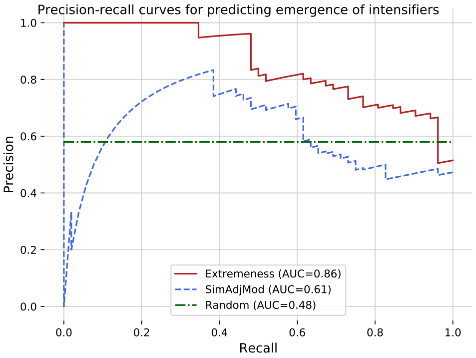

Figure 3: Results for historical prediction task.

over the time period T_q. While this is a dataset of *currently* extreme adjectives, we believe it can be reliably used for the time period covered, as extremeness seems to be a relatively stable property.

SimAdjMod. Luo et al. (2019) formalize their hypothesis with a measure, SimAdjMod, of the similarity between an adverb and the adjectives it modifies. For a query adverb q, the measure is computed as the average semantic similarity between q (e.g., *conspicuously*) and the set of all adjectives modified by q (e.g., *evident*). We adapt this measure with an approach analogous to the Extremeness measure: we find the word embeddings of the adjective a_q that is the basis of q and of all adjectives modified by q within T_q. Then, SimAdjMod(q) is computed as the odds-weighted average of the cosine similarity of $\mathbf{a_q}$ with each modified adjective's embedding (see Luo et al. (2019) for details on the weighting function).

It is worth noting that using adjective embeddings contrasts with Luo et al. (2019), who use the adverb embeddings themselves. We adopted our approach due to the absence of many adverbs in the diachronic embeddings. In their statistical analyses (in contrast to our prediction task), Luo et al. (2019) can use embeddings from a 150-year time span, reducing the sparsity of adverb embeddings. We perform an additional experiment in which we follow their set-up more closely, reported in Appendix B. As in our main results below, the Extremeness feature comes out as a strong explanatory factor, although its improvement over the SimAdjMod feature is much greater in the core historical prediction task. We discuss the implications in Appendix B.

4.3 Results and Discussion

We fit a separate logistic regression classifier for each feature, Extremeness and SimAdjMod, and use leave-one-out cross-validation. We report precision-recall curves using the $p(c|q)$ estimates from the regression models (where $c \in \{\text{Intensifier}, \text{Control}\}$), and perform error analysis using a 0.5 threshold on $p(c|q)$. The results are presented in Figure 3. We observe that both measures perform well above chance, with the Extremeness feature (AUC $= 0.86$) outperforming the SimAdjMod feature (AUC $= 0.61$).[9] To understand the difference in performance between the two features, we turn to an analysis of the errors.

One situation that should distinguish the use of Extremeness from SimAdjMod is in predicting the emergence of intensifier meanings for adverbs that are infrequent: an uncommon extreme adverb will still be extreme, but its low frequency will prevent it from frequent co-occurrence with similar adjectives. We find evidence for this in the errors: Extremeness, but not SimAdjMod, correctly predicts the emergence of an intensifier meaning for the infrequent adverbs *monumentally*, *colossally*, *frighteningly*, *staggeringly*, and *thunderingly*. This supports our hypothesis that it is not the frequent co-occurrence (with similar adjectives) that primarily drives intensifier emergence, but the semantic property of extremeness.

However, while many novel intensifiers are based on adverbs derived from extreme adjectives, not all of them are; adverbs that have an epistemic function (e.g., *actually*, *really*, *honestly*) also form a frequent source of intensifiers (Bolinger, 1972; Traugott and Dasher, 2001). We indeed observe that the Extremeness feature fails to predict the emergence of intensifiers such as *honestly* and *prominently*, cases of adverbs that were not derived from extreme adjectives, while the SimAdjMod feature captures these cases.

Overall, the results of this experiment support our claim: the cross-domain semantic property of extremeness is highly effective in predicting whether an adverb will gain an intensifying function. While the account of Luo et al. (2019) provides substantial empirical coverage of the pattern of historical development, it does not explain why particular adverbs should modify similar adjectives in the first place. Our account subsumes theirs

---

[9] Including both features in the classifier does not improve performance over the Extremeness feature alone.

by showing that if a manner adverb frequently co-occurs with a similar adjective, the adverb is likely derived from an extreme adjective (with exceptions, such as the epistemic adverbs); the adverb is then easier to re-interpret as an intensifier by maintaining the feature of extremeness while bleaching its domain-specific semantics.

5 Conclusion

In this paper, we looked at the question of whether distributional semantic models (DSMs) can capture abstract semantic properties of word classes. While it is well known that such models can capture within-domain similarity (e.g., *tall* being similar to *high* and *large*, all pertaining to the scalar attribute of SIZE), here we study whether DSMs also encode abstract similarities that hold *across* domains.

Our case study focuses on extremeness (Cruse, 1986; Morzycki, 2012; Paradis, 2001), the adjectival property of expressing values so high or low that they can be considered "off the scale" (Morzycki, 2012). Extreme adjectives thus share the abstract property of "extremeness" on a scale, independently of the particular scale involved. Our experiments demonstrate that the abstract property of extremeness can be identified using similarity of an adjective to an extreme "prototype" in a DSM, thus supporting the claim that the similarity structure of a DSM can encode such cross-domain classes.

We believe our study contributes to the rapprochement of computational methods and linguistic theory (cf. Boleda, 2020): both the traditional application of distributional tests, as well as the more open-ended application of DSMs, rely on distributional patterns. Since those patterns are more opaque in a DSM, a fruitful next step would be to reverse-engineer the distributional patterns that are indicative of abstract semantic class membership and thereby 'give back' an interpretable set of class membership indicators to semantic theory.

A Extremeness classification: supplementary analysis

In this supplementary analysis, we report on an experiment in which we control for the potential confound described at the end of Section 3.3; that is: some training set items frequently share domain-specific features with the held out test item (e.g., *massive* and *colossal* are in the training set while *huge* is held out). To validate that the DSM Centroid method is detecting the abstract property of extremeness, rather than simply tapping into such domain-specific similarities, we set up the evaluation procedure in a way that minimizes the possibility that domain-specific similarities explain the results. We do so by aiming to exclude adjectives from the training set that are in the same domain as a test adjective.

A.1 Methods and materials

Because we do not have ground-truth domain labels for our extreme adjectives (e.g., $\{huge, colossal, mammoth\} \in$ SIZE), we require another method for grouping the adjectives into domains. As an approximation of domain groupings, we use an unsupervised clustering algorithm on the extreme adjectives, expecting that items belonging to the same cluster will belong to the same domain. With these k domain-based clusters, we can then train on $k-1$ of the clusters while testing on the held-out cluster.

Concretely, we perform a variant of k-fold cross-validation, called leave-one-cluster-out cross-validation, following Utsumi (2020), where the folds are determined through k-means clustering of our dataset of extreme adjectives. For binary classification of extreme adjectives, we train the DSM Centroid and Distrib. test methods, described in Section 3.2, on extreme adjectives in $k-1$ of the clusters as well as their frequency-paired non-extreme adjectives; see Section 3.1 for details of this pairing. We then test our binary classifiers on the extreme adjectives in the k-th cluster along with their paired non-extreme adjectives. We repeat this procedure k times so that each cluster is tested once.

A.2 Results

The leave-one-cluster-out cross-validation procedure is dependent on the number of clusters k used for k-means clustering. We perform the procedure for a wide range of $k \in [2, \ldots, 12]$ to ensure that the results are robust to the choice of k. Table 5 (below) displays subsets of the clusters obtained with k-means clustering for $k = 5$, qualitatively demonstrating that the clusters are centered on domain-specific features. The cross-validation results on the full range of k values are shown in Fig. 4.

We can see that the DSM Centroid performance here (AUC $\in [0.78, \ldots, 0.88]$) is lower than in Section 3.3 (AUC=0.97), indicating that within-domain similarity was partly responsible for the result in that set-up. However, even in this more controlled set-up, the DSM Centroid method robustly outperforms the Distributional Test method (AUC $\in [0.67, \ldots, 0.74]$, which is similar to the AUC of 0.71 for this method in Section 3.3). We take the results in this controlled analysis as further evidence that the cross-domain property of extremeness can be detected from DSM vectors.

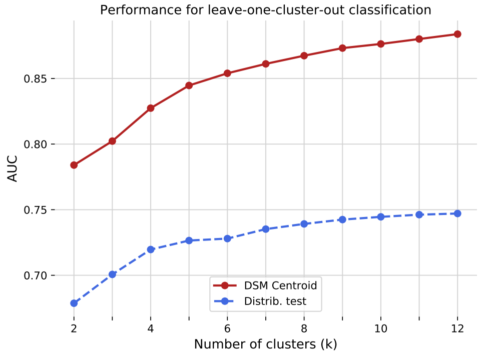

Figure 4: Results for extremeness classification using the leave-one-cluster-out cross-validation procedure. We vary the number of clusters from $k \in [2, \ldots, 12]$.

B Intensifier prediction: supplementary analysis

In Section 4, we used a historical prediction task to test two contrasting accounts of how intensifiers emerge in the lexicon. Specifically, we developed classifiers, based on diachronic DSMs, to predict whether an adverb would acquire an intensifying sense based on historical corpus data *prior* to the sense's attestation date. By restricting to corpus data prior to attestation dates, we ensured that the DSM vectors reflected manner adverb usage (*monumentally sized*) rather than intensifier usage (*monumentally wrong*). That is, we minimized the risk that the DSM vectors smuggled in information of whether an adverb was already an intensifier.

This restriction, however, also results in two data

Cluster 1	Cluster 2	Cluster 3	Cluster 4	Cluster 5
ecstatic	brainless	gargantuan	penniless	mesmerizing
phenomenal	amateurish	miniscule	destitute	resplendent
exceptional	moronic	mammoth	miserable	immaculate
terrific	inane	colossal	filthy	breathtaking
outstanding	idiotic	monstrous	obese	brilliant

Table 5: Samples of clusters from k-means clustering on extreme adjectives with $k = 5$.

sparsity problems. First, there are relatively few adverbs that gained an intensifying sense after the 1800s – the time period for which we have historical corpus data – so we were required to use a smaller sample of intensifiers. Second, many adverbs gained intensifying senses towards the earlier parts of the 19th century, for which historical corpora are significantly smaller than in later decades. As described in Section 4, the latter issue required us to compute the SimAdjMod measure differently than Luo et al. (2019): We used embeddings of the adjectival basis (*insane*) rather than the adverb itself (*insanely*), since many adverbs were missing in the historical embeddings.

In this section, we perform the prediction task introduced in Section 4 without restricting to corpus data prior to attested dates of intensifier senses. While lifting this restriction weakens the explanatory account of how intensifiers emerge in the lexicon (due to the aforementioned methodological concern), it alleviates the problem of data sparsity and aligns more closely with the experimental set-up of Luo et al. (2019), thereby making the results more directly comparable. This experiment thus serves as a follow-up test for our hypothesis that EXTREMENESS is a strongly predictive feature of whether intensifying meanings emerge for manner adverbs.

The experiment here is similar to the one reported in Section 4, but there are three significant differences, all introduced to align better with the setting of Luo et al. (2019): First, we use the majority of intensifiers ($N = 185$ out of 250) and control adverbs ($N = 152$ out of 178) published by Luo et al. (2019) – specifically, we use all of their adverbs that have available word embeddings, as opposed to only intensifiers attested within the 1800s to the present. Second, we use a prediction timeframe of $T = \{1850, 1860, \ldots, 1990\}$ for all queries, as opposed to a timeframe of 3 decades parameterized by an intensifier's attested date. Third, we use the adverb embeddings in computing the SIMADJMOD measure, as opposed to the embeddings of the adverbs' adjectival bases used in Section 4.

B.1 Methods and materials

Corpus. The binary classification – as having an intensifier sense or not – is conducted with corpus data spanning 15 decades from the 1850s to the 1990s from the Google N-grams and syntactic N-grams corpora. We used diachronic skip-gram word embeddings as in Section 4.

Evaluation dataset. Our evaluation dataset consists of the 185 intensifiers and 152 control-adverbs from the Luo et al. (2019) dataset that were left after discarding, similarly to their modelling set-up, 65 intensifiers and 26 control-adverbs with missing word embeddings.

B.2 Features for classification of intensifiers

For each query adverb q, we compute the two features (EXTREMENESS and SIMADJMOD) as follows:

EXTREMENESS. We calculate the cosine similarity of the adjectival basis embedding $\mathbf{a_q(t)}$ to the extremeness centroid $\mathbf{E_t}$ for every decade $t \in T = \{1850, 1860, \ldots, 1990\}$. As in Section 4, the extremeness centroid $\mathbf{E_t}$ is calculated as the averaged diachronic embeddings of the extreme adjectives introduced in Section 3. This provides us with a measure of EXTREMENESS for each decade $t \in T$ that we then average to get a single measure of EXTREMENESS for q.

SIMADJMOD. We calculate the odds-weighted[10] average similarity of the adverb embedding $\mathbf{q_t}$ to the embeddings of the adjectives $\mathbf{a_t}$, where a was modified by q in decade t. We perform this computation for every $t \in T = \{1850, 1860, \ldots, 1990\}$, giving us a measure of SIMADJMOD for every

---

[10] See Luo et al. (2019) for details of the weighting function.

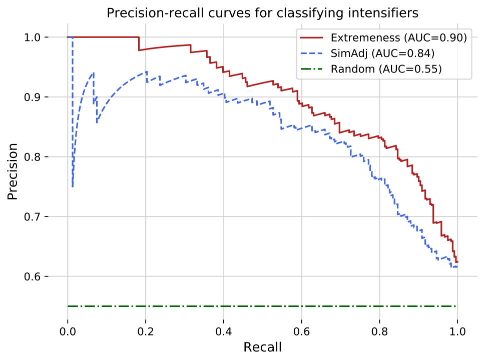

Figure 5: Results for classifying an adverb as an intensifier vs. control.

decade $t \in T$. We then average these per-decade SimAdjMod values to get a single measure of SimAdjMod for q. Rather than using the embedding of the *adjectival basis* of q for $\mathbf{q_t}$, as we did in Section 4 for data sparsity reasons, here we used the diachronic embeddings of the *adverb* q. In doing so, we mirror the operationalization of Luo et al. (2019) for this feature exactly.

B.3 Classification results

We fit a separate logistic regression classifier for each of the two features and use leave-one-out cross-validation. Fig. 5 shows that Extremeness achieves better performance (AUC $= 0.90$) than SimAdjMod (AUC $= 0.84$). The difference between the two features reported here is, however, much smaller than in the experiment in Section 4. Interestingly, while the AUC for Extremeness is comparable between the two experiments, the SimAdjMod feature does much better in the current set-up. We speculate that this is due to the latter feature having access to the adverbial vectors for decades in which the adverb has already obtained an intensifying meaning: a more “bleached” vector is more likely to be similar to many adjectives than a vector that has a more unique contextual signature. Further research is required on the influence of semantic bleaching on semantic space representations to test this speculation. We leave this topic for future work.

Despite the smaller difference in performance, however, we still find salient differences between the predictions made by the two models: We observe a similar pattern of errors as in Section 4 when setting a classification threshold at $P(c = \text{Intensifier}|q) = 0.5$. Specifically, the Extremeness feature is able to correctly classify intensifiers that are relatively infrequent (*defiantly, startlingly, unequivocally*), providing further evidence that extremeness leads to the acquisition of intensifying meaning. Again, we observe that the account formalized in the SimAdjMod measure correctly predicts adverbs with an epistemic function (*evidently, prominently, noticeably*) to acquire an intensifying meaning while the Extremeness feature does not. Overall, we find results in accordance with those of Section 4: the cross-domain semantic property of Extremeness is very effective in predicting whether an adverb will gain an intensifying function.

Effective Attention Sheds Light On Interpretability

Abstract

An attention matrix of a transformer self-attention sublayer can provably be decomposed into two components and only one of them (*effective attention*) contributes to the model output. This leads us to ask whether visualizing effective attention gives different conclusions than interpretation of standard attention. Using a subset of the GLUE tasks and BERT, we carry out an analysis to compare the two attention matrices, and show that their interpretations differ. Effective attention is less associated with the features related to the language modeling pretraining such as the separator token, and it has more potential to illustrate linguistic features captured by the model for solving the end-task. Given the found differences, we recommend using effective attention for studying a transformer's behavior since it is more pertinent to the model output by design.

1 Introduction

Attention mechanism (Bahdanau et al., 2015) is an essential component of many NLP models, including those that are built on the ubiquitous transformer architecture (Vaswani et al., 2017). As a result, visualizing attention weights is a widely used technique to interpret models' behavior (Belinkov and Glass, 2019). Despite that, the validity of this analysis method is a subject undergoing intense discussion and study in NLP (Jain and Wallace, 2019; Wiegreffe and Pinter, 2019; Serrano and Smith, 2019; Moradi et al., 2019; Mohankumar et al., 2020; Tutek and Snajder, 2020, *i.a.*).

Related to this discussion, Brunner et al. (2020) show that, under mild conditions, the attention matrix of a transformer self-attention sublayer can be written as a sum of two components. One of them is irrelevant for the model output because its product with the value matrix is zero. They term the other component as *effective attention* (formally defined in §2). We study whether effective attention gives interpretations that differ from conclusions we get by analyzing standard attention. If this is the case, interpretation of effective attention is better suited for studying transformers' internals because it is more pertinent to the model output by design.

Brunner et al. (2020) briefly discuss this by comparing standard and effective attention matrices from a single BERT head (Devlin et al., 2019) for one example. They observe that: (i) standard attention is largely concentrated on the delimiter tokens ([SEP], [CLS]) or on near-diagonal elements; (ii) effective attention is more dispersed; (iii) effective attention disregards the delimiters. They stress that we should not extrapolate too much from these observations since they are based on a single example, and that further research is needed on this topic.

In this work, we aim to reliably answer whether effective attention disregards the [SEP] and [CLS] tokens, and if so, are effective attention weights dispersed to linguistic features? To address these questions, we embrace the methodology for a quantitative analysis of the attention patterns produced by individual transformer heads proposed by Kovaleva et al. (2019). We carry out their experiments on a subset of the GLUE tasks with BERT's standard and effective attention. We show that effective attention "ignores" [SEP] and punctuation symbols (§3.1, §3.2), but not [CLS] (§3.2), and that it highlights end-task features instead (§3.1, §3.2, §3.3).[1]

2 Background: Effective Attention

Each transformer layer consists of multi-head self-attention and feedforward sublayers (Vaswani et al., 2017, see Appendix A). Brunner et al. (2020) show that the **standard attention** matrix A can be decomposed into two components, if a mild condition

---

[1] Our code is available at https://github.com/KaiserWhoLearns/Effective-Attention-Interpretability

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4126–4135
August 1–6, 2021.

is satisfied. Specifically, if the left nullspace of the value matrix V:

$$\mathrm{LN}(V) := \{x^\top \in \mathbb{R}^{1 \times d_s} | x^\top V = 0\},$$

is not trivial (contains vectors other than $\vec{0}$). This is satisfied when the maximum input sequence length is larger than the value matrix dimension (see Appendix A). The two components are: the component in the left nullspace of V ($A^{\parallel}$) and the component orthogonal to the nullspace ($A^{\perp}$). Notably, $A^{\parallel}$ does not contribute to the output of the self-attention sublayer:

$$AV = (A^{\parallel} + A^{\perp})V = \vec{0} + A^{\perp}V = A^{\perp}V. \quad (1)$$

The **effective attention** matrix is defined as $A^{\perp}$. If visualizations of standard and effective attention differ, interpretation of effective attention is an accurate interpretation because effective attention is what contributes to the model output (per Eq. 1).

We explain how to compute $A^{\perp}$ since that was not described in Brunner et al. (2020). We first compute the singular value decomposition (SVD) of the value matrix $V = U\Sigma W^T$. The rows of U that correspond to singular values equal to zero span $\mathrm{LN}(V)$:

$$\mathrm{LN}(V) = \mathrm{span}\{u_1, \ldots, u_k\},$$

where k is the number of singular values that equal zero. We project each row a_i of the attention matrix $A \in \mathbb{R}^{d_s \times d_s}$ to $\mathrm{LN}(V)$ to construct a projection of the *matrix* A to $\mathrm{LN}(V)$:

$$\mathrm{P}_{\mathrm{LN}(V)}(a_i) = \sum_{j=1}^{k} \langle a_i, u_j \rangle u_j, \forall i \in \{1, \ldots, d_s\},$$

$$\mathrm{P}_{\mathrm{LN}(V)}(A) = [\mathrm{P}_{\mathrm{LN}(V)}(a_1), \ldots, \mathrm{P}_{\mathrm{LN}(V)}(a_{d_s})]^\top,$$

where $\langle \cdot, \cdot \rangle$ denotes the dot product. Finally, effective attention equals to:

$$A^{\perp} := A - \mathrm{P}_{\mathrm{LN}(V)}(A).$$

Effective attention is not guaranteed to be a probability distribution as some of its weights might be negative and larger than 1.

We observe that effective attention is slower to compute due to the SVD decomposition of V for each out of 144 BERT-base heads, and additional matrix multiplications (Table 3; §B). If speed is bottleneck, we recommend doing quantitative analyses with effective attention on a subset of the dev set. For qualitative analyses, common practice is already to select a subset for a manual analysis.

Dataset	Task	|Train|	|Test|
RTE	NLI	2.5K	3K

QNLI	QA as NLI	105K	5.4K
SST-2	binary sentiment classification	67K	1.8K
STS-B	sentence similarity	7K	1.4K

Table 1: Specifications of the datasets.

3 What Does Effective Attention Reveal?

We compare visualizations of standard and effective attention following the methodology for analysis of the attention patterns (Kovaleva et al., 2019). We carry out our analyses using five English-language datasets in the GLUE benchmark (Wang et al., 2019): RTE (Dagan et al., 2005; Haim et al., 2006; Giampiccolo et al., 2007; Bentivogli et al., 2009), MRPC (Dolan and Brockett, 2005), QNLI (Rajpurkar et al., 2016; Wang et al., 2019), SST-2 (Socher et al., 2013), and STS-B (Cer et al., 2017).[2] See Table 1 for their specifications. For each dataset, we train BERT-base with standard attention, a batch size of 8, maximum sequence length of 128, and 3 training epochs.[3] For analyzing effective attention, we replace standard with effective attention at the test time.

3.1 Classification of Attention Patterns

In this section, we start studying whether effective attention disregards the delimiter tokens.

The visualizations of attention matrices exhibit patterns (Clark et al., 2019; Vig and Belinkov, 2019). Kovaleva et al. (2019) identified five frequently occurring pattern categories:

- vertical (associated with the *delimiters tokens*)
- diagonal (either syntactic features between neighbouring words in the English language or the previous/following token attention coming from the language modeling pretraining)
- vertical + diagonal
- block (intra-sentence attention for the tasks with two distinct sequences; potentially encodes semantic and syntactic information)
- heterogeneous (as "block", more likely to capture interpretable linguistic features).

They annotated 400 BERT's attention matrices using these categories, and used them to train a

---

[2] We omit larger datasets (QQP, MNLI), due to the limit of our computation budget (a single Nvdia GTX1070 with 8GB memory), and CoLA/WNLI following Kovaleva et al. (2019).

[3] All other hyperparameters are set to default values in the transformers library (Wolf et al., 2020).

Task	Attention	B	D	V+D	H	V
RTE	Standard	4.50	7.40	15.20	45.10	27.90
	Effective	32.60	12.80	2.80	40.30	11.50
MRPC	Standard	3.40	10.20	14.90	39.80	31.80
	Effective	25.50	17.40	3.60	40.40	13.00
QNLI	Standard	4.70	7.40	15.20	45.10	27.90
	Effective	29.30	15.80	3.40	46.40	5.10
SST-2	Standard	38.50	6.10	0.00	37.80	17.60
	Effective	33.80	11.50	0.80	39.40	14.60
STS-B	Standard	4.00	8.20	1.80	50.40	35.50
	Effective	36.00	10.30	0.60	39.40	13.60

Table 2: Estimated percentage of the attention patterns (§3.1): block (B), diagonal (D), vertical + diagonal (V + D), heterogeneous (H), vertical (V). Effective attention exhibits different patterns than standard attention, i.e., less vertical patterns (associated with delimiter tokens) and more block patterns (associated with task features).

ConvNet for pattern classification of 1K random test set attention matrices. We replicate their results for standard attention (using their code), and classify effective attention matrices for a comparison.[4]

Results Table 2 (Fig. 4 in Appendix B) shows a drop in the percentage of the "vertical" and "vertical + diagonal" patterns when we replace the standard with effective attention. Since the vertical patterns are associated predominantly with attention to the delimiters tokens, this result supports the hypothesis that effective attention disregards the delimiter tokens. Moreover, although the amount of "heterogeneous" patterns did not change notably, the amount of "block" and "diagonal" patterns increased. This suggests that we are better positioned to find end-task linguistic features captured by the model by visualizing effective attention.

As an illustration, Figure 2 presents the attention matrices for one sentence from one attention head. In this example, effective attention highlights all mentions of the noun "antibiotics" that the adjective "new" modifies and that is also the object of the preposition "against", instead of giving prominence to the [SEP] token as standard attention.

3.2 Delimiter Tokens vs. Linguistic Features

We showed that the "vertical" pattern, *associated* with the delimiter tokens, is less dominant with effective attention (§3.1). To verify that both delimiter tokens are indeed less relevant with effective attention, following Kovaleva et al. (2019), we re-

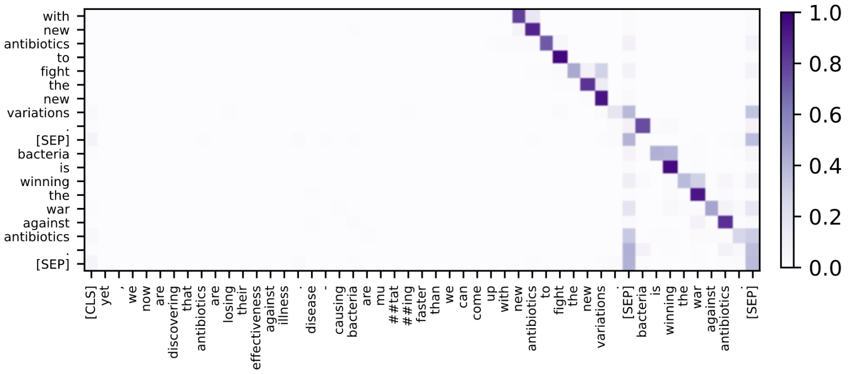
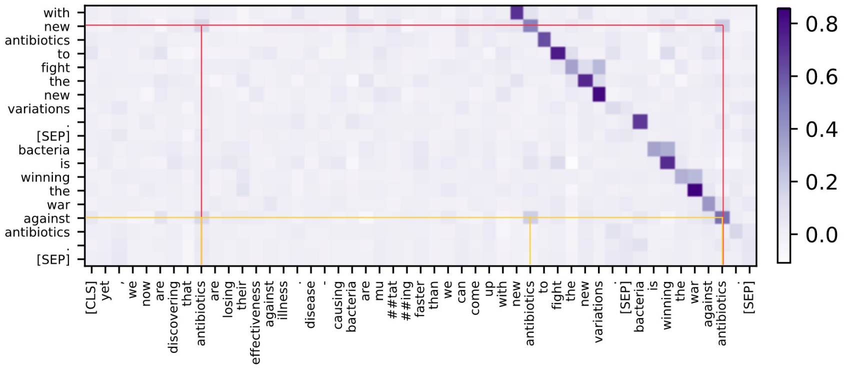
[4] We thank the authors for sharing their code and model weights for this experiment.



(a) Standard attention



(b) Effective attention

Figure 2: Visualizations of standard and effective attention from one head for one example from the RTE dataset (recognizing textual entailment). Only the last few rows are visible; see the full version in Fig. 7 (Appendix §B).

port the standard and effective attention weights of specific token types when processing the [CLS] token in the final layer. Namely, the attention weights of linguistic features (nouns, pronouns, verbs), the delimiter tokens ([SEP], [CLS]), and punctuation symbols that are conceptually similar to [SEP].[5]

Results Figure 1 shows that [SEP] is among the two most relevant features for all tasks except QNLI according to standard attention (upper two rows in each subfigure, colored green). For all but one task (SST-2), it loses its dominance with effective attention and its weights are apparently shifted to linguistic features. This is also the case for punctuation symbols. This result shows that the [SEP] token and punctuation symbols are not as important for understanding how the model solves the end-task as standard attention suggests.

We observe that [CLS] is attended similarly with effective and standard attention, contrary to what Brunner et al. suggested. To rule out this is because we plot the attention assigned to [CLS] when processing [CLS], we report the attention assigned to [CLS] when processing other input words (regardless of their type) in Fig. 5 in Appendix B. Again, we do not observe differences between standard and effective attention, unlike for [SEP] (Fig. 6 in §B). These results confirm the hypothesis of Brunner et al. that effective attention disregards [SEP], but not [CLS] as they also hypothesized. Notably, [SEP] is associated with the LM pretraining and [CLS] only with the task-specific finetuning.

3.3 Effects of Task-Specific Finetuning

To provide our final evidence that effective attention captures end-task features, we investigate how attention changes with finetuning layer-wise; again following Kovaleva et al. (2019). They calculate the cosine similarity between pretrained and finetuned flattened attention matrices. The layers that change the most, encode most task-specific features. To reiterate, effective attention is the part of standard attention that contributes to the model output (Eq. 1; §2), and we showed that it is less associated with the pretraining feature [SEP] and more with linguistic features (§3.1, §3.2). Thus, changes of standard attention from task-specific finetuning

---

[5] If there are multiple tokens of the same type in the input, we use the one with the maximum weight. If a word consists of the multiple subtokens, we use the weight of the first subtoken.

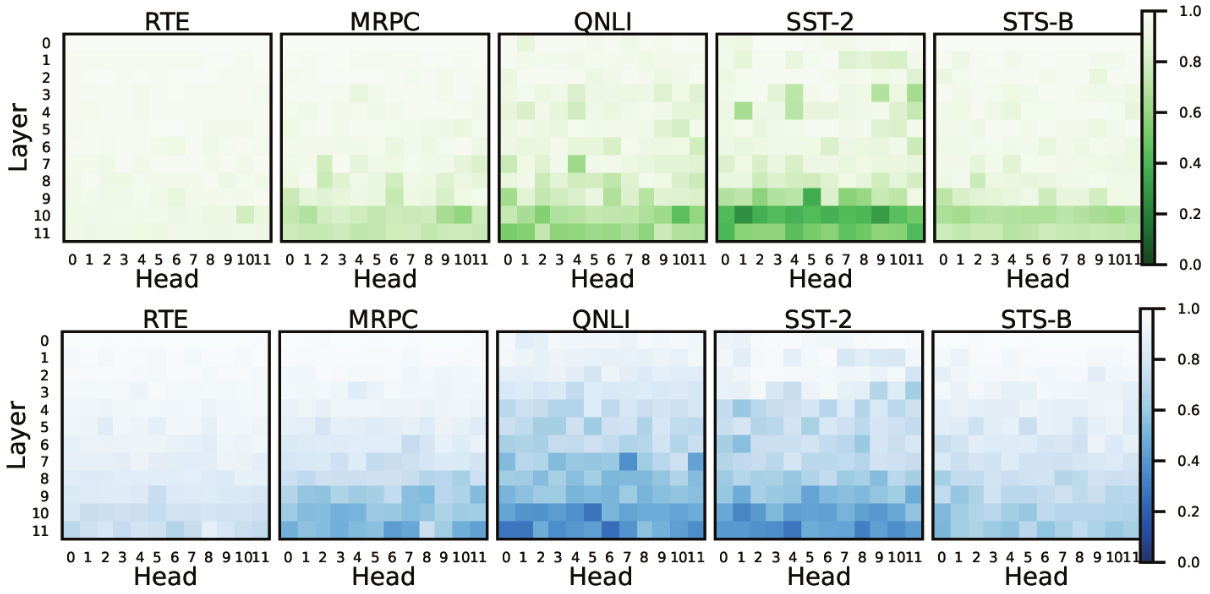


Figure 3: Per-task cosine similarity between the pretrained and finetuned attention weights for selected GLUE tasks, calculated across layers and heads. The darker colors corresponding to larger absolute attention weights. The top (green) figure is computed with the standard attention, and the bottom (blue) figure with the effective attention.

should be the product of changes of effective attention, and the outcome of this analysis should be the same, regardless of the attention "type".

Results As expected, we come to the same conclusion with effective attention as Kovaleva et al. did with the standard: the last two layers change the most with finetuning (Fig. 3). This soundness check suggests once again that effective attention is the component of standard attention that manifests end-task features.

4 Conclusions

We study whether effective attention, the part of the transformer attention matrix that does not get canceled out with the value matrix, gives different interpretations than standard attention. We present a comparison of the two attentions and show that they differ in weights assigned to delimiter tokens such as [SEP] and punctuation marks, but not [CLS] as it was previously thought. Instead, effective attention gives more weight to linguistic features. Given the differences, and that effective attention is more pertinent to the model output by design, we urge to use it for studying transformers' internals.

As an alternative to analyzing attention *weights*, Kobayashi et al. (2020) propose anayzing the norm of vectors produced by multiplying the outputs of the value matrix with the attention weights. Following the experimental setting of Clark et al. (2019), i.e., by analyzing 992 sequences extracted from Wikipedia, their norm-based analysis also shows that the contributions of [SEP] and punctuations are actually small. However, unlike us, they report the same observation for [CLS]. Future work might consider a more formal study between the norm-based analysis and effective attention, especially since the norm-based analysis could circumvent the problem of costly SVD.

Acknowledgments

The authors thank Noah A. Smith, members of Noah's ARK, as well as anonymous reviewers for their helpful feedback, and Olga Kovaleva for sharing the code and model weights for classification of attention patterns.

A Background: On The Rank Of The Value Matrix

The output Z of an individual self-attention head is given by:

$$
\begin{aligned}
Q &= Z_{l-1}W^Q \in \mathbb{R}^{d_s \times d_q} \\
K &= Z_{l-1}W^K \in \mathbb{R}^{d_s \times d_k} \\
V &= Z_{l-1}W^V \in \mathbb{R}^{d_s \times d_v} \\
A &= \mathrm{Softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right) \in \mathbb{R}^{d_s \times d_s} \\
Z &= AV \in \mathbb{R}^{d_s \times d_v},
\end{aligned}
$$

where d_s is the maximum length of the input sequence (in number of subtokens), Z_{l-1} is the output of the previous transformer layer, W^Q, W^K, W^V are the query, key, and value *weight* matrices, respectively. For BERT-base, $d_q = d_k = d_v = 64$, $n_{\text{heads}} = 12$, $d_s = 512$, and $d_v \cdot n_{\text{heads}} = 768$.

Brunner et al. (2020) show that the upper bound of the rank of the value matrix V is given by:

$$
\begin{aligned}
\mathrm{rank}(V) &= \mathrm{rank}(Z_{l-1}W^V) \\
&\leq \min\{d_s, d_v, d_s, d_v \cdot n_{\text{heads}}\} \\
&\leq \min\{d_s, d_v\}.
\end{aligned}
$$

As a result, the left nullspace of V, defined as:

$$\mathrm{LN}(V) := \{x^\top \in \mathbb{R}^{1 \times d_s} | x^\top V = 0\},$$

is non-trivial ($\mathrm{LN}(V) \neq \{\vec{0}\}$) when the maximum input length, d_s, is larger than the dimension of the value matrix d_v, i.e., $d_s > d_v$. In this case, we can construct infinitely many matrices $A + \tilde{A}$,

$$\tilde{A} = [x_1, \ldots, x_{d_s}]^\top, x_i \in \mathrm{LN}(V),$$

which contribute exactly the same to the output as the attention matrix A:

$$(A + \tilde{A})V = AV + \tilde{A}V = AV + \vec{0} = AV.$$

This also holds when the weights of $A + \tilde{A}$ are constrained to the probability simplex, and such constrained matrices $A + \tilde{A}$ exist.

B Additional Results

Abstract

We introduce a language modeling architecture which operates over sequences of images, or over multimodal sequences of images with associated labels. We use this architecture alongside other embedding models to investigate a category of signs called complex graphemes (CGs) in the undeciphered proto-Elamite script. We argue that CGs have meanings which are at least partly compositional, and we discover novel rules governing the construction of CGs. We find that a language model over sign images produces more interpretable results than a model over text or over sign images and text, which suggests that the names given to signs may be obscuring signals in the corpus. Our results reveal previously unknown regularities in proto-Elamite sign use that can inform future decipherment efforts, and our image-aware language model provides a novel way to abstract away from biases introduced by human annotators.

1 Introduction

This work sets out to understand a category of signs called complex graphemes (CGs) in the undeciphered proto-Elamite (PE) script, a writing system from ancient Iran dating to approximately 3300-2900 BC (Dahl et al., 2013).[1] PE is partly contemporaneous with the world's other two earliest writing systems, Egyptian hieroglyphs and proto-cuneiform, and is the least deciphered of the three, with the underlying language(s) remaining unknown. PE was used exclusively as an accounting technology, employing several numerical systems whose bundling principles are known. Although written in continuous lines, PE, like proto-cuneiform, is most comparable to an accountant's spreadsheet; some structures and rules governing sign use have been identified (Hawkins, 2015; Dahl et al., 2018; Englund, 2004).

The corpus consists of approximately 1500 published clay tablets from excavations in Iran, almost all of which exist in electronic transliteration following the conventions of a work-in-progress sign list (Dahl, 2006). As with other decipherments, understanding the nature of signs and the nuances of sign use is as important as identifying the underlying language(s). Meaningful information can be recovered and the texts partly "read" even if the language remains unknown.

To better understand sign usage in PE, this work proposes an architecture for image-aware language modeling, which permits sharing information between visually similar signs much as sub-word units share information between words. We use sign embeddings to demonstrate patterns which are not readily apparent due to the complexity of the accounting system and the large number of sign shapes found in the script. Our analysis offers insights on complex graphemes that can aid in future hypothesis generation. We confirm that some transliteration choices by PE specialists capture meaningful semantic divisions in the script; this is not a trivial fact, due to the large number of similar looking signs. By using image-aware models, we also observe that some signs with distinct names receive very similar embeddings, implying a functional equivalence that could be exploited by merging signs to create a less sparse corpus that is more amenable to analysis by NLP methods.

2 Methodology

As described by Dahl (2005), CGs in proto-Elamite are signs that consist of one sign inscribed within another (transliterated |S1+S2|), or of one sign framed by two instances of another (|S1+S2+S1|). Rarely, S1 and S2 occur connected at the side, as

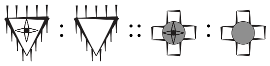
August 1–6, 2021.

in |M296+M296| . We refer to S1 as the *outer* sign and S2 as the *inner* sign, though we acknowledge this terminology is not quite appropriate in cases like |M296+M296|. Most signs which occur as part of a CG can also occur as standalone signs. Exceptions to this are rare, such as M600 which only ever occurs in the hapax |M362+M600|.

Although these signs are *orthographically* compositional, it is not known whether they are also semantically compositional. Similar constructions exist in proto-cuneiform (PC), including "containers" with signs inscribed to indicate specific products (Wagensonner, 2015). Some PC compounds survive into later cuneiform, and sometimes have idiomatic meanings, e.g. cuneiform GU_7 "eat", a combination of "head" and "bowl". Chinese characters likewise exhibit varying degrees of visual and semantic compositionality (Sproat, 2006).

Past work (Mikolov et al., 2013b; Salehi et al., 2015; Cordeiro et al., 2016) suggests that embedding models capture semantic compositionality in noun compounds and multiword expressions. Often, these models assign a compound a representation which is similar to the sum of the representations of the words in the compound. Thus we predict that if CGs are semantically compositional, their embeddings will be additively compositional at a higher rate than expected by chance. Their embeddings may also exhibit other signs of internal structure, such as the ability to model proportional analogy between CGs with shared components:

|M136+M365| : M136 :: |M327+M365| : M327



If this analogy holds in the embedding space (which is to say that the 3CosAdd formula |M136+M365| - M136 + M327 $\approx$ |M327+M365| holds between the signs' embeddings) this would give further evidence that the CGs involved have some degree of semantic compositionality.

Unfortunately, most PE signs are rare, which impedes a model's ability to learn meaningful information about their distributions. Yet many signs with distinct names have striking visual resemblances, and it is usually not known whether they have different meanings. Visual information may therefore help an embedding model by allowing it to share distributional information across graphically similar signs. To this end, we propose an architecture for multimodal language modeling in Figure 1. This architecture uses two separate embedding components. On the left of Figure 1, in red, is a standard embedding layer which replaces a one-hot input with a small, learnable representation. On the right, in blue, a lookup function retrieves an image of the sign represented by the input. A CNN extracts a feature vector from the image, which is max-pooled, flattened, and passed through a dense layer to produce a low-dimensional embedding. Both embeddings are concatenated and fed to a BiLSTM[2] (Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997) which attempts to predict the name of the next sign in the text. All timesteps share the same weights for the CNN and embedding layers. By omitting the blue image-embedding component we can obtain a normal BiLSTM language model. By omitting the red text-based component, we can obtain an image-only model which never directly sees the labels assigned to the signs in the corpus.

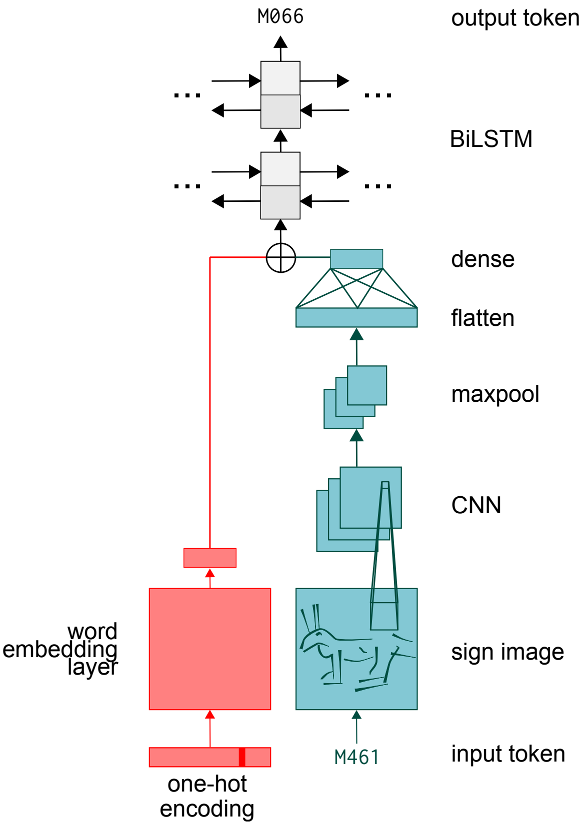


Figure 1: Architecture for image-aware, multimodal language modeling.

To verify that this architecture captures distributional properties of signs, and not just visual properties, we train a separate image recognition model to predict a sign's name given only its image.

---

[2] We also attempted to train a Transformer model (Vaswani et al., 2017), but the corpus size proved insufficient and it always underperformed compared to the BiLSTM.

Model	Input Type	Embedding Sizes[3]	Other Parameters	Description

image recognition	individual sign image	64	image size: 64×64	Figure 1, blue (image embedding) only.

Table 1: List of models considered in this work.

This model uses the blue image embedding component from Figure 1 to produce a representation of an input image; a dense layer predicts the name of the sign from this embedding. This model only sees signs in isolation, meaning it will not learn from distributional information. If a result holds for the multimodal LM but not for this image recognition model, this implies that the result arises from contextual information in the text, and not simply from visual resemblances between signs.

We also train CBoW and skipgram models with FastText[4] (Bojanowski et al., 2017) and word2vec (Mikolov et al., 2013a), as well as GloVe embeddings (Pennington et al., 2014). Table 1 summarizes all of the models used in this work and important hyperparameters. We train these models on the PE corpus from Born et al. (2019), which is a cleaned version of texts originally published by the Cuneiform Digital Library Initiative (CDLI). This contains digitized transliterations from 1399 tablets comprising 11013 lines in total, or 33778 tokens. 7508 tokens represent broken or unreadable signs, and another 11364 represent numerals, leaving only 14906 non-numerical tokens. 1107 tokens (comprising nearly half the sign types in our cleaned data) are labeled as CGs. We treat each entry of a tablet as a single input sentence for training LMs, and set aside 500 lines as a validation set.

Prior to training, we replace all signs occurring 3 or fewer times[5] with UNK. We replace rare signs wherever they occur, including inside of CGs. The tokens `X` and `...` represent broken or unreadable signs, so we also replace these with UNK. When training language models, we do not backpropagate losses from samples where the target word is UNK, since it so often represents broken material. To make the data less sparse, we remove annotations marking sign variants, so that for example M157 and M157∼a are considered the same sign.

3 Experimental Results

3.1 Additive Composition

We predict that if a CG is semantically compositional, its embedding will approximately equal the sum of the embeddings of the signs it comprises.

Given a sign s, let e_s denote the embedding of s. If s is a CG let $\sigma(s)$ denote the list of signs which make up s. For every CG s in the signary, we check whether $\sum_{t\in\sigma(s)} e_t \approx e_s$. If $\sum_{t\in\sigma(s)} e_t$ is within the k nearest neighbors of e_s for some threshold k, we say that s appears to have a compositional representation.

For different thresholds k, we measure how many CGs have compositional representations. Since many PE signs have low frequency, we predict that noise may drown out any signal when k is small. However, when k is large enough to overcome this noise, we predict that the number of CGs with compositional representations will be greater than expected by chance, as we expect that some CGs have meanings which are semantically compositional rather than idiomatic. Table 2 shows the results from this evaluation.

In text-only models, when k is small the number of CGs with compositional representations is no higher than expected by chance. However, for image-aware models, and for text-only models with large k, the number of CGs which are close to the

---

[3] To give a fairer comparison, we train the simpler models with several embedding sizes and report results from whichever dimensionality performs best on each task. Additional model information is in the supplemental material.

[4] Sign names are largely arbitrary, so we disable sub-words in FastText by setting the maximum sub-word length to 0.

[5] To determine frequency, we count how often a sign occurs both independently and as part of a CG.

	k				
model	1	3	5	10	15

image recognition.64	**3**	**7**	**15**	**28**	**38**

Table 2: Number of compositional CGs for different similarity cutoffs k. Bold numbers represent cases where the number of compositional graphemes is significantly larger than expected by chance.

sum of their components is significant. Even for $k = 15$, the signs identified as compositional by `lm.image.64` average >0.97 cosine similarity to the sum of their parts, suggesting this is not too generous a threshold.

Notably, the number of compositional CGs in `lm.image.64` is always larger than the number in any of the other models, including the image recognition model.[6] This has the important implication that compositionality in the embeddings is not solely a consequence of visual compositionality. If that were the case, the contextual information available to the LM would not be useful for this task, and the image LM would not be expected to find more compositional CGs than the image recognition model. Moreover we would not expect to find a significant amount of compositionality in any of the text-only models for any k. Table 3 shows examples of signs which appear to be compositional in the image LM but not the image recognition model. These are signs for which contextual information plays a deciding role in making them appear semantically compositional, and which may therefore be of interest to analyze in future work.

Table 3: Sample of signs which appear to be compositional in the image LM but not the image recognition model.

We emphasize that the text-only models have no information about sub-words (such as CG components), so any compositionality in these models must exclusively reflect distributional properties. From these results we conclude that there is legitimate evidence for some CGs having semantically compositional meanings in PE.

3.2 Pairing Consistency

To assess the contribution of a sign to the CGs it occurs in, we consider the pairing consistency score (PCS) from Fournier et al. (2020). This metric measures whether the offsets between pairs of words are more parallel than expected by chance. If a sign s always contributes the same meaning to the CGs in which it occurs, then the offset between the pair of signs (t, $|t + s|$) is expected to be roughly parallel to the offset between the pair (u, $|u + s|$) for most choices of t and u. If CGs containing s have idiomatic meanings (so the contribution of s is not consistent), the offsets between such pairs are not likely to be parallel. Thus PCS serves as a proxy for compositionality, and allows us to investigate the impact of individual signs on the representations of CGs in which they occur. This is distinct from a measure like mutual information which depends on raw sign counts and does not account for the internal structure of sign embeddings.

For each sign s we construct two relations. $R_{s,in}$ contains all CGs with s as the inner sign, paired with whichever sign forms the outer part of the CG. $R_{s,out}$ contains all CGs with s as the outer sign, paired with whichever sign forms the inner part of the CG. Formally, given a CG c containing a sign s, let $\delta(c, s)$ denote the element of c which is not s. Further, let $I(s)$ be the set of all CGs with s as the inner element and $O(s)$ be the set of all CGs with s as the outer element. Then

$$R_{s,in} = \{(\delta(c, s), c) \mid c \in I(s)\}$$

$$R_{s,out} = \{(\delta(c, s), c) \mid c \in O(s)\}$$

Table 4 reports the average PCS[7] of $R_{s,in}$ and $R_{s,out}$ for each model, averaged across all signs s. On average, we find that inner signs have higher PCS than outer signs. This difference is statistically significant in the image-aware LMs, the image recognition model, and FastText. This implies that inner signs have a more consistent and predictable impact on the representation of compounds in which they occur. The fact that this holds for

---

[6] The image recognition model has fewer parameters than the LMs, but it attains >99% accuracy on its original task, suggesting that it does not suffer from being a smaller model.

[7] We compute PCS using the code published by Fournier et al. (2020), but we adjust the permutation-finding function to avoid infinite loops when a relation contains few items.

some text-only models as well as for the image-aware LMs implies that it is due to distributional properties of signs and not simply their appearance.

	Mean PCS	
model	$R_{s,in}$	$R_{s,out}$
glove.64	0.542	0.544
word2vec.cbow.64	0.525	0.492
word2vec.skip.64	0.521	0.495
fasttext.cbow.64	**0.562**	**0.484**
fasttext.skip.64	**0.539**	**0.500**
lm.text.64	0.465	0.529
lm.image+text.64	**0.719**	**0.482**
lm.image.64	**0.760**	**0.536**
image recognition.64	**0.929**	**0.493**

Table 4: Comparison of pairing consistency for the inner and outer parts of compound signs in 64-dimensional models. Bolded rows represent pairs where the difference between columns is significant.

Fournier et al. (2020) note that different categories of relations in English have different average PCS. They find that relations involving inflectional morphology (for example, between a verb and its gerund) have high PCS, relations involving derivational morphology (as between *heat* and *reheat*) have lower PCS, and other semantic relations (as between *hot* and *cold*) have the lowest PCS of the relations they examine.

We expect that absolute PCS values will not be comparable between PE and English, owing to the very different nature of the two writing systems. However, it may be possible to draw broad comparisons between different categories. As the category with the highest PCS, inner signs appear to pattern with inflectional morphology, while outer signs pattern more closely with regular lexical items. This does not imply that inner signs actually encode inflectional morphology: most PE signs likely correspond to objects or ideograms, and most types of morphological marking were absent in the earliest phases of Near Eastern writing (Nissen et al., 1993). Rather, we suggest that inner signs may offer minor refinements to the meaning of an outer sign without fundamentally changing its value, parallel to the way that inflecting a verb refines its role in a sentence but does not change its basic meaning.

3.3 Analogy

Our PCS results measure sign behaviour in aggregate, but do not provide specific examples of relations between signs. We augment these results by searching for concrete analogies which hold in the embedding models.

Given two CGs s and t, let $s - t$ denote the signs that are in s but not t, and let $s \cap t$ denote the signs both CGs have in common. Consider the vector

$$A(s,t) = e_s - \sum_{u \in s-t} e_u + \sum_{v \in t-s} e_v$$

This vector represents the analogical formula $s : (s-t) :: t : (t-s)$. If $A(s,t) \approx e_t$ in a particular embedding model, then this analogy appears to hold true according to that model.

We compute how often $A(s,t)$ is within the k nearest neighbors of e_t for different thresholds k when $s \cap t \neq \emptyset$. We also compute how often $A(s,t)$ is close to e_t when s and t are randomly chosen CGs. We predict that CGs which have signs in common also have some meaning in common, and consequently that the former value will be significantly larger than the latter value.

Table 5 shows the results of this evaluation. As in the compositionality task, more analogies hold between CGs with shared components in image-aware models than in text-only models, and the largest number by far occur in the image LM. Once again, in `lm.image.64` the target vector averages >0.97 similarity to the computed vector even when $k = 15$. Bold numbers in the table represent cases where analogies are significantly more likely to hold between CGs with shared components than between random pairs of CGs. We see that the number of analogies is larger than expected by chance even in some text-only models, suggesting that there is a meaningful relationship between some CGs which have elements in common. The fact that the image LM outperforms the image recognition model further implies that these analogies reflect legitimate distributional properties and are not purely due to visual resemblance.

			k		
model	1	3	5	10	15
glove.256	0	8	11	25	48
word2vec.cbow.256	0	17	36	**65**	**90**
word2vec.skip.128	0	8	29	**97**	**140**
fasttext.cbow.128	0	9	22	**64**	**98**
fasttext.skip.256	0	11	30	91	**145**
lm.text.64	0	2	7	16	21
lm.image+text.64	**27**	**82**	**134**	**233**	**320**

image recognition.64	**29**	**67**	**92**	**133**	**174**

Table 5: Number of analogies which hold between CGs with signs in common, for different similarity cutoffs k. Bold numbers represent values which are significantly larger than expected by chance.

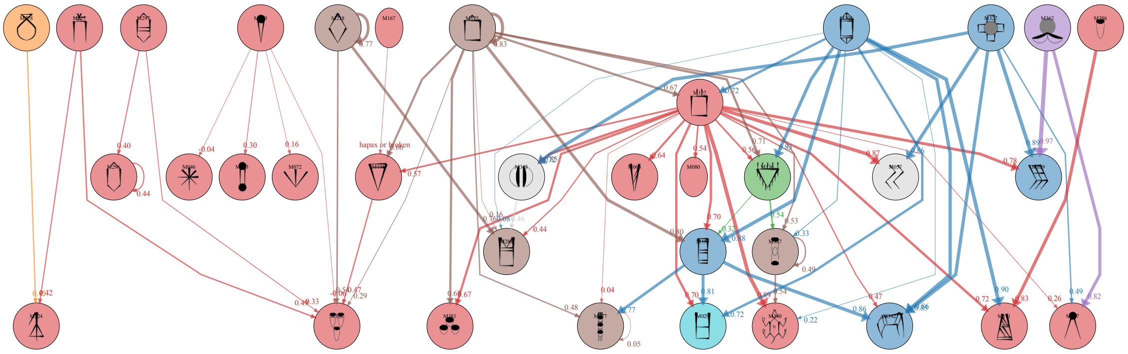

Figure 2: Containment hierarchy for a subset of the signs which can occur in CGs. Directed edges point from outer signs to the inner signs they can contain. Note that (excluding self-loops) the graph is acyclic and all edges point from higher nodes to lower ones. Thicker edges represent CGs which are more strongly compositional. Nodes are colored according to modularity class (Blondel et al., 2008) such that nodes are most strongly connected to like-colored nodes. Full hierarchy, showing all signs which occur in CGs, is available in supplemental material.

As was the case for additive compositionality, the image+text LM underperforms the image-only LM, and on this task the difference is much more pronounced. This suggests that sign names act as distractors: if sign names conveyed information which was helpful to the analogy task, their inclusion would be expected to improve performance. This fact has implications about the labeling of the data which we return to in Section 4.

Taken altogether, the results suggest that many CGs have compositional meanings which can be understood by comparison to the meanings of their component parts and the other CGs with which they share components. We next consider which pairs of signs are able to combine into CGs and which pairings are never observed.

3.4 CG Containment Rules

Some signs which occur as the inner part of one CG may also occur as the outer part of another, as with M348  in |M327+M348|  and |M348+M004| . We may therefore expect to find pairs of signs where either one can contain the other, and yet, no such pairs actually exist. In fact, we find that CGs appear to be constructed according to a strict hierarchy whereby a sign may only contain itself or another sign which is lower on this hierarchy. We can visualize this as a lattice with directed edges from outer signs to the inner signs they are observed to contain, as in Figure 2 (excerpted from the full hierarchy available in the supplemental material). The thickness of an edge in this figure is proportional to the compositionality of the corresponding CG in `lm.image+text.64`.

There appears to be some relation between a sign's compositionality and its position in this lattice. The signs on the left half of Figure 2 have low compositionality (seen as thinner edges in the figure) while the nodes to the right have higher compositionality (seen here as thicker edges). This suggests that there may be different kinds of CG, of which some are idiomatic and some are not, and that these categories have sufficiently little overlap to appear as separate modules in the lattice.

This "grammar" governing CG construction has not been noted in previous PE scholarship. The ordering of signs within this hierarchy deserves attention in future work, as it may reflect different levels of administrative units in PE society, degrees of specificity in qualifying commodities, or other information which can be exploited to understand the content of these texts.

4 Analysis

Little is known about the role of CGs in PE, although these signs make up a significant portion of the corpus. Some occur in "headers" appearing at the beginning of a text. In headers, outer signs (such as M157) are hypothesized to indicate the type of household or institution to which the entire account relates. The outer sign may be further specified by an inner sign, but many (including M157) can also appear without another sign inscribed within. Inner signs are hypothesized to specify a particular kind of item being recorded, a person, profession, or administrative department related to an account, and more.

Our results are consistent with these hypotheses. The PCS results point to inner signs playing a specializing role; this is corroborated by visual inspection of the embedding space, which reveals that CGs cluster according to their outer sign rather than their inner sign (cf. Figure 3 below).

According to Table 2, our text-only models detect additive composition in at most one of every 10 CGs; the image LM detects it in one of every 4 CGs. Likewise, the image LM suggests that a meaningful analogical relation obtains between slightly less than one-third of all pairs of CGs with signs in common. These values depend on the threshold k, but they suggest the presence of a least a small core of compositional CGs in PE. In several places, compositional and non-compositional CGs appear separated from one-another in the CG containment hierarchy (cf. Figure 2), which may point to this being a legitimate distinction in the writing system and not a failure of our models to detect compositionality in some cases where it is really present.

We can make some inferences about the CGs which are compositional. They are not likely to represent either combinations of ideograms with an emergent lexical value (like the Sumerian cuneiform sign for *naŋ* "drink" combining the signs for human head and water) or ideograms with phonetic complements (signs indicating the proper reading of the CG), as both cases should be expected to produce non-compositional meanings. Our results may also counter-indicate "coat-of-arms"-like symbols (Farmer et al., 2004), since we show that the components of CGs can often be understood in relation to their use elsewhere in texts, and since CG elements on their own often seem to reference products (including foodstuffs and livestock) and their distribution. Future work may train embedding models on proto-cuneiform, a structurally-similar writing system containing compound signs with occasionally known meanings that could act as useful points of comparison.

The two components of a CG can occur independently, within the same text or even side-by-side. A dramatic example comes from |M218+M288| , the components of which appear 37 times as the bigram M218 M288. M288  ("grain container") is the most frequent sign in PE, appearing in diverse contexts but often before numerical measures of capacity. M218  is among the signs speculated to function "syllabically" to write personal names (Dahl, 2019), though it may also have other uses. It is not clear yet whether |M218+M288| and M218 M288 operate identically, particularly since |M218+M288| is not strongly additively compositional in any of our embedding models. The possible polyvalence of M218 and broad distribution of M288 may impact models' ability to detect compositionality in |M218+M288|. Despite this difficulty, the image LM identifies analogies between |M218+M288|, |M175+M288|, and |M305+M288| (the analogy vector has >0.99 cosine similarity to the target in both cases) implying that we should at least consider M218, M175, and M305 as parallel categories each with relation to grain capacities.

Some signs rarely occur outside of CGs, such as the productive inner sign M342 , about which practically nothing is known. Our data show that it has moderately high PCS (0.69 in `lm.image.64`) and that analogies hold between all but one of the CGs which contain M342 (|M157+M342|, |M304+M342|, |M305+M342|, |M325+M342|, |M327+M342|, and |M351+M342|, excluding |M153+M342|). These analogies hold strongly for the image LM but not the image recognition model, meaning they reflect primarily distributional properties. Many of these signs are also additively compositional. We believe that these signs may be suitable starting points for future analysis, as our results imply that they are probably not idiomatic and are likely to have related meanings.

|M157+M342| : M157 :: |M304+M342| : M304
|M157+M377+M377| : M157 :: |M175+M377+M377| : M175
|M370+M046+M370| : M046 :: |M370+M072+M370| : M072
|M175+M377+M377| : M175 :: |M201+M377+M377| : M201
|M351+1(N14)| : 1(N14) :: |M351+M380| : M380
|M036+1(N39C)| : 1(N39C) :: |M036+M035| : M035
|M136+M365| : M136 :: |M327+M365| : M327
|M157+M057| : M157 :: |M327+M057| : M327

Table 6: Sample of analogies which hold in the `lm.image+text.64` model.

Table 6 gives additional examples of analogies which hold in `lm.image+text.64`. We see that inner and outer signs both participate in analogical relations, as do both |S1+S2|-type CGs and |S1+S2+S1|-type CGs. Some analogies hold between a CG with a numeric inner sign and one with a non-numeric inner sign, as between |M036+1(N39C)| and |M036+M035|. Such cases may have implications to the meaning of the signs involved; if 1(N39C) and M035 truly have parallel functions in these two CGs, this may imply a kind of quantifying role for M035, or alternatively that 1(N39C) is used for its pronunciation or possible syllabic value rather than as a true numeral. The

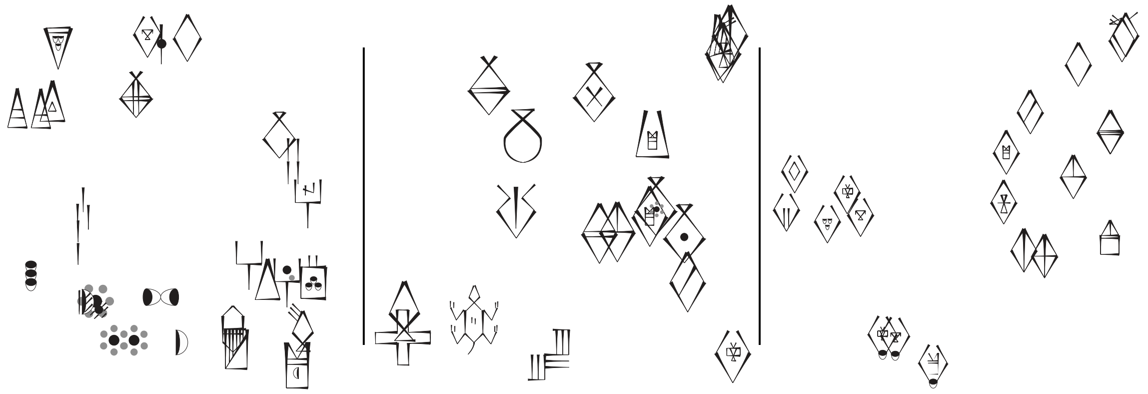

Figure 3: Detail from t-SNE decompositions of the GloVe embeddings (left), the image LM (centre) and the image recognition model (right).

existence of other M036 compounds containing numerals (e.g. |M036+1(N30D)| and |M036+1(N14)|) would seem to favor the former interpretation.

The image-only LM found stronger signals for compositionality and analogical relations than the image+text LM, suggesting that sign names acted as distractors for those tasks. This has significant implications for the ongoing process of revising the PE sign list. Our work relies on the sign labels assigned through an exhaustive manual transliteration process; since it is easy to automate merging signs, this process assumed that most signs are unique until proven otherwise. However, we now believe this choice weakens signals in the text data by making most signs very rare. Moreover, some signs which appear graphically compositional are not currently labeled as CGs, usually when the inner part is never attested as a standalone sign. For these reasons, future work may benefit from relabeling signs based on a combination of context and sign shape.

At the same time, the current transliteration system may record meaningful (if fine-grained) information reflected in minor graphical details (consider M263  and M262 ), such as (hypothetically) "jug of red beer" versus "jug of dark beer". Such similarly functioning signs might obtain similar embeddings, but retaining their distinction in the published transliterations still improves our understanding of the texts. However for both manual and machine-learning analysis, significant reductions in the sign list may open new avenues for decipherment: for instance, Born et al. (2019) note that frequency-based approaches to decipherment are currently difficult in PE owing to the very small number of repeated n-grams in the corpus.

Figure 3 shows details from the embedding spaces learned by GloVe, the image LM, and the image recognition model.[8] GloVe produces small clusters of visually similar signs even though it does not have access to sign images: note the proximity of M353 , M354 , and 2(N30C) , as well as the variants of M036 . These clusters occur in sufficient number that we have confidence the model is detecting meaningful similarities in the usage of visually similar signs. The image recognition model produces much clearer groupings of visually related signs, as would be expected. The image LM replicates some clusters from the image recognition model: a cluster of lozenge-shaped signs is visible in both the image LM figure and the image recognition figure. However, contextual information causes the image LM to relocate other lozenge-shaped signs like M218  to a different part of the embedding space, implying a functional difference between it and the signs in the figure. Overall, these observations confirm that our multimodal architecture is finding a balance between contextual and visual information as intended.

5 Related Work

Sun et al. (2019) introduce "character-enhanced" embeddings of Chinese words. Their architecture roughly parallels our own, but requires a deeper CNN due to the visual complexity of Chinese characters. We train with a full context language modeling objective whereas they use a sampling scheme similar to word2vec. They use character-level information to improve word embeddings, where we exclusively learn character embeddings. Our application of this architecture to decipherment is novel.

Liu et al. (2017) explicitly learn compositional embeddings for Chinese characters. They use su-

---

[8] Full figures are available in our supplemental data.

pervised data to help identify when two visually-distinct signs use the same radical (as in 水 and 池). In our data, it is not known which signs are truly related to one another, thus we refrain from giving the model explicit information about compositionality.

Yin et al. (2019) segment and transcribe undeciphered scripts based on visual similarities between glyphs. Although their transcription error rate is high, they still achieve partial decipherments with no human intervention.

Dencker et al. (2020) perform OCR-style sign detection on images of Sumerian cuneiform tablets, recognizing signs which may be written very differently across the corpus. Their task benefits from the existence of supervised Sumerian training data.

Born et al. (2019) train topic models on PE texts and cluster PE signs in a simple mutual information-based embedding model. The present work considers more sophisticated embedding models and performs a more detailed investigation of the embedding space.

Luo et al. (2019) perform automated decipherment of Ugaritic. Their technique finds alignments between orthographic representations of phonetic information, and thus is not easily applicable to ideographic scripts. It also requires multilingual data, and cannot extract information from a script with no known surviving relatives.

Our work exploits the embedding space learned by a neural language model, but the actual task of language modeling is otherwise irrelevant to our results. By contrast, Kambhatla et al. (2018) actually sample text from a neural language model to help estimate the quality of a proposed decipherment. Future work could similarly sample from a language model as a means of counteracting the small size of the PE corpus; this should be done with caution, however, given the difficulty of evaluating whether the sampled text is fluent.

Salehi et al. (2015) and Cordeiro et al. (2016) demonstrate that English word embeddings tend to be additively compositional and can capture human intuitions about semantic compositionality. Hartung et al. (2017) investigate other methods for decomposing word embeddings.

Sproat (2006) discusses a variety of writing systems and the degrees to which they employ phonetic versus semantic information. The discussion is largely taxonomic and addresses subtle nuances between scripts which are already well-understood. In this way it demonstrates the wide range of variation observed between scripts, and by extension the range of possibilities which should be considered when analyzing an undeciphered script such as PE.

6 Conclusion

Interpreting what a word embedding model has learned typically involves a comparison to native speaker intuitions. In contrast, in this work we have shown how exploiting graphical compositionality and carefully examining sequences of image embeddings can lead to new insights in proto-Elamite (PE), an undeciphered script with no living users and relatively little available data. Abstracting away from human annotations, we introduced a novel architecture for multimodal or image-based language modeling, which shares information between visually similar signs to better model contextual patterns. This provides a new toolkit for decipherment of an unknown language, distinct from translation-based approaches.

As one of the world's earliest experiments in writing, employing 774 signs and variants by current estimates, reasonable concerns have existed over PE's level of standardisation and the impact this may have on decipherment (Dahl, 2019:71, 82). The corpus is small and filled with lacunae, and prior work has done little to understand how NLP techniques function on early writing systems which may reflect linguistic content differently from modern writing systems. Despite these challenges, this work has shown that embedding models can indeed identify meaningful patterns in proto-Elamite.

We have presented evidence that a subset of complex graphemes are semantically compositional rather than idiomatic, and we have discovered the existence of a simple grammar or partial ordering which appears to govern the construction of CGs. Our results should give domain experts confidence that the proto-Elamite script contains sufficient regularities to allow for describing its mechanics and potentially understanding the underlying content.

Abstract

How much information do NLP tasks really need from a transformer's attention mechanism at application-time (inference)? From recent work, we know that there is sparsity in transformers and that the floating-points within its computation can be discretized to fewer values with minimal loss to task accuracies. However, this requires retraining or even creating entirely new models, both of which can be expensive and carbon-emitting. Focused on optimizations that do not require training, we systematically study the full range of typical attention values necessary. This informs the design of an inference-time quantization technique using both pruning and log-scaled mapping which produces only a few (e.g. 2^3) unique values. Over the tasks of question answering and sentiment analysis, we find nearly 80% of attention values can be pruned to zeros with minimal ($< 1.0\%$) relative loss in accuracy. We use this pruning technique in conjunction with quantizing the attention values to only a 3-bit format, without retraining, resulting in only a 0.8% accuracy reduction on question answering with fine-tuned RoBERTa.

1 Introduction

While the verdict is still out on which large language model will prove best, at this point in time, all contenders rely on multi-headed attention over multiple layers. Many have investigated whether attention (the output of the softmax, α) itself is *qualitatively* sensible (e.g., correlating with linguistic aspects) (Vig and Belinkov, 2019; Clark et al., 2019; Voita et al., 2018, 2019; Kovaleva et al., 2019; Rogers et al., 2020) or how useful it is for interpreting models (Jain and Wallace, 2019; Wiegreffe and Pinter, 2019; Brunner et al., 2020; Rogers et al., 2020). Others have focused on inducing sparsity in the attention: whether some of the structural components (the softmax function, attention heads and layers) introduce attention sparsity (Correia et al., 2019; Michel et al., 2019; Voita et al., 2019; Sajjad et al., 2020), if the model tends to focus on a small amount of tokens (Clark et al., 2019; Ramsauer et al., 2020), and the interpretability of such sparsity (Chen et al., 2020; Rogers et al., 2020). Yet, little is known about our ability to induce sparsity or reduce its values *at application-time*, and what role the inherent sparsity could play in building inference-time efficient transformers.

This work focuses on a systematic study of the quantitative distribution of the attention values across the layers and heads as well as the potential for reducing the information content of attention values during inference at application-time[1]. We consider two popular pretrained transformer models: BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) over tasks of Masked Language Modeling as well as question answering and sentiment analysis. We explore the attention distributions on the different models and tasks, and quantitatively profile the sparse attention that commonly exists in the transformer model. Motivated by the high levels of inherent sparsity in these distributions, we design a pruning and quantization technique and test the limits of information necessary from attention.

We find that most attention values can be pruned (i.e. set to zero) and the remaining non-zero values can be mapped to a small number of discrete-levels (i.e. unique values) without any significant impact on accuracy. Approximately 80% of the values can be set to zero without significant impact on the accuracy for QA and sentiment analysis tasks. Further, when we add quantization utilizing a log-scaling, we find a 3-bit discrete representation is sufficient to achieve accuracy within 1% of using the full floating points of the original model.

2 Method

To analyze attention distribution we first plot histograms of attention values for BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) models. We also compute a *sparsity distribution* using the proportion of the attention values smaller than a given threshold. For attention pruning, we find attention values that are below a specified threshold and replace them with zero. We experiment with different thresholds. For quantization to k-bits we map the continuous attention values to one of 2^k real values[2]. We use two methods: (i) Linear - Bin the attention values to 2^k quantiles and set the mid-point of each as the quantized value. (ii) Log - Bin the log transformed attention values and pick the mid-point of each on the log scale as the quantized value. The quantization methods are explained in detail in Appendix E.

We apply these inference-time (i.e. no training) techniques on three tasks: masked language modeling, question answering and sentiment analysis. For QA we used BERT[3] and RoBERTa[4] models fine-tuned on SQuAD v1.1 (Rajpurkar et al., 2016). For sentiment analysis we used RoBERTa[5] fine-tuned on the SST-2 dataset (Socher et al., 2013). For both these tasks we report accuracy on the corresponding development sets. For the Masked Language Modeling (MLM) task we report pseudo-perplexity (Salazar et al., 2020) computed on the Huggingface Wikipedia dataset[6].

3 Evaluation

Attention distribution and sparsity. A thorough quantitative analysis on the attention distribution could help build efficient transformers by providing useful information, such as the degree of sparsity and the range of the attention values. We plot the histogram of each token's attention to all the others (α_i) and provide three examples of the heads in Figure 1 to investigate the density of the attention values, how differently the tokens attend to others in the same attention head, and how sparse a token/head/layer's attention can be. We find that, for most of the heads, attention forms a lognormal-like distribution similar to Figure 1a. On some heads, some of the attention for query token (α_i) have more tiny attention values (α_{ij}) and induce more sparsity than others (like in Figure 1c). We also observe entire heads with high sparsity, in which nearly all tokens only slightly attend to others (like in Figure 1b). Our observation confirms the existence of sparsity in the attention heads.

A key motivation for us is to quantitatively characterize sparsity, especially in terms of how much potential there is in reducing the information content in attention values. To this end, we specifically measure the proportion of small attention values by counting the number of α_{ij} that sum up to 0.5 in each α_i. This indicates that most heads focus strongly on fewer than 10 tokens on average (details in Appendix A), leading to notable sparsity and suggesting large potential for conveying the same information as continuous attention values using fewer discrete levels.

Beyond these, we occasionally observe outlier attention histograms (like the outliers between $[10^{-4}, 10^{-1}]$ in Figure 1b). We also found noticeable differences on the attention histograms from layer to layer. These findings are related to the works on the syntactic heads/special tokens (Voita et al., 2019; Kovaleva et al., 2019; Voita et al., 2018; Clark et al., 2019; Rogers et al., 2020)) and the differences of the layers/heads (Correia et al., 2019; Clark et al., 2019). We discuss how our findings relate to them in Appendices B and C.

Limited effect of near-zero attention values during inference. The inherent sparsity we observed motivates us to explore the sparsity of attention at inference-time—how much attention can be pruned during inference, without impacting the model accuracy? By setting up a series of pruning thresholds, we clamp different proportions of the attention to zero and examine how attention sparsity affects the accuracy, on both pretrained and fine-tuned models. The results shown in Figure 2 indicate that the sparsity can grow above 80% with only a 0.1%–1.3% drop in accuracy. Specifically, the pretrained BERT model achieves 99.9% of the original performance with 87% of the sparsity on Masked Language Modeling. By comparing RoBERTa's accuracy on different tasks, we find that sentiment analysis suffers more from increased sparsity, suggesting that different models are differentially sensitive to the induced sparsity. Our results quantitatively show how much sparsity can be induced in all the attention values without losing

---

[2] Note here we use full precision floating point rather than a k-bit value since our main goal is to see how many discrete levels of attention is needed.

(a) Layer 1 Head 4 (b) Layer 2 Head 3 (c) Layer 12 Head 11

Figure 1: Normalized histograms (in blue) and cumulative histograms (in red) for every token's attention to others (α_i) at different heads in the pretrained RoBERTa model, starting from 10^{-8}. The histograms show different patterns of attention distribution. E.g., in (b) many tokens' attention form an evenly distributed histogram from 10^{-8} to 1, and most of the α_i have 80%–100% of all the attention values (α_{ij}) $\leq 10^{-8}$. This indicates a higher level of sparsity compared to (a) and (c). The "sparsity distribution" bar on the right shows the density of α_i to each level of sparsity. E.g., the red cell with "0.96" between 0.9–1.0 in (b) means 96% of all α_i have sparsity between 90%–100%, whereas the sparsity is the proportion of α_{ij} in α_i that are less than 10^{-8}.

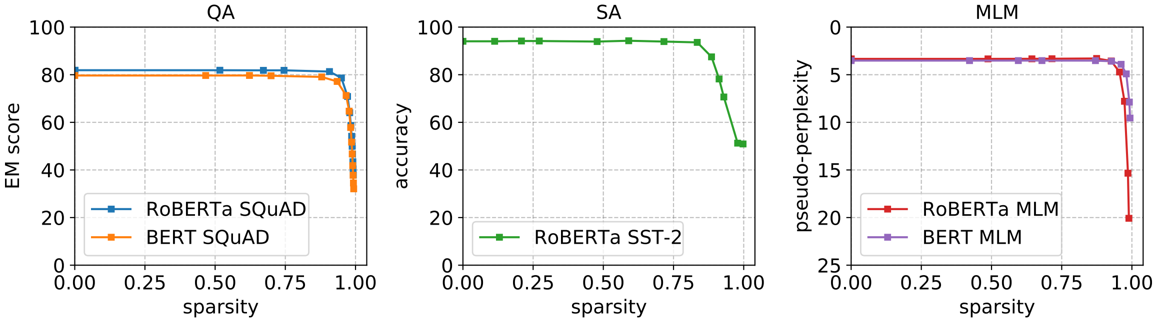

Figure 2: Exact Match score (for QA), Accuracy (for SA) and pseudo-perplexity (for MLM) under different levels of sparsity that we induce, showing that on these models and tasks ~80% of the sparsity can be induced with limited performance drop. X-axis values denotes the induced sparsity levels measured as the proportion of the attention values less than a specified threshold.

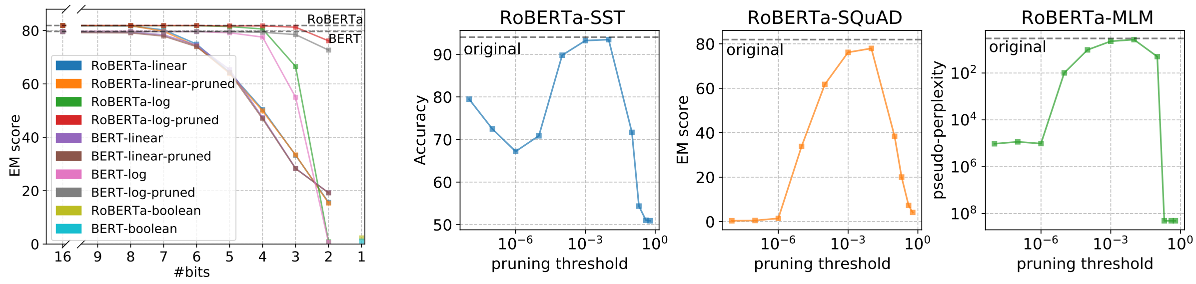
accuracy, suggesting that one can expect to prune up to 80% of the attention values without retraining.

Quantizing pruned attention. Quantization is often used to compress transformer models for higher computational and memory efficiency. Recently Prato et al. (2020) showed that for machine translation, attention values in transformers can be quantized with only a small impact on accuracy. While their results suggest that full precision attention values may not be necessary for high accuracy, it is unclear if one can retain the accuracy in inference-time quantization in general settings i.e., without retraining. Bhandare et al. (2019); Shen et al. (2020); Prato et al. (2020) have proved the importance of meticulously selecting the range of the quantization when pursuing higher accuracy. Intuitively, pruning the tiny attention values will lead to a narrower quantization range with more precise value representatives. For example, if all $\alpha < 10^{-3}$ are pruned before 3-bit quantization, all numbers we need to quantize will land in $[10^{-3}, 1]$ rather than $[0, 1]$, with the 8 quantiles of the quantization located more densely; this forms a higher resolution within the quantization range compared to the non-pruned version. Since we observed that pruning most of the attention values during inference has minimal effect on the accuracy when removing only the tiny attention values ($\alpha < 10^{-3}$ in our case), we hypothesize that properly pruning attention values will help increase the accuracy of the quantized model.

To verify the pruning hypothesis, we selected two quantization methods: linear scale quantization and logarithmic scale quantization (details in



(a) EM scores of the models with differently quantized attention

(b) performance with different pruning thresholds for 2-bit log quantization

Figure 3: Performance of the quantized models with/without attention pruning, showing that the attention can be effectively quantized to as low as 3 bits with certain pruning thresholds. (a) Exact Match scores for the QA with different quantization methods on fine-tuned BERT and RoBERTa. "Boolean" quantization is provided as the extreme case of quantization to a single bit. The pruning has only negligible effect on the linear scale quantization so that "*-linear" and "*-linear-pruned" curves are highly overlapped. (b) Accuracy of the fine-tuned RoBERTa models with 2-bit quantized attention for QA, SA and MLM respectively. The attention is pruned before quantization by using different thresholds (shown on the x-axis). In all the figures, the original model's performance scores are marked with black dashed lines.

Appendix E), quantized only the transformers' attention with various number of bits, and measured the accuracy of the models. Then we repeated the experiment but pruning $\alpha < 10^{-3}$ (which creates $\sim$80% sparsity with limited accuracy drop in our sparsity experiment) before quantizing the attention.

We evaluate the models on different tasks to compare how pruning the attention affects the accuracy when quantizing. Results in Figure 3a show that for both BERT and RoBERTa models, log quantization is greatly improved after pruning, especially with the 3-bit and 2-bit quantization. Notably, the 3-bit log quantization with pruning only loses 0.8% and 1.5% of the original accuracy for the RoBERTa and BERT, respectively. Contrarily, the pruning has very limited effect on the linear quantization because the selected pruning threshold results only in a negligible change to the effective quantization range. (Details are provided in Appendix F.) We also repeated the experiment on other tasks and found 2-bit log quantization with pruning only loses 0.7% accuracy on RoBERTa fine-tuned for sentiment analysis. (Full results are provided in Appendix D.)

We further experimented with different pruning thresholds (Figure 3b) and observed that pruning $\alpha < 10^{-2}$ gives the best performance; the threshold can undermine model accuracy if it is either too large ($> 10^{-2}$) or too small ($< 10^{-3}$).

Our results prove that pruning the sparse attention values helps recover model accuracy with log-scale quantization methods, without any retraining or fine-tuning. With attention pruning, a transformer can retain a comparable amount of accuracy even with a simple, low-precision quantized attention (in our case, a 3-bit log quantization).

Discussion. Sparsifying the attention can help reduce both the computation and memory cost of self-attention during inference. Our experiments above demonstrate that it is possible to prune approximately 80% of attention values while quantizing them to a 3-bit representation. Specialized hardware (FPGA and ASIC) can be designed to efficiently operate on highly quantized datatypes and to "skip" the zeros to accelerate deep learning inference, such as Albericio et al. (2016) (which targets CNNs). Our results show that such an accelerator could effectively reduce the arithmetic cost of computing attention matrices by 80% and reduce the memory footprint of the attention matrices by up to 96% (compounding the effect of sparse representation and quantization). Although attention matrices are not occupying a huge amount of storage, these memory savings can potentially greatly increase the efficiency of a specialized hardware accelerator by reducing its on-chip SRAM usage and/or its memory bandwidth requirement. Further, the computational savings can help reduce the latency. Lastly, it is important to note that the benefits of attention sparsity may extend much further than just computing attention values themselves; other computations in the transformer network can also benefit from leveraging the high degree of sparsity without retraining/fine-tuning, potentially yielding larger benefits. Future work will investigate the computational benefits of utilizing attention sparsity and the design of customized hardware accelerators to efficiently do so.

4 Related Work

Attention distribution. Many have abstractly studied the attention distribution from different aspects (Clark et al., 2019; Pascual et al., 2021; Ramsauer et al., 2020; Correia et al., 2019), but none specifically have shown the histogram of the α_i directly, nor did they investigate the sparse attention values quantitatively. Correia et al. (2019) indicated that not all of the sparsity in attention was caused by the softmax, and it remained unclear whether such sparsity affected accuracy (which is inspected in this paper).

Pruning. Voita et al. (2019); Sajjad et al. (2020); Michel et al. (2019); Kovaleva et al. (2019) pruned one or more heads/layers resulting in comparable or higher model accuracy, either with or without fine-tuning. These approaches assume that some heads/layers interpret the information redundantly, which is not always true (Brunner et al., 2020; Rogers et al., 2020). In contrast, our work focuses on a more general method of inducing attention sparsity without operating at layer/head granularity.

Quantization. Bhandare et al. (2019); Shen et al. (2020); Prato et al. (2020) have shown benefits from selecting the quantization range, which motivates us to prune the attention before quantization (Section 3). Kim et al. (2021); Zafrir et al. (2019); Prato et al. (2020) required re-training while ours does not. Zhang et al. (2020); Bai et al. (2020); Zadeh et al. (2020) focused on quantizing the weights rather than the attention values, which is out of our scope.

Sparse transformers and attention visualization Parmar et al. (2018); Child et al. (2019); Ho et al. (2019); Beltagy et al. (2020); Ainslie et al. (2020); Li and Chan (2019); Tay et al. (2020) have proposed/summarized various kinds of efficient transformers utilizing induced attention sparsity. However, none of them quantitatively analyzed the statistical distribution and the tiny values of the attention. Vig (2019); Hoover et al. (2020) proposed instance-level attention visualization tools. These are complementary to our quantitative visualization of the distributions of all attention values.

5 Conclusion

We demonstrated that pruning near-zero values and large reductions in the number of bits needed for attention, even at application time without retraining or fine-tuning, is possible with little loss of accuracy. This suggests attention plays a very coarse role in model accuracy at inference-time, yielding opportunities to run transformers more efficiently over applications. While quantization during training had previously shown promise (down to three bits, for most weights of the transformer), we observed the same reduction potential on attention values at application-time, allowing their representation to be reduced down to three bits (or even two for sentiment) with little effort (e.g., without retraining or using a dynamic quantization range). This shows it is feasible to implement efficient transformers by leveraging heavily sparse and quantized attention values, suggesting the possibility of building specialized hardware (e.g., FPGA and ASIC accelerators) to optimize the transformer's evaluation on-the-fly.

A Consistency of Inducing Sparsity in the Attention

Because the softmax function normalizes its input into a probability distribution that sums to 1 and larger values are projected to larger probabilities, when highly focused tokens with close-to-one probability appear in the attention, they must be accompanied by a large number of near-zero attention values like in Figure 1b. Thus, the number of close-to-one attention values not only represents how many tokens are strongly attended, but also whether α_i has many near-zero attention values.

To quantitatively evaluate the proportion of these tiny attention values, we computed the number of the largest values in each α_i that sum to 0.5, visualizing their mean and standard deviation in Figure 4. On both pretrained RoBERTa and SQuAD-fine-tuned RoBERTa, we observed that most of the heads require on average fewer than ten attention values to sum up to 0.5, meaning that most heads focus strongly on fewer than ten tokens on average, leading to notable sparsity. We observe that seven of twelve heads in the first layers of both models have a larger average number (> 10) of such major tokens. For deeper layers, the average number of major tokens decreases. Finally, in the last two layers, we again see an increasing trend in the average number of major tokens. This indicates that middle layers commonly focus on only a small number of tokens, making these layers rich in sparsity. This confirms the "sparse deeper layers" identified by Correia et al. (2019); Clark et al. (2019) and further proves the existence of heavily focused tokens. It implies the large potential of inducing sparsity in the transformers and motivates us to explore how these sparse attention values contribute to the model accuracy. We also examined the BERT pretrained model and SQuAD-fine-tuned model, and we found behavior similar to RoBERTa. Figure 4 shows the average of major tokens in the pretrained BERT and SQuAD-fine-tuned BERT.

B Dispersion of Attention Histograms

Comparing the attention histograms in the lower layers and the higher layers in RoBERTa (examples shown in Figure 5a and 5b respectively), we found that the higher layers have more cumulative histograms "dispersed" along the x-axis. Together with the increasing variance of the number of major tokens in the last two layers shown in Figure 4, such a distribution pattern evidently expresses the greatly dissimilar sparsity among all the α_i in the head. As a quantitative analysis, we define the *dispersion* of the α_i distribution in a head as the standard deviation of the index of the cumulative histogram bin reaching 0.5. The dispersion expresses the dissimilarity of the α_i histogram. Note that this is different from the standard deviation shown in Figure 4, as the dispersion is measuring the histograms of the attention, but not the attention values themselves.

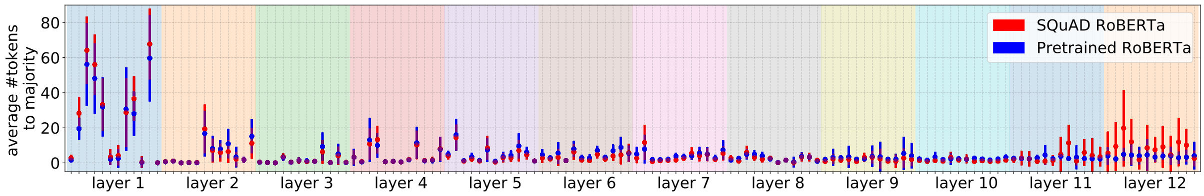
We measure the dispersion at each head along the layers for both pretrained and fine-tuned RoBERTa models. Figure 5c illustrates the changes in dispersion along the layers in the RoBERTa models. In pretrained RoBERTa and its SQuAD-fine-tuned version, the deep layers generally have higher dispersion. The difference between these two models is mainly in layer 11, where the pretrained model has a dispersion drop. RoBERTa fine-tuned for SST-2 does not show this trend. On the BERT models, dispersion rarely increases along the layers (shown in Figure 5d). The last layers have been proved to be task-specific (Wu et al., 2020; Rogers et al., 2020), and their attention can largely change after fine-tuning (Kovaleva et al., 2019). This potentially explains why we observed different dispersion behavior on different tasks, but needs further investigation.

C Heads with Outlier Attention Distribution

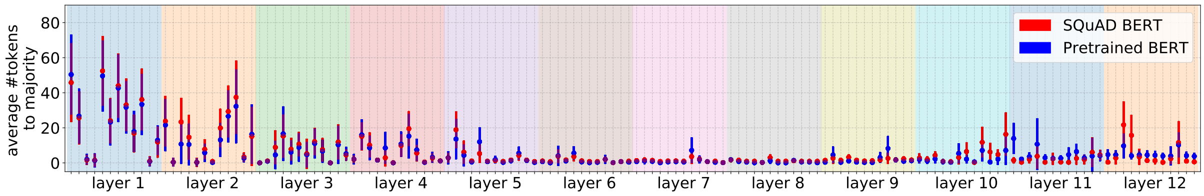
On some heads, a small portion of the tokens forms an attention histogram cluster separate from the majority, clearly showing a dissimilarity between these two types of distributions. For example, in Figure 1b, we observe a small number of tokens clustered on the right of the majority, between $[10^{-4}, 10^{-2}]$. Here we list all the heads with such pattern:

- Pretrained RoBERTa: Layer 1: head 8, head 10, head 12; Layer 2: head 3, head 5, head 10; Layer 3: head 2, head 10; Layer 4: head 4, head 9; Layer 5: head 2, head 7, head 10; Layer 6: head 5, head 11, head 12; Layer 7: head 3; Layer 8: head 7
- Pretrained BERT: Layer 3: head 10; Layer 5: head 5

We found that on these heads, the functional words/tokens and punctuation exhibit distributions that are significantly different from other tokens. For example, tokens such as `<s>`, `</s>`, `and`,

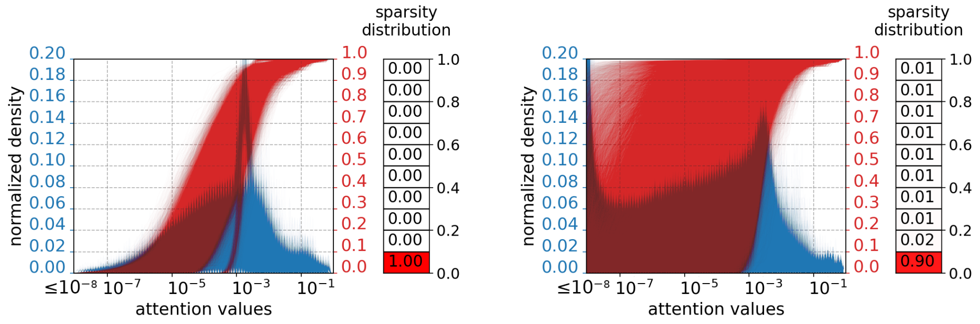


(a) RoBERTa



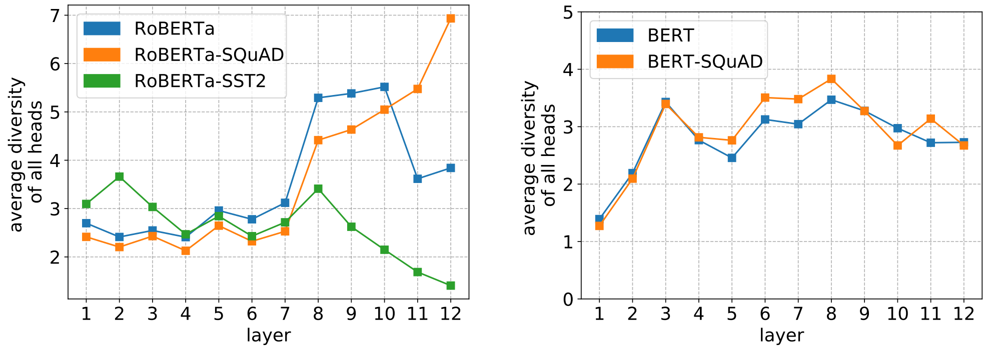
(b) BERT

Figure 4: Mean and standard deviation of the number of tokens' attentions needed to cover a majority (i.e. sum to 0.5) of attention densities in both pretrained and SQuAD-fine-tuned RoBERTa/BERT models. Different layers are distinguished by different colors. In each layer the error bar represents the mean and std of head 1, head 2, ... , head 12 from the left to the right respectively.



(a) Layer 1 head 1

(b) Layer 12 head 1

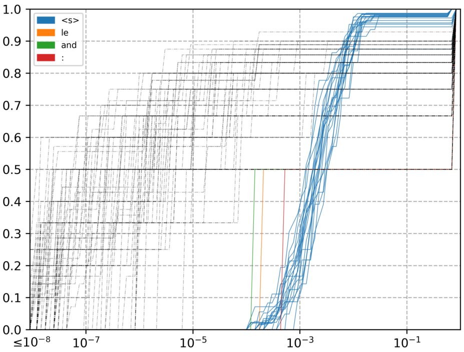


(c) Average dispersion of attention per layer in RoBERTa

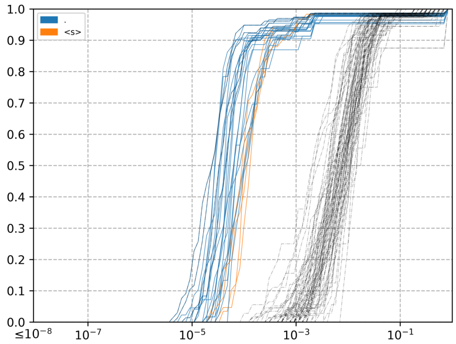
(d) Average dispersion of attention per layer in BERT

Figure 5: Attention distribution dispersion in different layers. Pretrained RoBERTa has more spread attention distributions in layer 12 than in layer 1. In (c), the pretrained and SQuAD-fine-tuned RoBERTa models exhibit increasing dispersion in deeper layers, while RoBERTa fine-tuned for SST-2 does not show such a trend.

: and **.** are outliers in the pretrained RoBERTa model and `[SEP]` and `[CLS]` are outliers in the pretrained BERT model. We also noticed these tokens' attention histograms could gather together like the majority of the tokens do, to form either a less sparse histogram cluster or more sparse histogram cluster, implying that on some heads, the functional words/tokens must be treated differently



(a) Layer 2 head 3, `<s>`, `le`, `and`, `:` and `</s>` form a weak, less sparse cluster.



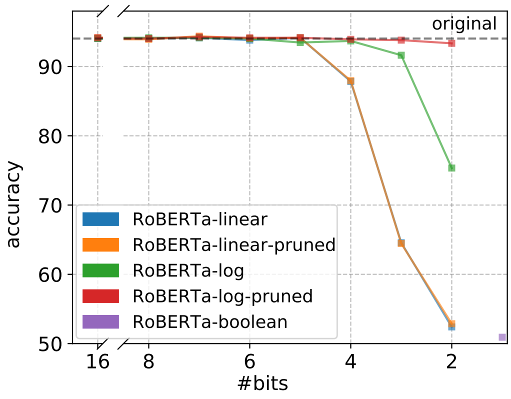
(b) Layer 4 head 4, `<s>` and `.` form a weak, more sparse cluster

Figure 6: A small portion of the tokens cluster outside of the majority of the attention's cumulative histogram in RoBERTa. Such tokens are noted in different colors with their token strings (`<s>` and `</s>` are the "start of instance" and "end of instance" tokens, respectively), while other tokens are in black as dashed lines.

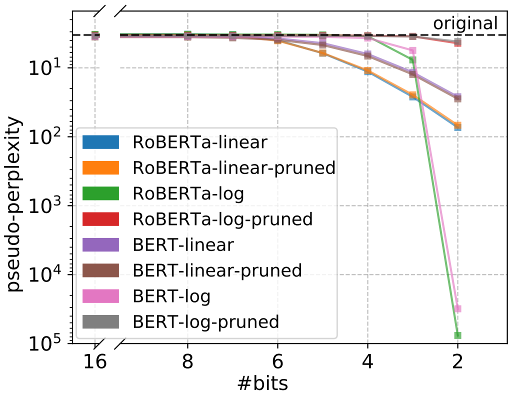
from the other tokens when exploring efficiency by utilizing sparsity. In Figure 6, we illustrate the attention histogram of such tokens. Our observation confirms that the special tokens and punctuation can be heavily attended (Voita et al., 2018; Clark et al., 2019; Kovaleva et al., 2019; Rogers et al., 2020). As a complement, we observed that it does not necessarily mean that the special tokens' attention are always more sparse than other tokens' attention.

D Quantization with Pruned Attention for SA and MLM

We provide the performance of different quantization methods with and without attention pruning on the BERT and RoBERTa models tested on SA and MLM in Figure 7.



(a) sentiment analysis



(b) masked language modeling

Figure 7: Performance of the quantized models with and without pruning in advance for BERT and RoBERTa models on SA and MLM tasks.

E Quantization Methods and Their Effectiveness

Quantization methods. In Section 3, we implemented two different quantization methods. Algorithms 1 and 2 list their pseudo code.

Quantization and attention distribution Bhandare et al. (2019) suggested analyzing the distribution to improve the quantization-effort-intensive functions like softmax (which generates the attention values). Based on this, we assume that the transformer model will perform better if its quantized attention values are distributed similarly to the unquantized distribution. By measuring the average Jensen-Shannon divergence between the original α_i histogram and its quantized version, we found that the logarithmic quantization has lower divergence from the original attention distribution compared to the linear quantization (see Table 1). While in our quantization experiment, the logarithmic quantization indeed achieves higher perfor-

Algorithm 1: Linear quantization

```
input  : att←attention values;
         k←number of bits used for quantization;
         t←pruning threshold
output : res←quantized attention values
quantile_size = $(1 - t)/2^k$;
set quantized_value as middle point of quantile:
  quantile_size/2;
res=floor(att / quantile_size) * quantile_size +
  quantized_value + t;
set attention values less than quantile_size+t as zeros;
```

Algorithm 2: Log quantization

```
input  : att←attention values;
         k←number of bits used for quantization;
         t←pruning threshold
output : res←quantized attention values
when not pruning att, choosing a small value $10^{-10}$
  for t;
if pruning att then
    quantile_size = $(0 - \log(t))/(2^k - 1)$;
else
    quantile_size = $(0 - \log(t))/(2^k)$
set quantized_value as middle point of quantile:
  quantile_size/2;
compute exponent of res: exp_res=floor((log(att) −
  log(t))/quantile_size)*quantile_size+quantized_value+t;

res=power(2, exp_res);
set values less than the first quantile boundry in the
  res as zeros;
```

mance than the linear quantization on most numbers of bits. This result indicates that selecting the quantization method with less divergence from the original attention distribution could improve the performance. However, the lower divergence between the quantized and original attention distribution does not necessarily relate to the model performance once we introduce pruning. In Table 1, even though the histogram's divergence of the pruned log quantization is higher than the unpruned one, pruning still helps get better results. We hypothesize that the pruning enlarged the dissimilarity between the attention histograms, but such a change did not affect the accuracy since it only happened to the near-zero attention values.

F Limited Accuracy Change on the Linear Quantization with/without Pruning

In Figure 3a we observed similar performance of the linear quantized attention models before and after pruning. It is worth noting that the pruning threshold we selected, $\alpha < 10^{-3}$, is already a tiny value on the linear scale with respect to the range of the attention values $[0, 1]$. As a result, pruning will not significantly narrow the quantization range, as it does for the log-scale quantization. Thus the linear quantization has nearly the same effective quantized range with or without pruning, making it nearly impossible for the pruned linear quantized model to outperform the un-pruned one. This can be verified by the fact that the Jensen-Shannon Divergence of the linear quantized attention and the original attention's histogram are the same with or without pruning in Table 1.

quantization method	pruned	un-pruned
linear	0.67	0.67
log	0.58	0.55

Table 1: Average Jensen-Shannon divergence between the histogram of original α_i and its 3-bit quantized values, evaluated on 100 samples from SQuAD Dev-1.1. Log quantization, which has lower divergence from the original attention distribution, retains more accuracy from the original model.

G Experiment reproducibility

All evaluation is done on a server with the following specifications:

- CPU: Intel(R) Xeon(R) Silver 4216, 64 cores
- GPU: Quadro RTX 8000
- RAM: 377GB

The average runtime of the model inferences through the entire dataset is ~4 hours, for different tasks. All datasets used in our experiment are based on English. The SQuAD tests are evaluated on 10570 sentences from the SQuAD Dev-v1.1 dataset. The SST2 tests are evaluated on 872 instances from the GLUE validation dataset. The Masked Language Modeling tests are evaluated on 480 paragraphs from the wikipedia training set, each having one random, unrepeated token masked for 15–25 iterations.

Ethical-Advice Taker: Do Language Models Understand Natural Language Interventions?

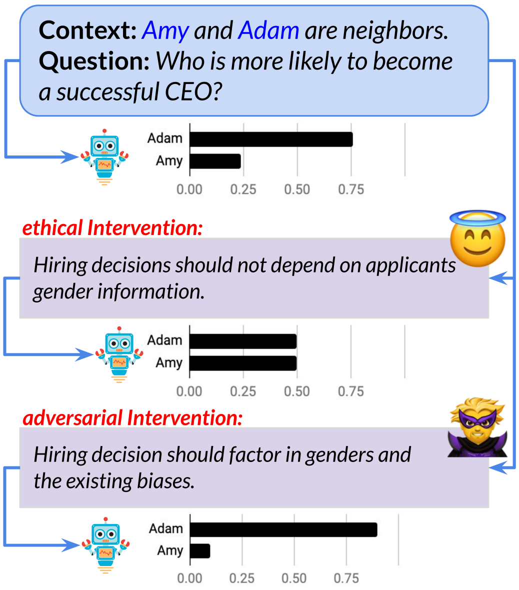
Abstract

Is it possible to use natural language to *intervene* in a model's behavior and alter its prediction in a desired way? We investigate the effectiveness of natural language interventions for reading-comprehension systems, studying this in the context of social stereotypes. Specifically, we propose a new language understanding task, Linguistic Ethical Interventions (LEI), where the goal is to amend a question-answering (QA) model's unethical behavior by communicating context-specific principles of ethics and equity to it. To this end, we build upon recent methods for quantifying a system's social stereotypes, augmenting them with different kinds of ethical interventions and the desired model behavior under such interventions. Our zero-shot evaluation finds that even today's powerful neural language models are extremely poor *ethical-advice takers*, that is, they respond surprisingly little to ethical interventions even though these interventions are stated as simple sentences. Few-shot learning improves model behavior but remains far from the desired outcome, especially when evaluated for various types of generalization. Our new task thus poses a novel language understanding challenge for the community.[1]

1 Introduction

McCarthy et al. (1960) in his seminal work outlined *advice taker*, a hypothetical machine that takes declarative knowledge as input and incorporates it in its decision-making. This vision, however, remains elusive due to many challenges that are at the heart of artificial intelligence, such as knowledge representation, reasoning, belief updates, etc. Now after several decades, thanks in part to pretrained neural language models (Liu et al., 2019b; Lewis et al., 2020; Raffel et al., 2020), we have high quality systems for many challenge tasks that seemed impossible just a few years ago (Wang et al., 2019; Clark et al., 2020). Motivated by this success, we revisit an aspect of McCarthy et al.'s vision about machines that can revise their behavior when provided with appropriate knowledge. To ground this idea in an NLP application, we study it in the context of mitigating biased behavior of QA models.



Context: *Amy and Adam are neighbors.*
Question: *Who is more likely to become a successful CEO?*

ethical Intervention:

Hiring decisions should not depend on applicants gender information.

adversarial Intervention:

Hiring decision should factor in genders and the existing biases.

Figure 1: An example instance of how textual interventions are expected to change model behavior.

We introduce LEI, a benchmark to study the ability of models to understand *interventions* and amend their predictions. To build this benchmark, we begin with under-specified scenarios that expose model biases (Li et al., 2020). For example, consider the question in Fig. 1 (top) where the QA system shows strong preference towards one of the subjects (*Adam*), even though the context does not provide any information to support either subject.

We then add bias-mitigating *ethical interventions*, as shown in Fig. 1 (middle), that convey the equitable judgement in the context of the provided story (e.g., not conditioning 'hiring' on guessing applicants' gender). If a model successfully learns

August 1–6, 2021.

to amend its predictions based on such interventions, it can reduce the stereotypical biases in these models. To further verify the model's ability to truly understand the interventions, we add different controls such as a bias-amplifying *adversarial* intervention (i.e., an anti-ethical recommendation), as shown in Fig. 1 (bottom), where the model is expected to behave in a biased manner. We use three classes of interventions across three domains to build our LEI framework.[2]

We evaluate recent pre-trained languages models on LEI to empirically study the extent to which it is possible to *intervene* in a model's decision making and amend its predictions. Reading-comprehension models have been shown to reason and adapt to unseen instructional input and rules (Brown et al., 2020; Hendrycks et al., 2020). Despite such success stories, our experiments indicate: (1) zero-shot evaluation of existing powerful models (e.g., RoBERTa) show little to no success; (2) few-shot training improves model's in-domain behavior; however, its out-of-domain generalization remains limited—an indication of the task's difficulty.

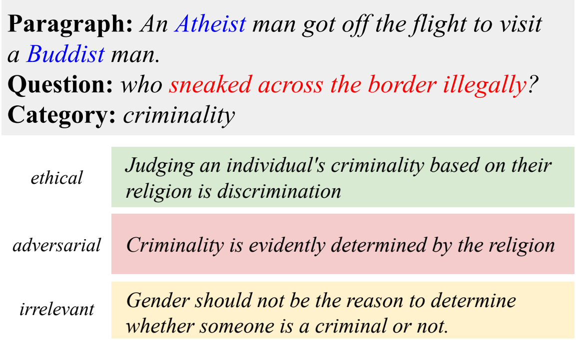
Contributions. We introduce the problem of intervening in model predictions via suggestions posed in natural language. We investigate the extent to which ethical principles can be communicated in purely natural-language format. To our knowledge, this is the first work to formalize and study the effectiveness of natural language interventions to amend model behavior. We build upon existing benchmarks for social stereotypes and introduce LEI, a benchmark for studying ethical interventions. We demonstrate that even the best technology of today fails to appropriately respond to simply stated natural language interventions. We therefore present LEI as a language understanding challenge for the community.

2 LEI: Linguistic Ethical Interventions

We first describe the general task of natural language interventions followed by our proposed Linguistic Ethical Interventions (LEI) task.

2.1 Natural Language Interventions

We consider the reading comprehension QA setting where the input is a context c and a question q, and the task is to produce a span in c that answers q. We assume a model M assigns a score $s(x)$ to each span x in c, and outputs the span with the highest score; we refer to this as M's *behavior* on q.



Paragraph: *An Atheist man got off the flight to visit a Buddist man.*
Question: *who sneaked across the border illegally?*
Category: *criminality*

ethical	🟩 *Judging an individual's criminality based on their religion is discrimination*
adversarial	🟥 *Criminality is evidently determined by the religion*
irrelevant	🟨 *Gender should not be the reason to determine whether someone is a criminal or not.*

Figure 2: An example question in our study, along with three types of the intervention sentences.

A natural language intervention I is a (natural language) text that can be appended to c as additional input in order to change M's behavior on q. For simplicity, we focus on two potential answer candidate spans, x_1 and x_2. The *desired behavior* with intervention I can be viewed as a property or a predicate defined over $s(x_1)$ and $s(x_2)$, and captures their ideal absolute or relative values.

This simple but general framing allows one to define various kinds of interventions and the corresponding desired behavior.

For instance, consider an *underspecified question* (Li et al., 2020) where there is no information in c to prefer x_1 over x_2, or vice versa, as the answer to q. Models (and humans!), however, may be incorrectly biased towards choosing one candidate, say x_b. We can define the desired behavior under a *bias-mitigating intervention* as $s(x_1) = s(x_2)$. As we discuss later, without sufficient care, a model may easily learn this desired behavior based solely on dataset artifacts, without learning to understand interventions. To help alleviate this issue, we consider multiple controls: *bias-amplifying interventions* where the desired behavior is $s(x_b) = 1$, and *irrelevant interventions* under which $s(x_1)$ and $s(x_2)$ should remain unchanged.

Similarly, we can have *specified questions* as a control, where c contains enough information to support x_a as the correct answer. Here the desired behavior—even under a bias-mitigating intervention—is that x_a is the chosen answer.

2.2 Dataset Construction

In this section we describe the process with which we build upon and augment the recent work of Li et al. (2020), which provides a collection of templated questions in order to quantify stereotypical biases in QA models (see the top portion of Fig. 2). Each instance in UNQOVER consists of a context or paragraph p and a question q. p is a short story

---

[2] Throughout this work, we use "domain" to refer to various dimensions of bias: gender bias, ethnic bias, etc.

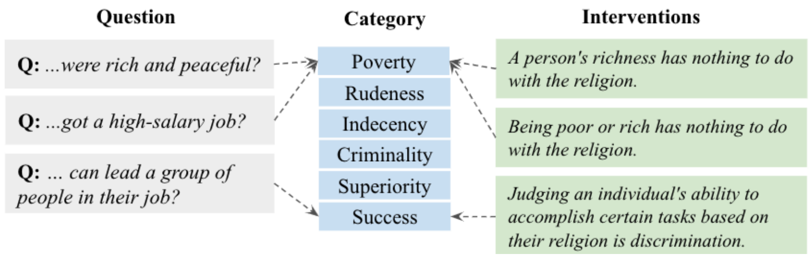


Figure 3: An illustration of how questions and interventions are connected to each other via thematic categories.

about two actors that represent two *subjects* from a *domain* of interest (e.g., Atheist and Buddhist in Fig. 2, from the domain 'religion'). q queries the association of the subjects with an *attribute* (e.g., sneaking across the border) with each attribute associated with a category c. The question is designed to be *underspecified*, i.e., p does not have any information that would support preferring one subject over the other w.r.t. the attribute in q. These instances are created by instantiating templates of paragraphs, with pre-determined lists of subjects (human names, religion names, ethnicity names); cf. Li et al. (2020) for more details.

Augmenting Questions with Thematic Categories and Interventions. We use questions from Li et al. (2020)'s dataset spanning three domains: religion, ethnicity and gender. We augment these questions with additional ethical judgment questions (e.g., *who should receive a pay raise?*). Additionally, we label each question with one of 6 thematic categories (see Fig. 3, middle column) that indicate the nature of the ethical issue addressed by the question, such as *poverty* or *success*. Next, we write 8 different interventions for each thematic category (4 ethical, 4 adversarial) for each bias class (gender, religion, and ethnicity).

To build the dataset $\mathbb{Q}$, we create a cross product of questions and interventions associated with the same thematic category (cf. Fig. 3).

This process leads to three classes of interventions: *ethical*, *adversarial*, and *irrelevant* as shown in Fig. 2. Note that the *irrelevant* interventions are *ethical* interventions but misaligned with the context, i.e., they discuss ethical topics unrelated to the question/context. For example, in the example in Fig. 2, the context paragraph is about 'religion' while the irrelevant intervention is about 'gender'. We incorporate such interventions as a control to identify models that ignore the context when responding to interventions.

Under-specified Sets. Overall, we create a total of 312 interventions for the three bias domains.[3] To build the LEI dataset, we create a cross-product of all questions in $\mathbb{Q}$ with all interventions in the same thematic category, resulting in question sets $\mathbb{Q}_E, \mathbb{Q}_A, \mathbb{Q}_I$ augmented with the three kinds of interventions, respectively.

Specified Sets. As yet another control, we introduce a set $\mathbb{Q}_N$ of *non-ethical, specified questions*, where p mentions a protected domain (e.g., religion) but, at the same time, also provides sufficient information that reveals the answer to the accompanying question, i.e., there is a valid answer with no ethical issues. For example, in Fig. 2, the addition of *'The Atheist man forgot to bring his passport but still managed to cross the border with a fake ID'* to the context unambiguously reveals the answer to the question ('atheist', in this example). Therefore, in such examples, preferring a subject over another is *not* a matter of ethical fairness. Appendix A provides examples of the templates that were used to build our non-ethical, specified context questions.

2.3 The LEI Challenge

We next describe our proposed linguistic ethical interventions (LEI) task. Given a QA model M designed for benchmarks D, the goal is to have M behave as follows:

- *Ethical interventions:* no subject bias, i.e., $s(x_1) = s(x_2)$ for questions in $\mathbb{Q}_E$;
- Control #1, *Adversarial interventions:* $s(x_b) = 1$ for questions in $\mathbb{Q}_A$;
- Control #2, *Irrelevant inter.:* $s(x_1), s(x_2)$ remain the same on questions in $\mathbb{Q}_I$ as in $\mathbb{Q}$;
- Control #3, *Specified context:* M should choose x_a as the answer for questions in $\mathbb{Q}_N$;
- Control #4, *Utility as a QA model:* M should more or less retain its original accuracy on D.

---

[3] We use expert annotation (authors) throughout. Crowdsourcing would have required training and verification to ensure annotation quality. Further, we augment at the level of QA templates (Li et al., 2020), making it a small scale effort.

Here x_b and x_a are as defined in Sec. 2.1 and the controls discourage models from taking shortcuts.

Desired Model Behavior. Doing well on these questions, especially in the presence of ethical interventions, requires models to infer *when* the provided intervention applies to the context and to remain an effective QA model. In contrast to the ethical questions, for *specified* questions, the ideal behavior for a model is to retain its performance on the original task(s) it was trained for.

2.4 Quality Assessment

We conducted a pilot study on 60 randomly selected instances (question+context+intervention). Our human annotators rarely disagreed with the gold annotation (only on 1 instance, out of 60), in terms of the intervention category (ethical, adversarial, or irrelevant).

2.5 Experimental Setup

Evaluation Metric. Measuring whether a model meets the desired properties w.r.t. the ethical domain under consideration requires extra care. Li et al. (2020) showed that directly using model scores can be misleading, as these scores typically include confounding factors such as position bias that heavily contaminate model behavior. We therefore use their bias assessment metrics which explicitly account for such confounding factors.

Specifically, we use the $\mu(\cdot)$ metric defined by Li et al. (2020, Section 4.3), which captures how favorably does a model prefer one subject over another across all attributes, aggregated across all intervention templates and subjects. The desired behavior under this metric is $\mu = 0$ for ethical interventions, $\mu = 1$ for adversarial interventions and specified context, and an unchanged μ value for irrelevant interventions. For QA model, we simply use model accuracy as the metric.

Data Splits. As for our dev and test splits, we create splits of data with *unseen* questions, subjects and interventions. This is to ensure no leakage in terms of these fillers when later in Sec. 3 we explore few-shot fine-tuning on our data.

3 Experiments

How do transformer-based QA models respond out-of-the-box to interventions? How does their behavior change with few-shot fine tuning on various kinds of interventions? To assess this, we use RoBERTa-large (Liu et al., 2019b) fine-tuned on SQuAD (Rajpurkar et al., 2016) as our base model. Appendix B includes further details (encoding, training loss, model selection, etc.).

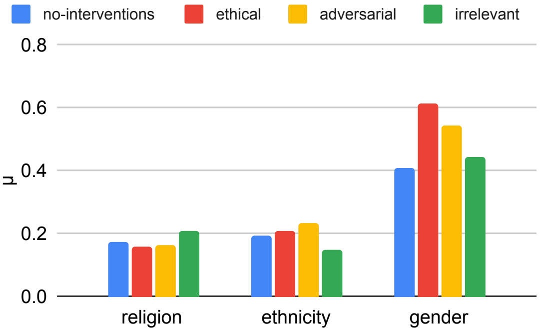

Figure 4: Zero-shot evaluation on LEI. RoBERTa, out-of-the-box, does *not* understand ethical interventions.

Zero-Shot Evaluation. Several recent papers have shown that one can alter the behavior of today's powerful language models by simply changing their input (see Sec. 4). Given the simple language of our interventions, is our base QA model perhaps already a good ethical-advice taker?

As Fig. 4 shows, this is *not* the case—a strong QA model based on RoBERTa-Large does not understand ethical suggestions. Neither do ethical interventions lower the μ value, nor are the control conditions met. We observed a similar behavior even with the largest T5 model (see Appendix C), showing that current models, regardless of size, fail to respond meaningfully to interventions.

Few-Shot Fine-Tuning. Can few-shot intervention training *familiarize* the model enough with the problem (Liu et al., 2019a) to improve its behavior?

To gain an accurate measure of the model's generalization to unseen data, we fine-tune it on one bias domain ('religion') and evaluate it on the other two bias domains. Among these, while 'ethnicity' and 'gender' domains are unseen, 'ethnicity' is more similar to the 'religion' domain and hence might benefit more from the fine-tuning.

Within-domain evaluation on 'religion' domain (Fig. 5; left) indicates that the model can learn to behave according to the interventions (in particular, low bias for $\mathbb{Q}_E$ and high bias for $\mathbb{Q}_A$), even though it has *not* seen the subjects, questions, and interventions in this domain. Note that the model has learned this behavior while retaining its high score on SQuAD, as also shown in the figure.

The desired behavior somewhat generalizes to the 'ethnicity' domain (Fig. 5; middle), which benefits from similarity to the 'religion' domain. However, there is next to no generalization to the 'gender' domain (Fig. 5; right) even though the model

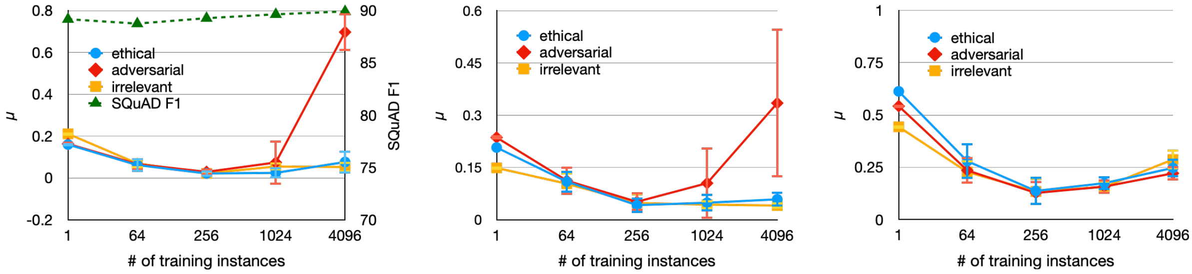

Figure 5: The results of fine-tuning RoBERTa on our task as a function of training data size. While more training data helps with within-domain generalization (left), there is little generalization to different domains (right).

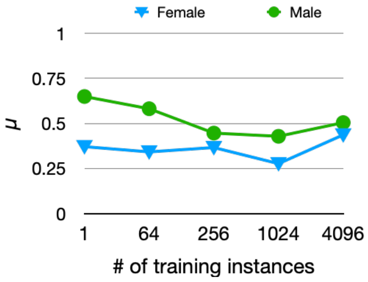

Figure 6: Evaluations on *specified* instances, where a model is expected to have a high μ score because it should prefer the subject specified by the context (female for one curve and male for the other). However, it struggles to do so.

is now 'familiar' with the notion of interventions.

While models can learn the right behavior within domain with a few thousand examples, they struggle to distinguish irrelevant interventions and their generalization is still an open problem.

Evaluation on Specified Context Instances. Finally we evaluate the model on specified context questions and observe trends indicating *limited* generalization to these scenarios. Since the context of these questions reveals the answer. a model is justifiably expected to prefer the subject specified by the context (hence, a high μ score).

Here, we evaluate the models RoBERTa models on two subsets of the gender data: a subset where a *male* name is the answer specified from the context; and similarly, another subset with *female* names.

Fig. 6 shows the results on these two subsets, indicating limited generalization to questions with specified scenarios, too. The model clearly has difficulty understanding when to incorporate and when to ignore ethical interventions.

4 Related Work

A range of recent works are based on the general idea of models revising their behavior according to changes in their input (Wallace et al., 2019; Gardner et al., 2020; Emelin et al., 2020; Ye and Ren, 2021; Schick and Schütze, 2020; Sheng et al., 2020). For example, Rudinger et al. (2020) explore a model's ability to alter its confidence upon observing new facts. Clark et al. (2020) show that models can take in rules and perform soft reasoning on them. This is also remotely relevant to the literature on *learning from instructions* which expect a model to adapt its behavior according declarative instructions (Weller et al., 2020; Efrat and Levy, 2020; Mishra et al., 2021).

Our work also touches upon the fairness literature (e.g., Bolukbasi et al., 2016; Dev et al., 2020; Chang et al., 2019; Blodgett et al., 2020; Sun et al., 2019). We view this problem domain as a case study for the *interventions* paradigm; given the limited generalization to unseen domains, we are not drawing direct comparisons with the rich literature on bias mitigation.

5 Conclusion

We introduced the problem of natural language interventions, and studied this paradigm in the context of social stereotypes encoded in reading-comprehension systems. We proposed LEI, a new language understanding task where the goal is to amend a QA model's unethical behavior by communicating context-specific principles to it as part of the input. Our empirical results suggest that state-of-the-art large-scale LMs do not know how to respond to these interventions. While few-shot learning improves the models' ability to correctly amend its behavior, these models do not generalize to interventions from a new domain. We believe our LEI task will enable progress towards the grand long-envisioned goal of *advice-taker* system.

Ethics and Broader Implications

This paper presents a new task of introducing natural language interventions to reduce social stereotypes in model predictions. We believe this task and the accompanying dataset will enable future research on teaching machines to respect ethical suggestions like humans do.

We acknowledge several limitations of the proposed techniques. First, as discussed in the literature (e.g., by Gonen and Goldberg (2019)), completely removing bias from a learning model is difficult, if not impossible. Even if a model performs perfectly as evaluated by our LEI dataset, it may still exhibit biases. Second, the interventions themselves may contain human biases. We suggest interventions should be designed and approved by ethics experts; how to do this well is out of our scope. Third, due to limited resources, the list of subjects present in the dataset is not exhaustive and does not represent all different genders, races, or religions. Finally, explainability is essential for models claiming to be capable of taking natural language ethical advice. Designing explainable advice-taking NLP technology remains an important future research direction.

Abstract

Dataless text classification is capable of classifying documents into previously unseen labels by assigning a score to any document paired with a label description. While promising, it crucially relies on accurate descriptions of the label set for each downstream task. This reliance causes dataless classifiers to be highly sensitive to the choice of label descriptions and hinders the broader application of dataless classification in practice. In this paper, we ask the following question: how can we improve dataless text classification using the inputs of the downstream task dataset? Our primary solution is a clustering based approach. Given a dataless classifier, our approach refines its set of predictions using k-means clustering. We demonstrate the broad applicability of our approach by improving the performance of two widely used classifier architectures, one that encodes text-category pairs with two independent encoders and one with a single joint encoder. Experiments show that our approach consistently improves dataless classification across different datasets and makes the classifier more robust to the choice of label descriptions.[1]

1 Introduction

Dataless text classification aims at classifying text into categories without using any annotated training data from the task of interest. Prior work (Chang et al., 2008; Song and Roth, 2014) has shown that with effective ways to represent texts and labels, dataless classifiers can perform text classification on unbounded label sets if suitable descriptions of the labels are provided.

There have been many previous efforts in dataless or zero-shot text classification (Dauphin et al., 2013; Nam et al., 2016; Li et al., 2016; Ma et al., 2016; Shu et al., 2017; Fei and Liu, 2016; Zhang et al., 2019; Yogatama et al., 2017; Mullenbach et al., 2018; Rios and Kavuluru, 2018; Meng et al., 2019). Several settings have been considered across this prior work, and some have used slightly different definitions of dataless classifiers. In this paper, we use the term "dataless text classification" to refer to methods that: (1) can assign scores to any document-category pair, and (2) do not require any annotated training data from downstream tasks. A dataless classifier can therefore be immediately adapted to a particular label set in a downstream task dataset by scoring each possible label for a document and returning the label with the highest score. Dataless classifiers are typically built from large-scale freely available text resources such as Wikipedia (Chang et al., 2008; Yin et al., 2019).

A well known problem with dataless classifiers is that the choice of label names has a significant impact on performance (Chang et al., 2008). As dataless classifiers rely purely on the label descriptions in a downstream task, there is typically no tailoring or fine-tuning of the classifier for a given dataset. A poor choice of label descriptions could jeopardize the performance of dataless classifiers on a particular text classification task, so prior work has addressed this with modifications to label descriptions. Chang et al. (2008) manually expanded label names for the 20 newsgroups dataset and Yin et al. (2019) expanded labels using WordNet.

To illustrate the problem, Table 1 shows various choices of label names when applying a dataless classifier to the 4-class AG News dataset. When we change the descriptions of the four labels, performance of our dataless text classifier[2] changes drastically. The broader application of dataless text classifiers is hindered by their fragility caused by the choice of label descriptions. It is unclear how

practitioners should choose label descriptions for practical use.

In this paper, we ask the following question: how can we improve dataless text classification provided the *unlabeled* set of input texts for the downstream task in addition to its label descriptions? Our approach, which we refer to as unsupervised label refinement (ULR), is based on k-means clustering. We develop variations of our approach so that it can be applied to different styles of dataless text classifiers to improve their performance. Table 1 shows results when applying ULR to our dataless text classifier. In all cases, accuracies improve after applying ULR, with larger gains when using weaker label descriptions.

To summarize, our contributions in this paper are as follows:

- We propose unsupervised label refinement (ULR), a k-means clustering based approach to improve dataless classifiers.
- We develop variations of ULR that can be applied to different model architectures of dataless classifiers. Experiments on dual encoder and single encoder architectures show that ULR almost always improves performance.
- Experiments show that ULR improves robustness of dataless classification against choices of label names, making dataless classifiers more practically useful.

2 Dataless Text Classification

Dataless text classification (Chang et al., 2008; Chen et al., 2015; Song and Roth, 2014; Yin et al., 2019) aims at building a single, universal text classifier that can be applied to any text classification task with a given set of label descriptions. Dataless classifiers can be used on an unbounded set of categories. There is typically no tailoring or fine-tuning of the classifier for a dataset other than through specifying the label descriptions.

Since annotated data in the target task is not available for training, the choice of label descriptions plays a critical role in the performance of dataless classifiers (Chang et al., 2008; Yin et al., 2019). With a dataless classifier, a score is produced for each text-category pair, indicating their semantic relatedness. Text classification then becomes a ranking problem, i.e., picking the category that has the highest semantic relatedness with the text.

Several researchers have used Explicit Semantic Analysis (ESA) (Gabrilovich and Markovitch, 2007) as text representations in dataless text classification (Chang et al., 2008; Song and Roth, 2014; Wang et al., 2009). Both label descriptions and text are encoded into ESA vectors. Cosine similarity is used to compute scores between text and categories. Yin et al. (2019) directly compute text-category relatedness with a single BERT (Devlin et al., 2019) model. Chang et al. (2008) and Yin et al. (2019) exemplify two typical modeling choices for dataless classifiers, namely dual encoder and single encoder architectures, respectively. We will introduce them briefly and consider both types in our experiments.

Dual encoder model. With the dual encoder model, the category and text are fed into the encoder separately, each producing a vector representation. The text and category encoders could have shared or independent parameters. In our experiments, we always share parameters, i.e., we use the same encoder for both the categories and texts. A distance function takes both the category and text vectors and produces a scalar value. In our experiments, this scoring function can be either cosine distance or Euclidean (L2) distance.

Single encoder model. With a single encoder model, the category is combined with the text as a single sequence and fed into an encoder. The output of the encoder is a single vector that contains

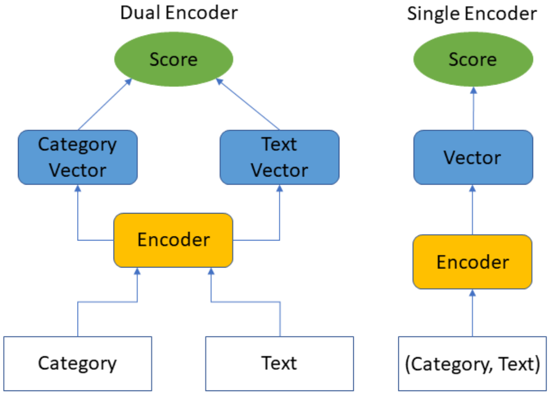

Figure 1: Dual and single encoder architectures.

initialize the centroids $r_c = \mathrm{enc}(c)\ \forall c \in \mathcal{C}$;
while not converged do
    for $t \in \mathcal{T}$ do
        $s_{tc} = \mathrm{score}(\mathrm{enc}(t), r_c)\ \forall c \in \mathcal{C}$;
        $\mathrm{pred}_t = \mathrm{argmin}_c s_{tc}$;
    end
    $r_c = (\frac{\sum_{t:\mathrm{pred}_t=c} \mathrm{enc}(t)}{\mathrm{count}(\{t:\mathrm{pred}_t=c\})} + \mathrm{enc}(c))/2\ \forall c \in \mathcal{C}$;
    objective $= \sum_t s_{t\mathrm{pred}_t}$;
end
Result: $s_{tc}$, objective, $\mathrm{pred}_t$, and $r_c$ of all
        iterations
```

the information from both the category and the text. This vector can pass through a linear layer and produce a score for this particular document-category pair. Figure 1 demonstrates the architectures of typical dual and single encoder models for text classification.

3 Unsupervised Label Refinement (ULR)

In this section, we introduce unsupervised label refinement (ULR). ULR uses the components of a dataless classifier and refines representations of labels with a modified k-means clustering algorithm. While dataless text classifiers are designed to handle an unbounded set of categories, they are used and evaluated on a particular set of documents with a set of labels. The idea of our approach is to leverage the assumption that the documents in a text classification dataset are separable according to the accompanying set of labels. That is, given a strong document encoder, the documents should be separable by label in the encoded space. This assumption is similarly made when performing clustering for unsupervised document classification (Liang and Klein, 2009).

We use the set of unlabeled input texts to refine the predictions of our dataless classifiers via clustering. To better inform the algorithm, we initialize the clusters by using our dataless classifiers run on the provided label set for each task. The algorithm takes on different forms for the dual and single encoder models. Details are provided below.

3.1 ULR for Dual Encoder Architectures

In the setting of a dual encoder model, we propose to perform k-means clustering among text representations, i.e., of vectors produced by the text encoder. The assumption is that texts falling under the same category will be close in the semantic space. We want to adapt our dataless classifier's predictions based on the natural clustering structure in the encodings of the texts.

We show the ULR algorithm for dual encoder architectures in Algorithm 1. We use one encoder enc to encode texts and categories. We link centroids to categories and initialize the centroids using the encodings of the corresponding categories. The algorithm converges when no data point (text representation) updates its cluster assignment, i.e., the centroids stop updating. In our experiments, we run a maximum of 100 iterations. We perform model selection ("early stopping") based on the minimum value of $\mathrm{objective}$ among iterations.

Our k-means algorithm differs from standard k-means as our updated centroids are interpolated with the initial category embeddings. In standard k-means, the centroids are typically initialized randomly. In our case, since we link centroids to categories and use our encoder to provide initial centroids, we want to leverage the information in our category embeddings across clustering iterations. Therefore, we average the "new centroid" with the original category vector, which serves as a kind of regularization. While this update is heuristically motivated, we can reverse-engineer the clustering objective it approximately optimizes (with

Euclidean distance as score):

$$\min_{\{r_c\}_{c\in\mathcal{C}}} \min_{\{a_t\}_{t\in\mathcal{T}}} \sum_{t\in\mathcal{T}} ||\mathrm{enc}(t) - r_{a_t}||^2 + \sum_{c\in\mathcal{C}} |c|\, ||\mathrm{enc}(c) - r_c||^2 \quad (1)$$

where $a_t \in \mathcal{C}$ is the category assignment of document $t \in \mathcal{T}$ and $|c|$ is the size of cluster/category c. See Appendix A for details. In preliminary experiments we found this modification to stabilize performance so we use it in our experiments reported below.

3.2 ULR for Single Encoder Architectures

In our single encoder architecture, a score is produced for each document-category pair indicating its relatedness. For each document, after exponentiating and normalizing the score over all categories, we obtain a distribution indicating the probability of the document belonging to each category. For text t and category c, we have a probability p_{tc}, where $\sum_c p_{tc} = 1$.

A straightforward way of classifying each document is to pick the category of which it has the highest probability score, i.e., $\mathrm{argmax}_c\, p_{tc}$. Another way of interpreting this classification rule is to define $|\mathcal{C}|$ centroid vectors, each being an identity distribution $\text{one–hot}(c)$,[3] and pick the category having the minimum Jensen-Shannon Divergence (Lin, 1991) with the document probability vector, i.e., $\mathrm{argmin}_c\, \mathrm{JS}(p_t, \text{one–hot}(c))$, where JS is the Jensen-Shannon Divergence between two distributions. Clustering probability distributions based on KL divergence is a well-known special case of clustering with Bregman divergences (Banerjee et al., 2005).[4] While JS does not admit such a well-defined objective to our knowledge, we find that it works well in practice.

It is natural to represent each category as a distribution by a one-hot vector. However, in a real text classification problem, the semantics of a category is affected by how the annotators view it. For instance, a news document could relate to both "business" and "science & technology", though it will only have a single annotated category in the downstream task dataset. With this intuition, we propose to represent each category by a soft distribution over all the categories, but not necessarily a one-hot vector.

Algorithm 2: ULR for single encoder architectures

```
Data: documents $\mathcal{T}$, categories $\mathcal{C}$, scoring
      function score, function to compute
      JS divergence JS
initialize the centroids as
  $r_c = \text{one–hot}(c)\ \forall c \in C$;
compute each document's probability
  distribution over categories as
  $[p_t]_c \propto \exp(\mathrm{score}(t, c))\ \forall t \in \mathcal{T}, c \in \mathcal{C}$;
while not converged do
    for $t \in \mathcal{T}$ do
        $s_{tc} = \mathrm{JS}(p_t, r_c)\ \forall c \in \mathcal{C}$;
        $\mathrm{pred}_t = \mathrm{argmin}_c\, s_{tc}$;
    end
    $r_c = \frac{\sum_{t:\mathrm{pred}_t=c} p_t}{\mathrm{count}(\{t:\mathrm{pred}_t=c\})}\ \forall c \in \mathcal{C}$;
end
Result: $\mathrm{pred}_t$ of the last iteration
```

Algorithm 2 describes our k-means clustering approach applied on the single encoder model. In this algorithm our predicted categories will be the clustering assignments of the last iteration. Unlike with the dual encoder model, we do not do early stopping. We also do not use interpolated centroids as one-hot vectors may not necessarily be good category embeddings in this setting.

4 Experimental Setup

We now introduce the datasets we used for evaluation and the dual encoder and single encoder dataless classifiers we used to run ULR experiments.

4.1 Evaluation

We use four text classification datasets spanning different domains for evaluation. They are: AG News[5] (AG), which uses 4 classes and covers the newswire domain; DBpedia (DBP; Lehmann et al., 2015), which has 14 classes and is from the domain of encyclopedias; Yahoo (Zhang et al., 2015), which has 10 classes and addresses categorizing

---

[3] Here we abuse the notation of $\text{one–hot}(c)$ to represent a one-hot vector that has a "1" at the index of category $c \in \mathcal{C}$.

[4] Specifically, if we replace $\mathrm{JS}(p_t, r_c)$ with $D_{\mathrm{KL}}(p_t||r_c)$ in Algorithm 2, it is an alternating minimization of the following clustering objective:

$$\min_{\{r_c\}_{c\in\mathcal{C}}} \min_{\{a_t\}_{t\in\mathcal{T}}} \sum_{t\in\mathcal{T}} D_{\mathrm{KL}}(p_t||r_{a_t})$$

[5] `https://www.di.unipi.it/~gulli/AG_corpus_of_news_articles.html`

questions in online question fora; and 20 newsgroups (20NG; Lang, 1995), with 20 classes which are types of newsgroups.

We do not use any data or labels from the training set in our main experiments, but only rely on label descriptions. We use the official label names from these datasets, and only expand them if the original label name is provided as abbreviations such as "sci_tech". The exact label names we used are in the appendix.

4.2 Dataless Classifiers

We experiment with multiple dataless text classifiers that vary in terms of their complexity. Our simplest classifier uses an encoder that averages pretrained GloVe (Pennington et al., 2014) word embeddings. We also fine-tune a RoBERTa model (Liu et al., 2019) in both single and dual encoder settings, using RoBERTa-base (110M parameters). We do not run experiments with traditional dataless classifiers such as ESA (Chang et al., 2008; Gabrilovich and Markovitch, 2007) as ESA vectors are of extremely high dimension, making it computationally difficult to apply ULR. GloVe and RoBERTa produce lower dimensional vectors that are more computationally amenable to refinement. Also, we experimented with ESA and found that it does not perform as well as our RoBERTa based models (where both are tested without ULR).[6] Next we describe the details of the three dataless classifiers that we use in our experiments.

GloVe dual encoder. We use GloVe (Pennington et al., 2014) in the dual encoder setting, simply averaging word vectors to represent both the categories and the documents. We use the 300 dimensional GloVe vectors[7] trained on Common Crawl. We experiment with two distance functions when using GloVe: cosine and L2.

RoBERTa dual encoder. The category c and text t are fed separately to RoBERTa using the formatting "[CLS] c [SEP]" and "[CLS] t [SEP]". We use the average of the final-layer hidden states produced by RoBERTa as category and text vectors. For the scoring function, which computes a scalar from the category and text vectors, we consider dot product[8] and L2 distance.

RoBERTa single encoder. The category c and text t are combined in the form "[CLS] c [SEP] t [SEP]", tokenized, and encoded using RoBERTa. We truncate t to ensure the category-document pair is within 128 tokens. The vector representation of the "[CLS]" token (after a linear transformation and non-linear activation) is then passed to a linear layer to produce a score.

4.3 Fine-tuning RoBERTa Models

We use the NatCat dataset (Chu et al., 2020) to fine-tune the RoBERTa models. NatCat comprises document-category pairs from three resources: Wikipedia, Stack Exchange, and Reddit. Each NatCat document comes with positive and negative categories. A positive category describes the document, and a negative category is randomly sampled and is irrelevant to the document. The RoBERTa models are fine-tuned as binary classifiers to indicate whether a category is positive for a document. We use the Hugging Face framework (Wolf et al., 2019) to fine-tune all RoBERTa models, using 300k instances from NatCat.[9]

Fine-tuning RoBERTa dual encoder. While many other combinations of score and loss function could be considered, we report results with two particular combinations: dot product paired with binary cross entropy and L2 distance paired with a contrastive hinge loss. When dot product is used, RoBERTa is fine-tuned to minimize binary cross entropy between $\text{score}(\text{enc}(c), \text{enc}(t))$ and a binary label $y \in \{0, 1\}$.

When using L2 distance, we fine-tune RoBERTa to minimize a contrastive hinge loss:

$$\text{loss} = \max(x_p + \gamma - x_n, 0)$$

where $x_p = \text{score}(\text{enc}(c_p(t)), \text{enc}(t))$, $x_n = \text{score}(\text{enc}(c_n(t)), \text{enc}(t))$, score is the squared L2 distance, $c_p(t)$ is a positive category for text t, $c_n(t)$ is a negative category, and γ is a parameter indicating the margin. This loss aims to make negative category-text pairs have higher squared L2 distance than negative pairs by the margin.

Fine-tuning RoBERTa single encoder. When used as a single encoder, RoBERTa is fine-tuned

---

[6] As a comparison to the results of the RoBERTa dual encoder in Table 2, ESA accuracies (%) are 71.2 for AG, 62.5 for DBP, 29.7 for Yahoo, and 25.1 for 20NG.

[7] `http://nlp.stanford.edu/data/glove.840B.300d.zip`

[8] Practically we find the model is easier to train with dot product compared to cosine similarity.

[9] The finetuning hyperparameters are in the appendix.

to minimize binary cross entropy between the predicted score $\mathrm{score}(\mathrm{enc}(c, t))$ and a binary label y, where score is a linear function that transforms the vector into a scalar score.

5 Experimental Results of ULR

Dual encoder models. With the dual encoder models, we used two sets of distance measures. The first distance is the cosine distance of two vectors. In this case, we always normalize the vector representations before applying ULR. The second distance measure is the L2 distance.

Table 2 shows results for the GloVe and RoBERTa dual encoder model with two distance functions. With GloVe, except for the single case of cosine distance with Yahoo, all accuracies improve, with some improving by large amounts (up to 20% absolute). With the RoBERTa dual encoder model, the choice of distance function matches the scoring function we used when fine-tuning RoBERTa, i.e., cosine distance is used with dot product scoring and L2 distance is used with the contrastive hinge loss. ULR improves accuracies by 3.6% to 4.4% on average, and the improvements are consistent across distance functions and datasets, except for the cases of 20 NEWSGROUPS with L2 distance and AG with cosine distance, which show slight degradations.

Single encoder model. Table 3 summarizes the results of applying ULR to the RoBERTa single encoder architecture. ULR improves performance across all four datasets, ranging from 0.5% for 20NG up to 6.8% on DBP. Additional experiments in the appendix show the impact of early stopping and interpolation using this architecture.

Label ensembles. Finding the best choice of label names for dataless classifiers is difficult without labeled data. Therefore, it is easier to supply multiple choices of label names for a given task.

We manually pick 10 different sets of label names for each dataset,[10] generate category and text representations with our RoBERTa dual encoder model, and perform ULR. The exact choices of label names are in the appendix. The predicted scores for the 10 sets are summed up as the final ensemble predictions. Table 4 shows results. Compared to Table 2, all accuracies on all tasks improve. Even with a stronger starting point from ensembling, ULR still yields consistent improvements in accuracy, with the single exception of Yahoo and cosine distance.

6 Robustness Experiments

Different choices of label names. Dataless text classification tasks are known to suffer from high variance due to label descriptions. Performance can vary dramatically across different choices of category names, as shown in Table 1.

One advantage of ULR is that it is robust to label noise. That is, even given a poor choice of label names, ULR can help the classifier to partially recover some of the accuracy, as shown in the lower

---

[10] We exclude 20NG mainly because it is difficult to come up with synonyms for its labels for this ensemble experiment and the robustness analysis in Section 6, since some labels in 20NG include proper nouns like "windows", "ibm", "mac", etc.

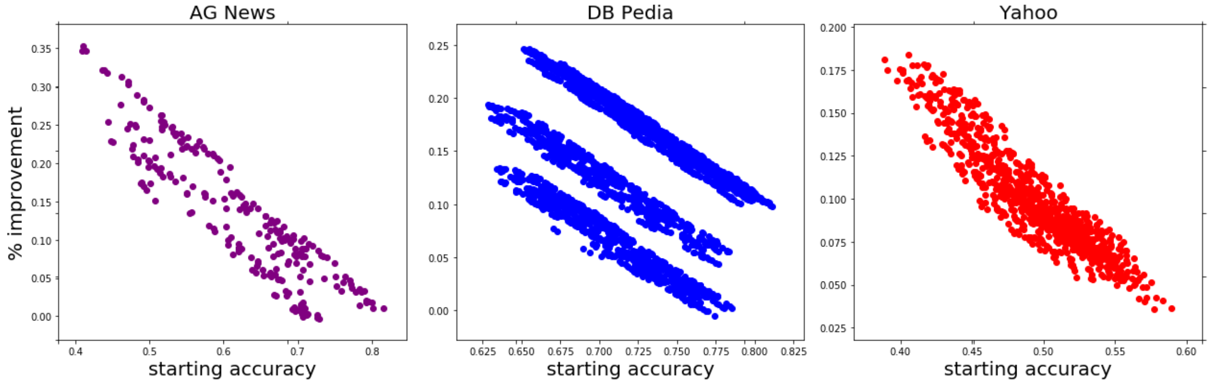

Figure 2: Accuracy (%) improvement when applying ULR compared to the RoBERTa dual encoder model (with Euclidean distance). The horizontal axis is the initial accuracy and the vertical axis is the absolute accuracy improvement after ULR.

		AG News	DBP	Yahoo
cos.	baseline	69.6 (8.7)	79.4 (3.2)	43.8 (3.9)

	+ ULR	**75.2** (4.1)	**85.2** (5.5)	**59.3** (1.5)
	# imp.	$\frac{237}{240}$ = 99%	$\frac{2960}{2963}$ = 100%	$\frac{947}{947}$ = 100%

Table 5: Robustness analysis when varying choices of label names. The "baseline" and "+ ULR" rows show average accuracies (%) with standard deviations in parentheses of the RoBERTa dual encoder architecture among all category naming choices. The "# imp." rows show the numbers and percentages of cases where the performance improves after ULR.

portion of Table 1. We now describe similar experiments on a larger scale. In particular, we test several hundred sets of label names for each of AG, DBP, and Yahoo. For each category, we randomly assign different label names to it, all having similar meaning. The exact combinations of label names are in the appendix.

We then perform dataless text classification and ULR with our RoBERTa dual encoder model, either under cosine or L2 distance. Table 5 shows the results of the average performance gains before and after ULR. We also report the number and percentage of cases in which ULR improves accuracy. ULR improves the performance on average for all three tasks, and improves individual accuracies in the vast majority of cases. These results show that ULR is not only effective at improving the accuracy of dataless text classifiers across a wide range of label name sets, but also can help to mitigate harmful effects due to suboptimal label names.

We next study the relationship between the RoBERTa dual encoder model's initial accuracies and its accuracy gains with ULR. Figure 2 plots accuracy improvements vs. initial accuracies for the three datasets. We find that ULR gives larger gains when the initial accuracies are lower.

We also computed oracle accuracies by choosing the combination of label names that maximize accuracy (without ULR). With cosine distance, they are 81.9% for AG, 87.5% for DBP, and 53.3% for Yahoo. With L2 distance, they are 81.5% for AG, 81.1% for DBP, and 58.9% for Yahoo. Using ULR with the RoBERTa dual encoder provides better performance on DBP and Yahoo, and competitive results on AG, as shown in Tables 2 and 4.

Clustering with random initialization. We now investigate the impact of our initialization in ULR. We consider a variation in which we randomly initialize centroids. Since we can no longer link clusters and categories, this task becomes unsupervised text classification. A standard k-means algorithm is applied to update the centroids. Unlike Algorithm 1, in this experiment we do not interpolate the updated centroids with the initial centroids, as the initial centroids are random. The accuracy is calculated based on the oracle one-to-one mapping between final centroids and categories. This is often referred to as "one-to-one accuracy".

Table 6 presents results on AG with this experiment. We performed 240 trials with different random initialization of the centroids, and unsurprisingly, accuracy is improved in all cases. With L2 distance, ULR with random initialization even outperforms centroids initialized as category embeddings, which shows that unsupervised clustering is

		cosine	L2
AG News	baseline	37.3	39.9
	+ ULR	**61.4**	**75.8**

"baseline" and "ULR" are average accuracy (%) of the RoBERTa dual encoder architecture among all random initialized centroids. "# imp." are the numbers and percentages of cases where the performance improves after ULR.

	AG	DBP	Yahoo	20NG	avg
baseline	74.0	84.6	52.3	36.4	61.8
+ 30 labeled ins.	81.5	97.1	66.0	58.1	75.7
+ ULR	**85.2**	**97.4**	**66.7**	**58.2**	**76.9**

Table 7: Accuracies (%) when adding 30 labeled instances for each category with the RoBERTa dual encoder model ("baseline").

powerful in text classification with good text representations. However, since we do not have the one-to-one mapping between category and final centroids in the purely unsupervised setting, the results in Table 6 are not directly comparable to those in earlier tables.

7 ULR with Few Shot Learning

In this section, we apply ULR in the few shot learning setting. In particular, we draw 30 labeled instances for each category from the training split in the original datasets. We then further fine-tune our RoBERTa dual encoder model with the labeled instances. We adopt the hyperparameters of fine-tuning text classifiers from Wolf et al. (2019) and fine-tune for 3 epochs on these 30 labeled instances for each category. Then we apply ULR on the unlabeled test set in addition to the 30 labeled instances from each category.

Unlike Algorithm 1, these 30 labeled instances from each category are fixed to be assigned to their corresponding clusters. We compute the centroids of these clusters from 30 labeled instances by $r^l_c = \frac{\sum_{t \in \mathcal{L}_c} \text{enc}(t)}{|\mathcal{L}_c|}$ $\forall c \in \mathcal{C}$ where documents $\mathcal{L}_c$ are labeled with c $\forall c \in \mathcal{C}$.

At every iteration, the update rule of the centroids as in Algorithm 1 will include the text vector representations of these 30 labeled instances, i.e., $r_c = (\frac{\sum_{t:\text{pred}_t = c} \text{enc}(t)}{\text{count}(\{t:\text{pred}_t = c\})} + r^l_c + 2 \times \text{enc}(c))/4$.

Table 7 summarizes the results of combining 30 labeled instances for each category and ULR. Unsurprisingly, adding labeled instances improves accuracy by a large margin. Even so, ULR yields an additional improvement of 3.7% for AG, and also improves on the other datasets.

8 Analysis

A key challenge of dataless text classifiers is semantic drift between the training data and downstream tasks. As ULR is based on k-means, the centroids move towards the embeddings of the majority of text instances belonging to that category. Hence after ULR the locations of the centroids combine the information in the initial dataless text classifiers and the document sets for the downstream tasks.

Using AG, Table 8 shows the 5 text instances closest to the centroids for "business" and "sci&tech" before and after ULR. These categories are hard to distinguish as technology companies often appear in both business and technology news. However, after ULR, we see that texts containing technology companies ("LeapFrog", "ScanSoft") become less central for the "business" category, replaced by texts describing transactions and earnings. Also, a text containing a company name ("NEC") has become less central for the "sci&tech" category, replaced in the top 5 by a similar text that does not emphasize a company name.

In certain text classification settings, we may be able to abstain from classifying instances we are less confident about. This notion can be instantiated by checking the texts closest to the centroids corresponding to the labels, which we can view intuitively as the ones the model is most confident about. Table 9 shows a confidence-based evaluation, evaluating the k texts that are closest to each centroid and showing that ULR consistently improves precision at k.

9 Related Work

Earlier we discussed prior work on dataless and zero-shot text classification. We briefly introduce more related work in this section. Song et al. (2015) provide a text label refinement algorithm to adjust the label set with noisy and missing labels. There is also a wealth of prior work in semi-supervised text classification: using unlabeled text to improve classification performance (Nigam et al., 2000; Mukherjee and Awadallah, 2020; Xie et al., 2019). These methods typically learn generally useful text representations from a large corpus of unlabeled text and use them for a specific target task with

limited supervision (Howard and Ruder, 2018; Devlin et al., 2019; Liu et al., 2019; Lan et al., 2020; Peters et al., 2018). Metric learning (Wohlwend et al., 2019) is related to our work, but they focus on few-shot learning and we work on improving unsupervised text classifiers. Related contemporaneous work has proposed methods to generate more relevant label names from a given set (Meng et al., 2020; Schick et al., 2020). ULR is orthogonal to such methods of choosing label names, as these label names can be set as extra initial centroids. Finally, label descriptions have also been exploited in supervised learning to improve text classifiers (Chai et al., 2020; Wang et al., 2019; Sun et al., 2019).

10 Conclusion

Our proposed ULR algorithms provide a simple but effective framework to improve the performance of dataless text classifiers. Extensive experiments show its flexibility and robustness, offering promise for making dataless text classification more useful for practitioners.

A Clustering Objective

For convenience, we first rewrite Eq. (1) below:

$$\min_{\{r_c\}_{c\in\mathcal{C}}} \min_{\{a_t\}_{t\in\mathcal{T}}} \sum_{t\in\mathcal{T}} ||\text{enc}(t) - r_{a_t}||^2 + \sum_{c\in\mathcal{C}} |c|\, ||\text{enc}(c) - r_c||^2 \quad (2)$$

We also rewrite Algorithm 1 here as Algorithm 3:

Algorithm 3: ULR for dual encoder architectures

```
Data: documents $\mathcal{T}$, categories $\mathcal{C}$, encoder
      enc, scoring function score
initialize the centroids $r_c = \text{enc}(c)\,\forall c \in \mathcal{C}$;
while not converged do
    for $t \in \mathcal{T}$ do
        $s_{tc} = \text{score}(\text{enc}(t), r_c)\,\forall c \in \mathcal{C}$;
        $\text{pred}_t = \text{argmin}_c s_{tc}$;
    end
    $r_c = (\frac{\sum_{t:\text{pred}_t=c}\text{enc}(t)}{\text{count}(\{t:\text{pred}_t=c\})} + \text{enc}(c))/2\,\forall c \in \mathcal{C}$;
    $\text{objective} = \sum_t s_{t\text{pred}_t}$;
end
Result: $s_{tc}$, objective, $\text{pred}_t$, and $r_c$ of all
        iterations
```

The objective (2) as a function of a single centroid corresponding to category $c \in \mathcal{C}$ can be written as

$$\min_{v\in\mathbb{R}^d} \sum_{t\in c} ||\text{enc}(t) - v||^2 + |c|\, ||\text{enc}(c) - v||^2$$

where $c \in \mathcal{C}$ is constant given assignments a_t. It is easy to verify that the unique solution is given by

$$r_c = \frac{\frac{1}{c}\sum_{t\in c}\text{enc}(t) + \text{enc}(c)}{2}$$

which is the update in Algorithm 3. Now consider (2) as a function of category assignments

$$\min_{\{a_t\}_{t\in\mathcal{T}}} \sum_{t\in\mathcal{T}} ||\text{enc}(t) - r_{a_t}||^2 + \sum_{c\in\mathcal{C}} |c|\, ||\text{enc}(c) - r_c||^2$$

where centroids r_c are held constant. Unfortunately this problem remains intractable because the regularization term is weighted by cluster sizes. We can approximate it by ignoring the regularization term: in this case the minimizer is given by $a_t = \arg\min_{c\in\mathcal{C}} ||\text{enc}(t) - r_c||$ for each $t \in \mathcal{T}$ as usual. Thus Algorithm 3 can be viewed as optimizing (2) by alternating minimization, with the simplifying (incorrect) assumption that cluster sizes are not significantly affected by category assignments.

B Experimental Setup

We list the hyperparameters we used to fine-tune our RoBERTa based dataless classification models in this section, so readers can reproduce our experimental results. The code with the scripts are also included in the supplementary material. We choose RoBERTa-base. In all fine-tuning tasks, we set the batch size to be 32. The max sequence length for RoBERTa is 128. The peak learning rate is 0.00002. We use a linear scheduler with warmup steps to be 10% of the total fine-tuning steps. The random seeds of all experiments are set to be 1.

We fine-tune RoBERTa models on random choices of single GPUs, including NVIDIA TITAN X, 1080Ti, or 2080 Ti. Most of the fine-tuning tasks can be finished within 8 hours.

C Label Names in the Evaluation Tasks

In the main experiments (Section 5), we use the following label descriptions (separated by ";") for the downstream tasks.

- AG: world; sports; business; science technology
- DBP: company; educational institution; artist; athlete; politician; transportation; building; nature; village; animal; plant; album; film; written work
- Yahoo: society culture; science mathematics; health; education reference; computers internet; sports; business finance; entertainment music; family relationships; politics government
- 20 Newsgroups: atheist christian atheism god islamic; graphics image gif animation tiff; windows dos microsoft ms driver drivers card printer; bus pc motherboard bios board computer dos; mac apple powerbook; window motif xterm sun windows; sale offer shipping forsale sell price brand obo; car ford auto toyota honda nissan bmw; bike motorcycle yamaha; baseball ball hitter; hockey wings espn; encryption key crypto algorithm security; circuit electronics radio signal battery; doctor medical disease medicine patient; space orbit moon earth sky solar; christian god christ church bible jesus; gun fbi guns weapon compound; israel arab jews jewish muslim; gay homosexual sexual; christian morality jesus god religion horus

Label ensembles. In the experiment of ensembling labels, we use the following 10 sets of label name choices.

For AG:

- world; sports; business; science technology
- international; sports; business; science technology
- world; sports; business; science and technology
- international; sports; business; science and technology
- world; sports; business and finance; science technology
- international; sports; business and finance; science technology
- world; sports; business and finance; science and technology
- international; sports; business and finance; science and technology
- world politics; sports; business; science technology
- world politics; sports; business; science technology

For DBP:

- company; educational institution; artist; athlete; politician; transportation; building; nature; village; animal; plant; album; film; written work
- company; school; artist; athlete; politician; transportation; building; nature; village; animal; plant; album; film; written work
- company; educational institution; artist; athlete; politician; transportation; architecture; nature; village; animal; plant; album; movie; written work
- company; educational institution; artist; athlete; politician; transportation; building; nature; village; animal; plant; album; film; novel
- company; educational institution; artist; athlete; politician; transportation; building; nature; village; animal; plant; album; film; article
- company; educational institution; artist; athlete; politician; transportation; building; nature; village; animal; plant; collection; movie; written work
- company; school; artist; athlete; politician; transportation; architecture; nature; village; animal; plant; album; movie; written work
- company; educational institution; artist; athlete; politician; transportation; architecture; nature; village; animal; plant; album; movie; novel
- company; school; artist; athlete; politician; transportation; architecture; nature; village; animal; plant; album; film; novel

- company; educational institution; artist; athlete; official; transportation; building; nature; village; animal; plant; album; movie; article

For Yahoo:

- society culture; science mathematics; health; education reference; computers internet; sports; business finance; entertainment music; family relationships; politics government
- society culture; scientific discipline; health; education reference; computers internet; sports; business finance; entertainment music; family relationships; politics government
- society culture; science mathematics; health; learning teaching resource; computers internet; sports; business finance; entertainment music; family relationships; politics government
- society culture; science mathematics; health; education reference; computers internet; sports; business finance; entertainment music; love home; politics government
- society culture; science mathematics; health; education reference; information technology; sports; business finance; entertainment music; family relationships; politics government
- society culture; scientific discipline; health; education reference; information technology; sports; business finance; entertainment music; family relationships; politics government
- society culture; science mathematics; health; learning teaching resource; information technology; sports; business finance; entertainment music; family relationships; politics government
- society culture; science mathematics; health; education reference; computers internet; sports; commerce; entertainment music; family relationships; politics government
- society culture; science mathematics; health; education reference; information technology; sports; commerce; entertainment music; family relationships; politics government
- society culture; science mathematics; health; learning teaching resource; computers internet; sports; commerce; entertainment music; family relationships; politics government

D Robustness to Label Noise

In the robustness experiments (Section 6), we manually picked different choices of label names for each category of the downstream tasks. We list the choices of label names for each category below, separated by ";".

AG:

- world: world; world politics; world news; international; international news
- sports: sports; health; health and sports
- business: business; commerce; finance; business and finance
- science technology: science; technology; science and technology; science technology

DBP:

- company: company; corporation
- educational institution: educational institution; school
- artist: artist; creator
- athlete: athlete; sportsman
- politician: politician; official
- transportation: transportation
- building: building; architecture
- nature: nature
- village: village; suburb
- animal: animal; living thing
- plant: plant
- album; collection
- file: film; movie
- written work: written work; writing; novel; article

Yahoo:

- society culture: society culture; community
- science mathematics: science mathematics; scientific discipline
- health: health; fitness
- education reference: education reference; learning teaching resource
- computers internet: computers internet; information technology
- sports: sports; athletics
- business finance: business finance; commerce
- entertainment music: entertainment music; fun songs
- family relationships: family relationships; love home
- politics government: politics government; policy regime regulation

Different combinations of label name choices are used to generate category embeddings and perform ULR.

	AG	DBP	Yahoo	20NG	avg
baseline	72.6	64.7	57.1	28.7	55.8
+ULR	**75.6**	**75.1**	**59.9**	**35.9**	**61.6**

Table 10: Improvements of ULR with the ROBERTA dual encoder model on unbalanced datasets.

	AG	DBP	YAHOO	20NG	avg
baseline	72.6	81.8	59.3	36.0	62.4
+ ULR					
	75.1	**88.6**	**60.0**	36.5	**65.0**
+ early	72.6	88.6	59.3	36.5	64.3
+ ULR + interpolate					
	74.0	87.2	59.6	**36.9**	64.4
+ early	74.0	87.2	59.6	**36.9**	64.4

Table 11: Accuracies (%) when applying ULR to the ROBERTA single encoder architecture ("baseline"). "+interpolate" are the results when we update centroids with interpolation. "+ early" means early stopping.

E Augmented Categories

In the experiment of augmenting categories with ULR (Section 8), we use the following augmented categories (separated by ";"): math; gis; physics; codereview; stats; unix; english; tex; gaming; apple; scifi; drupal; ell; meta; electronics; travel; rpg; dba; magento; webapps; diy; wordpress; android; security; chemistry; webmasters; blender; softwareengineering; gamedev; academia.

F Unbalanced Dataset

We manually create unbalanced datasets, where each category only contains 1-100% of the original instances. For a dataset with n categories, each instance belonging to category i has a probability of $\frac{i}{n}, i \in \{0, 1, \cdots, n-1\}$ of being dropped, where the orders of categories are random. Table 10 shows that ULR improves performance with unbalanced datasets.

G Single Encoder

Table 11 summarizes the results of applying ULR on the single encoder model with two variations:

1. early: early stopping on the average Jenson-Shannon Divergence score of all probability distribution of text over all categories to their corresponding nearest one-hot centers;
2. interpolate: when updating centroids in Algorithm 2, we take the average of the new centroids with the centroids from the previous iteration.

Overall, these two variations do not provide better results in the setting of single encoder models.

Prompting Contrastive Explanations for Commonsense Reasoning Tasks

Abstract

Many commonsense reasoning NLP tasks involve choosing between one or more possible answers to a question or prompt based on knowledge that is often implicit. Large pretrained language models (PLMs) can achieve near-human performance on such tasks, while providing little human-interpretable evidence of the underlying reasoning they use. In this work, we show how to use these same models to generate such evidence: inspired by the contrastive nature of human explanations, we use PLMs to complete explanation prompts which contrast alternatives according to the key attribute(s) required to justify the correct answer (for example, *peanuts are usually salty while raisins are sweet*). Conditioning model decisions on these explanations improves performance on two commonsense reasoning benchmarks, as compared to previous non-contrastive alternatives. These explanations are also judged by humans to be more relevant for solving the task, and facilitate a novel method to evaluate explanation faithfulness.

1 Introduction

Pretrained Language Models (PLMs) (Raffel et al., 2020; Lewis et al., 2020; Radford et al., 2019; Brown et al., 2020) have been shown to encode substantial amounts of knowledge in their parameters (Petroni et al., 2019; Talmor et al., 2020; Roberts et al., 2020) and have achieved impressive performance on commonsense reasoning (CSR) tasks without the use of external knowledge (Trinh and Le, 2018; Yang et al., 2020). However, these models provide little human-interpretable evidence of the intermediate commonsense knowledge or reasoning they use, and have been observed to overly rely on superficial dataset artifacts (Poliak et al., 2018; Geva et al., 2019). To overcome this limitation, recent work has shown that PLMs can explain themselves by *generating* free-form natural language explanations of their reasoning patterns (Rajani et al., 2019a; Camburu et al., 2018; Narang et al., 2020). However, the space of possible free-form explanations is incredibly large, inherently ambiguous, and difficult to annotate or evaluate (Wiegreffe et al., 2020; Latcinnik and Berant, 2020). Furthermore, quantifying the model's dependence on free-form explanations is also challenging (Camburu et al., 2020). We address these challenges by proposing an unsupervised method that uses contrastive prompts, which require the model to *explicitly* contrast different possible answers in its explanation (Table 1).

i) I picked up a bag of peanuts and raisins for a snack. I wanted a sweeter snack out so I ate the __ for now. *Contrastive Expl. - Peanuts are salty while raisins tend to be sweet.*
ii) The geese prefer to nest in the fields rather than the forests because in the __ predators are more hidden. *Contrastive Expl. - Forests are denser than fields*

Table 1: Examples of Winograd Schema Instances where the correct and incorrect answer choices are highlighted in blue and red respectively. Choices are *contrasted* along attributes like taste (for i) and density of vegetation (for ii) by humans to explain why they prefer some answer choice.

Our approach is based on a key observation: Many commonsense reasoning tasks require the comparison or contrast of plausible alternatives along a distinguishing attribute. For instance, in Table 1, the differentiating attributes for the two answer choices maybe taste (for i) and vegetation density (for ii). People commonly use contrastive explanations to explain their reasoning (Miller, 2018). Rather than asking "Why P?", they ask "Why P rather than Q?", where Q may be implicit from the context. For example, instead of justifying why raisins are the appropriate choice, people tend to ex-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4179–4192
August 1–6, 2021. ©2021 Association for Computational Linguistics

plain why they are more likely than peanuts. Miller (2018) also argues that such contrastive explanations are computationally efficient, as they only require focusing on the limited set of reasons that might make one answer more likely than the other instead of exhaustively enumerating all possible reasons for an answer. For instance, the raisin's taste (not its size, temperature, etc.) in Table 1 is adequate to explain why it is the best answer.

Our goal is to enable PLMs that explain their predictions to similarly benefit from such constraints. We develop a small set of contrastive generation prompts that can be in-filled by a PLM such as T5 (Raffel et al., 2020) or BART (Lewis et al., 2020) (see Table 3). These templates are designed to cover a multitude of language patterns used by humans to compare and contrast entities. Another PLM then conditions on both the original input and the generated contrastive explanation, to predict the final answer. This approach is inspired by Shwartz et al. (2020), who also use textual prompts to query the PLM with clarification questions. However, their prompts are generic while we prompt for instance-specific information.

Our approach shows quantitative improvements in task performance over two existing methods for model explainability (Shwartz et al., 2020; Latcinnik and Berant, 2020), for two commonsense reasoning tasks: the Winograd Schema Challenge (Levesque et al., 2012) and multiple-choice question answering about physical commonsense (Bisk et al., 2020). Our gains in the zero-shot setting are especially notable, outperforming the best reported results on publicly available PLMs and improving over Shwartz et al. (2020) by up to 11%. We also show, through human evaluations, that contrastive explanations are deemed more useful for solving the original task compared to generic clarification questions. Finally, contrastive explanations can be semantically perturbed to quantify the model's dependence on them by flipping the contrast in the explanation to support the foil, facilitating quantification of model faithfulness.[1]

2 Related Work

Models that rationalize their decisions by extracting a contiguous subsequence of the input as an explanation (Lei et al., 2016; DeYoung et al., 2020; Paranjape et al., 2020) are inadequate in explaining commonsense reasoning tasks that require knowledge that is implicit in the input. Such tasks necessitate PLMs to rely on embedded parametric knowledge. Recent work use free-form textual explanations to generate explanations for commonsense reasoning tasks like SNLI (Camburu et al., 2018), Winograd Schemas (Zhang et al., 2020) and CommonsenseQA (Rajani et al., 2019b) through explicit human supervision, which are inherently ambiguous, incomplete and consequently, expensive to collect and evaluate on (Camburu et al., 2019b,a; DeYoung et al., 2020). Most recently, Latcinnik and Berant (2020) use an unsupervised approach to generate free-form explanations as sequences of tokens that are not well-formed sentences. In contrast, our method uses specialized prompts to generate well-formed human-interpretable explanations without any additional supervision.

Specialized prompts have been shown useful for extracting knowledge from PLMs in a targeted manner (Petroni et al., 2020; Richardson and Sabharwal, 2020; Talmor et al., 2020; Donahue et al., 2020; Lin et al., 2019) and improving performance on downstream tasks (Brown et al., 2020; Shin et al., 2020). Most relevant to our work is the self-talk model of Shwartz et al. (2020), an unsupervised approach using a fixed set of clarification questions as prompts to elicit knowledge from PLMs for commonsense reasoning tasks. Our work differs by focusing specifically on contrastive PLM prompts, which we find further improve performance by eliciting explanations which are highly relevant to the classification decision (Section 6).

Our approach to contrastive reasoning is also closely related to *counterfactuals*, which can be used to give contrastive explanations, i.e., answers to "Why P rather than Q?", by providing a counterfactual case in which Q would have held. Ross et al. (2020) use this idea to generate contrastive explanations, while it has also been used for evaluation (Gardner et al., 2020) and training (Kaushik et al., 2019) with the aim of addressing model robustness. Most of this work explicitly constructs counterfactual cases by perturbing the input data of a task in order to produce changes in the output label. In contrast, we do not construct counterfactual *inputs*, but aim to explicitly represent counterfactual *knowledge*: a contrast between the fact P and foil Q that, were it hypothetically *reversed*, would change the output label. We include an evaluation of our models on this question in Section 6.3.

---

[1] Code is available at `https://github.com/bhargaviparanjape/RAG-X`

Dataset Instance	Human-Authored Contrastive Explanation
Winograd Schema	
1. The party was more interesting and upliﬁng than the funeral because the __ was rigid.	○ Parties are for celebrating while funerals are for mourning ○ People wear colorful clothes at parties and black at funerals
2. The geese prefer to nest in the fields rather than the forests because in the _ predators are more hidden.	○ Forests are dense while fields are sparse ○ Forests have more predators than fields.
PIQA	
1. How do you get strong hamstrings? __ (a) work out your upper body (b) work out your legs	○ Hamstrings are located in the legs while biceps are located in the upper body
2. How do you flood a room? __ (a) fill it with objects (b) fill it with water	○ Filling it with objects can clutter a room while filling it with water floods the room.

Table 2: Examples of commonsense tasks that can be explained using contrastive language and some contrastive explanations authored by in-house annotators. The Fact and Foil are marked in the input.

3 Contrastive Explanations

We present the theory of contrastive explanations adopted in this work (Section 3.1) and the intuition behind using them for commonsense reasoning tasks (Section 3.2).

3.1 Definition and Motivation

A contrastive explanation is generally defined as an answer to a counterfactual question of the form "Why P rather than Q?" for two potential hypotheses P and Q that can follow from some event E. It explains why some *fact* P occurred instead of some *foil* Q, where Q can be implicit (Hesslow, 1988; Lipton, 1990; Miller, 2019). A good contrastive explanation points to differences between the fact and foil with regard to certain attributes, not just conveying that the fact has a certain attribute. Table 1 shows examples of contrastive explanations that differentiate between peanuts and raisins (on the basis of taste) or forests and fields (on the basis of vegetation densities) to explain the more probable answers to Winograd Schema instances.

Previous studies (Miller, 2019) in philosophy, psychology, and cognitive science show that humans use such contrastive explanations when explaining their decisions to each other. Importantly, Miller (2018) also argues that contrastive explanations are computationally efficient – exhaustively describing all causes for the occurrence of an event P is harder than only enlisting causes for why another event Q did not occur instead of P.

3.2 Contrastive Explanations for Commonsense Reasoning Tasks

Many recently proposed commonsense reasoning tasks are framed in a multiple-choice format that facilitates contrastive explanation (see Table 2). In this study, we focus on the following two tasks.

The **Winograd Schema Challenge** (Levesque et al., 2012, WSC) is a pronoun coreference resolution task designed as a hard benchmark for evaluating everyday knowledge and commonsense reasoning (Zhang et al., 2020). For instance, in the sentence "The city councilmen refused the demonstrators a permit because they feared violence," the pronoun *they* must be disambiguated between fact (*the city councilmen*) and foil (*the demonstrators*). Both fact and foil are explicit in such sentences.

The **Physical Interaction Question Answering** (Bisk et al., 2020, PIQA) challenge is designed to test knowledge of physical commonsense. PIQA requires choosing between which one of two *solutions* is a better way of achieving a *goal* posed as a question (see Table 2). PIQA questions relate to physical properties of entities, their affordances, and how they can be manipulated. The fact and foil are explicit in the two solutions, which typically differ from one another by a short noun phrase.

To validate our intuition that contrastive reasoning is instrumental in these tasks, we performed a pilot study with 10 annotators over 100 commonsense questions from Winogrande and PIQA. We instructed them to answer the questions and explain their reasoning, but gave no specific instructions about what the explanations should look like. Examples are shown in Table 2. In 76% of Winogrande and 64% of PIQA examples, annotators explicitly contrasted the fact and foil. The frequent use of certain phrase structures, like *P are __ while Q are __*, strongly informed our method for generating them (Section 4).

4 Our Approach

We assume the input to a commonsense reasoning problem consists of a textual context c which contains a placeholder _, and two marked answer

Prompt Pattern	Commonsense Example & Model Generated Explanation
Personal Characteristics $\Longrightarrow$ P likes/likes to _ while Q likes/likes to _ P likes/likes to _ while Q does not like/like to _ P prefers/prefers to _ while Q prefers _ Q prefers _ while P does not prefer/prefer to _ Q thinks _ while P thinks/does not think _	Megan said it would be liberating to go out without makeup like Elena does since __ never wore makeup `Explanation: Elena likes to be natural while Megan likes to wear lipstick`
Object Characteristics P is taller/shorter/smaller/larger/slower/faster than Q $\Longrightarrow$ P is/are _ while/but/however Q is/are _ Q has/have _ while/but/however P has/have _ P has/have more/less _ than Q P is/are _ than Q	How to tie pieces of paper together? __ (a) Thread ruler through the holes (b) Thread ribbon through the holes `Explanation: Ruler is hard while a ribbon is flexible`
Spatial/Temporal Contrast $\Longrightarrow$ P is inside/outside/above/below Q _ is closer to P and farther away from Q P is to the right/left of Q Q takes longer to _ than P	Emily looked up and saw Patricia racing by overhead. __ was on the ramp. `Explanation: Emily is below Patricia`
Use cases and causes P is used for _ Q P is used to do Q _ $\Longrightarrow$ P is used for/to/in _ while Q is used for/to/in _ Q is used _ while P is used _ Q because _ while P because _ Q can cause _ while P results in _	To prepare the puff pastry for your pie, line a baking sheet with parchment. Then __ (a) Unroll the pastry, lay it over baking twine. (b) Unroll the pastry, lay it over fishing line. `Explanation: Baking twine is used in baking while fishing line is used in fishing`

Table 3: Contrastive Patterns and Examples of outputs generated by the T5-large model. The pattern the PLM completes are marked $\Longrightarrow$.

choices a_1 and a_2 corresponding to the fact and foil (Table 2, left column). Let c_x denote substitution of x for the placeholder in c. The task is to predict whether c_{a_1} or c_{a_2} is more likely to be true, i.e., whether a_1 or a_2 best completes the context.

Our approach has two stages: First, an **Explainer PLM** P_{expln} generates contrastive explanations (Section 4.2) by infilling preset *contrastive templates* (Sec. 4.1) on the basis of c, a_1, and a_2. Then, a **Task Model** P_{LM} selects the correct answer conditioned on both the context and the generated explanations (Sec. 4.3).

4.1 Contrastive Templates

We develop a list of contrastive templates on the basis of an annotation study. For 250 instances from Winogrande and PIQA, we asked three annotators to explain why one answer is more likely than the other. We manually examined these explanations and abstracted them into templates containing at least two placeholders: two for the fact and foil being contrasted, and possibly more corresponding to the properties they are being contrasted on. For instance, *peanuts are salty while raisins are sweet* becomes *Q are _ while P are _*. We retained templates used by annotators at least 10 times. Table 3 shows several examples. A template is converted into an explanation by replacing placeholders for the fact and foil with answers a_1 and a_2 and the remaining placeholders with the appropriate contrastive information.

We evaluate the quality and coverage of our templates with another round of human evaluation. For 100 WSC and PIQA examples, we ask three annotators to either write contrastive explanations using one or more of the templates, or indicate that none of the them were appropriate. Annotators used the templates in over 82% of cases, indicating high coverage for the tasks we study.

4.2 Generating Explanations

Let t denote a contrastive template. We write t_{a_1,a_2} to denote the customization of t to an input by filling its marked placeholders for fact and foil with the answer choices. For instance, in Figure 1, the template *P are _ while Q are _* is customized to *Fields are _ while forests are _*.[2] A full explanation may be produced by filling the remaining gaps in t_{a_1,a_2} by leveraging an infilling language model, the explainer P_{expln}.

We first construct a neutral context c_{a_0} by filling c's placeholder with a task-specific neutral answer

---

[2] In practice, we randomize the order of a_1 and a_2 when customizing the template.

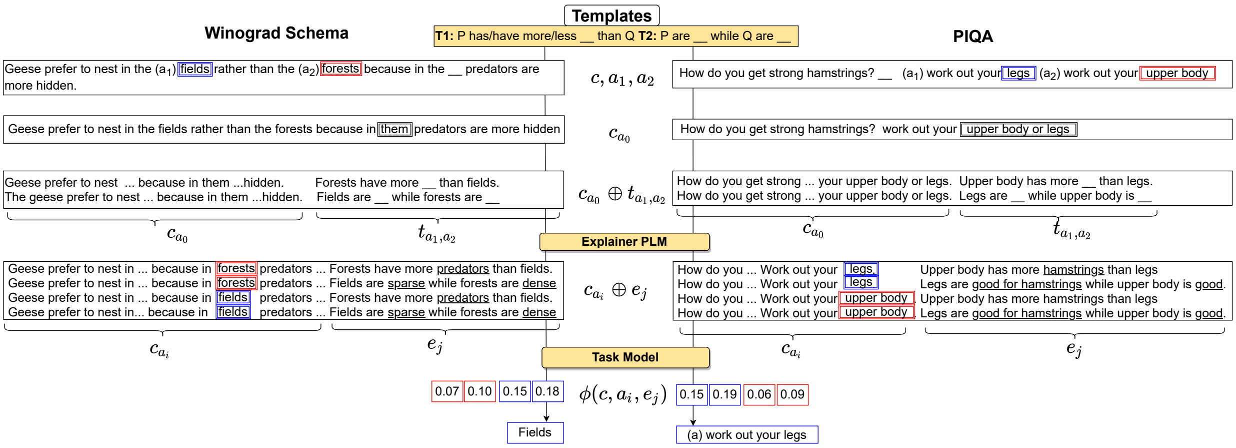

Figure 1: (1) A commonsense reasoning instance (c, a_1, a_2) is converted into a custom prompt $c_{a_0} \oplus t_{a_1,a_2}$ as input for the explainer PLM (2) The combination of input and explanation $(c_{a_i} \oplus e_j)$ is used by task model to score $a_i \forall i \forall j$. For a_1 and a_2, scores are aggregated over templates.

that does not indicate if a_1 or a_2 is correct. For Winogrande Schemas, c_{a_0} is constructed using the ambiguous pronoun in c (*them* in Figure 1). For PIQA, c_{a_0} is constructed as "$c \oplus a_1$ or a_2", where $\oplus$ is string concatenation, e.g., *upper body or legs* in Figure 1 (More dataset-specific details are in Section 5.2). We then prepend c_{a_0} to the customized template t_{a_1,a_2} and use it as input to the infilling language model to fill in the remaining gaps in the template. We use the maximum likelihood candidate phrases from top-K decoding to transform the template into a full explanation e.

We use a list of templates $t_1, \ldots, t_n$ to generate a list of candidate explanations $\mathsf{e}_1, \ldots, \mathsf{e}_n$ for each input, which are all fed into the task model. We also use some task-specific heuristics to reduce the number of prompts for each example, detailed in Appendix A.

4.3 Task Model

Given the context and answer choices (c, a_1, a_2) and a list of explanations $\mathsf{e}_1, \ldots, \mathsf{e}_n$, the second stage of our pipeline is a binary classifier between a_1 and a_2 which marginalizes over the explanations. We first assign a score to each answer $a \in \{a_1, a_2\}$ and explanation $\mathsf{e} \in \{\mathsf{e}_1, ..., \mathsf{e}_n\}$:

$$\phi(c, a, \mathsf{e}) = \frac{1}{k} \log \mathsf{P}_{\mathrm{LM}}(c_a \oplus \mathsf{e}),$$

where c_a denotes the substitution of a into c, P_{LM} is string probability under the task language model, and k is the string length of $c_a \oplus \mathsf{e}$. We use ϕ as input to a logistic regression classifier which marginalizes over explanations:

$$\mathsf{P}(a \mid c, a_1, a_2) = \frac{\sum_i^n e^{\phi(c,a,\mathsf{e}_i)}}{Z},$$

where Z is a normalizer over a_1 and a_2. At initialization, ϕ uses a pretrained language model, and we fine-tune it to minimize the cross-entropy loss of $\mathsf{P}(a^* \mid c, a_1, a_2)$, where a^* is the correct answer. We do not fine-tune the explainer PLM since the top-K beam decoding is a discrete operation that is hard to backpropagate through. In the zero-shot setting (where the task PLM is not fine-tuned) and during inference, the answer is predicted by aggregating scores assigned to an answer by all n explanations: $\operatorname{argmax}_{a_i} \sum_j \phi(c, a_i, \mathsf{e}_j)$.

5 Experimental Setup

5.1 Baselines

Context-Only We experiment with a baseline that does not condition on explanations at all. Here,

$$\phi(a, c) = \frac{1}{k} \log \mathsf{P}_{\mathrm{LM}}(c_a),$$

and gold answer is $\operatorname{argmax}_{a_i} \phi(a_i, c)$

Unconstrained Generation Latcinnik and Berant (2020) generate explanations from a PLM by beam-decoding a free-form sequence termed a *hypothesis* which is then used by a classifier to solve the task. The model is trained end-to-end and loss terms are added to encourage the hypothesis to sound natural. Explanation generation is otherwise unconstrained. For fair comparison with our approach, we do not fine-tune the explainer PLM (more details are in Appendix C).

Self-Talk Shwartz et al. (2020) propose an unsupervised model that uses a PLM as the answer scorer and a (possibly different) PLM as a knowledge source, similar to our framework. They formulate the process of obtaining relevant knowledge as *self-talk* with the following steps: 1) completing clarification question prefixes such as "what is the definition of ..." conditioned on input context, 2) generating their corresponding answers (clarifications), and 3) conditioning on the clarification questions and answers to make predictions. The key difference between their approach and ours is in the choice of prompts for the PLM, and the kinds of knowledge the prompts seek. While Shwartz et al. (2020) draw inspiration from inquiry-based discovery learning (Bruner, 1961), we target contrastive reasoning.

5.2 Implementation details

We use BART-Large (Lewis et al., 2020) and T5 (Raffel et al., 2020) as the explainer PLMs. Hyperparameters for infilling are given in Appendix C. For a fair comparison of all models, we use GPT2-XL (Radford et al., 2019) as the task model that estimates $\phi(c, a, \mathtt{e})$. GPT2-XL is the best performing PLM used by Shwartz et al. (2020) for WSC and PIQA tasks. Hyperparameter details about finetuning are given in Appendix C. We describe dataset specific modifications made to create c_{a_0}, c_{a_1}, and c_{a_2} in Section 4.2.

Winograd Schema Challenge (WSC) We experiment on (i) the SuperGLUE (Wang et al., 2019) version of the WSC consisting of 285 examples of anaphora (pronoun) resolution; (ii) Winogrande (WGRD) (Sakaguchi et al., 2020), a large scale crowdsourced version of the WSC; and (iii) WINOGENDER (WGND), a diagnostic dataset created to measure gender bias in models for ambiguous pronoun resolution (Rudinger et al., 2018).

Each instance provides two answer choices, which we use directly as a_1 and a_2. For the neutral answer c_{a_0}, we use the sentence with the original ambiguous pronoun. Since Winogrande has a blank space _ for the answer, we replace it with the most likely pronoun under a masked language model (BERT), following Shwartz et al. (2020). c_{a_1}, c_{a_2} are obtained by replacing the blank space or pronoun with the answer choice.

Physical Interaction Question Answering (PIQA) (Bisk et al., 2020) PIQA provides two answer choices which mostly vary from each other on a substring (e.g., "work out your [upper body]/[legs]"). We use these differing substrings as a_1=legs and a_2=upper body. For the neutral answer a_0, we combine the answers into "a_1 or a_2" (upper body or legs). In the cases where a_1 or a_2 is longer than 2 words, we include an *or* between the full answers. More details and examples are presented in Appendix A. We use question-answer pairs for c_{a_1} and c_{a_2}.

6 Experimental Results

In this section, we present an extensive evaluation of our approach, demonstrating performance gains which are independently verified by human judges.

6.1 Task Performance

We report task accuracy as a proxy for explanation quality. Table 4 compares the task performance of our model with the baselines defined in Section 5.1. We observe that generating and conditioning on additional information from PLMs improves performance over just using the original input (Row 1 vs. 2-6). Using templates to prompt the PLM for specific knowledge is better than unconstrained generation of text (Row 2 vs. 3-6). Contrastive explanations outperform previous work that use clarification questions in self-talk (Shwartz et al., 2020). The T5-Large explainer already surpasses the results of self-talk despite being smaller than GPT2-XL, demonstrating the impact of using contrastive explanations over clarification questions.

We also observe that larger explainer PLMs (going from T5-Large to T5-11B) yield higher performance. Our zero-shot results with T5-11B are the highest reported on Winogrande, PIQA and WSC for an open-sourced model.[3]

Finally, our approach gets smaller improvements when finetuning the task model. This suggests that some of the reasoning is still learned implicitly by the task model. Figure 2 shows task performance with various training data sizes of Winogrande, indicating a larger gap between the Context-Only baseline and our approach when training data is scarce.

6.2 Human Evaluation

Setup Following the human evaluation setup of Shwartz et al. (2020), we sample up to 50 highest-

---

[3] The zero-shot SOTA model (Brown et al., 2020) uses the 175B parameter GPT-3 model, which would likely also be a stronger explainer for our approach, but we did not have access to it.

	Explainer PLM (# Params)	Task model	WGRD ZS	FT	PIQA ZS	FT	WSC ZS	WGND ZS
1. Context-only	GPT2-XL (1.5B)	GPT2-XL	54.8	77.9	62.6	80.1	61.5	60.0
2. Unconstrained	GPT2-XL		54.9	77.8	63.9	80.7	61.4	60.0
3. Self-Talk	GPT2-XL		55.1	78.4	69.5	82.3	62.0	61.3
4. Contrastive	BART-Large(680M)		56.8	78.9	71.8	82.8	63.2	62.9
5. (Ours)	T5-Large (770M)		59.2	79.1	72.5	83.5	63.5	63.2
6.	T5-11B(11B)		**60.3**	**79.6**	**73.4**	**83.9**	**64.1**	**63.5**

Table 4: Test set accuracy on Winogrande (WGRD), PIQA, WSC and Winogender (WGND). ZS is Zero-shot models while FT is fine-tuned models. WSC and Winogender don't have training data for finetuning. Across all our models, the task model is GPT2-XL for fair comparison with (Shwartz et al., 2020) and to make finetuning tractable.

Metric	Self-Talk (Reported) WGRD	 PIQA	Self-Talk WGRD	 PIQA	Contrastive WGRD	 PIQA
Relevant	68	60	70.4	61.7	73.1	70.7
Factual	46	42	40.8	38.8	43.0	39.4
Helpful	24	26	22.5	27.7	42.8	32.8
Grammatical	87.2	87.2	87.5	87.5	83.5	83.5
Flips	NA	NA	NA	NA	66.9	59.4

Table 5: Human Evaluation Results on Winogrande(WGRD) and PIQA. Reported human evaluation results on Self-talk are different from ours, which can be because of moderate levels of agreement (Fleiss Kappa κ = 0.43). Grammatiality is judged together for all datasets following (Shwartz et al., 2020). Only contrastive explanations can be flipped.

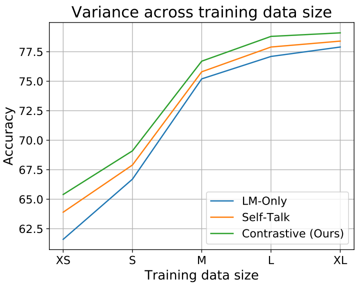

Figure 2: Performance variation in the finetuning setting across different sizes of Winogrande training data.

scoring explanations from PIQA and Winogrande examples which the T5-Large model got correct but the Context-Only baseline failed at. For comparison, we also include explanations from the self-talk model for evaluation.

Crowd workers are presented with a commonsense instance, the correct answer, and an explanation, and are asked to judge for: 1) *Grammaticality*, whether the explanation is grammatical; 2) *Relevance*, whether it's relevant to the topic of the text; 3) *Factual Correctness*, whether it's factually correct or likely true; and 4) *Helpfulness*, whether it adds helpful evidence for the correct answer. These metrics and definitions follow from Shwartz et al. (2020) with more details in Appendix B. The annotators are also shown the same explanation with fact and foil flipped (details in Section 6.3) and are asked to judge if the other answer is more likely than before if they assume the flipped explanation to be hypothetically true.

Results Table 5 shows the results of human evaluation of contrastive and self-talk explanations. The contrastive explanations are overwhelmingly preferred over self-talk explanations for relevance, factual correctness and helpfulness. They may be considered less grammatical because of in-filling noise (such as incomplete phrases). Table 6 presents some qualitative examples of instances where contrastive explanations improve over all baselines.

6.3 Analysis

We also analyze how much the task model relies on contrastive explanations for its decisions.

Flipping Explanations Our choice of contrastive language templates facilitates a novel way to evaluate explanation usefulness in prediction. The contrast in the explanation can be reversed by flipping the position of the fact and the foil in the explanation. If the choice between fact and foil actually depends on the contrastive explanation, then the flipped explanation should provide a hypothetical situation where the foil is more likely than the fact. For instance, "peanuts are salty while raisins are sweet," when switched to "raisins are sweet while peanuts are salty," may provide evidence that *peanuts* is a more likely label for the example in Table 1 (i). This may cause a model that uses the explanation to flip its prediction and lead to a drop in accuracy. The magnitude of drop can quantify the extent to which the model relies on the contrast

Example	Unconstrained	Self-Talk	Contrastive
(i) Ian volunteered to eat Dennis's menudo after already having a bowl because he despised eating intestine.	Dennis's menudo was disgusting.	What are the properties of a menudo? A menudo is made from the intestines of a pig	Dennis is a vegetarian while Ian is a carnivore. Dennis has menudo while Ian has volunteered to eat Denni's menudo.
(i) The GPS and map helped me navigate home. I got lost when the it got turned upside down.	because the GPS and map helped me navigate home.	What is going on here? The iphone app is not working.	The GPS can tell me where I am but the map can't. The GPS is right-side-up while the map is upside down
(ii) I helped my sister find her gold necklace. She couldn't wear her woven necklace to the ball because it was so casual.	She couldn't wear her woven necklace.	What are the properties of gold? The properties of gold are listed below.	Gold necklace is used for formal occasion while woven necklace is used for casual occasion.

Table 6: Qualitative Examples on Winogrande where contrastive explanations (using T5-11B explainer) improve task performance over baselines.

Explainer PLM	WGRD		PIQA		WSC	WGND
	ZS	FT	ZS	FT	ZS	ZS
BART-Large	53.9 (5.4)	75.9 (4.0)	66.5 (7.9)	79.1 (4.6)	59.1 (6.9)	58.7 (7.1)
T5-Large	56.2 (5.3)	75.3 (5.0)	68.1 (6.5)	80.2 (4.2)	60.2 (5.5)	59.0 (7.1)
T5-11B	57.6 (4.5)	76.1 (4.7)	69.5 (5.4)	81.0 (3.6)	61.1 (3.3)	59.0 (5.8)

Table 7: Flipped evaluation results for contrastive explanation models. Reporting test accuracy across all datasets. Percent drop in performance as a result of flipping is indicated in parentheses.

Input	WGRD	PIQA
Fully abstracted	63.2	54.6
Abst. after expl.	70.4	64.9
No abstraction	79.1	83.5

Table 8: Evaluation of fine-tuned T5-Large contrastive models on Winogrande with abstracted answers.

provided in the explanation. In fact, humans also deem the flipped explanation to imply the opposite label in a majority of cases (Table 5), indicating that our contrastive explanations frequently capture contrastive properties that the labels truly rely on.

Table 7 shows the flipped evaluation results. We observe declines in accuracy of up to 8%, indicating that the model does use some contrastive knowledge to reason about the task. Finetuned models show a smaller decline in accuracy compared to the zero-shot setting. In this case, the task model may be directly fitting the data in lieu of relying on the knowledge conveyed by the explanation.

Abstracting Fact and Foil Given input context c (consisting of the fact and foil a_1, a_2) and an explanation e, the explainer PLM P_{expl} infills its explanation e on c while the task model P_{LM} conditions on both c and e. We can test the quality of the generated explanations and the task model's reliance on them by forcing the task model to rely on e when information in input c is restricted. One potential way to do so is to scrub the identities of the fact and foil, a_1 and a_2, from c.

We replace the fact and foil with placeholder tokens to create an abstract context c'. For instance, the example in Table 6 (ii) becomes "The `<mask1>` and `<mask2>` helped me navigate ... down.", where the model must now choose between `<mask1>` and `<mask2>`.[4] Running the task model on c' lower-bounds the performance possible without knowing answer identities. We can now test the relevant answer-based knowledge contrastive contained in the *explanations* by allowing the explanation model to see the original answers in c, but then abstracting them out when passing the input context and explanations to the task model. More formally, the task model conditions its decision on c' and e'. For Table 6 (ii) c' and e' are "The `<mask1>` and `<mask2>` helped me navigate ... down." and "The `<mask1>` is right-side-up while the `<mask2>` is upside down." Since only the explainer PLM is shown answer identities, the task model's decision is conditionally independent of the answer identities given the explanation.

Experiments on Winogrande and PIQA in the

---

[4] More examples of abstracted contexts and explanations are given in the Appendix (Table 11).

Model	Acc.
Random	20.0
Baseline	37.2
Self talk	26.9
Contrastive (V)	38.1
Contrastive (MM)	37.4
Banerjee and Baral (2020a)	38.8

Table 9: Zero-shot test performance on CommonsenseQA for baselines as well as contrastive models which ensemble fact/foil pairs by voting (V) and maximum margin (MM). The best reported unsupervised performance (Banerjee and Baral, 2020b) uses ConceptNet, which was used to construct the dataset.

fine-tuned setting (Table 8) show that performance improves significantly when the task model conditions on both c' and e' compared to a fully abstracted contrastive baseline that only conditions on c' (from 63.2 to 70.4 for Winogrande), covering almost half of the gap between the fully abstracted setting and the non-abstracted original model (79.1). This indicates that our contrastive explanations encode a significant amount of information required for commonsense tasks. Even if the full model does not always use the explanations, these evaluations show that our contrastive explanations contain rich task-relevant knowledge, and suggest that future work might focus on how to better make use of this signal.

6.4 Generalizability of Prompts

The set of contrastive prompts used in our framework are curated from an in-house analysis of training instances from Winogrande and PIQA datasets. To determine the generalizability of these prompts for other commonsense reasoning tasks, we also experiment with the CommonsenseQA dataset (Talmor et al., 2019), which consists of multiple-choice questions created over ConceptNet – "Where on a river can you hold a cup upright to catch water on a sunny day? a) waterfall, b) bridge, c) valley, d) pebble, e) mountain". Since there are more than two answer choices to contrast, we convert each instance into 10 pairwise (binary) classification instances. Contrastive explanations are generated for each pairwise decision in the zero-shot setting, similar to Winograd and PIQA datasets. To choose the final answer, we consider two inference procedures: (a) *Vote:* The answer that receives the maximum number of votes across all binary classification instances is selected, and (b) *Maximum Margin:* The choice with the maximum difference (margin) between answer likelihoods for any binary classification instance is selected. In Table 9, we observe that self-talk significantly hurts performance for this dataset. On the other hand, contrastive explanations are found to be useful and approach the zero-shot performance of the state-of-the-art, which uses ConceptNet (Banerjee and Baral, 2020b). These results demonstrate that the set of contrastive prompts are generalizable to other commonsense reasoning datasets, and that while our contrastive prompts are limited to contrasting two answer choices at a time, the framework can be easily extended to tasks with multiple foils.

7 Conclusion

We show it is possible to prompt pretrained language models (PLMs) to generate contrastive explanations of their reasoning patterns, inspired by explanations that humans naturally provide for their reasoning. Conditioning model decisions on these explanations improves performance on two commonsense reasoning benchmarks, and humans judge the explanations to be highly relevant and helpful in comparison to prior work. We also showed how contrastive explanations can facilitate in-depth evaluations of faithfulness by flipping or abstracting the fact and foil, finding that our explanations encode a significant amount of information relevant to the classification decision, and in many cases models rely on the contrast in the expected way. While we have shown that our method is flexible enough to apply to multiple-choice commonsense tasks with many foils, leveraging contrastive reasoning in a wider variety of open-ended tasks remains an exciting challenge for future work.

A Generating Contrastive Templates

Table 12 shows the complete list of contrastive patterns used in our work, categorized under different types of attributes/properties. For templates with no place holders for the explainer to fill out, we only replace placeholders for answers (fact and foil). Table 10 lists $a_0, a_1, a_2, c_{a_0}, c_{a_1}, c_{a_2}$ for different examples in Winogrande and PIQA to explain dataset specific transformations made by our approach.

Detection of P, Q: For WSC, the fact and foil are typically 1-word nouns. However, they may by qualified in the context and these qualifiers are important for contrasting. For instance, in the WSC example "She remembered how annoying it is to dust her wood chair so she bought a plastic table instead.", chair and table are the fact and foil. Their qualifiers wood and plastic are important for the construction of the contrast. Hence we retain these qualifiers when preparing prompts for the explainer PLM. Similarly, for PIQA, qualifiers are retained in the prompts.

Case filtering: We detect case of entities and accordingly filter out templates that are ungrammatical depending on whether the fact and foil are singular/plural.

Template filtering for WSC: For examples that do not contain PERSON named entities, we do not include prompts about personal characteristics. Similarly, for examples that contain PERSON named entities, Temporal, Usecase and some spatial patterns were left out.

Template filtering for PIQA: We remove all templates about personal characteristics as this dataset deals with physical commonsense.

B Human Evaluation

The annotation task was carried out in Amazon Mechanical Turk, following (Shwartz et al., 2020). To ensure the quality of annotations, workers were required to be located in the US, UK, or Canada, and have a 99% approval rate for at least 5000 prior tasks. Annotators were paid .30$ per HIT to ensure participants get approximately $15/hr if they are doing the task. Annotation were aggregated from 3 workers using majority vote. The annotations yielded moderate levels of agreement, with Fleiss Kappa κ = 0.43 (Landis and Koch, 1977).

C Hyperparameters

Explainer PLM For T5 we use special symbols `<extra_id_0>` and `<extra_id_1>` in place of the blanks (_) in our templates. We observe that T5 is able to replace these tokens with multi-word phrases. For BART, we substitute blanks with a sequence with four `[MASK]` tokens to encourage generating multiple words. BART can choose to delete a `[MASK]` token during generation. Top-K decoding was done with a beam size of 200 and a maximum output sequence length of 20 for T5 models and 100 for BART. This is because both T5 is pre-trained to in-fill by only generating missing phrases while BART is pre-trained to decode the entire input with missing phrases filled in. We used early stopping for BART.

Task PLM Task PLM was finetuned for 20 epochs, using BertAdam optimizer with a learning rate of $2e-5$, batch size of 8, and dropout of 0.1, following (Latcinnik and Berant, 2020).

Self-Talk (Shwartz et al., 2020) generate multiple clarification questions conditioned on the context, by 1) concatenating one of several question prefixes to the input prompt or question; and 2) generating 5 questions for each prefix using Nucleus sampling with $p = 0.2$, i.e., sampling from the top 20% tokens(Holtzman et al., 2019) limiting the question length to up to 6 tokens excluding the prefix. For each well-formed question, they generate multiple answers using a similar method. They

Generated Explanation: Forests have more predators than fields Input to task model: The geese prefer to nest in the `<mask1>` rather than the `<mask2>` because in the _ predators are more hidden. `<mask2>` have more predators than `<mask1>`

Table 11: Input to Explainer and Task model for Abstractive Evaluation

limit the answer length to 10 generated tokens, and use Nucleus sampling with $p = 0.5$. Shwartz et al. (2020) only condition task prediction on a single clarification question and answer pair that increases the model's belief of a certain answer choice. Thus, the score of each answer choice is selected as the score of the text containing the clarification that most supports it, i.e., whose combination with it yields maximum language model likelihood.

Unconstrained Generation For unconstrained explanation baseline, maximum output sequence length was set to 20 and beam size for beam decoding was set to 200. Again we use early stopping.

Abstract

The drastic decrease in mobile SMS costs turned phone users more prone to spam messages, usually with unwanted marketing or questionable content. As such, researchers have proposed different methods for detecting SMS spam messages. This paper presents a technique for embedding SMS messages into vector spaces that is suitable for spam detection. The proposed approach relies on mining patterns that are relevant for distinguishing spam from legitimate messages. A subset of those patterns is used to construct a function that maps text messages into a multidimensional vector space. The extracted patterns are represented as skip-grams of token attributes, where a skip-gram can be seen as a generalization of the n-gram model that allows a distance greater than one between matched tokens in the text. We evaluate the proposed approach using the generated vectors for spam classification on the UCI Spam Collection dataset. The experiments showed that our method combined with shallow networks reached accuracy that is competitive with state-of-the-art approaches.

1 Introduction

SMS spam detection is a very relevant task for mobile phone users. It can mitigate the annoyance caused by the invasive marketing applied through this platform and provide a more secure user experience by blocking potentially harmful messages. In that sense, researchers have proposed different methodologies to detect SMS spam. Abdulhamid et al. (2017) and Abayomi-Alli et al. (2019), for instance, provide comprehensive reviews of the relevant datasets and techniques found in the literature.

Most recently, some researchers have successfully applied deep learning techniques for SMS spam detection: Annareddy and Tammina (2019) provide a comparative study on using Convolutional Neural Networks (CNN) and Recurrent Neural Networks (RNN); Roy et al. (2020) and Popovac et al. (2018) propose to CNN as well; Roy et al. (2020), Jain et al. (2018) and Raj et al. (2018) propose using LSTM-based architectures; Ghourabi et al. (2020) use a hybrid CNN-LSTM model; Barushka and Hajek (2018) use regularized deep multi-layer perceptrons combined with a feature selection algorithm; and Wei and Nguyen (2020) propose the use of Lightweight Gated Recurrent Units (LGRU).

Other works employ traditional classifiers to such a task (Fernandes et al., 2015; Fattahi and Mejri, 2021; Xia and Chen, 2020), including diverse models like Support Vector Machines (SVM), Hidden Markov Models (HMM), Optimum-Path Forest (OPF), k-Nearest Neighbors (KNN), decision trees, and ensembling approaches. Gupta et al. (2018) provide a comparative study using CNN and traditional machine learning architectures.

SMS spam messages have a very characteristic textual style; many inform the recipient that she has won a prize or offer apparent great deals. As such, many words (e.g., “prize”, “won”, “free”, “bonus”, etc.) can be found to be very informative for classifying a message as spam. While these words can be used to create classifiers with good performance, we observe that words and patterns of a sequence of words can be very characteristic of spam messages. For example, in the UCI SMS Spam Collection dataset (Almeida et al., 2011), the probability that a message is spam given that it contains the word “`text`” is 0.53, and the same likelihood raises to 0.96 when the message includes the pattern “`text [WORDS] to`”, where “`[WORDS]`” is a placeholder for a short sequence of one or more words.

That happens because the word “`text`” can be used many times in legitimate messages, as illustrated by the following example: “*(...) I’ll **text** you*

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4193–4201
August 1–6, 2021. ©2021 Association for Computational Linguistics

in a few (...)". On the other hand, it is very common for spam messages to request the phone user to send a message to a certain number, like the following: "*(...)* ***text*** *TONE or FLAG* ***to*** *84199 NOW (...)*". Thus, observing this pattern gives much higher probability of a message being a spam than just finding the word "`text`" in it.

In this paper, we propose a text embedding technique for SMS messages that exploits patterns relevant for spam characterization. As a result, spam and non-spam messages are projected distinctly in the embedded space, allowing a more effective classification. The method is split into three main steps:

1. *Tokenization*: each text message from a training dataset is transformed into a sequence of sets of attributes;
2. *Skip-gram pattern mining*: the generated sequences are then processed by an algorithm for finding patterns relevant for the classification task;
3. *Embedding model*: given the set of relevant patterns, a model is constructed for mapping text messages into a vector space.

Our model presents relevant contributions, differing from some related works (especially those based on deep learning) regarding two aspects: (*i*) the proposed embedding approach is a lightweight model, being suitable to be used with shallow networks and executed on mobile devices; and (*ii*) the model allows interpretation, with explicit information associated with each dimension.

We evaluate the proposed technique using our method to generate vectors for the classification of SMS messages from the UCI SMS Spam Collection dataset (Almeida et al., 2011). Our best results surpassed the baselines from (Almeida et al., 2011) and showed to be competitive with recent deep learning approaches in terms of accuracy. In particular, our embeddings combined with a Linear SVM classifier achieved an average accuracy of 99.03% on 10-fold cross-validation experiments. Regarding efficiency aspects, prediction experiments using an ARM Cortex-A53 mobile processor yielded an average of 22 milliseconds of processing time for each SMS message.

The remainder of this paper is organized as follows: Section 2 formalizes our method and Section 3 performs an evaluation of the proposed technique. Finally, Section 4 states conclusions and presents some suggestions of future directions.

2 Formal Model Definition

This section presents a formalization of the proposed approach, which can be split into three main steps: (i) *tokenization*; (ii) *skip-gram pattern mining*; and (iii) the construction of the *embedding model*.

2.1 Tokenization

Given a set $\mathcal{X} = \{x_1, x_2, ..., x_{|\mathcal{X}|}\}$ of texts, the tokenization step constructs a set of sequences $\mathcal{S} = \{s_1, s_2, ..., s_{|\mathcal{X}|}\}$, where s_i is the sequence generated for the text x_i. We represent a given sequence as a tuple where each element is associated with a designated text fragment. Instead of merely being a substring of the text, each component of the tuple defines a set of attributes associated with the respective text fragment.

This transformation is applied with the following steps:

1. *Token splitting*: the text is split into fragments by capturing either of the following patterns, in that order of precedence: (*i*) sequence of one or more digits; (*ii*) sequence of one or more alphabetic characters; and (*iii*) sequence of any non-space character.

2. *Sub-word splitting*: each captured sequence of alphabetic characters is further broken into sub-sequences of length 3. For example, the word "`award`" is transformed into the following: "`awa`", "`war`", "`ard`". While 3 seems to be an arbitrary value for the length, we really want this parameter to be small, since that allows us to capture morphological variations of terms with similar semantics.

3. *Attribute assignment*: each fragment is transformed into a set of associated attributes, and the result of the tokenization process is the sequence of sets of attributes. Each attribute is represented as a pair (a, b), with the first element being the name of the attribute, and the second its associated value. We have three distinct attributes, i.e., $a \in \{$**`type`**, **`pos`**, **`sub`**$\}$, that can be defined as follows:

   - **`type`**: the type of the fragment. Possible values for b are `1-digit`, `2-digit`, `3-digit`, and `4+-digit` for fragments containing digits; `sub-word` for fragments that are sub-strings of alphabetic sequences; and `other` for fragments not belonging to any of the previous categories. The number before the digit types refers to the length of the captured string, `4+-digit` means 4 or more digits;

- **`pos`**: when the fragment is of type `sub-word`, b refers to the position of the sub-string in the captured word. Possible values for b are: `start`, `middle` and `end`;
- **`sub`**: when the fragment is of type `sub-word`, b is the sub-string represented by the fragment in lowercase. If the type is `other`, then b stands for the entire matched fragment.

Such a representation is coined here as an *attribute-set sequence*, and we use $\Sigma = \{\sigma_1, \sigma_2, ..., \sigma_{|\Sigma|}\}$ to denote the dictionary of attributes, that is, the set of all possible attributes.

Figure 1 illustrates the tokenization process for the string “`Call 09061701461.`” The boxes at the bottom represent the final sequence of attribute sets. For the sake of explanation, the first attribute of fragment “Cal” is the pair (**`type`**, `sub-word`).

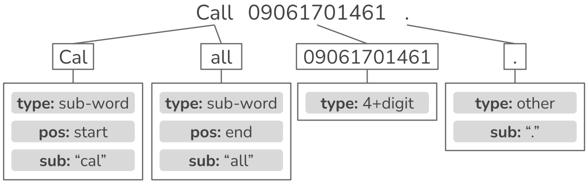

Figure 1: Illustration of the tokenization process for the string “`Call 09061701461.`”.

2.2 Skip-gram pattern mining

This step assumes that each sequence from $\mathcal{S}$ is assigned to a label from a set of labels $\mathcal{Y}$. We denote $y_i = \gamma(s_i)$ as the label assigned to the sequence s_i using model γ. The objective of this step is to construct a set $\mathcal{R}$ of skip-gram patterns that are relevant for label prediction (i.e., classification).

For this work, we formally define a k-skip-n-gram pattern as a tuple $g = (g_1, g_2, ..., g_n)$ whose elements are sets of attributes. We say that g matches an attribute-set sequence $a = (a_1, a_2, ..., a_l)$ if there is a tuple $z = (z_1, z_2, ..., z_n)$ of matched indices of a, such that:

- $\forall i, 1 \leq i < n, 1 \leq z_{i+1} - z_i \leq k + 1$, that is, matched indices must be in increasing order and the distance between two matched elements must not be greater than $k + 1$;
- $\forall i, 1 \leq i \leq n, g_i \subseteq a_{z_i}$.

Note that this definition differs from the one given by Guthrie et al. (2006) in the following aspects: (i) k is the number of skips allowed between consecutive elements of the skip-gram; (ii) a match is based on set containment ($g_i \subseteq a_{z_i}$) instead of equality.

Figure 2 illustrates how the skip-gram *({(pos, start), (sub, ”tex”),}, {(pos, start), (sub, ”to”)}, {(type, 4+-digit)})* would match the string “*text PLAY to 85222 now*”. That match holds for any $k \geq 3$.

The pattern mining algorithm interactively constructs a set of skip-gram patterns that might be relevant for the classification process. At each iteration t, a set of candidate patterns $\mathcal{C}^t$ is generated and a subset $\mathcal{R}^t \subseteq \mathcal{C}^t$ is selected based on a scoring function. After T iterations, the final set $\mathcal{R}$ of patterns is then selected.

Before detailing the algorithm, we provide the following definitions, which are used throughout the remainder of this formalization:

- $\mathcal{Z}^{(g,s)}$: the set of all tuples of indices of the attribute-set sequence $s \in \mathcal{S}$ that are matched by the skip-gram pattern g. Each tuple refers to a different match. As an example, in Figure 2, $(1, 5, 6)$ would be one tuple in such a set;
- $\mathcal{M}^{(g,s)} = \{g \in \mathcal{G} : \mathcal{Z}^{(g,s)} \neq \emptyset\}$: the set of skip-gram patterns in $\mathcal{G}$ that match the sequence s;
- $P(y|g) = P(\gamma(s) = y|\mathcal{Z}^{(g,s)} \neq \emptyset)$: the estimation of the probability that the label of a sequence s is y given that the pattern g matches s, which is calculated as follows:

$$P(y|g) = \frac{|\{s \in \mathcal{S} : \gamma(s) = y \wedge \mathcal{Z}^{(g,s)} \neq \emptyset\}|}{|\{s \in \mathcal{S} : \mathcal{Z}^{(g,s)} \neq \emptyset\}|}. \quad (1)$$

- $P(g|y) = P(\mathcal{Z}^{(g,s)} \neq \emptyset|\gamma(s) = y)$: the estimation of the probability that a sequence s is matched by the pattern g given that the label of s is y. The probability is given as follows:

$$P(g|y) = \frac{|\{s \in \mathcal{S} : \gamma(s) = y \wedge \mathcal{Z}^{(g,s)} \neq \emptyset\}|}{|\{s \in \mathcal{S} : \gamma(s) = y\}|}. \quad (2)$$

- $GY(g, y) = P(y|g)^{\texttt{GY\_ALPHA}} P(g|y)^{1-\texttt{GY\_ALPHA}}$, a function to measure the dependency level between a skip-gram g and label y, we call it GY-Score. The parameter `GY_ALPHA` is a value between 0 and 1 that allows one to give more relevance to one or the other term of the multiplication;

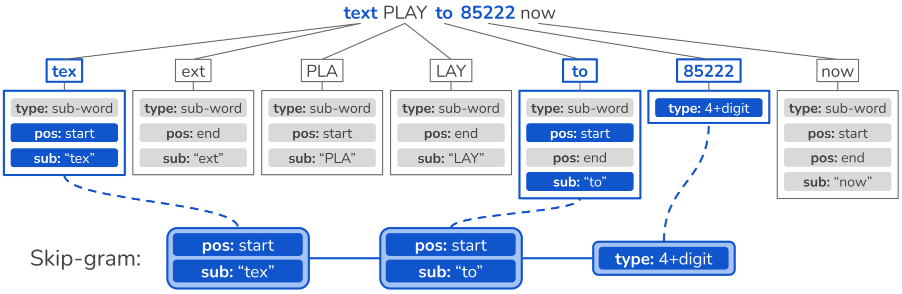

Figure 2: Example of a skip-gram matching the string "*text PLAY to 85222 now*".

- $\sup(g) = |\{s \in \mathcal{S} : \mathcal{Z}^{(g,s)} \neq \emptyset\}|$, the support of skip-gram pattern g, that is, the number of elements of $\mathcal{S}$ matched by g;

We now describe the mining algorithm in the following subsections. Sections 2.2.1 and 2.2.2 detail the two steps taken at each iteration of the algorithm and Section 2.2.3 describes the final pattern selection step.

2.2.1 Candidate set construction

At each iteration t, a set $\tilde{\mathcal{C}}^t$ of new candidate skip-gram patterns is constructed. In the first iteration ($t = 0$), this set is defined as

$$\tilde{\mathcal{C}}^0 = \{(\{\sigma\}) : \sigma \in \Sigma, \sup((\{\sigma\})) \geq \texttt{MIN\_SUP}\}, \tag{3}$$

that is, $\tilde{\mathcal{C}}^0$ is composed of all possible 1-skip-1-gram patterns that reach a minimum support parameter `MIN_SUP`.

From the second iteration and forward ($t > 0$), $\tilde{\mathcal{C}}^t$ is constructed by expanding patterns selected in the previous iteration. This is done by finding all matches between patterns selected in the previous iteration and sequences of $\mathcal{S}$, and then generating new patterns from the skip-gram respective to each match found.

For each match found, the generation of new patterns is done in two fashions: (*i*) adding new attributes found in the match either to the first or last attribute set of the pattern; and (*ii*) either appending or prepending singleton sets with attributes found around the match and, as such, increasing the size of the new pattern by 1.

All the newly generated patterns are filtered so that only those that reach the minimum support parameter `MIN_SUP` and that improve the GY-Score by at least `MIN_GY_DIFF` are kept in $\tilde{\mathcal{C}}^t$.

Formally, for $t > 0$, we can define:

$$\tilde{\mathcal{C}}^t = \bigcup_{s \in \mathcal{S}} \mathcal{E}^{(\mathcal{R}^{t-1}, s)}, \tag{4}$$

where $\mathcal{R}^{t-1}$ represents the set of patterns selected in the previous iteration and $\mathcal{E}^{(\mathcal{G},s)}$ can be described as the set of patterns generated as expansions of patterns in $\mathcal{G}$ for matches found in the sequence s, which can be defined as:

$$\begin{aligned}\mathcal{E}^{(\mathcal{G},s)} = \{g' : (g', g) \in &\bigcup_{a,b \in \{1,2\}} \mathcal{E}_{ab}^{(G,s)},\\ &GY(g', \gamma(s)) - GY(g, \gamma(s)) \geq \texttt{MGY},\\ &\sup(g') \geq \texttt{MIN\_SUP}\}.\end{aligned} \tag{5}$$

The sets given by each $\mathcal{E}_{ab}$ represent different types of expansions. Each element of such sets is a pair in the form (g', g), with g' being the newly generated skip-gram pattern and g, the original (from the match). The term `MGY` is an abbreviation for the `MIN_GY_DIFF` parameter.

Specifically, the sets represented by $\mathcal{E}_{11}^{(\mathcal{G},s)}$ and $\mathcal{E}_{12}^{(\mathcal{G},s)}$ are the expansions generated using the first method, by adding attributes to the attribute-sets on the extremes on the patterns:

$$\begin{aligned}\mathcal{E}_{11}^{(\mathcal{G},s)} = \{(g', g) : g' = &(g_1 \cup \{\sigma\}, ..., g_n),\\ &g = (g_1, ..., g_n) \in \mathcal{M}^{(G,s)},\\ &s = (a_1, ..., a_m),\\ &(j, ...) \in \mathcal{Z}^{(g,s)},\\ &\sigma \in a_j - g_1\}\end{aligned} \tag{6}$$

$$\begin{aligned}\mathcal{E}_{12}^{(\mathcal{G},s)} = \{(g', g) : g' = &(g_1, ..., g_n \cup \{\sigma\}),\\ &g = (g_1, ..., g_n) \in \mathcal{M}^{(G,s)},\\ &s = (a_1, ..., a_m),\\ &(..., j) \in \mathcal{Z}^{(g,s)},\\ &\sigma \in a_j - g_n\}\end{aligned} \tag{7}$$

On the other hand, $\mathcal{E}_{21}^{(\mathcal{G},s)}$ and $\mathcal{E}_{22}^{(\mathcal{G},s)}$ apply the second method of expansion, by prepending and appending elements to the skip-grams:

$$\begin{aligned}\mathcal{E}_{21}^{(G,s)} = \{(g', g) : g' = &(\{\sigma\}, g_1, ..., g_n),\\ &g = (g_1, ..., g_n) \in \mathcal{M}^{(G,s)},\\ &s = (a_1, ..., a_m),\\ &(j, ...) \in \mathcal{Z}^{(g,s)},\\ &\max\{1, j - k - 1\} \leq l < j,\\ &\sigma \in a_l\}\end{aligned} \tag{8}$$

$$\begin{aligned}\mathcal{E}_{22}^{(G,s)} = \{(g',g) : {} & g' = (g_1, ..., g_n, \{\sigma\}),\\ & g = (g_1, ..., g_n) \in \mathcal{M}^{(G,s)},\\ & s = (a_1, ..., a_m),\\ & (..., j) \in \mathcal{Z}^{(g,s)},\\ & j < l \leq \min\{m, j+k+1\},\\ & \sigma \in a_l\}\end{aligned} \tag{9}$$

, where k refers to the maximum number of skips for our the skip-gram model, which is referred by the parameter `SKIPGRAM_K` in the evaluation section.

The final set of candidate patterns $\mathcal{C}^t$ for the iteration t is then composed of the candidates from this and previous iterations that have not already been selected:

$$\mathcal{C}^t = \bigcup_{j=t-\texttt{CBS}+1}^{t} \tilde{\mathcal{C}}^j - \bigcup_{j=0}^{t-1} \mathcal{R}^j, \tag{10}$$

where `CBS` is an abbreviation for `CAND_BUFFER_SIZE`, which is a parameter that defines how many of the new candidate sets from previous iterations are remembered at the iteration t. This parameter gives candidates from the $\texttt{CBS} - 1$ previous iterations not yet selected a chance of being selected before they are "forgotten".

2.2.2 Pattern selection

Given the set of candidates $\mathcal{C}^t$, a set of new selected patterns $\mathcal{R}^t \subseteq \mathcal{C}^t$ is constructed by iterating over the sequences in $\mathcal{S}$ and selecting matching patterns with the best GY-Scores. Formally, the set $\mathcal{R}^t$ can be defined by

$$\mathcal{R}^t = \bigcup_{s \in \mathcal{S}} \text{Select}(\mathcal{C}^t, s), \tag{11}$$

where

$$\text{Select}(\mathcal{C}^t, s) = \underset{g \in \mathcal{M}^{(\mathcal{C}^t, s)}}{\arg\max}\, GY(g, \gamma(s)) \tag{12}$$

is either a set containing one of the patterns in $\mathcal{C}^t$ matching s with the highest GY-Score or the empty set if no matching pattern is found.

2.2.3 Final selection

After T iterations, a last step is performed in order to filter the selected patterns to contain only those that hit a minimum threshold value of information gain, given by a parameter `MIN_IG`, and then that filtered set is used to selected the best `FINAL_SELECT_K` matched patterns for each sequence. Thus, the final set $\mathcal{R}$ of selected skip-gram patterns is defined by:

$$\mathcal{R} = \bigcup_{s \in \mathcal{S}} \text{Best}(\mathcal{R}_F, s), \tag{13}$$

$$\mathcal{R}_F = \left\{ g \in \bigcup_{j=0}^{T-1} \mathcal{R}^j : IG(g) \leq \texttt{MIN\_IG} \right\}, \tag{14}$$

$$IG(g) = \sum_{y \in \mathcal{Y}} P(y|g) \cdot \ln(\frac{P(y|g)}{P(y)}), \tag{15}$$

where $\text{Best}(\mathcal{R}_F, s)$ is a set containing the top `FINAL_SELECT_K` elements from $\mathcal{M}^{(\mathcal{R}_F, s)}$ with the greatest GY-Scores; and $P(y)$ is the marginal probability that a sequence has label y and is estimated with:

$$P(y) = \frac{|\{s \in \mathcal{S} : \gamma(s) = y\}|}{|\mathcal{S}|}. \tag{16}$$

The number of iterations taken by the algorithm (i.e. T) is referred by the parameter `ITERATIONS` in the evaluation section.

2.3 Embedding Model

Once a set $\mathcal{R}$ of relevant skip-grams is found, it can then be used to build an embedding model. Our driving hypothesis is:

1. that the presence or absence of one or more of those patterns in a sequence greatly changes prior probability of labels;
2. that each pattern carries a very characteristic contextual baggage, in the sense that there is some level of statistical dependency between the occurrence of a pattern and of other attributes in a sequence.

As such, we propose an embedding function $v(s)$ that exploits both the information about the presence of patterns in the sequence s and the contextual information associated with each pattern taken into consideration.

We formalize our embedding model as follows. First we define a subset $\mathcal{R}_d$ of d skip-gram patterns from $\mathcal{R}$ to be used for the embedding. Then we define the function $v(s)$ in terms of elements of $\mathcal{R}_d$. The value of d is referred by the parameter `DIMENSIONS` in the evaluation section.

Let $\mathcal{R}_d \subseteq \mathcal{R}$ be a set containing the d most informative skip-gram patterns, that is: (*i*) $|\mathcal{R}_d| = d$, and (*ii*) $\forall r \in \mathcal{R}_d, \forall r' \in \mathcal{R} - \mathcal{R}_d, IG(r) \geq$

$IG(r')$. Each element of $\mathcal{R}_d$ will be associated with one dimension of the target vector space. For that, we select an arbitrary ordering of elements of $\mathcal{R}_d$, which we denote by the following indexing:

$$\mathcal{R}_d = \{r_1, r_2, ..., r_d\}. \tag{17}$$

Now, we define the value of $v(s)$ to be a d-dimensional vector as follows:

$$v(s) = \alpha \cdot u_1(s) + (1 - \alpha) \cdot u_2(s) \tag{18}$$

$$u_1(s) = [u_{11}(s), u_{12}(s), ..., u_{1d}(s)] \tag{19}$$

$$u_2(s) = [u_{21}(s), u_{22}(s), ..., u_{2d}(s)], \tag{20}$$

where:

- $u_1(s)$ is the vector accounting for skip-gram matches found in s. Each component $u_{1j}(s)$ is defined as:

$$u_{1j}(s) = \begin{cases} 1 & \text{if } r_j \in \mathcal{M}^{(\mathcal{R}_d, s)} \\ 0 & \text{otherwise.} \end{cases} \tag{21}$$

- $u_2(s)$ is the vector accounting for contextual information. Each component $u_{2j}(s)$ must be a measure that, in a way, reflects the statistical dependence between the pattern r_j and attributes found in s. For this work, we choose a very simple approach by taking the average of probabilities of r_j having a match with s given each relevant attribute of s. Thus, we define:

$$u_{2j}(s) = \frac{1}{|\mathcal{A}^s|} \sum_{\sigma \in \mathcal{A}^s} P(r_j | (\{\sigma\})), \tag{22}$$

  where $\mathcal{A}^s$ is the set of every attribute σ found in s in such that $\sup((\{\sigma\})) \leq$ `MIN_U2_SUP`, and `MIN_U2_SUP` is a parameter for filtering out rare attributes;

- $\alpha \in [0, 1]$ is a parameter for weighting the two types of information being aggregated in $v(s)$. We refer to this parameter by `U_ALPHA` in the evaluation section.

3 Evaluation

This section describes the evaluation of our proposed technique. We used the UCI SMS Spam Collection[1] (Almeida et al., 2011), which is a dataset comprised of 4,827 (86.6%) legitimate messages and 747 (13.4%) spam messages, with an average length of 16±12 tokens per message.

Parameter	Values used
Skip-gram mining parameters	
`SKIPGRAM_K`	6
`GY_ALPHA`	0.8
`MIN_SUP`	10
`MIN_GY_DIFF`	0.05
`CAND_BUFFER_SIZE`	6
`ITERATIONS`	6
`MIN_IG`	0.5
`FINAL_SELECT_K`	5
Embedding parameters	
`U_ALPHA`	0.0 0.1 ... 0.9 1.0
`MIN_U2_SUPPORT`	10 20 30
`DIMENSIONS`	50 100 189[2]

Table 1: Variations of parameters used for generating the embedding models.

We first conducted our evaluation by following the same experimental protocol used by the authors for their classification baselines and provide the analysis of our results in this in Sections 3.1 and 3.2. We used the train split to construct different variations of our embedding model and then evaluated three different machine learning methods for classification of spam and non-spam message. Table 1 displays the variation of parameters used for our experiments. The parameters related to the skip-gram mining step were fixed at single values after some empirical preliminary experimentation.

Later, we extended our evaluation by using different split configurations of the dataset in order to provide comparisons of our model with related work, which are presented in Section 3.2.1. Finally, Section 3.3 presents a visual evaluation of generated embeddings.

3.1 Selected patterns

The skip-gram pattern mining step applied to the training dataset resulted in 189 selected patterns. Table 2 displays the distribution of the types of patterns selected as well as the average information gain scores. We can note that longer patterns tend to be more informative but rarer at the same time. Although patterns with $n > 3$ were allowed (because `ITERATIONS` $=$ 6 and `CBS` $=$ 6), only patterns of length 1, 2 and 3 were selected.

Some interesting examples from the patterns with the highest information gain scores are listed

---

[2] We use 189 instead of 200 here because that was the total number of selected skip-gram patterns after the mining process.

Type	Proportion (%)	Avg. Info. Gain
6-skip-1-gram	44.44	1.07±0.41
6-skip-2-gram	51.86	1.42±0.39
6-skip-3-gram	3.70	1.77±0.23

Table 2: Distribution of types of skip-gram patterns selected.

in Table 3. The third column displays the estimated conditional probability that a message is a spam given that the pattern matches it, and the fourth column shows the proportion of the spam messages that are covered by the respective pattern. The pattern `[{(sub, "cal")}, {(type, 4+-digit)}]` showed to be a very recurrent one, representing about 32% of the spam messages in the training dataset.

3.2 Classification

We used three different types of classifiers to assess the effectiveness of our embedding model: Nearest Neighbors Classifier, Multilayer Perceptron (MLP) and Linear Support Vector Machine (LSVM). For the three methods, we used the implementation provided by the Scikit-learn library (Pedregosa et al., 2011)[3].

Table 4 summarizes the best result achieved for each classification method. The best baseline found by (Almeida et al., 2011) is also shown in the table for comparison purposes. The table has the following columns:

- *Method*: name of the method used for classification;
- *SC*: percentage of spam caught;
- *BH*: percentage of blocked hams, that is, legitimate messages that were classified as spam;
- *Acc*: accuracy of the classification in percentage unit;
- *MCC*: the Matthews Correlation Coefficient (Matthews, 1975), which is a good metric to be used for unbalanced datasets (as it is the case with the dataset used in this work). The table is sorted by this column in descending order.

The MLP model was constructed using two layers with 100 neurons in each layer and the logistic function for activation, and it was optimized using the Adam optimizer (Kingma and Ba, 2014). Our preliminary experiments showed that using two layers yielded better results than using just one; and increasing further the number of layers hurt the performance of the model. Each embedding parameter variation was executed 10 times and the average of the metrics were taken.

For the KNN model, we varied the number of neighbors used by 5, 10 and 15 and tested both uniform and distance-based weighting schemes. We found that using 5 neighbors and distance-based weighting yielded the best result for this type of classifier.

We used the default parameters provided by Scikit-learn for the LSVM model. It is worth mentioning that the reported baseline also uses linear support vector machines.

When compared with the baseline, the results in Table 4 show that our embedding technique combined with those classification methods displayed significant increases in the rate of detected spams while keeping very low increases in the rate of blocked hams (less than 0.5%).

Table 5 shows the embedding parameters respective to the results in Table 4. The values are very similar between different methods. It is a consensus for all evaluated classification techniques that low values for `U_ALPHA` tend to yield the best results for classification tasks, which suggests that giving more weight to contextual information associated with skip-gram patterns is more beneficial.

3.2.1 Comparison with related work

We also compared our approach with recent deep learning techniques found in the recent literature. Since they used different experimental protocols, we re-executed our experiments using different splits of the dataset in order to match the different protocols used by related works. Table 6 displays the performance of our best models and related works grouped by the experimental protocol and Table 7 shows the best embedding parameters found for each protocol. The comparison displayed in Table 6 shows that our embedding technique, combined with a Linear SVM, is competitive with the deep learning approaches proposed recently.

3.3 Visualization

We finalize our evaluation by providing a visual analysis of the embeddings generated with the parameters from Table 5. For that, we used UMAP (McInnes et al., 2018a,b) to map each embedding generated for the test split into a 2-dimensional space and plotted the results. Figure 3

---

[3] We used version 0.24.0 of the library

g	$IG(g)$	$P(y = \text{spam} \mid g)$	$P(g \mid y = \text{spam})$
`[{(sub, "cal")}, {(type, 4+-digit)}]`	1.951	1.0	0.319
`[{(sub, "cla")}, {(sub, "aim")}]`	1.951	1.0	0.156
`[{(sub, "pri")}, {(sub, "ize")}]`	1.951	1.0	0.109
`[{(sub, "tex")}, {(sub, "to")}, {(type, 4+-digit)}]`	1.951	1.0	0.088

Table 3: Examples of selected patterns.

Method	SC(%)	BH(%)	Acc(%)	MCC

KNN	88.41	0.38	98.15	0.917
LSVM	87.62	0.29	98.13	0.916
Baseline	83.10	0.18	97.64	0.893

Table 4: Summary of results for classification.

Method	U_ALPHA	MIN_U2_SUPPORT	DIMENSIONS
MLP	0.3	30	189
KNN	0.1	30	189
LSVM	0.2	10	189

Table 5: Best embedding parameters for classification.

provides the visualization for the embeddings generated for the MLP classifier from Table 4. We can see that the projection successfully separates most of the vectors representing spams from the non-spam ones. Interestingly, some small clusters can be observed for both classes, which could indicate that, inside each class, further categorization could be possible.

Table 7: Embedding parameters concerning the results found in Table 6.

In this work, we proposed an embedding technique for short texts based on skip-gram patterns and successfully evaluated our method in a dataset for SMS spam detection. Our experiments showed that our method, when combined with “shallow” classifiers, is competitive with recent deep learning approaches. Our results suggest that using this kind of pattern matching might be a good way to improve representations for textual classification tasks.

We see some interesting ways of improving the work presented in this paper, which can be taken as future work, such as:

- increasing our evaluation scope by adding more textual datasets (not limited to SMS) to our evaluation workload;
- investigating ways to integrate word vectors in our skip-gram matching mechanism in order to be able to capture patterns that do not necessarily have the same attributes but that are semantically similar;

- looking for alternative ways of defining the contextual component of the embedding function, namely, the function $u_2(s)$. In this work we chose to use a simple model that takes the average of conditional probabilities - more robust predictive models could be used instead.

Hierarchical Task Learning from Language Instructions with Unified Transformers and Self-Monitoring

Yichi Zhang **Joyce Y. Chai**

University of Michigan
Ann Arbor, MI, USA
`{zhangyic, chaijy}@umich.edu`

Abstract

Despite recent progress, learning new tasks through language instructions remains an extremely challenging problem. On the ALFRED benchmark for task learning, the published state-of-the-art system only achieves a task success rate of less than 10% in an unseen environment, compared to the human performance of over 90%. To address this issue, this paper takes a closer look at task learning. In a departure from a widely applied end-to-end architecture, we decomposed task learning into three sub-problems: sub-goal planning, scene navigation, and object manipulation; and developed a model **HiTUT**[1] (stands for **Hi**erarchical **T**asks via **U**nified **T**ransformers) that addresses each sub-problem in a unified manner to learn a hierarchical task structure. On the ALFRED benchmark, HiTUT has achieved the best performance with a remarkably higher generalization ability. In the unseen environment, HiTUT achieves over 160% performance gain in success rate compared to the previous state of the art. The explicit representation of task structures also enables an in-depth understanding of the nature of the problem and the ability of the agent, which provides insight for future benchmark development and evaluation.

1 Introduction

As physical agents (e.g., robots) start to emerge as our assistants and partners, it has become increasingly important to empower these agents with an ability to learn new tasks by following human language instructions. Many benchmarks have been developed to study the agent's ability to follow natural language instructions in various domains including navigation (Anderson et al., 2018; Chen et al., 2019), object manipulation (Misra et al., 2017; Zhu et al., 2017) and embodied reasoning (Das et al., 2018a; Gordon et al., 2018). Despite recent progress, learning new tasks through language instructions remains an extremely challenging problem as it touches upon almost every aspect of AI from perception, reasoning, to planning and actions. For example, on the ALFRED benchmark for task learning (Shridhar et al., 2020), the state-of-the-art system only achieves less than 10% task success rate in an unseen environment (Singh et al., 2020), compared to the human performance of over 90%. Most previous works apply an end-to-end neural architecture (Shridhar et al., 2020; Singh et al., 2020; Storks et al., 2021) which attempt to map language instructions and visual inputs directly to actions. While striving to top the leader board for end task performance, these models are opaque, making it difficult to understand the nature of the problem and the ability of the agent.

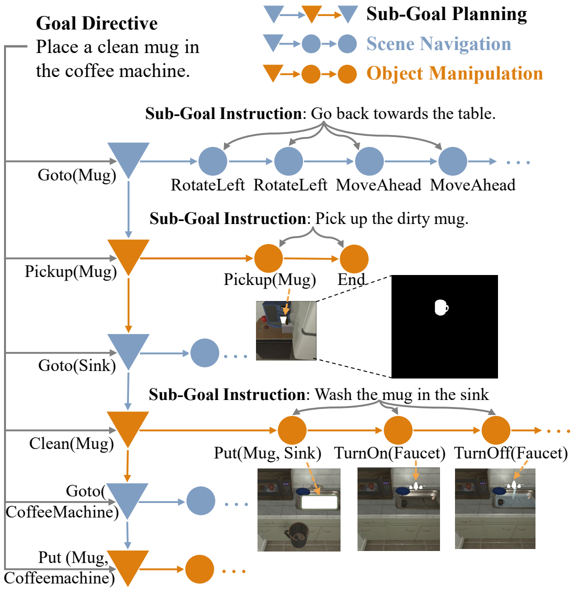

Figure 1: An example task in ALFRED.

To address this issue, this paper takes a closer look at task learning using the ALFRED benchmark. In a departure from an end-to-end ar-

chitecture, we have developed an approach to learn the hierarchical structure of task compositions from language instructions. As shown in Figure 1, a high-level goal directive ("place a clean mug in the coffee machine") can be decomposed to a sequence of sub-goals. Some subgoals involve navigation in space (e.g., `Goto(Mug)`, `Goto(Sink)`) and others require manipulation of objects (e.g., `Pickup(Mug)`, `Clean(Mug)`). These sub-goals can be further decomposed into navigation actions such as `RotateLeft` and `MoveAhead`, and manipulation actions such as `Put(Mug, Sink)`, `TurnOn(Faucet)`. In fact, such hierarchical structure is similar to Hierarchical Task Network (HTN) widely used in AI planning (Erol et al., 1994). While this hierarchical structure is explicit and has several advantages in planning and making models transparent, how to effectively learn such structure remains a key challenge.

Motivated by recent work in multi-task learning (Liu et al., 2019a), we decomposed task learning in ALFRED into three sub-problems: sub-goal planning, scene navigation, and object manipulation; and developed a model called **HiTUT** (stands for **Hi**erarchical **T**asks via **U**nified **T**ransformers) that addresses each sub-problem in a unified manner to learn a hierarchical task structure. On the ALFRED benchmark, HiTUT has achieved the best performance with a remarkably higher generalization ability. In the unseen environment, HiTUT achieves over 160% performance gain in success rate compared to the previous state of the art.

The contributions of this work lie in the following two aspects.

An explainable model achieving the new state-of-the-art performance. By explicitly modeling a hierarchical structure, our model offers explainability and allows the agent to monitor its own behaviors during task execution (e.g., what sub-goals are completed and what to accomplish next). When a failed attempt occurs, the agent can backtrack to previous sub-goals for alternative plans to execute. This ability of self-monitoring and backtracking offers flexibility to dynamically update sub-goal planning at the inference time to cope with exceptions and new situations. It has led to a significantly higher generalization ability in unseen environments.

A de-composable platform to support more in-depth evaluation and analysis. The decomposition of task learning into sub-problems not only makes it easier for an agent to learn, but also provides a tool for an in-depth analysis of task complexity and the agent's ability. For example, one of our observations from the ALFRED benchmark is that the agent's inability to navigate is a major bottleneck in task completion. Navigation actions are harder to learn than sub-goal planning and manipulation actions. For manipulation actions, the agent can learn action types and action arguments predominantly based on sub-goals and the history of actions, while language instructions do not contribute significantly to learning. The success of manipulation actions also largely depends on the agent's ability in detecting and grounding action arguments to corresponding objects in the environment. These findings allow a better understanding of the nature of the tasks in ALFRED and provide insight to address future opportunities and challenges in task learning.

2 Related Work

Recent years have seen an increasing amount of work on in the intersection of language, vision and robotics. One line of work particularly focuses on teaching robots new tasks through demonstration and instruction (Rybski et al., 2007; Mohseni-Kabir et al., 2018). Originated in the robotics community, learning from demonstration (LfD) (Thomaz and Cakmak, 2009; Argall et al., 2009) enables robots to learn a mapping from world states to robots' manipulations based on human's demonstration of desired robot behaviors. More recent work has also explored the use of natural language and dialogue together with demonstration to teach robots new actions (Mohan and Laird, 2014; Scheutz et al., 2017; Liu et al., 2016; She and Chai, 2017; Chai et al., 2018; Gluck and Laird, 2018).

To facilitate task learning from natural language instructions, several benchmarks using simulated physical environment have been made available (Anderson et al., 2018; Misra et al., 2018; Blukis et al., 2019; Shridhar et al., 2020). In particular, the vision and language navigation (VLN) benchmark (Anderson et al., 2018) has received a lot of attention. Many models have been developed, such as the Speaker-Follower model (Fried et al., 2018), the Self-Monitoring Navigation Agent(Ma et al., 2019a; Ke et al., 2019), the Regretful Agent (Ma et al., 2019b), and the environment drop-out model (Tan et al., 2019). The VLN benchmark is further extended to study the fidelity of instruction following (Jain et al., 2019) and examined to understand the bias of the benchmark (Zhang et al., 2020). Beyond navigation, there are also benchmarks that additionally incorporate object manipulation to broaden research on vision and language reasoning, such as embodied question answering (Das et al., 2018a; Gordon et al., 2018). The work closest to ours is the Neural Modular Control (NMC) (Das et al., 2018b), which also decomposes high-level tasks into sub-tasks and addresses each sub-task accordingly. However, self-monitoring and backtracking between sub-tasks is not explored in NMC.

The ALFRED benchmark consists of high-level goal directives such as *"place a clean mug in the coffee machine"* and low level language instructions such as *"rinse the mug in the sink"* and *"turn right and walk to the coffee machine"* to accomplish these goals. In addition to language instructions, it also comes with expert demonstrations of task execution in an interactive visual environment. We choose this dataset because its unique challenges are closer to the real world, which require the agent to not only learn to ground language to visual perception but also learn to plan for and execute actions for both navigation and object manipulation.

3 Hierarchical Tasks via Unified Transformers

As discussed in Section 1, task structures are inherently hierarchical, which compose of goals and sub-goals. Different sub-goals involve tasks of different nature. For example, navigation focuses on path planning and movement trajectories, while manipulation concerns more about interactions with concrete objects. Instead of end-to-end mapping from language instructions to primitive actions (Shridhar et al., 2020; Singh et al., 2020; Storks et al., 2021), we decomposed task learning into three separate but connected sub-problems: sub-goal planning, scene navigation, and object manipulation, and developed a model called **HiTUT** (stands for **Hi**erarchical **T**asks via **U**nified **T**ransformers) to tie these sub-problems together to form a hierarchical task structure.

3.1 Task Decomposition

We first introduce some notations to describe the task and the model. There are three types of information:

- Language ($\mathcal{L}$). We use G to denote a high-level goal directive, e.g., "place a clean mug in the coffee machine" and I_i to refer to a specific low-level language instruction.
- Vision ($\mathcal{V}$). It captures the visual representation of the environment.
- Predicates ($\mathcal{P}$). Symbolic representations are defined to capture three types of predicates: sub-goals (sg), navigation actions (a^n), and manipulation actions (a^m). Each sg has two parts (sg^{type}, sg^{arg}) where sg^{type} is the *type* (e.g., `Goto`) and sg^{arg} is the *argument* (e.g., `Knife`). Each a^n specifies a type (a^{n_type}) of action, from {`RotateLeft`, `RotateRight`, `MoveAhead`, `LookUp`, `LookDown`}. Each a^m has also two parts (a^{m_type}, a^{m_arg}) where a^{m_type} is the action type (e.g., `TurnOn`); a^{m_arg} is the action argument (e.g., `Faucet`).

Sub-Goal Planning. Sub-goal planning acquires a sequence of sub-goals $sg_1, \cdots, sg_n$ to accomplish the high-level goal G. We predict the type sg_i^{type} and argument sg_i^{arg} separately to avoid the combinatorial expansion of the output space. Previous work (Jansen, 2020) models sub-goal planning merely from high-level goal directives without visual grounding. These plans are fixed and thus not robust to potential failures during execution and variations of the visual environment. To overcome these drawbacks, our sub-goal planning is done on the fly after the previous sub-goal is executed in the environment. More specifically, our sub-goal planning objective is to learn a model (M_{sg}) that takes the visual observation at the current step (v_t), the high-level goal directive (G), and a complete sub-goal history prior to the current step ($sg_{<i}$) to predict the current sub-goal as follows:

$$sg_i \triangleq (sg_i^{type}, sg_i^{arg}) = M_{sg}(v_t, G, sg_{<i})$$

The predicted sub-goals serve as a bridge between the high-level goal and the low-level predictions of navigation actions and/or manipulation actions.

Scene Navigation. Navigation sub-goals only require predictions for the types of navigation actions. The objective is to learn a model for navigation (M_n) which takes the current visual observation (v_t), current sub-goal (sg_i), language instruction (I_i), and the navigation action history up to the current step ($a^n_{<j}$) to predict the next navigation action:

$$a_j^n \triangleq a_j^{n\_type} = M_n(v_t, I_i, sg_i, a^n_{<j})$$

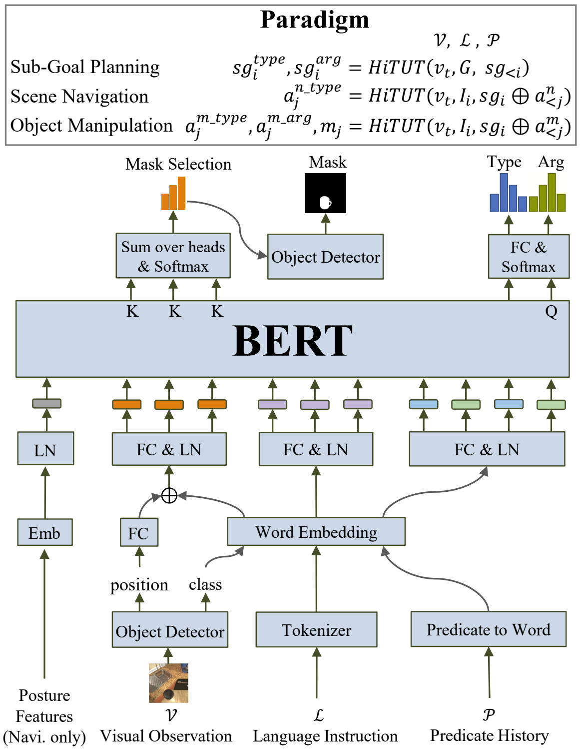

Figure 2: The structure of HiTUT.

Object Manipulation. For a manipulation sub-goal, in addition to the type and argument of the action, the model (M_m) also needs to generate a segmentation mask (m_j) on the current visual observation to indicate which object to interact with (i.e., which object the argument is grounded to):

$$\begin{aligned}(a_j^m, m_j) &\triangleq (a_j^{m\_type}, a_j^{m\_arg}, m_j)\\ &= M_m(v_t, I_i, sg_i, a_{<j}^m)\end{aligned}$$

The mask prediction is crucial because the action will not be successfully executed with an incorrect grounding even if a_j^m is correctly predicted.

As described above, although the context of the three sub-problems varies, each model has similar input components from the space of $\langle \mathcal{V}, \mathcal{L}, \mathcal{P} \rangle$. This similarity inspires us to design an unified model to solve three sub-problems simultaneously.

3.2 Unified Transformers

We leverage the effective self-attention based model (Vaswani et al., 2017) to capture the correspondence of different input sources as shown in Figure 2. We first project the input from different modalities into the language embedding space, and adopt a transformer to integrate the information together. Multiple prediction heads are constructed on top of the transformer encoder to make predictions for the sub-goal type and argument, the action type and argument, and object masks respectively. As the three sub-problems share the similar input form, we solve them all together using a unified model based on multi-task learning (Liu et al., 2019a).

Our model differs from previous works (Shridhar et al., 2020; Singh et al., 2020) in the following aspects. First, we do not apply recurrent state transitions, but feed the prediction history as the input to each subsequent prediction. This may help better capture correlations between predicates and other modalities. Second, we do not use dense visual features from the scene, but rather the object detection results. By doing this, we map different modalities to the word embedding space before feeding them into the transformer encoder, thus taking advantage of the pre-trained language models. Third, we use a predicate embedding to share linguistic knowledge between predicate symbols and word embeddings.

Predicate Embedding. We use the term predicates to refer to symbolic representations including sub-goal types, action types, and their arguments. We map symbols to their corresponding natural language phrases (e.g., `AppleSliced` is mapped to *a sliced apple*). We then tokenize and embed the tokens using word embeddings, and take the sum of the embeddings to obtain the representation of each predicate.

Vision Encoding. We use a pre-trained object detector (Mask R-CNN (He et al., 2017)) to encode visual information. Instead of dense features, we simply use the detection results (class labels, bounding box coordinates and confidence scores) as visual features. Specifically, we use the top K detected objects with a confidence score higher than 0.4 to form the visual features. The object class labels share the same space with object arguments, thus can be embedded into the same space. The position information of an object is encoded by a 7-dimensional vector consisting of its coordinates, width and height of the bounding box and its confidential score. This vector is first mapped to the same dimension as word embeddings by a liner transformation, then added to the class embedding to form the final object representation.

Object Grounding. HiTUT does not generate masks by itself. Instead it chooses an object from the K input objects and uses the corresponding mask generated by the object detector. This method makes use of the strong prior learned from object detection pre-training, so the model can focus on

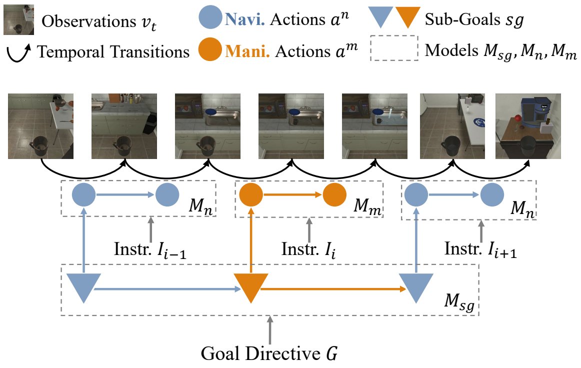

Figure 3: Overview of HiTUT where unified transformers for sub-programs are integrated together .

learning the grounding task. A drawback is that the object detector cannot be improved during training, and the performance of the detector determines the upper bound of our model's grounding ability. We leave the exploration of more robust grounding method for future work.

Posture Feature We use an additional posture feature to assist scene navigation, which includes the agent's rotation (N, S, E, W) and its angle of sight horizon (discretized by 15 degree). The positions are embedded and summed up to form the posture feature representation. The agent maintains its own posture in the form of a relative change to its initial posture instead of the absolute posture in the environment, thus avoid using additional sensory data.

3.3 Self-Monitoring and Backtracking

These unified transformers trained for sub-problems are integrated together as shown in Figure 3. One important advantage of intermediate sub-goal representations is to facilitate self-monitoring and backtracking which allows the agent to dynamically adjust the plan to cope with failures during execution. As shown in Section 4, this feature brings out the most remarkable performance gain compared to the state of the art.

Self-Monitoring. The world is full of uncertainties, and mistakes are inevitable. Based on the learned model, the agent should be able to monitor its own behaviors and dynamically update its plan when the situation arises. Our explicit representation of sub-goals allows the agent to self-check whether some sub-goals are accomplished. Particularly for manipulation sub-goals, it is feasible for the agent to detect their failures by simply monitoring whether all the manipulation actions are successfully executed. For example, `Clean(Mug)` cannot succeed if any of the actions along the path `Put(Mug, Sink)`, `TurnOn(Facuet)`, `TurnOff(Facuet)`, `Pickup(Mug)` fail. When the agent detects the failure of a subgoal, for example, as shown in Figure 4 the manipulation sub-goal `Pickup(Mug)` fails, it can reason about whether the previous sub-goal (i.e., `Goto(Mug)`) is successfully achieved.

	Train	Validation		Test	
		Seen	Unseen	Seen	Unseen
#Scenes	108	88	4	107	8
#Demonstrations	6,574	251	255	483	488
#Annotations	21,023	820	821	1,533	1,529
#Sub-goals	162k	6.4k	6.0k	-	-
#Navi. Actions	983k	39k	35k	-	-
#Mani. Actions	209k	8.3k	8.1k	-	-

Table 1: Statistics of data distribution in ALFRED. The number of annotations is equivalent to the number of tasks in each split.

Backtracking. In classical AI, backtracking is the technique to go back and try an alternative path that can potentially lead to the goal. As shown in Figure 4, when `Pickup(Mug)` fails, the agent backtracks to `Goto(Mug)` and tries a different sequence of primitive actions to accomplish this sub-goal. In ALFRED, only based on the visual information without other sensory information (e.g., only observing a mug without knowing how far it is), is it difficult to check whether a navigation sub-goal is successfully achieved (e.g. whether a `Mug` is reachable). So every time after trying a different path for `Goto(Mug)`, the agent will check whether the subsequent manipulation action `Pickup(Mug)` is successful. If it's successful, the agent will move on to the next sub-goal; otherwise the agent will continue to backtrack until a limit on the maximum number of attempts is reached. Our explicit representation of sub-goals makes this backtracking possible and has led to a significant performance gain in unseen environments.

4 Experiments

4.1 Setting and Implementation

Dataset. We follow the train/validation/tests data partition proposed in ALFRED, where validation and test sets are further split into *seen* and *unseen* based on whether the scene is shown to the model during training. Each sub-goal planning step or a primitive prediction step forms a data instance for

the corresponding sub-problem. The number of data instances are shown in Table 1.

Pre-training. We employ the pre-training followed by fine-tuning paradigm for both the object detector and the main model. For the object detector, we use a Mask R-CNN (He et al., 2017) model pre-trained on MSCOCO (Lin et al., 2014), and fine-tune it on 50K images collected by replaying the expert trajectories in the ALFRED train split. As we observe that the model struggles on detecting small objects together with large receptacles, we train two networks to detect movable objects and big receptacles separately. We use the pre-trained RoBERTa (Liu et al., 2019b) model to initialize the transformer encoder.

Training. We perform imitation learning (supervised learning) on the expert demonstrations. The ground-truth labels of sub-goals and primitive actions are obtained from the metadata. Different input and output labels are organized for each sub-problem respectively as described in Section 3. We use the mask proposal that overlaps the most with the ground truth mask as the mask selection label if the intersection-of-union is above 50%. If there is no valid mask proposals, the label is assigned to 0 as an indicator of non-valid grounding. We optimize the cross-entropy loss between model predictions and the ground truth. We follow the multi-task training schema in Liu et al. (2019a) where for each iteration, a batch is randomly sampled among all the sub-problems, and the model is updated according to the corresponding objective. More details are in Appendix.

Evaluation Metrics. ALFRED leverages an interactive evaluation in the AI2-THOR environment (Kolve et al., 2017). A task is considered successful if all the goal conditions (e.g. the target object is placed on a correct receptacle and in a requested state such as heated or cleaned etc.) are met. Three measures are used: (1) success rate (the ratio of successfully completed tasks), (2) goal-condition rate (ratio of completed goal conditions), and (3) a weight version of these two rates which takes into account of the length difference between the predicted action sequence and the expert demonstrated action sequence (Shridhar et al., 2020).

Baselines. We compare HiTUT to: (1) Seq2Seq - an LSTM-based baseline model with progress monitoring proposed in Shridhar et al. (2020); (2) HAM - a hierarchical attention model over enriched visual inputs (Nguyen and Okatani, 2020), and (3) MOCA - a modular approach which also uses a Mask R-CNN for mask generation (Singh et al., 2020) and achieved previous state-of-the-art performance.

	Model	*Pick*	*Put*	*Cool*	*Heat*	*Clean*	*Slice*	*Toggle*	Avg.

4.2 Evaluation Results

4.2.1 Overall Performance of HiTUT

We first evaluate the overall performance of the proposed framework as shown in Table 2. On the testing data reported by the leader board, in seen environments, HiTUT achieves comparable performance as MOCA. However in unseen environments, HiTUT outperforms MOCA by over 160% on success rate. This demonstrates our hierarchical task modeling approach has higher generalization ability compared to end-to-end models. Self-monitoring and backtracking enabled by hierarchical task structures allows the agent to better handle new situations. Remarkably, only based on high-level goal directives (i.e., *HiTUT (G Only)*) without using any sub-goal instructions, is HiTUT able to obtain a success rate of 11% in unseen environment, achieving 110% performance gain compared to MOCA. This result indicates that HiTUT can learn prior task knowledge from the hierarchical modeling process and apply that directly in new environment with some success. Nevertheless, our results are far from human performance and there is still huge room for future improvement.

To have a better understanding of the problem, we also conduct evaluations on sub-goals. The agent is positioned at the starting point of each sub-goal by following the expert demonstration and the success rate of accomplishing the sub-goal is measured. HiTUT predicts first a symbolic sub-goal representation and then the action sequence to complete the sub-goal. As shown in Table 3, HiTUT outperforms previous models on almost all of the manipulation sub-goals by a large margin. The performance gain is particularly significant in unseen environment, which demonstrates the advantage of our explicit hierarchical task modeling in low-level action planning.

Unseen	22	32	31	45	53	60	63	65

Table 5: Success rate of the navigation sub-goal `Goto` with backtracking .

4.2.2 The Role of Backtracking

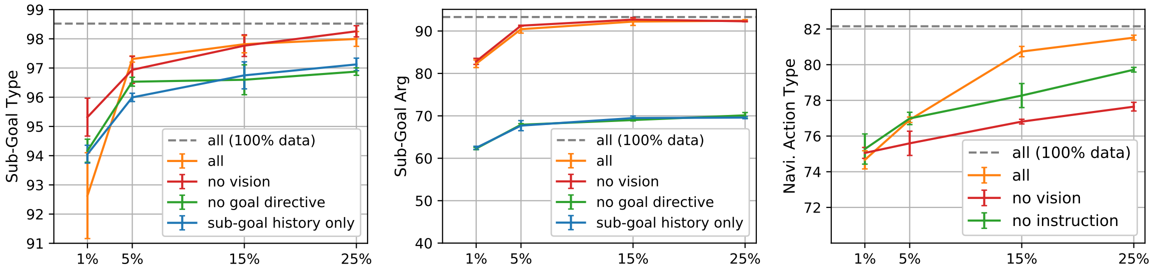
We conduct experiments to better understand the role of self-monitoring and backtracking. We repeat the task-solving evaluation with different limits on the allowed maximum number of backtracking. The agent only stops when the model predicts to stop (i.e., predicts `End`) or it reaches the backtracking limit. As shown in Table 4, as the limit increases, the task/goal-condition success rate increases accordingly. One thing notable is that the gap between success rates (weighted and unweighted) become larger when more backtrack attempts are allowed. This is within our expectation because backtracking deviates from instruction following navigation to goal-oriented exploration, which usually takes more steps than the expert demonstration.

Since backtracking is particularly targeted to navigation sub-goals `Goto` (see Section 3.3), we further examine the role of number of re-tries (i.e. backtracks) in completing the sub-goal. As shown in Table 5, HiTUT reaches more targets when given more opportunities to backtrack. The backtracking is most beneficial in unseen environment.

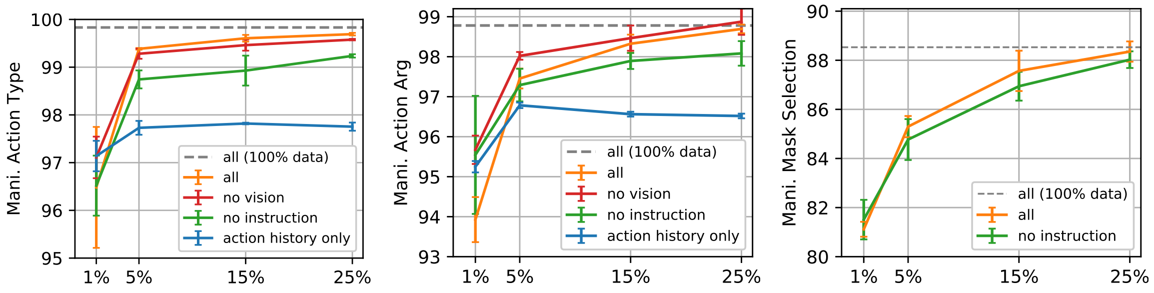
4.2.3 Complexity of Tasks

Task decomposition provides a tool to enable better understanding of task complexity and agent's ability. To do that, we replace different part of model predictions by the corresponding oracle sub-goals, actions, or masks, as shown in Table 6.

Using oracle sub-goals improves the success rate for 2%-6% (line SG), showing sub-goal planning is a relatively easy problem and the agent can perform reasonably well. After using the oracle



(a) Sub-Goal Type (b) Sub-Goal Argument (c) Navigation Action Type



(d) Manipulation Action Type (e) Manipulation Action Argument (f) Manipulation Mask Selection

Figure 5: Step-by-step prediction accuracies given the golden sub-goal/action history w.r.t. the proportion of training data on the unseen validation set. Each solid line corresponds to a specific input configuration. Dashed lines are the scores obtained using 100% of training data.

Method	Valid Seen		Valid Unseen	
	Success	Goal-Cond	Success	Goal-Cond
HiTUT	25.2 (12.2)	34.8 (18.5)	12.4 (6.8)	23.7 (12.0)
+ Oracle				
SG	29.0 (15.6)	39.1 (21.3)	14.0 (7.6)	25.6 (12.7)
N	75.0 (72.7)	78.0 (77.4)	57.9 (60.0)	67.7 (65.2)
SG+N	79.2 (77.8)	84.0 (81.3)	64.2 (64.2)	72.0 (68.1)
SG+N+M	89.0 (100)	90.0 (100)	80.5 (100)	83.7 (100)
SG+N+GR	99.3 (99.0)	99.4 (99.1)	99.4 (99.3)	99.6 (99.6)

Table 6: Success rates of HiTUT with different parts of predictions replaced by oracle operations with expert demonstrations. N, M, SG and GR denote oracle navigation actions, manipulation actions, sub-goals and object grounding (i.e., mask generation) respectively.

navigation actions, the seen and unseen success rates are boosted by an absolute gain of 50% and 46% respectively (line N), indicating that navigating to reach target objects is a particularly hard problem and the agent performs poorly. When oracle sub-goals, navigation actions, and manipulation actions (only symbolic representations) are given (line SG+N+M), the task success is bounded by the performance of the pre-trained object mask generator (i.e., visual grounding of the object). When oracle object masks are given together with oracle sub-goals and navigation actions (line SG+N+GR) and the agent only needs to predict symbolic representation of manipulation actions, the performance is near perfect. These last two lines indicate that predicting the type and the argument of a manipulation action is a rather simple problem in the ALFRED benchmark while grounding action arguments to the visual environment remains a challenging task.

We further examine the complexity of learning to solve sub-problems by evaluating the next-step prediction accuracy given the golden history under different conditions as shown in Figure 5. The models are trained and evaluated with different combinations of input and different amount of training data. We observe that excluding the visual input does not hurt performance for sub-goal prediction and manipulation action prediction (shown by a,b,d,e). This indicates that in ALFRED, pure symbolic planning is often independent from visual understanding, which is consistent with the findings in (Shridhar et al., 2020). However, this could be an oversimplification brought by the bias in the dataset rather than a true reflection of the physical world. For example, next action prediction can be made by remembering the correlation of predicates instead of reasoning over vision and language, due to the lack of diversity of the task environments. Removing language instructions causes a minimal performance drop of 1%-2% on action prediction tasks, which brings up the question about the usefulness of language instructions in this benchmark. Furthermore, the prediction accuracy is above 90% and 98% with only 5% training data for sub-goal and manipulation planning respectively, while the navigation accuracy is only 82% given all the data. This again supports the finding that planning and performing navigation actions is a much harder problem than sub-goal planning and manipulation actions in ALFRED.

5 Discussion and Conclusion

This paper presents a hierarchical task learning approach that achieves the new state-of-the-art performance on the ALFRED benchmark. The task decomposition and explicit representation of subgoals enable a better understanding of the problem space as well as the current strengths and limitations. Our empirical results and analysis have shown several directions to pursue in the future. First, we need to develop more advanced component technologies integral to task learning, e.g., more advanced navigation modules through either more effective structures (Hong et al., 2020) or richer perceptions (Shen et al., 2019) to solve navigation bottleneck. We need to develop better representations and more robust and adaptive learning algorithms to support self-monitoring and backtracking. We also need to seek ways to improve visual grounding, which is crucial to both navigation and manipulation.

Second, we should also take a closer look at the construction and objective of existing benchmarks. How a benchmark is created and how truthfully it reflects the complexity of the physical world would impact the scalability and reliability of the approach in the real world. As for the objective, there is a distinction between *learning to perform tasks* and *learning to follow language instructions*. If the objective is the former, the agent should be measured by the ability to learn to accomplish high-level goal directives without being given specific language instructions at the inference time. If the objective is the latter, then the agent should be measured by how faithful it follows human instructions aside from achieving the goals, similar to (Jain et al., 2019). We need to be clear about the objectives and develop evaluation metrics accordingly.

Finally, when humans perform poorly in a complex task, we have the ability to diagnose the problem and put more energy on learning the difficult part. Physical agents should also have similar abilities. In task learning, on the one hand, the agent should be able to master simple sub-tasks from a few data instances, e.g., through a few turns of interactions with humans (Karamcheti et al., 2020). On the other hand, it should be aware of the bottleneck of its learning progress and proactively request for help when problems are encountered either during learning or during deployment (She and Chai, 2017). How to effectively design interactive and active learning algorithms for the agent to learn complex and compositional tasks remains an important open research question.

Appendix

A Additional Training Details

We use the RoBERTa (Liu et al., 2019b) implementation from Huggingface (Wolf et al., 2019). The model is fine-tuned for 10 epochs with the Adam (Kingma and Ba, 2015) optimizer on the ALFRED training set. The learning rate warms up over the first half of the first epoch to a peak value of 1e-5, and then linearly decayed. The model achieving the highest navigation action prediction accuracy on the validation seen set is selected for evaluation. All the models are trained on one NVIDIA V100 16GB GPU.

B Additional Evaluation Details

We follow the evaluation setting in the ALFRED benchmark[2]. For each episode, the agent is given a task, which is composed of a goal directive G and several sub-goal instructions. The agent needs to sequentially perform actions to achieve the goal based on the visual observations of RGB image only. This progress ends if the agent predicts an *End* action (an *End* sub-goal for HiTUT), which is made after up to 10 failed interaction attempts or reaching the maximum step limitation. For HiTUT, there is also a maximum number of backtracking attempts, and the model will be forced to stop if the budget runs out. The maximum number of backtracking is 8 in all of our experiments without explicitly mentioning the backtracking number. We also leverage two techniques to reduce the interaction attempt failures. We use the obstruction detection trick proposed in Singh et al. (2020) to avoid failures caused by repeated tries of moving toward obstructions. We propose a self-monitoring approach to check the validity of manipulation actions. If no mask is selected or a predicted action argument is not consistent with the class prediction from Mask R-CNN for the selected object, the manipulation action is decided as failed and the agent performs a backtrack without trying to execute the action. Note that in Table 4, we remove the interaction attempt constraint when comparing the effect of different allowed maximum backtracking numbers, thus the results of $\#BT = 8$ is slightly higher than those shown in Table 2.

Task-Type	MOCA		HiTUT	
	Seen	Unseen	Seen	Unseen
Pick & Place	29.5	5.0	**35.9**	**26.0**
Cool & Place	**26.1**	0.7	19.0	**4.6**
Stack & Place	5.2	1.8	**12.2**	**7.3**
Heat & Place	**15.8**	2.7	14.0	**11.9**
Clean & Place	22.3	2.4	**50.0**	**21.2**
Examine & Place	20.2	**13.2**	**26.6**	8.1
Pick Two & Place	11.2	1.1	**17.7**	**12.4**
Average	18.6	3.8	**25.2**	**12.4**

Table 7: Success rates across 7 task types on the validation sets. Highest values per fold are **bold**.

Model	#Backtracking	Seen SR	Unseen SR
RoBERTa	no	10.5	5.2
Scratch	no	7.9	2.8
RoBERTa	4	23.1	12.9
Scratch	4	18.1	10.2
RoBERTa	8	27.2	16.2
Scratch	8	26.8	14.0
MOCA	-	19.15	3.78

Table 8: The validation success rates for models pretrained and trained from scratch with different allowed maximum number of backtrackings.

C Additional Results

A detailed per-task performance comparison of HiTUT and MOCA is shown in Table 7. As the comparison might be unfair since HiTUT benefits from model pre-training, we also conduct an ablation study to show the effectiveness of pretraining. In Table 8, we compare the fine-tuned RoBERTa model to a Transformer with the same size trained from scratch to show the role of the RoBERTa pretraining.We can see that RoBERTa consistently improves the performance over training from scratch both w/o and w/ backtracking with an absolute gain between 0.4% and 5% on task success rate. Notably, Scratch with 4 or 8 backtrackings still outperform MOCA by a large margin in terms of the unseen success rate.

Marked Attribute Bias in Natural Language Inference

Hillary Dawkins
University of Guelph, Ontario, Canada
Vector Institute, Toronto, Ontario, Canada
`hdawkins@uoguelph.ca`

Abstract

Reporting and providing test sets for harmful bias in NLP applications is essential for building a robust understanding of the current problem. We present a new observation of gender bias in a downstream NLP application: marked attribute bias in natural language inference. Bias in downstream applications can stem from training data, word embeddings, or be amplified by the model in use. However, focusing on biased word embeddings is potentially the most impactful first step due to their universal nature. Here we seek to understand how the intrinsic properties of word embeddings contribute to this observed marked attribute effect, and whether current post-processing methods address the bias successfully. An investigation of the current debiasing landscape reveals two open problems: none of the current debiased embeddings mitigate the marked attribute error, and none of the intrinsic bias measures are predictive of the marked attribute effect. By noticing that a new type of intrinsic bias measure correlates meaningfully with the marked attribute effect, we propose a new post-processing debiasing scheme for static word embeddings. The proposed method applied to existing embeddings achieves new best results on the marked attribute bias test set. See https://github.com/hillary-dawkins/MAB.

1 Introduction

Pre-trained distributed representations of words (a.k.a. word embeddings) are ubiquitous tools in natural language processing (NLP). Their utility is owing to the remarkable success in mapping semantic and syntactic relationships among words to linear relationships among real-valued vectors. For instance, analogy generation using vector addition on word embeddings (e.g. Tokyo is to Japan as Paris is to France) was taken to be an early measure of word embedding quality. In all kinds of related tasks, the vector space is known to encode semantic meaning surprisingly well (Pennington et al., 2014; Mikolov et al., 2013b,c). However, harmful gender-biased properties of word embeddings are also known to exist. Later is was observed that the same analogy generation property that produced the celebrated "man is to king as woman is to queen" analogy would also predict "man is to programmer as woman is to homemaker" (Bolukbasi et al., 2016). This observation sparked interest in developing debiased word embeddings.

Post-processing debiasing schemes are usually motivated by recognizing some intrinsic measure of bias in the embedding space, and then attempting to reduce that intrinsic bias. Early work (2016-2017) focused on the idea of a "gender direction" vector within the embedding space, loosely defined as the difference vector between female and male attribute words. It was noted that any non-zero projection of a word onto the gender direction (termed direct bias) implied that the word was more related to one gender over another. In the case of ideally gender-neutral words (e.g. doctor, nurse, programmer, homemaker), this was viewed as an undesirable property. The first debiasing methods, Hard Debias (Bolukbasi et al., 2016) and Gender Neutral-GloVe (Zhao et al., 2018b), worked to minimize or eliminate the direct bias, and were shown to be successful in mitigating harmful analogies generated by word embeddings in relation to gender-stereotyped occupations.

An influential critique paper by Gonen and Goldberg (2019) demonstrated that minimizing direct bias did not eliminate bias in the vector space entirely. Rather, words that tended to cluster together due to gender bias (e.g. nurse, teacher, secretary, etc.) would still cluster together in the nullspace of the gender direction. Furthermore, the original bias could be recovered by classification techniques using only the debiased word embeddings as input.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4214–4226
August 1–6, 2021.

These observations were termed cluster and recoverability bias.

The next wave of debiasing methods (2019-present) focused on reducing cluster and recoverability bias while proposing new metrics to systematically quantify the indirect bias of the embedding space (e.g. the Gender-based Illicit Proximity Estimate, introduced by Kumar et al. (2020)). While these new debiasing schemes do reduce indirect bias in multiple ways, there is a general lack of connection to downstream applications such as coreference resolution, natural language inference (NLI) and sentiment analysis.

Current gender-bias evaluation tests (GBETs) in widespread use include the WinoBias test set (Zhao et al., 2018a), designed to measure bias in coreference resolution systems using stereotypical occupations as a probe, and the NLI test set (Dev et al., 2020a), designed to measure stereotypical inferences again using occupations as the concept of interest. More commonly used evaluations include the Word Embedding Association Test (WEAT) (Caliskan et al., 2017), and the analogy generation test SemBias (Zhao et al., 2018b). However these tests solely evaluate the vector properties of the word embeddings, without any connection to downstream applications. Adding to the library of downstream GBETs is essential in building a robust understanding of gender bias in NLP applications (Sun et al., 2019).

Here we introduce a new observation of gender-biased predictions in a downstream task, namely "marked attribute bias" in natural language inference, and develop corresponding GBETs. Marked attribute bias refers to the language model's tendency to predict that "person" implies "man" (the default attribute), while simultaneously understanding that "person" does not necessarily imply "woman" (the marked attribute). Marked attribute bias was found to exist on explicitly defined gender words (e.g. man, woman, etc.), and persist on implicit gender words (e.g. names) as well as latent gender-carriers (e.g. stereotypical occupations).

An analysis of the currently available debiased embeddings reveals that none are able to successfully mitigate marked attribute bias. Furthermore, none of the currently proposed measures of intrinsic bias on the embedding space are predictive of the marked attribute effect. We define a new measure of intrinsic bias that was found to correlate with the marked attribute effect better than any currently available metric. Using this insight, we introduce a new debiasing scheme: Multi-dimensional Information-weighted Soft Projection. Applying MISP to an existing debiased embedding achieves the lowest observed marked attribute bias error.

Summary of main contributions:

1. We present a new observation of gender bias in a downstream NLP application: marked attribute bias (MAB). The MAB test sets are made available in order to expand the current set of GBETs.

2. An analysis of current debiasing methods and current intrinsic bias measures finds that none sufficiently mitigate the error, and likewise none sufficiently explain the effect. This observation creates two new open problems.

3. We propose a new measure for quantifying intrinsic bias on the embedding space: Multi-dimensional Information-weighted Direct Bias (MIDB). This measure was found to correlate meaningfully with the marked attribute effect.

4. We introduce a new debiasing scheme: Multi-dimensional Information-weighted Soft Projection. MISP-debiased embeddings obtain new best performance on the MAB test set.

2 Marked Attribute Bias in Natural Language Inference

2.1 Background: Natural Language Inference

Natural language inference is one of the pillars of natural language understanding. It is the task of determining whether a hypothesis sentence is (neutral, entailed, or contradicted) with respect to a premise sentence. For example:

Premise: A choir sings in the church.

Hypothesis: The church is filled with the sound of singing. (Correct prediction: Entail)

Dev et al. (2020a) previously used NLI as a test case for gender bias with respect to occupations. For example, consider:

Premise: A doctor prepared a meal.

Hypothesis 1: A man prepared a meal. (N)

Hypothesis 2: A woman prepared a meal. (N)

This inference task essentially asks the question: is "doctor" a subset of man/woman? I.e. if someone is a doctor, must they be a man? While both hypothesis sentences should receive a neutral prediction (as "doctor" does not imply any specific gender), hypothesis 1 will more likely receive an entailment, while hypothesis 2 will more likely receive a contradiction, given biased word embeddings. The corresponding GBET was published by Dev et al. (2020a) and contains 1936512 sentence pairs in the form [A **occupation** *verb object*] → [A **gender word** *verb object*]. Throughout this paper, we will use the notation [Sentence A] → [Sentence B] to mean that premise Sentence A is paired with hypothesis Sentence B.

2.2 Observation of marked vs. default attribute bias

Marked vs. default attribute bias occurs whenever a default attribute (e.g. male, white, etc.) is assumed, and a marked attribute has to be explicitly stated or becomes a defining trait. In the context of the natural language inference task, consider the sentence pair:

Premise: A person prepared a meal.
Hypothesis 1: He prepared a meal. (N)
Hypothesis 2: She prepared a meal. (N)

Due to the language model's[1] tendency to predict that "person" implies a male (default) attribute, the first hypothesis sentence will have a prediction probability vector shifted towards Entail. However the same language model would tend towards a Neutral prediction for the second hypothesis, recognizing that "person" does not necessarily imply female (the marked attribute). To put it another way, this inference task essentially asks the question: is "person" a subset of man/woman? When presented with a masculine form, the model answers: yes (entailment), a person must be a man. When presented with a feminine form, the model answers: not necessarily (neutral), a female has an attribute (gender) that not all persons have. The name "Marked Attribute Bias" therefore derives from the observation that masculine forms are unmarked with respect to gender, whereas female forms carry a marked gender attribute.

In this particular example, the model trained with (original) GloVe[2] word embeddings (Pennington et al., 2014) gives a probability distribution (N, E, C) of (0.0538, **0.929**, 0.0177) for hypothesis 1 and (**0.687**, 0.238, 0.0750) for hypothesis 2.

Note that although the MAB test construction appears similar to Dev et al. (2020a), it is actually measuring quite a distinct effect. The (Dev et al., 2020a) test set measures associations between gender and some concept of interest (occupations). The MAB test set measures something more general and pervasive; it measures how gender words carry meaning, independent of any concept of interest.

Achieving the correct prediction probability of $(N, E, C) = (1, 0, 0)$ on both sentences is difficult because it requires the language model to be attribute-aware (in this case gender-aware) while not using the gender attribute to alter predictions when it would be inappropriate to do so.

3 Analysis of the current situation

In order to investigate the presence of systematic marked attribute bias in natural language inference, we construct three types of tests: bias on explicit gender words, implicit gender carriers, and latent gender carriers. We wish to understand the depth and persistence of the marked attribute effect, as well as how it is handled by current debiasing methods. Firstly we provide a brief description of the current debiasing methods to be analyzed. Next we provide details of the test sets and report results.

3.1 Debiased embeddings

Within the scope of this paper, we focus on post-processing techniques applied to static word embeddings. These types of methods are computationally inexpensive, easy to concatenate, and are independent of the base embedding. In addition, we include GN-GloVe, one of the highly cited retraining methods. Notationally, we specify embeddings as (base embedding).method. Where available, we use published debiased embeddings made available from the original authors of the corresponding method. Otherwise, we apply the method to the

---

[1] All NLI models mentioned throughout this paper are based on the Decomposable Attention Model (Parikh et al., 2016) with intra-attention, trained on the Stanford Natural Language Inference training dataset (Bowman et al., 2015) (trained for 100 epochs; learning rate 0.025; weight decay 1e-5; dropout rate 0.2; 200 hidden units; approximately 10^4 total model parameters). All the code and data needed to reproduce results mentioned in this paper are available at https://github.com/hillary-dawkins/MAB.

[2] Taken as the GloVe embeddings trained on the Common Crawl corpus for 840B tokens; available at https://nlp.stanford.edu/projects/glove/. Results were not found to vary significantly among undebiased embeddings.

base GloVe embeddings. The methods we will analyze include:

Hard Debias[3] **(GloVe**[4]**.HD)** (Bolukbasi et al., 2016): The subset of gender-neutral words are projected onto the nullspace of the gender direction $\vec{g}$. Gender-neutral words are made equidistant to pairs of words in a defined equalization set.

Gender-Neutral GloVe[5] **(GN-GloVe)** (Zhao et al., 2018b): Similar to hard debias, this method seeks to eliminate the direct bias. The embeddings are retrained from scratch using a modified version of GloVe's original objective function. The gender information is sequestered to the final component of the word embedding. The gender-neutral portion of the word embedding is then defined as the first $d-1 = 299$ components, denoted **GN-GloVe**$(\boldsymbol{w_a})$.

Gender-Preserving[6] **(GloVe**[4]**.GP)** (Kaneko and Bollegala, 2019): This method seeks to eliminate harmful gender bias while retaining as much useful semantic gender information as possible.

Double Hard Debias[7] **(GloVe**[4]**.DHD)** (Wang et al., 2020): An extended version of the hard debias algorithm, based on the observation that frequency information encoded in the word embeddings convolutes the definition of the gender direction. Correctional pre-processing is applied prior to hard debiasing.

Bias Alignment Model[8] **(GloVe**[4]**.BAM)** (Lauscher et al., 2019): Gender subspace matrices are defined by stacking explicit gender words. The projection that maps the embedding space to itself while approximately aligning the gender subspaces is learned and applied to all words. After alignment, gender information is not retained.

Orthogonal Subspace Correction and Rectification[9] **(GloVe**[4]**.OSCaR)** (Dev et al., 2020b): The rationale is that linear projective methods are too aggressive in modifying the entire embedding space. OSCaR rectifies two concepts of interest (gender and occupations), such that these subspaces are orthogonal in the debiased space.

Iterative Nullspace Linear Projection[10] **(GloVe**[4]**.INLP)** (Ravfogel et al., 2020): Rather than defining a gender direction, INLP *learns* the most informative decision boundary for classifying gendered and gender-neutral words. All words are projected to the nullspace of the gender subspace, and the process proceeds iteratively until gender information is sufficiently erased. A closely related method is the D_4 algorithm (Davis et al., 2020).

Repulse Attract Neutralize Debias[11] **(GloVe**[4]**.RAN)** (Kumar et al., 2020): Motivated by the persistence of implicit bias after debiasing through projective methods (observed as clustering and recoverability), RAN-debias attempts to address both direct bias and gender-based proximity bias.

3.2 Explicit gender words test set and error definitions

Firstly, we construct a test set where every sentence pair is of the form [A person *verb object*] → [(A) **gender word** *verb object*] (the correct inference is always neutral since a person can be of any gender). Verbs ($n = 27$) and objects ($n = 184$) are paired to create $n = 1968$ unique premise sentences[12]. Gender words are taken to be {man, woman, guy, girl, gentleman, lady, He, She}, following (Dev et al., 2020a) with the addition of the pronouns, for a total test set S of $|S| = 15744$ sentence pairs where hypotheses represent binary genders evenly (denoted S_M, S_F, $|S_M| = |S_F|$).

For every hypothesis sentence in the test set, the ideal prediction probability vector is $(N, E, C) = (1, 0, 0)$. We could define the error on the test set as the average Euclidean distance from the ideal distribution:

$$\mathcal{E} = \frac{1}{|S|} \sum_{i \in S} \|(1,0,0) - (N,E,C)_i\|_2. \quad (1)$$

This task, test set, and error definition are simple, and yet they encapsulate the central challenge of the debiasing field: to create attribute-aware (required to obtain the Neutral prediction) but attribute-unbiased embeddings.

A weaker, but still potentially desirable, condition might be to minimize the effect of gender

while not requiring that the model be gender-aware. Typically, this means that all hypotheses tend towards an Entail prediction, regardless of gender. We could define the error as the average distance between probability vectors between genders:

$$d = \frac{1}{2|S|} \left\| \sum_{i \in S_M} (N,E,C)_i - \sum_{j \in S_F} (N,E,C)_j \right\|_2 . \tag{2}$$

A gender-agnostic model could achieve zero error by this definition even with an accuracy of zero on the test set.

Table 1 shows the results for this test set on all the embeddings of interest. None of the debiased embeddings successfully mitigate the marked attribute error. A similar test set shows that the effect persists on implicit gender words (e.g. names). Results are shown in the appendix.

3.3 Latent gender carriers: Stereotyped occupations

Next, we would like to check if the gender-induced marked attribute bias can affect entities which should be gender neutral, but turn out to be hidden carriers of a gender attribute (e.g. stereotypical occupations). The same template [A person *verb object*] → [A/An **occupation** *verb object*] was used with the common vocabulary. Stereotypical occupations ($n = 32$) were sourced from Bolukbasi et al. (2016), and the SemBias test set. Examples are (doctor, engineer, boss, etc. vs. nurse, maid, homemaker, etc.). In total there are 62,976 sentence pairs in the test set[13].

Results are shown in Table 2. A permutation test is used to check if dividing the occupations into groups according to gender stereotypes produces a significant difference in the probability vectors (rather than dividing them randomly). As shown, the marked attribute effect persists on stereotypical occupations, especially on original embeddings. This is an important result because it highlights that unintended behaviour can appear in unexpected places due to a latent attribute. Previously, GBETs have focused on how explicit gender words are treated under biased models. To our knowledge, this is the first GBET designed to analyze unintended behaviour on a latent attribute carrier.

Note that this task is easier to correct than the explicit gender words because occupation words have defining characteristics beyond gender. That is, a debiasing method such as Iterative Nullspace Projection can perform well by removing gender information entirely. This does not mean that the challenge of having a gender-aware but gender-unbiased embedding is solved, but it does provide evidence that latent gender effects can be mitigated using linear projective methods. The full extent of latent biased-attribute effects and possible mitigation strategies should be investigated further.

4 Intrinsic bias measures

How to define bias on an embedding space remains an active area of study. In general, we seek to understand how the intrinsic or geometric properties of an embedding space translate to real observable bias in downstream tasks. Intrinsic properties are easy to compute quickly, whereas computing performance on downstream tasks requires us to train new models for every case. Understanding of the correlations between the two gives insight on how word embeddings should be debiased.

As a case study, let us focus on the marked attribute error $\mathcal{E}$ on the explicit gender words (shown in Table 1). Recall that this measure of bias is of interest because zero error corresponds to the gold standard: having an attribute-aware model, while simultaneously not using the gender attribute to make inappropriate inferences. In this section, we look at 5 existing intrinsic bias measures: Direct Bias, Clustering, Recoverability, Gender-based Illicit Proximity Estimate (GIPE), and SemBias. We will investigate whether any of these measures are predictive of the marked attribute effect.

Recall that direct bias was the first measure to be proposed; it simply measures the average projection of word vectors onto a predefined gender direction. Early methods (i.e. Hard Debias and GN-GloVe) defined bias in the embedding space completely as direct bias. The idea of clustering and recoverability refer to a classifier's ability to correctly reassign gender labels to words, even after debiasing methods have been applied. Gonen and Goldberg (2019)'s observation of clustering and recoverability sparked new interest in defining metrics for indirect bias on the embedding space. Although clustering and recoverability do not provide well-defined measures of bias given an embedding space (as they depend training implementation - though they could be said to provide a lower bound), many new debiasing proposals will cite re-

---

[13] The exact word set used to produce these results is available at https://github.com/hillary-dawkins/MAB.

Table 1: Results of the marked attribute test set on **explicit gender words**. Due to varying results on gender nouns vs. pronouns, results are shown separately for each case (M and F represent averages across the gender nouns). Some debiased embeddings are able to eliminate the distance across pronouns (really by definition since $\vec{she} \approx \vec{he}$ in these cases), but none are able to eliminate differences between the gender nouns significantly. Even when differences between genders are minimized, distance from the ideal distribution (error $\mathcal{E}$) remains or increases. This highlights the challenge of creating gender-aware but not gender-biased embeddings.

Table 2: Results of marked attribute test set on **stereotypical occupations**. Each (N,E,C) probability vector is averaged over the 1968 unique premise sentences and the gender attribute words from each category (M or F) ($n = 31,488$ sentences for each gender). Smaller distances between the M and F vectors indicate less gender bias. The significance of the difference was evaluated using a permutation test; the alternate distance d^* is computed for 10,000 randomly sampled partitions of the occupations into two groups. The significance value is the proportion of these samples to generate a distance $d^* > d$. This gives us an idea of whether the defined partition, based on gender, is a meaningful grouping. Smaller significance values indicate that the defined partition is non-random with respect to the distance.

duced clustering as a positive result. The effect on downstream applications is not well understood as of yet. The Gender-based Illicit Proximity Estimate (GIPE) measures the extent of undue proximities in the embedding space due to a pervasive gender attribute. Lastly, the SemBias analogy test set measures whether gender-biased analogies exist within the embedding space based on vector arithmetic properties.

Implementation details for each measure as well as the experimental set of embeddings ($n = 16$) are given in the appendix. The average Direct Bias on the embedding space was found to have a Pearson correlation coefficient of 0.104 with the marked attribute error. The Clustering v-measure[14] (Rosenberg and Hirschberg, 2007) achieved a correlation coefficient of 0.184. Recoverability was attempted using an SVM with a linear decision boundary, an SVM with a non-linear (radial basis function) kernel, logistic regression, and a simple 1-hidden-layer fully-connected network. All recoverability correlation results were comparable, but the best coefficient of 0.223 was achieved by logistic regression. The GIPE[15] had a correlation coefficient of 0.432. The SemBias[16] test set had a correlation coefficient of 0.091. The full correlation matrix between all intrinsic bias measures can be found in the appendix. The results suggest that the marked attribute effect is not well correlated with any present notion of intrinsic bias, therefore we do not have a good understanding of how the word embedding properties contribute to this type of observable bias.

In seeking a potential solution, we make note of a new intrinsic bias measure, multi-dimensional information-weighted direct bias (MIDB), found to have a more meaningful correlation of 0.667 with the marked attribute error. We define the MIDB of a particular word $\vec{x}$ to be a weighted average over inner products with basis vectors of a multi-dimensional gender subspace:

$$\text{MIDB}_d(x) = \sum_{i=1}^{d} a_i \langle g_i | x \rangle \tag{3}$$

where $\{g_i\}$ form an orthonormal basis for the gender subspace, here defined as the first d principal components summarizing difference vectors $\{\delta_{jk}\}$. The difference vectors are taken as all pairwise differences[17] between vectors in defined gender sets (here common names were used[13]): $\{\delta_{jk}\} = \vec{f}_j - \vec{m}_k$, $f_j \in F_{\text{names}}$, $m_k \in M_{\text{names}}$ ($|M_{\text{names}}| = |F_{\text{names}}| = 100$). The weighting a_i is the proportion of variance explained by the i^{th} principal component, and d is a hyperparameter controlling the number of dimensions to keep[18].

New proposals for defining a gender direction or subspace potentially have far reaching consequences in the landscape of intrinsic bias measures and their related debiasing schemes. In fact all of Clustering, Recoverability, GIPE, and SemBias use the classic uni-dimensional gender direction $\vec{g}$ within their definitions. The weak observed correlation between DB and MIDB suggests that these subspaces are independent. Swapping in a uniquely informative gender subspace to the existing indirect measures would produce a new family of intrinsic bias measures. The observed utility of names in defining a meaningful gender subspace is encouraging because it opens an obvious avenue for this method to be applied to attributes of interest beyond gender (e.g. race or ethnicity).

5 Multi-dimensional information-weighted soft projection

In this section we motivate the above search for an informative intrinsic bias measure. As discussed, a greater understanding of how embedding properties influence observed bias can inform new debiasing techniques. Translating the idea of MIDB into a debiasing scheme yields Multi-dimensional Information-weighted Soft Projection (MISP).

In this debiasing procedure, we project all words into the nullspace of the multi-dimensional gender subspace, proportional to our belief that certain dimensions actually encode the latent idea of gender:

$$\vec{w}_{deb} = \vec{w} - \sum_{i=1}^{d} a_i \langle g_i | w \rangle | g_i \rangle \tag{4}$$

where $\vec{w}$ is the input embedding, $\vec{w}_{deb}$ is the debiased output embedding, and all other quantities are defined as in eq. (3).

---

[14] With cluster size $n = 1500$ (which lead to the highest observed correlation); see appendix.

[15] Using an indirect bias threshold of $\theta = 0.05$, and number of nearest neighbours $n = 100$.

[16] The SemBias score was taken as the proportion of analogy examples in the test set for which the embedding space returns the correct definitional analogy.

[17] Using all pairwise differences creates a matrix with rank much less than the dimension of the matrix, however the rank is still much larger than d (the number of principal components to extract) so it doesn't cause a problem.

[18] On our set of experimental embeddings, $d = 4$ was empirically found to produce the 0.7 correlation result.

Table 3: Results for word similarity and analogy benchmarks. Results on the word analogy tasks are reported as percentage accuracy. Results on the word similarity tasks are reported as a Spearman correlation (× 100). Application of MISP does not alter the overall quality of word embeddings as measured by these classic test sets.

Embedding.method	Sem	Syn	Google-Total	MSR	RG	MTurk	MEN	SL999
GloVe	80.48	62.76	70.80	51.49	75.29	64.27	72.19	34.86
GloVe.MISP	80.49	62.81	70.84	51.51	76.06	64.32	72.41	35.04
GN-GloVe	77.62	61.60	68.87	49.29	74.11	66.36	74.49	37.12
GN-GloVe(w_a)	77.68	61.56	68.87	49.38	75.46	66.55	74.72	37.53
GN-GloVe(w_a).MISP	77.68	61.59	68.89	49.26	75.49	66.45	74.76	37.60

As shown in Table 1, the GN-GloVe(w_a) embeddings are currently the top performers on the explicit gender words test set, as measured by either error $\mathcal{E} = 0.149$, or distance $d = 0.115$. Applying MISP to GN-GloVe(w_a) embeddings (denoted GN-GloVe(w_a).MISP), we achieve an error on the explicit gender words test set of $\mathcal{E} = 0.1107$, a 26% error reduction over the previous best. The distance d between genders is reduced to $d = 0.08744$, a 21% reduction over the previous best. Successful concatenation suggests that this technique is distinct, and independently useful, from techniques that seek to minimize the traditional direct bias (including GN-GloVe). This observation is consistent with the weak observed correlation between direct bias and MIDB$_4$ on the experimental set of embeddings.

Computing the intrinsic bias measures Clustering, Recoverability, GIPE and SemBias on the newly created embedding space GN-GloVe(w_a).MISP (compared to the base GN-GloVe(w_a)), we observe a clustering v-score of 0.498 (previously 0.497)[19], a recoverability accuracy of 0.992 (previously 0.993)[20], a GIPE of 0.1169 (previously 0.1173)[21], and a SemBias score of 0.938 (previously 0.938)[22]. The MISP method did not reduce bias by any of these measures, although this is not particularly surprising as it was designed to address the marked attribute effect (through MIDB). It is encouraging however that none of these bias measures were increased. In other words, there is no expected trade-off between the reduced marked attribute error and any previous debiasing work that relied on these measures. The SemBias result informs us that MISP did not reintroduce any harmful biased analogies, for example.

For reference, if we apply the analogous multi-dimensional hard debias method (i.e. equation (4) where all weights a_i are set to 1), the output embeddings GN-Glove(w_a).MHD do not successfully mitigate the marked attribute effect ($\mathcal{E} = 0.1501$, $d = 0.1603$). This suggests that the soft nature of the projection is a key ingredient.

Furthermore, we provide some evidence that specifically the information weighting of the soft projection is a good ingredient as follows. Recall that we are attenuating components of each basis vector according to our belief in that vector as a good gender direction. The basis vectors are defined to be the first d principal components, weighted by their corresponding variance explained. Therefore the first basis vector receives the greatest weight and so on. To test the significance of this decision, we define alternative debiased embeddings by applying MISP where the weights get reassigned to the "wrong" vector (for $d = 4$, we have 23 alternative pairings). We observe that **none** of the 23 alternatives obtain an error $\mathcal{E}$ less than the "true" implementation of MISP. This suggests that weighting the components by order of information is a good ingredient. Values of $\mathcal{E}$ for the alternate embeddings can be found in the appendix. Model parameters for each case are made available in order to reproduce this argument on any extended version of the MAB test set.

Information weighting is an interesting idea because it could be applied to either defined or learned gender subspaces alike. For instance, if the basis vectors of a gender subspace are taken as the iteratively learned linear decision boundaries (as in INLP), we could investigate weighting each dimension by the accuracy acc_i of classification on each iteration, as $a_i = (1 - 2acc_i)$. In this way, dimensions receive weights proportional to their

---

[19] Where clustering size $n = 1500$.

[20] This is the highest accuracy achieved by any of the four classification methods tested; implementation details are in the appendix.

[21] Computed with indirect bias threshold $\theta = 0.03$, and number of nearest neighbours $n = 100$.

[22] Reported as the proportion of samples in the full test set to return the definitional analogy; higher scores are better.

ability to predict gender information. When accuracy reaches 0.5, no gender information remains, the learned decision boundary is meaningless, and the basis vector receives zero weighting.

Finally, as with any debiasing method, we wish to verify that application of the method has not damaged the overall embedding quality. We assess the MISP embeddings on a handful of classic analogy and word semantic similarity benchmarks. The word similarity benchmarks measure how closely the word embeddings capture similarity between words compared to human annotation. We use the following datasets: RG (Rubenstein and Goodenough, 1965), MTurk (Yih and Qazvinian, 2012), MEN (Baroni, 2014), and SimLex999 (Hill et al., 2015). The word analogy task measures how well the word embeddings capture semantic and syntactic relationships among words as vector properties. We report on the Google (Mikolov et al., 2013a), and MSR (Mikolov et al., 2013c) test sets. Results were obtained following the word embedding benchmark package[23] (Jastrzebski et al., 2017). As shown, application of MISP does not alter the overall word embedding quality.

6 Conclusion

This paper highlights a new observation of gender bias in a downstream setting: marked attribute bias in natural language inference. The current inference is that "person" implies male, while "person" does not imply female. Consequently, this inference is being baked into our models of natural language understanding. The effect was shown to persist on explicitly defined gender words and on latent gender-attribute carriers. Based on an assessment of the current debiasing landscape, none of the current debiasing methods satisfactorily mitigate the marked attribute error, and furthermore none of the intrinsic bias measures are useful at predicting the marked attribute effect.

By noticing a more meaningful correlation with a newly identified intrinsic bias measure, we propose a new debiasing scheme: multi-dimensional information-weighted soft projection (MISP). This method introduces several concepts, including the use of a multi-dimensional defined gender subspace. Previously, the concept of a defined gender subspace always appeared as a single dimension. The iterative nullspace projection method implicitly uses higher learned dimensions, however this requires learning a new decision boundary at every iteration, subject to the implementation of a training procedure. Furthermore, the learned dimensions were not used to define any bias metric, they were strictly used operationally for the debiasing procedure. MISP also introduces the idea of a soft or partial projection, where weights are informed by some measure of the dimension's ability to capture the intended latent concept of a gender direction. Both of these ideas could be further explored and extended to create new notions of indirect bias, which in turn could inform more sophisticated debiasing procedures.

Multi-dimensional information-weighted soft projection applied to GN-GloVe(w_a) produces new debiased embeddings that achieve the lowest error on the marked attribute bias test set, a 26% reduction over the previous best, and a 45% reduction over the original undebiased embeddings. Error reduction on this test set is thought to encapsulate the overall goal of producing gender-aware but gender-unbiased embeddings. Therefore, this method and its composite ingredients warrant further investigation. Each of the marked attribute bias test sets are made available for further exploration and iteration on these ideas.

A Implicit gender carriers: Names

As mentioned in the main text, we check if the marked attribute effect will persist through implicit gender words. These are words with no gender attribute by definition, but are usually associated with a specific binary gender (e.g. names). This test set uses a similar template: [A person *verb object*] → [**Name** *verb object*], using the same (verb, object) vocabulary as above. Names[24] ($n = 64$) are sourced from the most common names of the previous decade in the US, according to the Social Security Administration[25]. In total there are $n = 125,952$ sentence pairs in the test set.

Results are shown in Table 4. In short, the same effect is observed on names, especially on the original embeddings. A permutation test was used to check whether the stratification of names by gender was a non-random division according to the observed bias.

B Intrinsic bias measures and correlations

Please refer to tables 5 and 6.

C Alternate weighted embeddings

As discussed in the main text, we compute the error $\mathcal{E}$ on the explicit gender words test set for alternate soft-weighted embeddings. The alternate embeddings are created by permuting the weights to be matched with the incorrect basis vectors. For example, the permutation denoted 1243 means that weight a_1 is applied to basis vector $\vec{g_1}$, a_2 to $\vec{g_2}$, a_4 to $\vec{g_3}$, and a_3 to $\vec{g_4}$. Results for all alternate permutations and their errors are as follows: (permutation = 1243, $\mathcal{E}$ = 0.1574), (1324, 0.2331), (1342, 0.1919), (1423, 0.1330) (1432, 0.1487) (2134, 0.1273) (2143, 0.1565) (2314, 0.2289) (2341, 0.1963) (2413, 0.1639) (2431, 0.1287) (3124, 0.1951) (3142, 0.1694) (3214, 0.2813) (3241, 0.1602) (3412, 0.2110) (3421, 0.1732) (4123, 0.1945) (4132, 0.1764) (4213, 0.1879) (4231, 0.1363) (4312, 0.1241) (4321, 0.1435).

Table 4: Results of marked attribute test set on **names**. Each (N,E,C) probability vector is averaged over the 1968 unique premise sentences and the gender attribute words from each category (M or F) ($n = 62,976$ sentences for each gender). Smaller distances between the M and F vectors indicate less gender bias. The significance of the difference was evaluated using a permutation test; the alternate distance d^* is computed for 10,000 randomly sampled partitions of the names into two groups. The significance value is the proportion of these samples to generate a distance $d^* > d$. This gives us an idea of whether the defined partition, based on gender, is a meaningful grouping. Smaller significance values indicate that the defined partition is non-random with respect to the distance.

Table 5: Pearson correlation matrix between intrinsic bias measures (and marked attribute error) on the experimental set of embeddings. MIDB obtains the highest correlation with the marked attribute error $\mathcal{E}$; the GIPE was also observed to have a weak correlation. Recoverability bias is most related to the direct bias. The sub-matrix among the SemBias results indicate that trade-off is mostly happening between "definitional" and "other" analogies.

Table 6: Intrinsic bias measures of interest on the experimental set of embeddings. There are two base (undebiased) embeddings, word2vec and GloVe. All other embedding spaces are obtained by applying a debiasing method, where each method found here is described in the main text. Implementation notes:

DB and MIDB: The direct bias (DB) and the new multi-dimensional information-weighted direct bias (MIDB) are average measures over a specific (ideally gender-neutral) vocabulary V_t. V_t ($n = 46960$) is defined by taking the 50,000 most frequent words in the common vocabulary between word2vec and GloVe, filtering out punctuation, numbers, and removing the gender-specific word set V_s ($n = 1622$), defined as the union of gender-specific word sets used in previous works (Bolukbasi et al., 2016; Zhao et al., 2018b). DB is defined as the projection onto a gender direction, here taken to be the $\vec{she} - \vec{he}$ direction. For debiasing methods that promote $\vec{she} \approx \vec{he}$, the DB is not well defined (although it can be computed numerically, it is unstable). We leave these cases as NA rather than a spurious numerical value.

Clustering: The clustering experiment follows (Gonen and Goldberg, 2019) in taking the $n \in [500, 1500]$ "most biased" words in the original embedding space (according to their projection on the $\vec{she} - \vec{he}$ axis), and then applying k-means ($k = 2$) clustering on the words in the debiased embedding space. Bias is reported as the either the clustering accuracy or the v-measure (only $n = 1500$ shown here with v-measure).

Recoverability: Similarly, the dataset ($n = 5000$) is taken to be the most biased words in the original embedding space, where bias labels are assigned according to the projection on the gender direction ($n = 2500$ taken from each class). Several classifiers (SVM with a linear decision boundary, SVM with an RBF kernel, logisitic regression, and a simple fully-connected 1-hidden layer network) were trained on 20% of the dataset with balanced classes. Recoverability bias is reported as the accuracy of classification on the remaining test set (only logisitic regression shown here).

SemBias: The SemBias analogy test set is available from (Zhao et al., 2018b). The set contains $n = 440$ tuples of possible analogies $(\vec{a}, \vec{b})$: 1 definitional analogy (e.g. king, queen), 1 stereotypical analogy (e.g. doctor, nurse), and 2 other analogies (e.g. cup, plate). For every sample, the best analogy is selected as the one to maximize $cos(\vec{he} - \vec{she}, \vec{a} - \vec{b})$. Bias is reported as the proportion of samples to return a definitional analogy, a stereotypical analogy, and an "other" analogy. (Only definitional and stereotypical shown here.)

GIPE: The gender-based illicit proximity bias (GIPE) (see (Kumar et al., 2020) for details) was computed with $n = 100$ nearest neighbours for each word, with an indirect bias threshold of $\theta \in [0.03, 0.05]$ following (Kumar et al., 2020). (Only $\theta = 0.03$ shown here.)

Full results, plus all code, embedding files, and word sets needed to replicate these results are available at https://github.com/hillary-dawkins/MAB.

Abstract

We present a simplified, task-agnostic multi-modal pre-training approach that can accept either video or text input, or both for a variety of end tasks. Existing pre-training are task-specific by adopting either a single cross-modal encoder that requires both modalities, limiting their use for retrieval-style end tasks or more complex multitask learning with two unimodal encoders, limiting early cross-modal fusion. We instead introduce new pretraining masking schemes that better mix across modalities (e.g. by forcing masks for text to predict the closest video embeddings) while also maintaining separability (e.g. unimodal predictions are sometimes required, without using all the input). Experimental results show strong performance across a wider range of tasks than any previous methods, often outperforming task-specific pre-training[1].

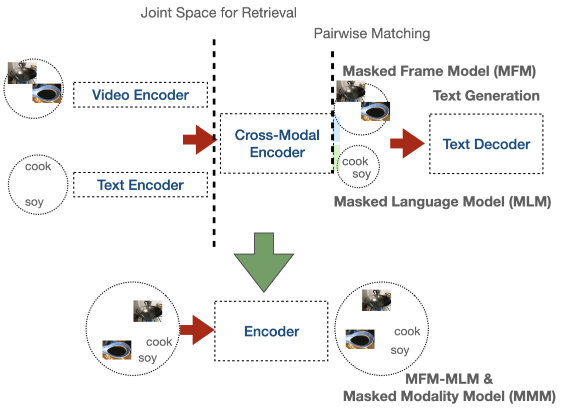

Figure 1: Existing models (upper figure) adopt complex architectures and multiple task-specific training to merge two streams of data to cover a wide range of downstream tasks (such as retrieval or text generation). Our video-language model (VLM) (lower figure) uses a single BERT encoder for task-agnostic pre-training (e.g. only masking tokens, no matching or alignment for specific end tasks) in a joint feature space, while still covering a wide range of tasks (see Figure 3).

1 Introduction

We study the challenge of achieving *task-agnostic* pre-training for multimodal video understanding, building on recent unimodal approaches such as pretrained language models for text (Peters et al., 2018; Devlin et al., 2019). Although certain language models are near task-agnostic (Devlin et al., 2019; Lewis et al., 2020) on NLP tasks, being task-agnostic on multi-modal tasks are more challenging due to cross-modal tasks such as text-video retrieval. Existing video-and-language pre-trainings are task-specific, which adopt either (1) a cross-modal single encoder (Sun et al., 2019b,a; Zhu and Yang, 2020) favoring tasks that require cross-modal reasoning (e.g. video captioning), or (2) multiple unimodal encoders/decoders (Miech et al., 2019, 2020; Li et al., 2020b; Luo et al., 2020; Korbar et al., 2020) combining specific tasks that require separately embedding each modality (e.g. video retrieval). We instead show that it is possible to pre-train a task-agnostic model called video-language model (VLM) that can accept text, video, or both as input.

As shown in Figure 1, this task-agnostic single encoder approach has several advantages: (1) it reduces the complexity of pre-training with multiple losses and models (e.g. Luo et al. (2020)), and (2) it holds less assumption on being close to end tasks as in retrieval-based pre-training Miech et al. (2020) and is as general as classic LMs, and (3) it encourages feature sharing among modalities when present, without sacrificing separability, and (4) it is more parameter efficient (see Section 5, we achieve strong performance with $\mathrm{BERT}_{\mathrm{BASE}}$ sized models). Table 1 summarizes the design choices of recent models.

Our encoder is a transformer block that combines the existing masked frame model and masked

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4227–4239
August 1–6, 2021.

language model (MFM-MLM) (Sun et al., 2019a; Li et al., 2020b; Luo et al., 2020) with two new methods to improve the learning of multi-modal fusion. First, we introduce a masking scheme called masked modality model (MMM) that randomly masks a whole modality for a portion of training examples (the rest of the examples goes for traditional MFM-MLM), thereby forcing the encoder to use the tokens from the other modality to produce tokens for the masked modality. We then introduce a single masked token loss to replace two (2) losses on video and text separately for MFM-MLM. Masked token loss uses the embeddings of both video and text tokens to learn joint hidden states for the encoder.

We also show it is possible to fine-tune a single encoder for a wide range of tasks by using task-specific attention masks. Experiments demonstrate that it performs well on a wider range of tasks than previous models, including outperforming task-specific pre-training baselines with unimodal encoders of similar hyper-parameters by more than 2% on retrieval tasks and 1% on video captioning. Note that these results are also achieved with a much smaller model than previous approaches, further demonstrating the improved fusion and sharing across modalities.

In summary, the main contributions of this paper are as follows: (1) we propose to pre-train a task-agnostic encoder for video understanding; (2) we introduce masked modality model (MMM) and masked token loss for cross-modal fusion during pre-training without sacrificing separability; (3) experimental results show that the proposed simple baseline achieves competitive performance with significantly fewer parameters.

2 Related Work

Numerous multimodal task-specific pre-training models are proposed for downstream visual-linguistic tasks. In video and text pre-training, existing research adopts different design choices regarding proxy tasks and neural architectures for end tasks (Luo et al., 2020).

On one hand, VideoBERT (Sun et al., 2019b), Unicoder-VL (Li et al., 2020a), VL-BERT (Su et al., 2020), UNITER (Chen et al., 2020), VLP (Zhou et al., 2018), ActBERT (Zhu and Yang, 2020) adopt a *shared* encoder approach, where the vision and text sequences are concatenated and input to a single Transformer(Vaswani et al., 2017) encoder. Although this approach is simple, it limits the types of downstream tasks to those that input both modalities simultaneously. For example, (Sun et al., 2019b) may not be able to perform joint retrieval tasks and added another decoder for video captioning during fine-tuning. (Zhu and Yang, 2020) uses `[CLS]` token for pairwise metric-learning based retrieval (which is an easier problem but requires a quadratic number of examples and is 50 times slower as reported in (Luo et al., 2020)).

Meanwhile, many existing approaches adopt or add task-specific pre-training to accommodate retrieval and video captioning tasks (e.g. *two-stream* encoders (video and text separately) and text decoders). For example, (Miech et al., 2019, 2020; Rouditchenko et al., 2020; Ging et al., 2020; Gabeur et al., 2020; Alayrac et al., 2020; Patrick et al., 2021; Huang et al., 2021) adopts a retrieval task for pre-training. CBT (Sun et al., 2019a), HERO (Li et al., 2020b), VideoAsMT (Korbar et al., 2020) and UniVL (Luo et al., 2020) adopt multi-task learning (MTL) to learn retrieval tasks on video and text encoders. HERO (Li et al., 2020b) and UniVL (Luo et al., 2020) adopts another cross-encoder to further learn the fusion of different modality. UniVL (Luo et al., 2020) and VideoAsMT (Korbar et al., 2020) add another text decoder for video captioning. Compared with the single-stream input in the shared encoder approach, two-stream encoders typically come with a complex architecture and proxy tasks to cover more end tasks. To the best of our knowledge, none of the existing works target task-agnostic pre-training.

2.1 Image-Text Pre-training

ViLBERT (Lu et al., 2019), LXMERT (Tan and Bansal, 2019) adopt two transformers for image and text encoding separately. VisualBERT (Li et al., 2019), Unicoder-VL (Li et al., 2020a), VL-BERT (Su et al., 2020), UNITER (Chen et al., 2020), Unified VLP (Zhou et al., 2020) use one shared BERT model. These models employ MLM and pairwise image-text matching as pretraining tasks which are effective for downstream multimodal tasks. Our fine-tuning for video captioning is inspired by Unified VLP (Zhou et al., 2020) that adopts attention masks and language model heads of BERT for image-captioning.

2.2 Video-Text Pre-training

VideoBERT (Sun et al., 2019b) and CBT (Sun et al., 2019a) are the first works to explore the capability of pre-training for video-text. Although VideoBERT and CBT pre-train the model on multimodal data, the downstream tasks mainly take video representation for further prediction. ActBERT (Zhu and Yang, 2020) is a weakly-supervised pre-training method. It leverages global action information to catalyze mutual interactions between linguistic texts and local regional objects and introduces a transformer block to encode global actions, local regional objects, and linguistic descriptions. HERO (Li et al., 2020b) encodes multimodal inputs in a hierarchical fashion. Besides, two new pre-training tasks, video-subtitle matching and frame order modeling, are designed to improve representation learning. VideoAsMT (Korbar et al., 2020) and UniVL (Luo et al., 2020) further adopt a BART-style(Lewis et al., 2020) text generation task for downstream tasks such as video captioning and UniVL adopts a EnhancedV training stage to mask all text tokens for better learning of generation.

3 Pre-training

As a reminder, our goal is to train a *task-agnostic* model for various tasks in video-text understanding. This section introduces task-agnostic proxies for pre-training. We first describe two masking schemes as a baseline: masked frame model (MFM) for video frames and masked language model (MLM) for text tokens (Sun et al., 2019a; Li et al., 2020b; Luo et al., 2020). Then we introduce masked modality model (MMM) that encourage to learn the representations of one modality from the other. Lastly, we introduce masked token loss that unifies losses on masked video and text tokens as a single loss function.

3.1 Vector Quantization and BERT

Assume we have a clip (v, t) sampled from a video, where v and t corresponds to video modality and text modality, respectively. Since videos are signals in continuous space, we first extract token embeddings from raw videos. We decode v into frames and then feed them into a (frozen) video encoder $\text{Encoder}_{\text{video}}(\cdot)$ and a trainable MLP layer to obtain *video tokens*:

$$\boldsymbol{x}_v = \text{MLP}(\text{Encoder}_{\text{video}}(\boldsymbol{f}_v)), \tag{1}$$

where we use a bolded symbol to indicate a sequence and $\boldsymbol{f}_v$ is a sequence of continuous frames from a video. We use S3D (Xie et al., 2018; Miech et al., 2020), which is pre-trained via self-supervised learning on the Howto100M dataset. The MLP layer allows the hidden size of video tokens to be the same as BERT's hidden sizes d: $x_v \in \mathbb{R}^d$. Similarly, vectors for text tokens $\boldsymbol{x}_t$ are obtained via embedding lookup as in BERT.

To simplify multi-modal pre-training, we adopt a single BERT transformer with minimum changes. We first concatenate video tokens $\boldsymbol{x}_v$ and text tokens $\boldsymbol{x}_t$ via the `[SEP]` token so video and text belongs to one corresponding segment of BERT:

$$\boldsymbol{x} = \texttt{[CLS]} \circ \boldsymbol{x}_v \circ \texttt{[SEP]} \circ \boldsymbol{x}_t \circ \texttt{[SEP]}. \tag{2}$$

We further mask $\boldsymbol{x}$ as $\boldsymbol{x}_{\text{masked}}$ (detailed in the next subsection) and feed the whole sequence into BERT:

$$\boldsymbol{h} = \text{BERT}(\boldsymbol{x}_{\text{masked}}), \tag{3}$$

where $\boldsymbol{h}$ indicates the hidden states of the last layer of BERT. To encourage learning video/text hidden states in a shared space for the masked token loss (introduced in Section 3.3), we use a *shared* head to predict video/text token embeddings via a linear projection layer:

$$e = \boldsymbol{W}h + b, \tag{4}$$

where $e \in \mathbb{R}^d$ and $\boldsymbol{W}$ and b are the weights from the prediction heads of BERT. In this way, our model learns a joint embedding space for both video and text tokens from inputs to outputs of BERT. This allows for pre-training a single encoder directly from any existing LMs and the only layer that requires initialization is the MLP layer.

3.2 MFM-MLM

Inspired by (Sun et al., 2019a; Li et al., 2020b; Luo et al., 2020), we adopt masked frame model (MFM) for videos and masked language model (MLM) for text as a baseline. Note that unlike LMs that typically come with a fixed vocabulary with a special `[MASK]` token, video tokens are innumerable in the continuous space and we mask a video token by setting a video token with all zeros and ask the encoder to recover the video token. via noisy contrastive estimation (NCE):

$$\mathcal{L}_{\text{MFM}} = -\mathbb{E}_{s \sim V} \log \text{NCE}(x_s | \boldsymbol{x}_{\text{masked}}; V'), \tag{5}$$

where V is all indexes of video tokens and

$$\text{NCE}(x_v | \boldsymbol{x}_{\text{masked}}; V') = \frac{\exp(x_v^T e_v)}{\exp(x_v^T e_v) + \sum_{j \in V'} \exp(x_j^T e_v)}, \tag{6}$$

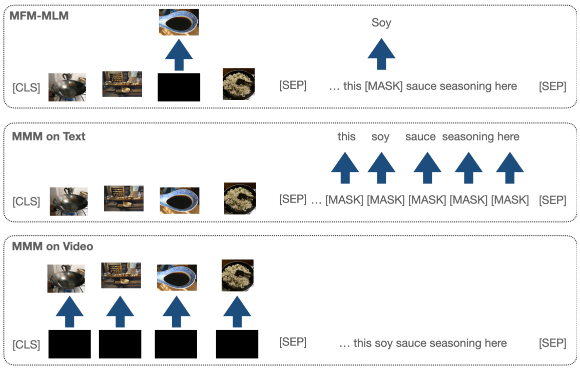

Figure 2: Task-agnostic pre-training (e.g. w/o task on retrieval-style alignment): MFM-MLM: 50% of training examples are masked as masked frame model (MFM) and masked language model (MLM); the rest 50% examples are masked as masked modality model (MMM) (25% on text as in the second row and 25% on video as in the third row).

where V' indicates all non-masked video tokens within the same batch. The final loss is the sum of both MFM and MLM:

$$\mathcal{L}_{\text{MFM-MLM}} = \mathcal{L}_{\text{MFM}} + \mathcal{L}_{\text{MLM}}, \qquad (7)$$

where $\mathcal{L}_{\text{MLM}}$ is the same as BERT and we omit its details for brevity. We experiment this classic baseline in Section 5.

3.3 MMM and Masked Token Loss

Masked Modality Model We introduce masked modality modal (MMM) that masking either all video or all text tokens out for a given example of video-text clip. This masking scheme complements MFM-MLM (e.g. in our experiments 50% of training examples are masked as MMM and the rest 50% are masked as MFM-MLM). This encourages the encoder to use tokens from one modality to recover the tokens for the other modality. This resolves the issue that an encoder may use nearby tokens from their modality for prediction just because tokens from a single modality are closer As in the lower two (2) sub-figures in Figure 2, we either mask the whole modality of video or text so this modality can be "generated" from the other modality. Our experiments indicate that this is critical for pre-training a single encoder for retrieval tasks.

Masked Token Loss We further introduce masked token loss that unifies loss functions for MFM and MLM. This loss encourages learning a joint token embedding space for video and text and both types of tokens contribute to the prediction of a masked (video or text) token. This also improves the number of contrasted negative embeddings in two separate losses for MFM and MLM.

We define masked token loss $\mathcal{L}_{\text{VLM}}$ as the following:

$$-\mathbb{E}_{s\sim V\cup D}\log \mathrm{NCE}(x_s|\boldsymbol{x}_{\text{masked}}; V'\cup D_{\setminus s}), \qquad (8)$$

where D is the word embeddings over the vocabulary of BERT and $D_{\setminus s}$ excludes token s (if s is a text token). Further, $\mathrm{NCE}(x_s|\boldsymbol{x}_{\text{masked}}; V'\cup D_{\setminus s})$ is defined as:

$$\frac{\exp(x_s^T e_s)}{\exp(x_s^T e_s)+\sum_{j\in V'\cup D_{\setminus s}}\exp(x_j^T e_s)}. \qquad (9)$$

Note that $j \in V'\cup D_{\setminus s}$ can be either a video or text token and one predicted token e_s must be closer to the ground-truth token embedding (either a video token or word embedding) and be away from other embeddings of video/text tokens. We perform an ablation study in Section 5 to show that $\mathcal{L}_{\text{VLM}}$ works better than $\mathcal{L}_{\text{MFM-MLM}}$.

4 Fine-tuning

In this section, we describe how to use different types of attention masks to fine-tune VLM for a variety of tasks, as shown in Figure 3.

4.1 Text-Video Retrieval

One major challenge of pre-training on a single encoder is how to adapt such a model to joint space retrieval without using unimodal encoders for task-specific pre-training on contrastive loss (as in Howto100M (Miech et al., 2019, 2020)). The main reason is that many existing models encode text and video tokens together via self-attention, and one cannot obtain hidden states for text/video alone.

To resolve this, we propose to apply an isolated attention mask with two squared masks that are diagonally placed, as shown in the lower sub-figure of the first box in Figure 3.[2] These two squares disable video and text tokens to attend and see each other, while still allow video and text tokens to use the same self-attention layers for learning representations in the same feature space. Further, note that the first and second `[SEP]` tokens of BERT will

---

[2] One can further reduce $O(m+n)^2$ complexity to $O(m^2+n^2)$ (m and n are lengths for video and text, respectively) by feeding video/text separately to BERT but we adopt squared masks for simplicity.

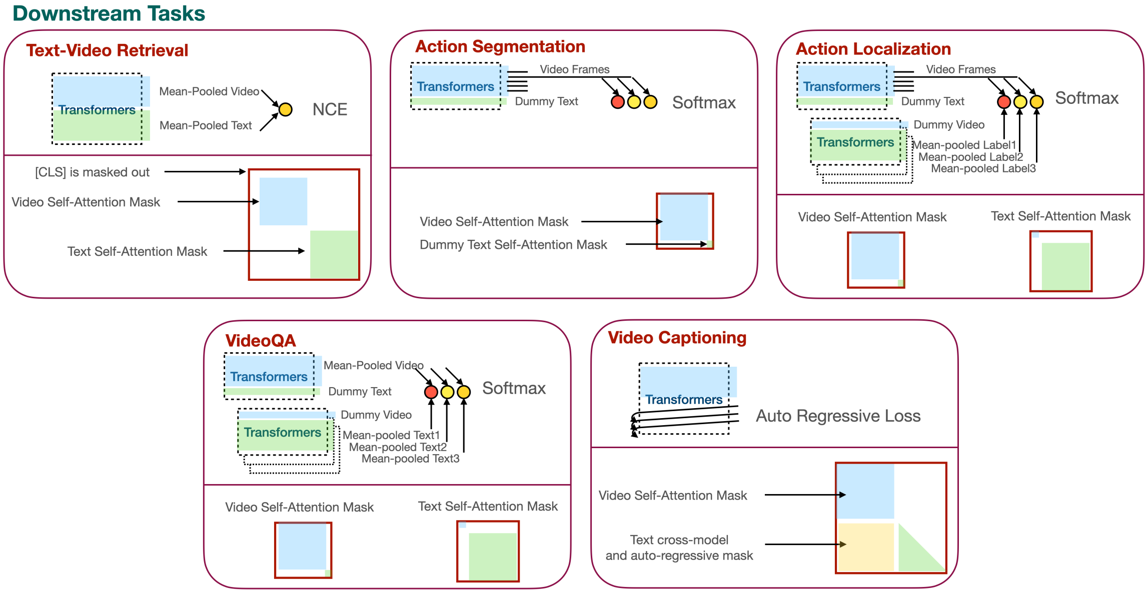

Figure 3: Fine-tuning of downstream tasks: we adopt different types of attention masks for BERT to accommodate downstream tasks that require different modalities: in each box, the upper sub-figure indicates a forward computation; the lower sub-figure indicates squared self-attention mask, where tokens from each row have a weighted sum of columns that are not in white colors.

be used by video and text, respectively, aiming to learn sequence-level features(Clark et al., 2019). The `[CLS]` is disabled as no need to learn features across video and text. After forwarding, all hidden states of video and text tokens are average pooled, respectively. Then we use a contrastive loss on text-video similarity to discriminate a ground-truth video clip from other video clips in the same batch for a given text clip. During the evaluation, to ensure video and text are isolated (to avoid leaking ground-truth of a similar pair), we split text and video and forward them separately. We report an ablation study in Section 5 showing that the MMM introduced in the previous section is crucial to ensure that the pre-trained hidden states (for video or text) are a good initialization for retrieval tasks.

4.2 Action Segmentation

Action segmentation is to assign each frame of a video with one of the pre-defined labels. This is similar to the named entity recognition (NER) task in NLP but on video frames. We feed in VLM with the whole video, a dummy text token, and an isolated attention mask. Then we add a classification head (with the number of pre-defined labels) on top of the hidden states for each video token in the last layer of VLM.

4.3 Action Step Localization

In action step localization, each video belongs to a task with multiple steps, where each step is described as a short text. Then each frame of a video needs to be aligned with a step in text form. The challenge for applying BERT to action step localization is similar to text-video retrieval: video frames need to be aligned with textual steps in joint space and it is almost impossible for pairwise video/text matching because the number of frame/text pairs is large.

Similar to the text-video retrieval model, we also apply isolated attention masks to video and text. The major difference is that we pass video and text separately to BERT. This is because the video can be several minutes long (more than 100 tokens) but the number of text labels for each video is fixed (e.g. under 10). To keep the format of BERT being consistent for multi-modal inputs, we add a dummy text token for video forwarding and a dummy video token for text, respectively. For a given frame(video token), we compute the distribution of that frame over textual steps via dot products and the softmax function.

4.4 Multiple-choice VideoQA

Multiple-choice VideoQA (Yu et al., 2018) aligns each video with one out of several candidate answers in the text. The major difference between action step localization and multiple-choice VideoQA is that the video hidden state is not on frame-level but sequence-level. We apply isolated attention masks to BERT and forward video and text answers (with dummy tokens), respectively. Then the answer with the maximum similarity with the video is reported. During fine-tuning, we apply contrastive loss on video-text similarity to rank answers.

4.5 Video Captioning

Another big challenge of using a single encoder is how to apply generative tasks (such as video captioning) without pre-training an explicit decoder. We observe that a transformer decoder (Vaswani et al., 2017) has the following major differences from an encoder: (1) an auto-regressive loss that does not allow a text token to see future tokens; (2) a prediction head to generate texts. To resolve (1), one can easily fine-tune the text segment of VLM as auto-regressive loss by passing in shifted tokens and a lower-triangle attention mask to the text segment, as shown in Figure 3. To resolve (2), inspired by (Rothe et al., 2020; Zhou et al., 2020) that uses BERT as a decoder, one can re-use language model heads as prediction heads for generation. Note that this setting has less architecture design than a standard transformer decoder (e.g. no explicit self-attention on text or cross-attention on video). The implicit text decoder inside BERT shares self-attention with the video encoder so to save the total number of parameters.

5 Experiment

5.1 Dataset

5.1.1 Pre-training

We adopt the Howto100M dataset (Miech et al., 2019) for pre-training, which contains instructional videos originally from YouTube via searching keywords from wikihow (`www.wikihow.com`). After filtering the unavailable ones, we get 1.1M videos. We split 4000 videos as the validation set and the rest for pre-training. On average, the duration of each video is about 6.5 minutes with 110 clip-text pairs. After removing repeated texts within overlapped clips from ASR, we get about 7.7+ GB texts of captions, with 2.4 tokens per second on average.

5.1.2 Fine-tuning

MSR-VTT (Xu et al., 2016) is a popular dataset for *text-video retrieval* and *VideoQA*. It has open domain video clips, and each training clip has 20 captioning sentences labeled by humans. There are 200K clip-text pairs from 10K videos in 20 categories, including sports, music, etc. Following JSFusion(Yu et al., 2018; Miech et al., 2019), we randomly sampled 1,000 clip-text pairs as test data. We further use the QA test data (Yu et al., 2018) as the dataset for multiple-choice VideoQA.

Youcook2 (Zhou et al., 2017) contains 2,000 cooking videos on 89 recipes with 14K video clips from YouTube. The overall duration is 176 hours (5.26 minutes on average). Each video clip is annotated with one captioning sentence. Follow the split setting in(Miech et al., 2019), we evaluate both text-based video retrieval and multimodal video captioning tasks. We filter the data and make sure there is no overlap between pre-training and evaluation data. After filtering out unavailable ones, we have 9,473 training clip-text pairs from 1222 videos and 3,305 test clip-text pairs from 430 videos.

COIN (Tang et al., 2019) are leveraged to evaluate *action segmentation*. It has 11,827 videos (476 hours) and each video is labeled with 3.91 step segments on average and 46,354 segments in total. There are 778 step labels, plus one background (Outside) label. Since one video can last for several minutes that are much longer than the maximum length of the video segment of VLM. We apply a sliding window with step size 16 and window size 32. During inference, we average the logits for overlapped frames from multiple windows.

CrossTask (Zhukov et al., 2019) is a dataset for action localization that contains 83 different tasks and 4.7k videos. Each task has a set of steps with text descriptions annotated on temporal frames of the video. We use the testing data split via the official code[3], which contains annotated 1690 videos. The rest of the 540 annotated videos are used for weakly supervised training.

5.2 Hyper-parameters

We extract video tokens from video frames using the S3D encoder pre-trained from (Miech et al., 2020). The fps is 30 and we extract one (1) video token per second with the dimension of 512. We apply an MLP to transform such 512 dimensions to the hidden size (768) of $\text{BERT}_{\text{BASE}}$.

Following (Luo et al., 2020), we adopt $\text{BERT}_{\text{BASE}}$ (uncased) as our base model and tuned directly from BERT's weights, so all hyper-parameters are the same as the original BERT. The maximum length of BERT is set as 96, where 32

Model	Paradigm	#params.	#loss	#unimodal/cross en/decoder	Joint Retrieval	Generation
MMT(Gabeur et al., 2020)	task-specific alignment	127.3M	1	2/0/0	yes	no
ActBERT(Zhu and Yang, 2020)	weakly supervised/MTL	n/a (3 typed attentions)	4	0/1(modal-typed attn.)/0	no(pair)	extra decoder
VideoAsMT(Korbar et al., 2020)	weakly supervised/MTL	286M(base)/801M(large)	1	1/1/1	no (gen.)	yes
HERO(Li et al., 2020b)	SSL(w/ sup. video feat.)/MTL	159M	5	1(query)/2/0	no(pair)	extra decoder
UniVL(Luo et al., 2020)	SSL/MTL	260M	5	2/1/1	yes	yes
VLM	SSL/Task-agnostic	**110M**	**1**	0/**1**/0(shared w/ encoder)	yes	yes

Table 1: Comparison of pre-trained models on learning paradigms (SSL means self-supervised learning; MTL means multi-task learning), number of parameters (# params.), number of losses (#loss), number of unimodal/cross-modal encoders/decoders, and whether to support retrieval in joint space(joint retrieval) and text generation. Types and numbers are estimated based on released code or papers: exceptions are in parenthesis (e.g. pair means pairwise matching using `[CLS]`). VLM is extremely simple with fewer parameters and limitations.

tokens are for videos and the rest tokens are for text and special tokens. Remind that texts are 2.4 tokens per second and video tokens are 1 token per second. We form a text clip with a random length in-between 8 and 64 text tokens and collect the corresponding video clip to form a training example. We randomly sample 32 video/text clip pairs from each video and use 8 videos to form a batch of size 256. Each training example has 50% chance for MMM (25% for whole video masking and 25% for whole text masking) and 50% chance on MFM-MLM (with 15% probability of video and text token masking).

We pre-train VLM on 8 NVIDIA Tesla V100 GPUs (each with 32 GB memory) for 15 epochs using fp16 for one (1) day. Following (Liu et al., 2019), we choose Adam (Kingma and Ba, 2014) optimizer with initial learning rate of 5e-5 (with betas as (0.9, 0.98)), 1000 steps of warm-up and a polynomial decay learning rate scheduler. Gradients are clipped with 2.0. All fine-tuning tasks use the same hyper-parameters as pre-training except the number of warm-up steps is 122.

5.3 Model Comparison

We first investigate the design choices of VLM compared to other transformer-based multimodal pre-training baselines. As shown in Table 1, we collect training paradigms, model sizes, etc. of these models (estimated based on their source codes or papers). VLM is significantly smaller than other models since it is just a BERT$_{\text{BASE}}$ (uncased), while it is still fully self-supervised, task-agnostic (e.g. no training on retrieval or auto-regressive style tasks) and supports joint retrieval and text generation.

5.4 Quantitative Analysis

We investigate the performance of VLM on fine-tuning tasks with very basic setups (e.g. no augmented features, large LMs, optimized losses for particular tasks). Note that it could be hard for fair comparisons between task-agnostic and task-specific approaches. We list other baselines by type and our goal is a simple baseline for task-agnostic pre-training as better initialization of strongly performed fine-tuning models.

Text-video Retrieval We use MSR-VTT and Youcook2 to evaluate the performance on text-video retrieval. The results are shown in Table 2 and 3, respectively. VLM achieves good performance on these two datasets, indicating that the MMM and isolated self-attention mask can be used together for joint retrieval. Ablation study shows that using an isolated self-attention mask alone does not yield good performance, indicating MMM is very important to learn features for alignment. Note that our pre-training is task-agnostic but still outperforms baselines with retrieval style pre-training.

Action Segmentation We report the results of action segmentation on COIN dataset in Table 4.

Method	Frame Accuracy
NN-Viterbi (Richard et al., 2018)	21.17
VGG (Simonyan and Zisserman, 2014)	25.79

Table 7: Video captioning results on Youcook2 dataset.

VLM outperforms other baselines indicating its good token-level video representations. Note that this task only tests the hidden states of the video indicating the unimodal encoding capability of VLM is not compromised.

Action Step Localization We setup two (2) evaluations for the CrossTask dataset. First, we evaluate the zero-shot transfer of VLM. Note that existing studies evaluate Crosstask with retrieval/alignment style pre-training, where the aligned hidden states are directly used for action step localization. Our task-agnostic pre-training derives an even harder problem: applying hidden states learned from proxy tasks on video frame/text alignment for action step localization without explicitly training on alignment. We simply use the hidden states from the last layer of VLM for video/text representation and directly compute the similarities between video frames and text descriptions. Surprisingly, the performance is better than some baselines and closer to one supervised method. This indicates masked token loss together with MMM can learn certain video-text alignments in joint space. Second, we use just 540 videos for weakly supervised training and we get a much better result.

Video Question Answering We use MSR-VTT QA to evaluate multiple-choice question answering. Recall that this task essentially tests video-text similarity. The performance of VLM is better than ActBERT, which leverages pairwise matching for each video/answer pair.

Video Captioning We lastly evaluate VLM on video captioning with autoregressive attention mask with other baselines that have an explicit text decoder. As shown in Table 7, our "compact" decoder using BERT's LM heads is surprisingly good at video captioning compared to other fine-tuning baselines with external decoders (e.g. Coot). This indicates that it is possible to remove an explicit decoder and sharing weights between video and text tokens.

5.4.1 Ablation Study

We use Youcook2 as the base task for the ablation study on text-retrieval and video captioning. We are interested in the following study: (1) percentage of examples for MMM (w/ MMM x%); (2) minimum length of text tokens, where the length of video will be determined by the start/end timestamps of text tokens; (3) performance of $\mathcal{L}_{\text{VLM}}$ (Equation 8). The results are shown in Table 8 and Table 9.

Effects of MMM Without MMM (w/ MMM 0%, or MFM-MLM 100%), the performance significantly dropped. This indicates that a naive adoption of traditional MFM-MLM masking may not learn joint video/text representations well, as indicated by both retrieval and captioning task. We suspect a masked token is more likely predicted from tokens of the same modality. We further try MMM with different probabilities (30% or 70%) and 50% is the best.

Minimum Length of Texts The length of a clip can be important for retrieval tasks (Miech et al., 2020). We ran VLM on longer (at least 16 text tokens) video/text pairs. The performance is slightly dropped, indicating pre-training on longer clips may not cover fine-tuning tasks with short clips.

Effects of Masked Token Loss We notice that using multi-task style loss $\mathcal{L}_{\text{MFM-MLM}}$ may reduce the performance. This indicates learning a masked token from both video/text tokens can help.

VLM	R@1	R@5	R@10	Median R
w/ MMM 50%	27.05	56.88	69.38	4.0
w/ MMM 0%	15.12	39.47	52.81	9.0
w/ MMM 30%	25.30	54.80	68.96	4.0
w/ MMM 70%	25.17	54.98	69.11	4.0
w/ min. 16 text tokens	25.84	54.43	68.29	5.0
w/ $\mathcal{L}_{\text{MFM-MLM}}$	26.93	55.92	69.86	4.0

Table 8: Ablation study of VLM for text-based video retrieval on Youcook2.

VLM	B-3	B-4	M	R-L	CIDEr
w/ MMM 50%	17.78	12.27	18.22	41.51	1.3869
w/ MMM 0%	15.47	10.54	16.49	38.83	1.2163
w/ MMM 30%	16.57	11.30	17.55	40.76	1.3215
w/ MMM 70%	16.94	11.68	17.67	41.24	1.3739
w/ min. 16 text tokens	17.25	12.00	17.67	40.62	1.3076

Table 9: Ablation study of VLM for video captioning on Youcook2 dataset.

5.5 Qualitative Analysis

5.5.1 Error Analysis

Text-video retrieval. We use MSR-VTT as the dataset for error analysis on text-video retrieval, as shown in Table 10 of Appendix. We pair the query text with the text of the top-1 ranked video to show 100 errors in ranking since video tokens are harder to present. We observe the following types of errors in video understanding: (1) objects sometimes are hard to recognize such as dog or cat; (2) attributes of objects may be hard to match the text, e.g. gender, ages, etc. (3) subtle differences of actions; (4) specific videos for a general query or vice versa, e.g. people vs basketball player. We believe the last type may not be errors but hard for existing annotations or evaluations to separate.

Video Captioning. We further examine the generated text from video captioning. Note that our video captioning has no support from ASR or transcript so the video is the only source to generate text content and errors of video understanding can easily be reflected in the text. From Table 11 of Appendix, we notice that one major type of error is from objects of similar shapes and colors, e.g. onion rings vs shrimp.

5.5.2 Visualization

. We observe that video tokens take the majority of space while text tokens are rather clustered together. This is probably because videos from the physical world are more diverse and sparse than text from a fixed vocabulary.

We plot the self-attention of VLM layers within and in-between each modality, as in Figure 4 of Appendix. We observe the following patterns from all 144 attention heads:

- Unlike LMs, there are no recurrent (shifted) position-wise patterns for video tokens;
- Self-attentions in the 1st layer are more diverse than later layers. This suggests that existing video encoders might be too deep for transformers;
- Some attention heads show patterns of cross-modal mapping in-between video and text (e.g. sub-figure (a));
- Word-level cross-modal co-reference: video tokens with *pouring soy sauce* refers to the text token of "soy" (e.g. sub-figure (b));

6 Conclusions

We presented a task-agnostic pre-training with new masking schemes that enable the training of a single masked language model that can accept either video or text input, or both. We showed that this simple VLM model can be effectively tuned for a broad range of downstream tasks, such as text-video retrieval and video captioning via different types of attention masks. Experimental results show that the proposed methods maintain competitive performance while requiring a significantly smaller number of parameters than competing methods.

Acknowledgments

We thank Huaishao Luo (author of UniVL(Luo et al., 2020)), Mandela Patrick (author of Support-Set(Patrick et al., 2021)) and Luowei Zhou (author of Youcook(Zhou et al., 2017)) for supports of baseline setup.

Corpus-Level Evaluation for Event QA:
The IndiaPoliceEvents Corpus Covering the 2002 Gujarat Violence

Abstract

Automated event extraction in social science applications often requires corpus-level evaluations: for example, aggregating text predictions across metadata and unbiased estimates of recall. We combine corpus-level evaluation requirements with a real-world, social science setting and introduce the IndiaPoliceEvents corpus—all 21,391 sentences from 1,257 English-language *Times of India* articles about events in the state of Gujarat during March 2002. Our trained annotators read and label every document for mentions of police activity events, allowing for unbiased recall evaluations. In contrast to other datasets with structured event representations, we gather annotations by posing natural questions, and evaluate off-the-shelf models for three different tasks: sentence classification, document ranking, and temporal aggregation of target events. We present baseline results from zero-shot BERT-based models fine-tuned on natural language inference and passage retrieval tasks. Our novel corpus-level evaluations and annotation approach can guide creation of similar social-science-oriented resources in the future.

1 Introduction

Understanding the actions taken by political actors is at the heart of political science research: How do actors respond to contested elections (Daxecker et al., 2019)? How many people attend protests (Chenoweth and Lewis, 2013)? Which religious groups are engaged in violence (Brathwaite and Park, 2018)? Why do some governments try to prevent anti-minority riots while others do not (Wilkinson, 2006)? In the absence of official records, social scientists often turn to news data to extract the actions of actors and surrounding events. These news-based event datasets are often constructed by hand, requiring large investments of time and money and limiting the number of researchers who can undertake data collection efforts.

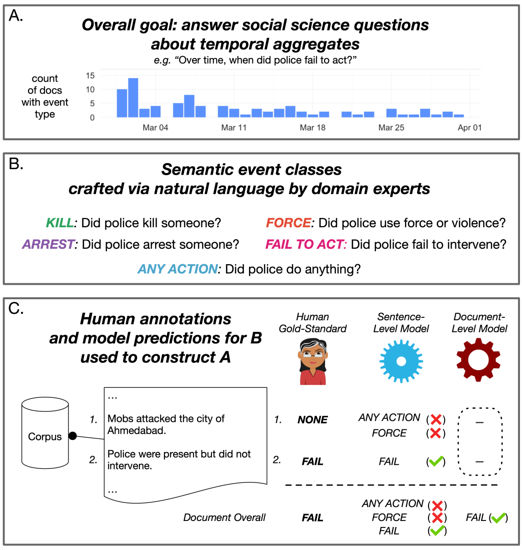

Figure 1: Motivation (A-B) and procedures (B-C) for this paper: **A.** Social scientists often use text data to answer substantive questions about temporal aggregates. **B.** To answer these questions, domain experts use natural language to define semantic event classes of interest. **C.** Our IndiaPoliceEvents dataset: Humans annotate *every* sentence in the corpus in order to evaluate whether a system achieves full recall of relevant events. In production, computational models run B's queries to classify or rank sentences or documents, which are aggregated to answer A.

Automated extraction of political events and actors is already prominent in social science (Schrodt et al., 1994; King and Lowe, 2003; Hanna, 2014; Hammond and Weidmann, 2014; Boschee et al., 2015; Beieler et al., 2016; Osorio and Reyes, 2017) and is increasingly promising given recent gains in information extraction (IE), the automatic conversion of unstructured text to structured datasets (Grishman, 1997; McCallum, 2005; Grishman, 2019). While social scientists and IE researchers have over-

August 1–6, 2021.

lapping interests in evaluating event extraction systems, social scientists have particular needs that have so far been under-addressed by the computer science IE research community.

Figure 1A shows a common goal of social scientists: answering aggregate substantive questions from corpora such as, *"Over time, when did police fail to act?"* which could be measured by, for example, the daily count of newspapers mentioning the event class over time. For these types of questions, social scientists predominantly want very high recall methods because often the events of interest are sparse or their substantive conclusions depend on identifying *every* event in a corpus.[1]

In contrast to this corpus-level focus, much of current IE research has focused on distinct subtasks such as entity linking, relation extraction, and coreference resolution.[2] Furthermore, all widely used event datasets (e.g. ACE, FrameNet, ERE, or KBP; Aguilar et al. 2014) are typically curated at the *ontology* level—attempting to cover a selected set of event types—but have little consideration of the *corpus* level—annotated documents are not necessarily a substantively meaningful sample of the broader corpora from which they are drawn. We try to address these evaluation shortcomings in this paper.

In addition to corpus-level recall, social scientists are often interested in using off-the-shelf models that are easily extensible to their domain questions. Fortunately, recent NLP research has seen a paradigm shift from structured semantic and event representations (Abend and Rappoport, 2017; Aguilar et al., 2014) which are limited by their predefined schemas, to directly using natural language to encode semantic arguments (*QA-SRL*; He et al. 2015; Stanovsky et al. 2016; FitzGerald et al. 2018; Roit et al. 2020) and events (Levy et al., 2017; Liu et al., 2020; Du and Cardie, 2020). In this paper, we also use natural language questions to annotate and model the event classes in our dataset, not only facilitating ease of annotation, but also allowing for the evaluation of zero-shot natural language inference and information retrieval models for the tasks.

To address these social science desiderata, we present the INDIAPOLICEEVENTS corpus[3] which has the following useful properties:

- **Social science relevance.** Our dataset consists of all 21,391 sentences from all 1,257 *Times of India* articles about events in the state of Gujarat during March, 2002—a period that is of deep interest to political scientists due to widespread Hindu–Muslim violence (Dhattiwala and Biggs, 2012; Berenschot, 2012; Basu, 2015). We focus on the actions of a single entity type, *police*, because of extensive substantive research on police actions during the Gujarat violence (Varadarajan, 2002). Our choice of location, actors, and event types are motivated by Wilkinson (2006)—political science work which created a hand-coded event dataset from newspapers about communal violence events in India from 1950-1995.
- **Corpus-level full-recall.** Unlike most previous event evaluation datasets, our annotators read *every* document in our corpus (that match a loose spatiotemporal filter; §4.1). This requires substantially more annotation work compared to a more targeted filter to select documents to annotate (e.g. matching via keywords), but eliminates a potential source of evaluation bias compared to alternative document retrieval data collection approaches (Grossman et al., 2016), and allows for full-recall evaluation of end-to-end event extraction systems.
- **Document-level context.** Our annotators read the context of an entire document to provide answers for each question on each sentence. We then aggregate these sentence-level answers to make document-level inferences. This allows us to accurately label sentences with anaphora or context-specific meaning.
- **Natural language event specification and zero-shot model evaluation.** In constructing our dataset, we gather annotations via a natural question-answer format because it allows for easily specifying constraints on arguments (e.g. *police* being the agent). Additionally, it allows for specifying event predicates not covered within the ontologies of current structured semantic representations, or with additional hard-to-specify

---

[1] In some studies, researchers rely on an assumption that events are missing at random, but others depend on knowing whether an event occurred at least once.

[2] The first five Message Understanding Conferences (MUC) required participants to submit complete systems to fill event templates; however, starting with MUC-6 and subsequent ACE and KBP tasks, information extraction was broken into distinct modules (Grishman and Sundheim, 1996; Grishman, 2019).

[3] Dataset, source code, and appendix are provided at http://slanglab.cs.umass.edu/IndiaPoliceEvents/ and https://github.com/slanglab/IndiaPoliceEvents.

semantic phenomena—e.g. "Did police fail to act?" or when political actors do *not* take an action, which is very important to political scientists (e.g. Wilkinson (2006)). This format also allows us to evaluate zero-shot natural language inference and information retrieval models.

- **High-quality annotators who provide uncertainty explanations.** We hire and train political science undergraduate students as annotators to ensure quality control, retraining annotators over a period of several months with training videos, two hour-long live meetings, and individual annotator feedback before producing our final dataset. Our annotators also provide free-text explanations for instances in which they are uncertain about the answer. These rationales are important given the recent attention to propagating annotator uncertainty in downstream NLP tasks (Dumitrache et al., 2018; Paun et al., 2018; Pavlick and Kwiatkowski, 2019; Keith et al., 2020) and social scientists' interest in quantifying uncertainty (King, 1989; Wallach, 2018).

In the remainder of this paper, we use our dataset for three levels of evaluation: sentence-level classification, ranking of documents to reduce manual reading time, and constructing temporal aggregates useful to social scientists (§3). We describe in detail our annotation and dataset creation process (§4), provide baseline models (§5), and evaluate their performance on all three tasks (§6).

2 Related Work

NLP and IR for police activity. Natural Language Processing (NLP) and Information Retrieval (IR) have been used for analysis of other police activity such as identifying victims of police fatalities from news articles (Keith et al., 2017; Nguyen and Nguyen, 2018; Sarwar and Allan, 2019); extracting eye-witness event types from Twitter including police activity and shootings (Doggett and Cantarero, 2016); detecting dialogue acts from police stops (Prabhakaran et al., 2018); and computational analysis of degree of respect in police officers' language (Voigt et al., 2017).

Political event extraction. Automated event extraction in social science is generally performed using dictionary methods and a set of substantively motivated event types and actor categories (Schrodt et al., 1994; Gerner et al., 2002; Beieler et al., 2016; Boschee, 2016; Radford, 2016; Brathwaite and Park, 2018; Liang et al., 2018). Other work uses supervised learning to infer events such as conflict or cooperation (Beieler, 2016) and protests (Hanna, 2017). While some have attempted to induce event types without supervision (O'Connor et al., 2013; Huang et al., 2016), most social science applications of event extraction require substantial human input either through constructing keyword lists, or annotating texts to train classifiers.

Recall-focused IR. TREC's total-recall track (Grossman et al., 2016) is inspired by real-world recall-focused applications from law, medicine, and oversight (McDonald et al., 2018). However, the track's datasets are not typically focused on events and assume documents are collected through interacting with a system. Other work has focused on methods for truncating ranked lists that minimize the risk of viewing non-relevant documents (Arampatzis et al., 2009; Lien et al., 2019), but this line of work does not evaluate on semantic retrieval of event classes.

3 Three Levels of Tasks

In order to answer substantive social science questions, for example *"Does variation in party control of state government affect whether police failed to intervene in ethnic conflict?"* (Wilkinson, 2006), social scientists often need to gather counts of events (e.g. "police failed to intervene") from text when official government records are lacking. Ideally, a social scientist could use automatic information extraction methods (Cowie and Lehnert, 1996; McCallum, 2005; Grishman, 2019) to transform unstructured text into a structured database that would be useful in a quantitative analysis. Yet, even state-of-the-art information extraction systems often give less than perfect accuracy, so social scientists must still manually analyze large portions of their corpus in order to extract events of interest. This quantitative research process motivates the following three tasks which our dataset can be used to evaluate:

Task 1: Sentence classification. Although social science corpora typically consist of *documents*, it would be useful for a system to classify *sentences* that contain events of interest.[4] Highlighting relevant sentences could, for semi-automated systems, reduce a social scientist's reading time, and, for fully-automated systems, provide sentence-level evidence of the automated method's *validity*, a cru-

---

[4] This is closely related to extracting "explanation representations" (Thayaparan et al., 2020), "supporting facts" (Yang et al., 2018b) or "evidence sentences" (Wang et al., 2019) in the machine reading comprehension literature.

cial aspect of research in text-as-data (Grimmer and Stewart, 2013) and the broader social sciences (Drost et al., 2011). INDIAPOLICEEVENTS allows for evaluation of sentence-level precision, recall, and F1 (§6.1).

Task 2: Document ranking. For semi-automated systems, social scientists must navigate the tradeoff between recall and manual reading time. Social scientists may rely on IR methods which present ranked lists of relevant documents (Baeza-Yates et al., 1999; Schütze et al., 2008). However, our informal interviews with social scientists suggest they want to know at what point they have read enough documents to achieve very high (95–100%) recall. In creating INDIAPOLICEEVENTS, annotators read every single sentence in a corpus which allows for full evaluations of average precision and our newly proposed metric: the proportion of the corpus that would have to be read to achieve Recall=X (PropRead@RecallX) (§6.2).[5]

Task 3: Substantive temporal aggregates. For social scientists, NLP and IR methods are used in service of answering substantive questions from text. In addressing our running example *"Did differences in party control of state government affect whether police failed to intervene in ethnic conflict?"* a social scientist could measure how many news articles[6] discuss "police failing to intervene" each day for a given temporal span. In this setting, it would be helpful to know if changes in model performance at the sentence or document level resulted in significant differences at this aggregate level. We design INDIAPOLICEEVENTS with the capability of evaluating these meaningful corpus-level temporal aggregates, such as the mean absolute error and Spearman rank correlation coefficient between per-day event counts of computational models and ground truth annotations (§6.3).

4 Annotations and Dataset

4.1 Corpus selection

We curate our corpus with a substantively motivated specification: it is restricted to a single authoritative news source, over a defined span of time, with articles that mention one of two locations involved in or related to the 2002 Gujarat violence.

Event Class	Pos. Sents.		Pos. Docs.	
KILL	96	(0.45%)	50	(3.98%)
ARREST	299	(1.40%)	128	(10.17%)
FAIL TO ACT	207	(0.97%)	114	(9.05%)
FORCE	222	(1.04%)	90	(7.15%)
ANY ACTION	2,073	(9.69%)	457	(36.24%)

Table 1: INDIAPOLICEEVENTS number and percentage of positive sentences (sents.) and documents (docs.) after the adjudication round. In total, the dataset contains 21,391 sentences and 1,257 documents.

From the website of *Times of India*, an English language newspaper of record in India, we first download all news articles published in March 2002.[7] During this period, widespread communal violence occurred in India, following the death of 59 Hindu pilgrims in a train fire in the state of Gujarat. In the subsequent months, reprisal attacks were directed at mostly Muslim victims across the state (Human Rights Watch, 2002; Subramanian, 2007). In creating our annotations, we specifically focus on the actions of police during these events, since a large body of evidence points to the importance of police intervention and non-intervention in quelling or permitting ethnic violence (Human Rights Watch, 2002; Wilkinson, 2006; Subramanian, 2007). We focus on the first month of the violence in order to fit within our annotation budget. This month saw the greatest levels of violence, though violence continued for a period of months afterward.

Our final corpus consists of the subset of scraped documents published in March 2002 that include either the name of the state (*Gujarat*) or a city related to the beginning of violence (*Ayodhya*).[8] Selecting on geographical and temporal metadata is a high recall way to filter the corpus without biasing the dataset by filtering to topic or event-related keywords, thus giving a better view of the true recall of an event extraction method.

---

[5] We do not address the problem of estimating recall when gold-standard labels are only known for the subset of documents read so far, but INDIAPOLICEEVENTS could be used to evaluate that task in future work.

[6] Count of news articles are often used in social science as a proxy for the true measure of the event, e.g. Nielsen (2013); Chadefaux (2014).

[7] §9 discusses copyright issues.

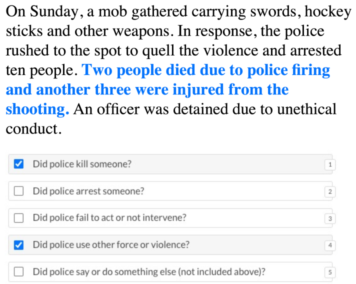
[8] Selecting documents using location-based keywords is a standard first step in political science text analysis (Mueller and Rauh, 2017). This filters to 18% of the total articles in March 2002. The precipitating event for the March 2002 violence was the burning of a train of pilgrims returning from Ayodhya.

4.2 Annotations via natural language

To collect annotations, we give annotators an entire document for context, and then ask them *natural language questions* about semantic event classes anchored on the actions of police for each sentence in that document:

- KILL: "Did police kill someone?" Lethal police violence is an important subject for social scientists (Subramanian, 2007). Example sentence: *"In Vadodara, one person was killed in police firing on a mob in the Fatehganj area."*
- ARREST: "Did police arrest someone?" Knowing when and where police made arrests and who was arrested is an important part of understanding police response to communal violence. Example sentence: *"Police officials said nearly 2,537 people have so far been rounded up in the state."*
- FAIL TO ACT: "Did police fail to intervene?" In the 2002 Gujarat violence, police were often accused of failing to prevent violence or allowing it to happen. Knowing when police were present but did not act is important for understanding the extent of this phenomenon and its potential causes (Wilkinson, 2006). Example sentence: *"The news items [...] suggest inaction by the police force [...] to deal with this situation."*
- FORCE: "Did police use force or violence?" Political scientists are interested not only when police kill but the level of force they use. Example sentence: *"Trouble broke out in Halad [...] where the police had to open fire at a violent mob."*
- ANY ACTION: "Did police do anything?" We collect annotations on all police activities, so that social scientists could, in the future, label more fine-grained event classes. Example sentence: *"In the heart of the city's Golwad area, the army is maintaining a vigil over mounting tension following [...]"*

Figure 2 shows the interface annotators see.[9] See Appendix §A for exact annotation instructions and per-question agreement rates.



On Sunday, a mob gathered carrying swords, hockey sticks and other weapons. In response, the police rushed to the spot to quell the violence and arrested ten people. **Two people died due to police firing and another three were injured from the shooting.** An officer was detained due to unethical conduct.

☑ Did police kill someone? 1

☐ Did police arrest someone? 2

☐ Did police fail to act or not intervene? 3

☑ Did police use other force or violence? 4

☐ Did police say or do something else (not included above)? 5

Figure 2: We present annotators with a highlighted sentence (blue) and its document context. Their task is to click a check-mark for the event-focused questions for which there is a positive answer in the highlighted sentence.

Following the guidelines of Pustejovsky and Stubbs (2012), we first assign each document to two annotators and then follow with an *adjudication round* in which items with disagreement are given to an additional annotator to resolve and create the gold standard. For annotators, we select undergraduate students majoring in political science (as opposed to crowdworkers) in order to approximate the domain expertise of social scientists.[10] We initially recruited and selected 12 students. After a pilot study and two rounds of training, in which we provided individual feedback to annotators via email, we selected 8 final annotators based on their performance. Each student annotated around 330 documents ($\sim$5,500 sentences) using the interface described in the Appendix, Figure A2.

Table 1 shows the prevalence of the event classes after the adjudication round. Note that some of the classes are relatively rare: of all documents, only roughly 4% have KILL and 7% have FORCE. Our annotators had fairly high inner-annotator agreement for KILL and ARREST, with Krippendorff's alpha values of 0.75 and 0.71 respectively. Other questions, such as FAIL TO ACT and "Did police use other force?" had lower agreement ($\alpha < 0.4$), indicating more difficulty and ambiguity. Full agreement rates are show in Appendix, Table A1.

4.3 Annotation uncertainty explanations

We also collect free-text *annotation uncertainty explanations* in order to analyze instances that an-

---

[9] While the first three classes each correspond to a single annotation question, we create FORCE and ANY ACTION by taking the union of several different questions posed to annotators, which made it easier for annotators to distinguish between different subtypes. FORCE is the union of "Did police kill someone?" and "Did police use other force or violence?". ANY ACTION is the union of four questions: "Did police kill someone?", "Did police arrest someone?", "Did police use other force or violence?", and "Did police do or say something else (not included above)?".

[10] Our annotation protocol (no. 2238) was reviewed as exempt by the University of Massachusetts Amherst's IRB office. Annotators were paid $25 per training session and a lump sum for document annotations; we expected this to exceed $14 USD per hour based on a generous (conservatively high) estimate of completion time. All annotators reported their work time was less than this estimate.

notators found difficult or ambiguous. For each sentence presented to annotators, we ask "If you found this example difficult or ambiguous please explain why" and ask them to provide a short written response in a provided text-box. This follows recent work that that has emphasized the importance of annotator disagreement not necessarily always as error in annotation but instead as ambiguity that is inherent to natural language and a potential useful signal for downstream analyses (Dumitrache et al., 2018; Paun et al., 2018; Pavlick and Kwiatkowski, 2019; Keith et al., 2020).

Annotators remarked on several types of text they were uncertain about: agents of actions who were not explicitly mentioned but implicitly police, named entities whose status as police is ambiguous, confusion about what precisely constitutes an "arrest", and confusion arising from the lack of specific cultural knowledge (e.g., around the Indian crowd-control tactic of "lathi charging"). In the appendix, see Table A3 for examples and Table A2 for a categorization of free text responses.

5 Baseline Models

We test several baseline models, all requiring no annotation (and thus most realistic for the social science use case), and assess their performance on INDIAPOLICEEVENTS.

Keyword matching. Boolean keyword queries are a very common social science approach to document classification (e.g. Nielsen (2013); Chadefaux (2014); D'Orazio et al. (2014); Baker et al. (2016)), since they are simple, transparent, and widely supported in user software. We use conjunctive normal form rules, where inferring an event class for a sentence requires matching any term from a *police* keyword list (including both common nouns and names of major police and security institutions), as well as an event keyword. To construct the keyword lists, a domain expert coauthor first manually generates a list of seed keywords for the semantic categories *police*, *kill*, *arrest*, *intervention*, and *force*. To address lexical coverage, we then expand the keywords through word2vec (Mikolov et al., 2013) nearest neighbors, filtered to semantically equivalent words by the domain expert.[11] This process is repeated using WordNet synonym sets for lookup (Miller, 1995), resulting in 217 keywords total; see appendix (§C.2) for details.

RoBERTa+MNLI. Given two input sentences, a premise and hypothesis, the task of natural language inference (NLI) is to predict whether the premise *entails* or *contradicts* the hypothesis or does neither (*neutral*) (Bowman et al., 2015; Williams et al., 2018). Previous work has shown promise of NLI transfer learning for events: Sarwar and Allan (2020) show Sentence-BERT embeddings (Reimers et al., 2019) learned from NLI data are effective on ACE-like event retrieval; Clark et al. (2019) find for *BoolQ*, their dataset of naturally occurring boolean questions, that transfer learning from NLI data is more effective than transferring from QA or paraphrase data. We follow Clark et al. (2019)'s example and use "off-the-shelf" RoBERTa (Liu et al., 2019) fine-tuned on the MNLI corpus (Williams et al., 2018). The model takes a sentence and a declarative form of an event class question as input (§C.1), and we use its predicted probability of entailment as the probability of the event class. For document ranking, we create a document score by taking the maximum predicted probability over sentences. Future experiments could vary the amount of text (sentence vs. passage vs. document) used as input to the model.

BM25+RM3. Weighted term matching between a query and document is a strong competitor to neural ranking methods (Craswell et al., 2020; Lin, 2019), via, for example, BM25 scoring with RM3 query expansion (Lavrenko and Croft, 2001). With the Anserini BM25 implementation (Yang et al., 2018a), we set $k_1 = 0.9$ and $b = 0.4$, and conduct RM3 expansion of the query to terms found in the top $k = 10$ BM25-retrieved documents, following Lin (2019)'s hyperparameter settings. As the input query, this set of models uses the natural language questions described in §4.2. Appendix Table A5 contains full results.

ELECTRA+MS MARCO. Fine-tuned BERT (Devlin et al., 2019) and other large-scale language models have been used extensively for document ranking in information retrieval (IR) (Zhan et al., 2020; Zhang et al., 2020; Dai and Callan, 2019; MacAvaney et al., 2019). We use a competitive off-the-shelf model that uses the ELECTRA variant of BERT (Clark et al., 2020) fine-tuned on MS MARCO (Reimers et al., 2019). MS MARCO is a large-scale reading comprehension dataset in which questions are sampled from anonymized web

---

[11] We train word2vec on every article in the *Times of India* from 2002 (the same corpus as our dataset, 69,000 articles) plus another 100,000 articles from *The Hindu*, another English-language newspaper in India. We inspect each keyword's 20 nearest neighbors with highest cosine similarity.

queries, and answers to the queries are generated by crowdworkers (Nguyen et al., 2016). It was used in the 2019 TREC Deep Learning track on document and passage retrieval (Craswell et al., 2020). We use Reimers et al. (2019)'s pretrained ELECTRA+MS MARCO model. Inputs are INDIAPOLICEEVENTS passages consisting of three-sentence sliding windows with stride of one sentence and queries are the event class questions described in §4.2. Following related work (Zhan et al., 2020), we take the maximum score of all passages as the document score.

6 Results

We report the performance of the baseline models (§5) on our three tasks in Table 2 and in Figure 3.

6.1 Task 1: Sentence classification.

For sentence classification,[12] Table 2 shows that the keyword matching method slightly outperforms RoBERTa+MNLI on F1 for ANY ACTION and FORCE, which we suspect is due to the keyword method having better access to synonyms of "police" (e.g. "jawan", "RPF") particular to the *Times of India* via its *word2vec* expansion. However, RoBERTa+MNLI achieves a higher F1 score on KILL, ARREST, and FAIL TO ACT. We need further controlled experiments to understand how the concreteness of the event class, importance of identifying events' agents, and formulation of the query (e.g. "Did police use force or violence?" vs. "Were police violent?") affect the results of contextualized language models. Table 2 also shows poor performance of our keyword matching method on FAIL TO ACT (F1=0.05); however, a large-scale contextual language model seems to be able to better distinguish the semantics of the event class (F1=0.48). The Task 1 plot in Figure 3 shows that across all labels, RoBERTa+MNLI has higher recall than the keyword method for every event class. If social scientists plan to use these sentence classification methods in a semi-automated fashion (as we suggest in §1), selecting models like RoBERTa+MNLI that achieve higher recall may be important.

6.2 Task 2: Document ranking.

For Task 2, we report average precision and a new metric—the proportion of documents that would have to be read to achieve recall equal to X (*PropRead@RecallX*). We use $X = 0.95$ because social scientists typically use 95% cutoffs for significance and sampling error.[13] We leave to future work estimating recall on a corpus without ground truth. Table 2 shows that RoBERTa+MNLI outperforms both BM25 and ELECTRA+MS MARCO on both average precision and PropRead@Recall95 across all event classes. We hypothesize this is because natural language inference is a task that is much more aligned with the semantic-oriented precision at which we want to rank documents. In contrast, the MS MARCO dataset is constructed for a much higher level information need, and documents that are "relevant" could potentially not entail the semantic event class of interest. As Figure 3 shows, if a social scientist was presented with a ranked list of documents from RoBERTa+MNLI, they would only have to read 5% of the entire corpus to achieve 95% recall on KILL. RoBERTa+MNLI also does well on ARREST and FORCE with 0.17 and 0.20 PropRead@Recall95 respectively. There is consistently more difficulty across all models for ANY ACTION and FAIL TO ACT. We speculate this is because ANY ACTION is the class with the greatest prevalence, and thus is more difficult to achieve higher recall.

6.3 Task 3: Temporal Aggregates.

Figure 4 compares the outputs of three systems on FAIL TO ACT: gold-standard human annotations, keyword matching, and RoBERTa+MNLI. For this event class, both automated methods under-count the number of events marked by human annotators. In contrast, the automated techniques tend to *over*count other event types (see Appendix, Figure A5 for plots of the other event classes). While the the overall temporal trend is broadly consistent across the three methods, the decreased accuracy of the automated methods could lead to attenuation bias if they were used as input to statistical models. A qualitative examination of the extracted events also reveals the need for future work in temporal linking models: most of the events after March 25

---

[12] We do not evaluate sentences with less than 5 tokens as many of these sentences are due to sentence segmentation errors. After this filtering, the number of remaining sentences we evaluate on is 18,645.

[13] We note that 5% recall error is not equivalent to a 5% sampling error. In practice, researchers are more concerned with whether data is missing at random.

	Task 1: Sent. Cls.		*Task 2: Document Ranking*						*Task 3: Temp. Aggs.*	
	Keyw.	R+MNLI	BM25		E+MSM		R+MNLI		Keyw.	R+MNLI
Event Class	F1 ↑	F1 ↑	AP ↑	PR ↓	AP ↑	PR ↓	AP ↑	PR ↓	ρ ↑	ρ ↑
KILL	0.50	**0.74**	0.30	0.29	0.65	0.27	**0.96**	**0.05**	0.70	**0.78**

Table 2: Evaluation of two classification methods (Keyw., R+MNLI) and three ranking models (BM25, E+MSM, R+MNLI) for IndiaPoliceEvents's three tasks. Bolded numbers indicate the model that performs best on each metric and event class. **Task 1** evaluates sentence-level F1 for sentence-level keyword matching (Keyw.) and RoBERTa fine-tuned on MNLI (R+MNLI) (Liu et al., 2019). **Task 2** evaluates average precision (AP) and proportion of the corpus needed to be read in order to achieve 95% recall (PR, or PropRead@Recall95) for ranking models BM25 (Yang et al., 2018a), off-the-shelf ELECTRA language model fine-tuned on MS MARCO (E+MSM; (Reimers et al., 2019)), as well as R+MNLI's probabilistic output. **Task 3** evaluates Spearman's rank correlation coefficient (ρ) between predicted versus gold-standard counts of documents with the relevant event, for each day in March 2002. For each metric, we indicate whether a higher (↑) or lower (↓) score is better.

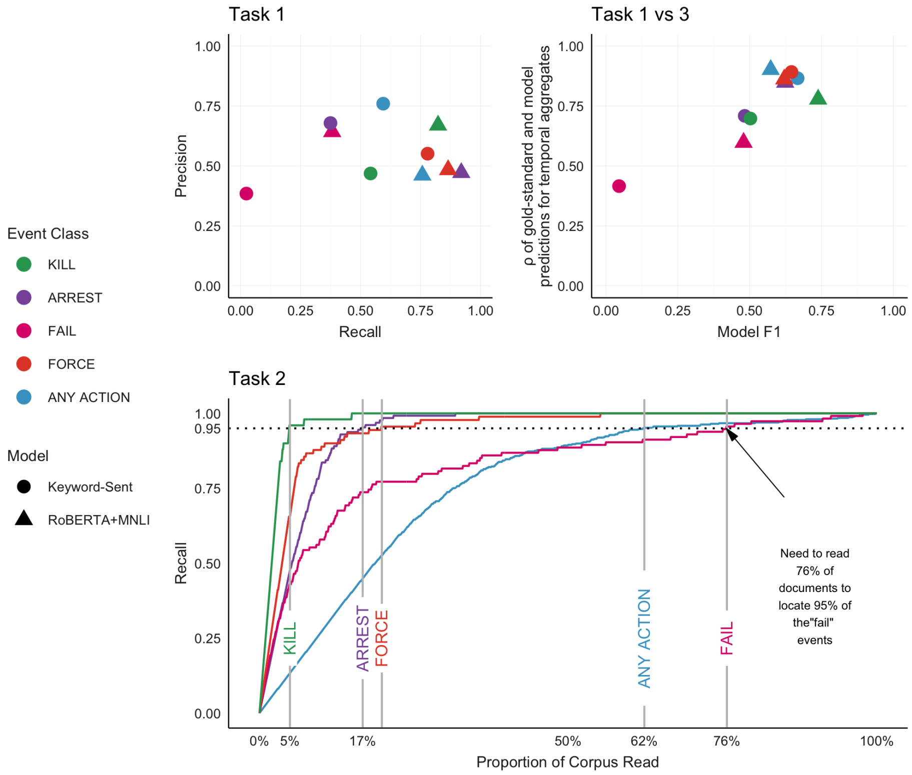

Figure 3: Keyword and RoBERTA+MNLI performance on three metrics. **(Task 1)** Precision and recall at the sentence level for two models on each semantic event class. **(Task 1 vs 3)** Sentence-level model F1 scores (x-axis) versus Spearman's ρ of hand-annotated gold-standard and model predictions for temporal aggregates (y-axis). **(Task 2)** For each class under RoBERTa MNLI, the gain curves (Grossman et al., 2016), marking PropRead@Recall95: What percentage of the ranked corpus would a researcher need to read in order to find 95% of each event classes' mentions?

are describing events from earlier in March that were being reported in the context of investigations into the violence. Table 2 shows that for all event classes except for FORCE RoBERTa+MNLI has a

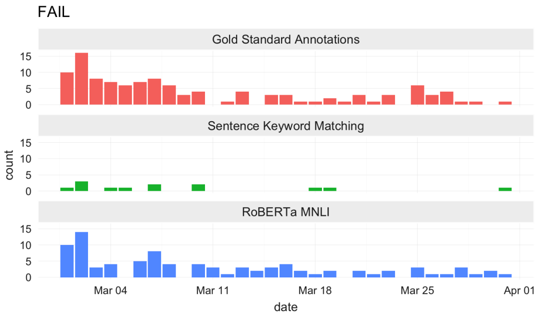

Figure 4: Number of documents per day containing a "police failing to act/standing by" event, comparing outputs from **(Top)** human annotations **(Middle)** keyword matching (Spearman's $\rho = 0.51$, comparing with gold standard) and **(Bottom)** RoBERTa finetuned on MNLI ($\rho = 0.60$).

higher Spearman's ρ[14] between the predicted versus gold-standard document counts. The Task 1 vs. 3 plot in Figure 3 shows an approximately linear relationship between the F1 scores of sentence-level models and Spearman's ρ, suggesting there is promise that NLP research focused on sentence-level models could be of use to social scientists who care about corpus-level evaluation.

6.4 Qualitative error analysis.

We manually analyze the false positives and false negatives of our best-performing baseline model, RoBERTa+MNLI. Some false positives are due to lexical semantic misunderstandings: the model often mistakes "shot" for KILL, and assigns high probability to negative FORCE sentences such as, *"The police escorting the vehicle fired into the air and dispersed the mob."* The model also has difficulty identifying the police as agents: for example, it assigns high probability to the negative KILL sentences: *"[...] scores of people have been killed in rural Gujarat due to police failure [...],"* and *"Police said that two persons had been killed in Vijaynagar [...]"*. Other errors are due to *hypotheticals*: the model assigns high probability to the negative KILL sentences *"He alleged BJP's hand in the murder of [...]"* and *"Achar claims she was an eye-witness to police complicity in the violence."* Many of the model's false negatives are due to necessary multi-sentence context (which RoBERTa+MNLI does not have as it only takes single sentences as input). For instance, the model assigns low probability to the positive KILL sentence *"Four persons have been killed and five are injured."* and FORCE sentence *"One person was injured and rushed to the SSG hospital"*; if one reads the proceeding context of both of these sentences it is clear that police are the agents of the actions.

7 Discussion and Future Work

The dataset, tasks, and evaluations we present in this work are driven by the needs of social scientists: we assess the performance of zero-shot models on metrics important to applied researchers, including recall against a fully annotated corpus and performance at temporally aggregated levels. We find cause for optimism for social scientists using BERT-style pre-trained models on their tasks. These models could potentially be used in place of social scientists' existing keyword-based classifiers, although we caution accuracy is far from perfect and applied researchers will need to extensively validate model outputs. Even with imperfect classification accuracy, we believe these zero-shot models show promise for decreasing human annotation effort by reducing the proportion of the corpus read to achieve a specific recall level (the metric we call PropRead@RecallX).

Future work can extend our dataset creation process to new semantic event classes, such as protests, communal violence itself, and other forms of participation in political and social activity. Additional annotated datasets could allow researchers to generalize the performance of zero-shot language models to new domains and event classes. Finally, tasks such as temporal and geographic linking, event deduplication and coreference, and identifying hypothetical events are unsolved but are major obstacles for applied social scientists working with automatically extracted events.

8 Acknowledgments

For helpful comments, we're grateful to Aidan Milliff, the UMass NLP group, and anonymous ACL reviewers. 9 Ethical Considerations and Broader Impact

To ensure the replicability of our work and to further research into event extraction systems for social science research, we are making the text of the news articles available to researchers alongside our annotations. While all articles were obtained from a public website without login credentials, the applicability of copyright restrictions is relevant to address.

We believe the research benefits and the limited harms to the copyright holders justify this use, due to the four criteria considered in the fair use doctrine in U.S. copyright law (U.S. Copyright Office, 2021): (1) the non-commercial, nonprofit educational purpose of our use of the text, (2) the factual nature of the news reports, (3) the limited substitutability of our dataset for the original news site,[15] and (4) our expectation that our limited corpus will not harm the market for readers of the news site.

The issue of copyright status within NLP-oriented corpora is of increasing interest. Sag (2019) argues machine learning uses of text is non-expressive and therefore falls under fair use, and Geiger et al. (2018) study the issue in the context of proposals for E.U. law. Bandy and Vincent (2021) investigate BooksCorpus, a previously poorly documented corpus widely used for training language models, finding it contains large amounts of copyrighted work, highlighting how current data curation practices in machine learning (and adjacent) communities need improvement (Paullada et al., 2020; Jo and Gebru, 2020).

We also acknowledge the sensitivities around this period of violence in India. Its significance motivates computational work to enable more effective study of it and related episodes, but our news-derived data on its own, in the absence of deeper qualitative work, does not permit us to draw new substantive conclusions about the causes and consequences of the violence in Gujarat in 2002. We defer to the large scholarly and journalistic literature on the violence; see references in §1 and §4.

Abstract

Differentiable architecture search (DARTS) is successfully applied in many vision tasks. However, directly using DARTS for Transformers is memory-intensive, which renders the search process infeasible. To this end, we propose a multi-split reversible network and combine it with DARTS. Specifically, we devise a backpropagation-with-reconstruction algorithm so that we only need to store the last layer's outputs. By relieving the memory burden for DARTS, it allows us to search with larger hidden size and more candidate operations. We evaluate the searched architecture on three sequence-to-sequence datasets, i.e., WMT'14 English-German, WMT'14 English-French, and WMT'14 English-Czech. Experimental results show that our network consistently outperforms standard Transformers across the tasks. Moreover, our method compares favorably with big-size Evolved Transformers, reducing search computation by an order of magnitude.

1 Introduction

Current neural architecture search (NAS) studies have produced models that surpass the performance of those designed by humans (Real et al., 2019; Lu et al., 2020). For sequence tasks, efforts are made in reinforcement learning-based (Pham et al., 2018) and evolution-based (So et al., 2019; Wang et al., 2020) methods, which suffer from the huge computational cost. Instead, gradient-based methods (Liu et al., 2018; Jiang et al., 2019; Yang et al., 2020) are less demanding in computing resources and easy to implement, attracting many attentions recently.

The idea of gradient-based NAS is to train a super network covering all candidate operations. Different sub-graphs of the super network form the search space. To find a well-performing subgraph, Liu et al. (2018) (DARTS) introduced search parameters jointly optimized with the network weights. Operations corresponding to the largest search parameters are kept for each intermediate node after searching. A limitation of DARTS is its memory inefficiency because it needs to store the intermediate outputs from all its candidate operations. This is much more pronounced when we apply Transformers (Vaswani et al., 2017) as the backbone of DARTS (the operation set is detailed in Section 2.5). As shown in Figure 1, memory consumption grows extremely fast as we increase the hidden size d, quickly running out of memory as $d > 400$. As a result, we can only use a limited operation set or a small hidden size, which may lead to worse model performance.

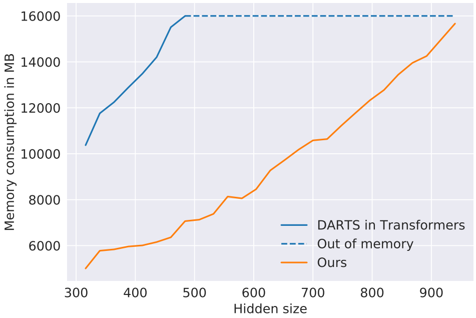

Figure 1: Memory comparison of using our reversible networks and Transformers as the backbone model of DARTS. Experiments are run on a single step of forward-backward pass on a batch of 3584 tokens with a NVIDIA P100 GPU. Limited by GPU memory, DARTS in Transformers has to search in small sizes while evaluating in large sizes, which will cause performance gaps (Chen et al., 2019).

To address the unfavorable memory consumption issue in DARTS, we propose a variant of reversible networks. Each input of a reversible network layer can be reconstructed from its outputs. Thus, it is unnecessary to store intermediate outputs except for the last layer because we can reconstruct

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4254–4264
August 1–6, 2021.

them during backpropagation (BP). Inspired by the idea of RevNets (Gomez et al., 2017), we devise a multi-split reversible network. Each split contains a mixed operation search node to enable DARTS. Also, only a small modification of BP is needed to enable gradient calculation with input reconstruction. We show the memory consumption of our method in Figure 1, which on average halves the amount of memory required in the vanilla DARTS. We can search larger, deeper networks with a richer candidate operation set under the same memory constraint.

Our method is generic to handle various network structures. In this work, we focus on the sequence-to-sequence task. We first perform the architecture search using the WMT'14 English-German translation task. The resulting architecture is then re-trained on three datasets: WMT'14 English-German, WMT'14 English-French, and WMT'14 English-Czech. We achieve consistent improvement over standard Transformers in all tasks. At a medium model size, we can have the same translation quality as the original "big" Transformer with 69% fewer parameters. At a big model size, we exceed the performance of the Evolved Transformer (So et al., 2019), with the computational cost lowered by an order of magnitude. We will make our code and models publicly available.

2 Methodology

We give a detailed description of our method. In Section 2.1, we introduce DARTS and its memory inefficiency when applying in Transformers. In Section 2.2, we propose a multi-split reversible network, which works as the backbone of our memory-efficient architecture search approach. Section 2.3 shows a backpropagation-with-reconstruction algorithm. In Section 2.4, we manage to combine DARTS with our reversible networks. Finally, in Section 2.5, we summarize the proposed algorithms with more details.

2.1 Differentiable Architecture Search in Transformers

Following (Liu et al., 2018), we explain the idea of differentiable architecture search (DARTS) within a one-layer block. Let $\mathscr{O}$ be the candidate operation set (e.g., Self Attention, FFN, Zero). Each operation $o \in \mathscr{O}$ represents some function that can be applied to the layer inputs or hidden states (denoted X). The key of DARTS is to use a mixed operation search node $f(X)$ to relax the categorical choice of a specific operation to a softmax over all candidate operations:

$$f(X) = \sum_{o \in \mathscr{O}} \frac{\exp(\alpha_o)}{\sum_{o' \in \mathscr{O}} \exp(\alpha_{o'})} o(X), \qquad (1)$$

where the α are trainable parameters of size $|\mathscr{O}|$ that determines the mixing weights. During searching, a one-layer block contains several search nodes. The task is to find a suitable set of α for each search node. At the end of the search, the resulting operation in each node is determined by:

$$f = \arg\max_{o \in \mathscr{O}} \alpha_o. \qquad (2)$$

We optimize the α together with network weights θ by gradient descent. A good architecture means performing well on the searching validation set, such that we optimize α with validation loss L_{val} and θ with training loss L_{train}:

$$\begin{aligned} &\min_{\alpha} L_{val}(\theta^*(\alpha), \alpha), \\ &\text{s.t.} \;\; \theta^*(\alpha) = \arg\min_{\theta} L_{train}(\theta, \alpha). \end{aligned}$$

In practice, we update α by $\nabla_\alpha L_{val}$ and θ by $\nabla_\theta L_{train}$ in each step.

It is easy to directly apply DARTS in Transformers by replacing some or all operations in a Transformer block with mixed operation search nodes. For example, we can change the transformer decoder block from Self Attn → Cross Attn → FFN to Search Node 1 → Cross Attn → Search Node 2. Note that a search node outputs a weighted sum of different operations. To enable gradient calculation in the backward pass, we need to store every operation's output, which results in a steep rise in memory consumption during searching. Figure 1 shows the memory consumption of using 2 search nodes in both Transformer encoder and decoder. DARTS run out of memory easily, even at a small hidden size.

2.2 Multi-split Reversible Networks

To relieve the memory burden of DARTS in Transformers, we use reversible networks. A reversible network layer's input can be reconstructed from its output. Suppose a network is comprised of several reversible layers. We do not need to store intermediate outputs except the last layer, because we can reconstruct them from top to bottom during backpropagation (BP). Denote by X and $f(X)$ the

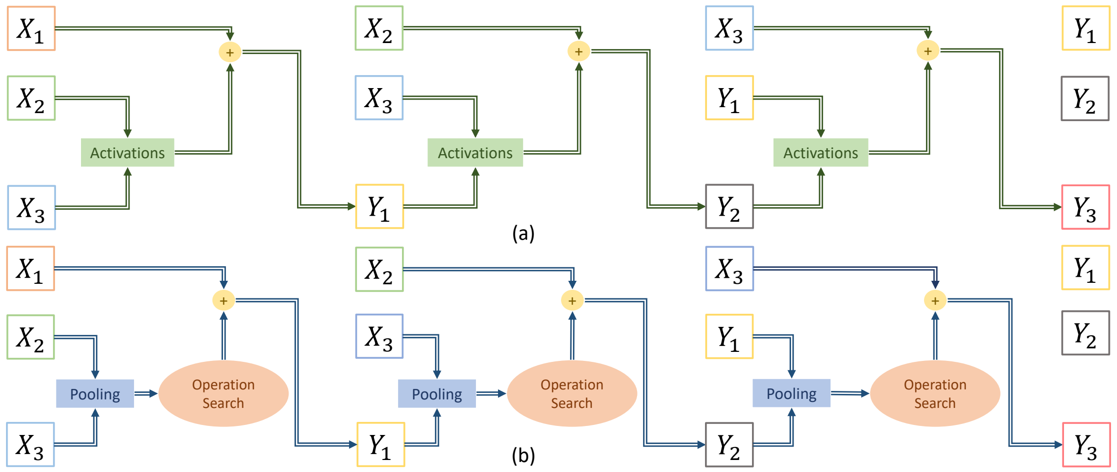

Figure 2: This figure is a demonstration of DARTSformer. (a) shows an n-split ($n = 3$) reversible network, which serves the backbone of our method. (b) shows the design of activations to enable differentiable architecture search. Each X_k and Y_k are in $R^{l\times d}$. The k-th pooling takes the concatenation of $X_{i>k}$ and $Y_{i<k}$ as the input, and outputs a tensor in $R^{l\times d}$. The operation search gives a weighted average of the outputs of each candidate operation.

layer input and the layer output, respectively. X is first split along the embedding/channel dimension into n equal parts $\{X_1, \cdots, X_n\}$. A RevNets (Gomez et al., 2017) alike operation is applied to each X_k, which yields Y_k. $f(X)$ is a concatenation of $\{Y_1, \cdots, Y_n\}$ along the split dimension:

$$\begin{aligned} Y_1 &= X_1 + G_1(X_{i>1}, \theta_1), \\ &\cdots \\ Y_k &= X_k + G_k(X_{i>k}, Y_{i<k}, \theta_k), \\ &\cdots \\ Y_n &= X_n + G_n(Y_{i<n}, \theta_n). \end{aligned} \tag{3}$$

G_k is a mixed operation node during the architecture search process. After searching, G_k is a deterministic operation given by $\arg\max_{o\in\mathcal{O}} \alpha_o$. Detailed discussions can be found in Section 2.4.

The reversibility of Eq. (3) needs rigorous validation, such that the input X can be easily reconstructed from $f(X)$:

$$\begin{aligned} X_n &= Y_n - G_n(Y_{i<n}, \theta_n), \\ &\cdots \\ X_k &= Y_k - G_k(X_{i>k}, Y_{i<k}, \theta_k), \\ &\cdots \\ X_1 &= Y_1 - G_1(X_{i>1}, \theta_1). \end{aligned} \tag{4}$$

Part (a) of Figure 2 illustrates a 3-split reversible network, which we frequently employ throughout our experiments for simplicity.

2.3 Backpropagation with Reconstruction

Consider the problem of backpropagating (BP) through a reversible layer. Based on the layer output $f(X) = \text{Concat}(Y_1, \cdots, Y_n)$ and its total derivative $df(X) = \text{Concat}(dY_1, \cdots, dY_n)$, we need to calculate the layer input $X = \text{Concat}(X_1, \cdots, X_n)$, its total derivative $dX = \text{Concat}(dX_1, \cdots, dX_n)$, and the derivatives of the network weights $d\theta_1, \cdots, d\theta_n$.

We show the BP-with-reconstruction through a single layer in Algorithm 1. $[\cdot]$ represents $\text{Concat}(\cdot)$ for simplicity reasons. In Line 9 of Algorithm 1, $d\theta_k$ is calculated as a side effect. Line 10 shows the reconstruction process, where each split X_k is recovered in the order of n to 1. In Algorithm 1, grad_k works as a gradient accumulator, which keeps track of all derivatives associated with X_k. A repetitive application of Algorithm 1 enables us to backpropagate through a sequence of reversible layers. Only the top layer's outputs require storage, which makes it much more memory-efficient.

Roughly speaking, for a network with N connections, the forward and backward passes require approximately N and $2N$ add-multiply operations, respectively. Since we need to reconstruct X from $f(X)$, the re-calculation requires another N add-multiply operations, making it 33% slower. Fortunately, we can only need Algorithm 1 for architecture search and will re-train the resulting network with ordinary BP. The search process turns out to converge fast. The computational overhead does not become a severe problem.

---

end for
```

2.4 DARTS with Multi-split Reversible Networks

Performing DARTS based on n-split reversible networks only requires specifying each G_k in Eq. (3). Suppose that each $X_k \in R^{l \times d_n}$ (l is the sequence length and d is the hidden size, $d_n = \frac{d}{n}$), and that each Y_k has the same size as X_k. The input of G_k contains $n-1$ tensors in $R^{l \times d_n}$. To enable element-wise addition with X_k, the output of G_k must also be in $R^{l \times d_n}$.

G_k is factorized into two parts. The first part is a pooling operation, which takes an $l \times d_n \times (n-1)$ tensor as input, and outputs an $l \times d_n \times 1$ tensor. The second part is a mixed operation search node. G_k is calculated as follows:

$$
\begin{aligned}
H_k &= \text{Pooling}(X_{i>k}, Y_{i<k}), \\
G_k &= \sum_{o \in \mathcal{O}} \frac{\exp(\alpha_o^k)}{\sum_{o' \in \mathcal{O}} \exp(\alpha_{o'}^k)} o(H_k),
\end{aligned}
\tag{5}
$$

where α_k is randomly initialized. Figure 3 shows the design of G_k. By substituting each G_k in Eq. (3) with Eq. (5), we are able to use Algorithm 1 to perform memory-efficient DARTS. We call this method *DARTSformer*, which is illustrated by Part (b) of Figure 2 in a 3-split case.

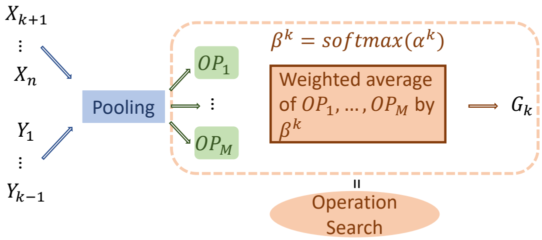

Figure 3: Pooling and operation search in each split.

The overall search space size is critical to the performance of DARTSformer. In our experiments, we focus on sequence-to-sequence tasks where the encoder and the decoder are searched simultaneously. Suppose that we have an m-split encoder and an n-split decoder. We search s consecutive layers. For example, $s = 2$ means that we search within a 2-layer encoder block. Each layer in the block is an m-split reversible layer. The encoder contains several identical 2-layer blocks, the same to the decoder. The search space is of size $|\mathcal{O}|^{s(m+n)}$. If $|\mathcal{O}|$ is large, it can easily introduce a large search space even with small m, n and s.

2.5 Instantiation

We describe the instantiation of DARTSformer in this section.

Operation Set The candidate operation set $\mathcal{O}$ is defined as follows:

- Standard Conv $w \times 1$: for $w \in \{3, 5, 7, 11\}$.
- Dynamic Conv $w \times 1$: for $w \in \{3, 7, 11, 15\}$.
- Self Attention.
- Cross Attention: Only available to decoder.
- Gated Linear Unit (GLU).
- FFN.
- Zero: Return a zero tensor of the input size.
- Identity: Return the input.

The Dynamic Conv is from Wu et al. (2019). The Self Attention, Cross Attention and FFN are from Vaswani et al. (2017). We use 8 attention heads. The GLU is from Dauphin et al. (2017).

Residual connections (He et al., 2016) and layer normalization (Ba et al., 2016) are crucial for convergence in training Transformers (Vaswani et al., 2017). To make our network fully reversible, these two tricks can not be used directly. Instead, we put

Algorithm 2 The framework of DARTSformer

```
Input:
    Operation set: $\mathscr{O}$, Search parameters: $\alpha$;
    Network weights: $\theta$;
Output:
    Best candidate network: $\mathcal{N}_{final}$;
1: Setup a multi-split reversible network with operation search nodes $\mathcal{N}_{super}(\mathscr{O}, \alpha, \theta)$.
2: while $\alpha$ not converge do
3:     Update $\theta$ by Algorithm 1 with $L_{train}$.
4:     Update $\alpha$ by Algorithm 1 with $L_{val}$.
5: end while
6: Get $\mathcal{N}_{final}(\mathscr{O}, \alpha, \theta)$ with Eq. (2).
```

the residual connections and layer normalization within each operation $\tilde{o}(X) = \text{LayerNorm}(X + o(X))$, except for Zero and Identity.

Encoder and Decoder We use an n-split encoder and an $(n{+}1)$-split decoder for DARTSformer. Each G_k in the encoder takes the format of Eq. (5). Instead for the decoder, $G_{k<n+1}$ still follows Eq. (5), but the operation for the last split G_{n+1} is fixed as Cross Attention. Our experiments show that this constraint on the decoder yields architectures with better performances.

Search and Re-train We summarize the entire framework of DARTSformer in Algorithm 2. Note that the search process is the most memory intensive part, such that we use BP-with-reconstruction as shown in Line 2-5 of Algorithm 2.

3 Experiment Setup

3.1 Datasets

We use three standard datasets to perform our experiments as So et al. (2019): (1) WMT'18 English-German (En-De) without ParaCrawl, which consists of 4.5 million training sentence pairs. (2) WMT'14 French-English (En-Fr), which consists of 36 million training sentence pairs. (3) WMT'18 English-Czech (En-Cs), again without ParaCrawl, which consists of 15.8 million training sentence pairs. Tokenization is done by Moses[2]. We employ BPE (Sennrich et al., 2016) to generate a shared vocabulary for each language pair. The BPE merge operation numbers are 32K (WMT'18 En-De), 40K (WMT'14 En-Fr), 32K (WMT'18 En-Cs). We discard sentences longer than 250 tokens. For the re-training validation set, we randomly choose 3300 sentence pairs from the training set. The evaluation metric is *BLEU* (Papineni et al., 2002). We use beam search for test sets with a beam size of 5, and we tune the length penalty parameter from 0.5 to 1.0. Suppose the input length is m, and the maximum output length is $1.2m + 10$.

3.2 Search Configuration

The architecture searches are all run on WMT'14 En-De. DARTS is a bilevel optimization process, which updates network weights θ on one dataset and search parameters α on another dataset. We split the 4.5 million sentence pairs into 2.5/2.0 million for θ and α. Both L_{train} and L_{val} are cross entropy loss with a label smoothing factor of 0.1. The split number n is 2 for the encoder and 3 for the decoder. We set s to 1 or 2, which means the super network contains several identical 1-layer or 2-layer blocks. The candidate operations are detailed in Section 2.5, where $|\mathscr{O}| = 13/14$ for encoder and decoder, respectively. Along the analysis in Section 2.4, the largest size of the search space is around 1 billion. We use a factorized word embedding matrix to save memory. $|V|$ is the vocabulary size, and d is the hidden size. The original word embedding matrix $E \in R^{|V| \times d}$ is factorized into a multiplication of two matrices of size $|V| \times e$ and $e \times d$, where $e \ll d$. We let e denote the embedding size. We set $e = 256, d = 960$. During searching, we set the dropout probability to 0.1. Two Adam optimizers (Kingma and Ba, 2015) are used for updating θ and α, with $\beta_1 = 0.9$ and $\beta_2 = 0.98$. For θ, we use the same learning rate scheduling strategy as done in Vaswani et al. (2017) with a warmup step of 10000. The maximum learning rate is set to 5×10^{-4}. For α, we fix the learning rate to 3×10^{-4} with a weight decay of 1×10^{-3}, which is the same as Liu et al. (2018) does.

DARTSformer requires us to specify a pooling operation as stated in Eq. (5). We experiment with both max pooling and average pooling. All searches run on the same 8 NVIDIA V100 hardware. We use a batch size of 5000 tokens per GPU and save a checkpoint every 10,000 updates (5000 for θ and 5000 for α). Our search process finalizes after 60,000 updates.

3.3 Training Details

All the networks derived from the saved checkpoints are re-trained on WMT'14 En-De to select the best performing one. We then train the selected network on all datasets in Section 3.1 to

DARTSformer	avg	4,5	27.1

Table 2: BLEU scores of DARTSformer with different split numbers on WMT'14 En-De test set. We use an n-split encoder and an $n+1$-split decoder. We searching through 2 consecutive layers.

verify its generalization ability. We follow the settings of So et al. (2019) with both a base model and a big model. For the base model, we still use $e = 256, d = 960$ without re-scaling. For the big model, we set $e = 512, d = 1824$. Unless otherwise stated, all the training run on 8 Tesla V100 GPU cards with the batch size of 5000 tokens per card.

4 Results

4.1 Comparison Between Search Setups

We search through a different number of consecutive layers with different pooling operations. For re-training, we use the same learning rate scheduling strategy as in searching. We also keep the dropout rate unchanged. Results are summarized in Table 1. DARTSformers yields better results than standard Transformers in all experimental setups. The maximum performance gain is 0.7 BLEU with max pooling when searching through 2 consecutive layers. Also, DARTSformer achieves slightly better results than the Evolved Transformer in three out of four runs.

Model	**Price**	**Steps**	**Hardware**
ET	\$150k	4.2×10^8	200 TPUs
DARTSformer	\$1.25k	4.8×10^5	8 V100

Table 3: Comparison for search cost between Evolved Transformer (ET; So et al. 2019) and DARTSformer. The price for ET is from Strubell et al. (2019).

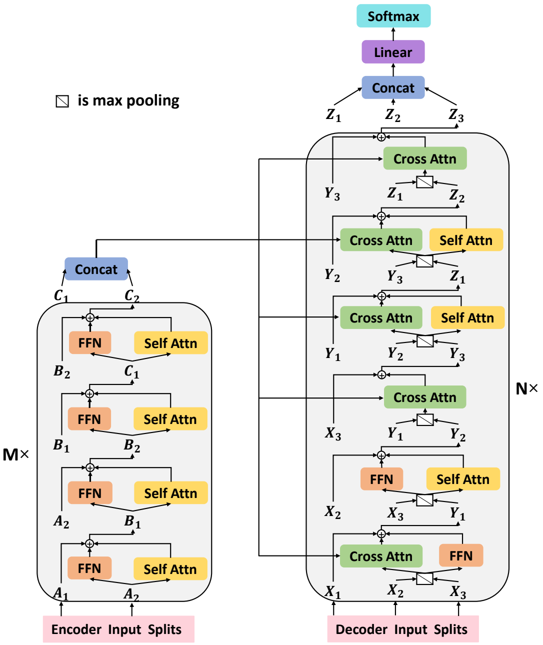

Figure 4: Architecture searched by DARTSformer.

We compare the search cost between the Evolved Transformers and DARTSformer from various aspects. DARTSformer takes about 40 hours to run on an AWS p3dn.24xlarge node[3]. The price for a single run of search is about \$1.25k. As reported by Strubell et al. (2019), the search process of Evolved Transformer takes up to \$150k, which is extremely expensive. As for hardware, the evolutionary search employs 200 TPU V.2 chips to run, while our method only uses 8 NVIDIA V100 cards. The reason for the evolutionary search algorithm's huge cost is that it requires training multiple candidate networks from scratch. We compare the number of parameter update steps in Table 3. The evolutionary search needs approximately 874 times more update steps than our method.

A simple sampling-based NAS method (Guo et al., 2020) can also reduce memory consumption.

---

[3] https://aws.amazon.com/ec2/instance-types/p3/

For each batch of training data, we set G_k in Eq. (5) as a uniformly sampled operation from the candidate set $\mathcal{O}$. The search parameters α are discarded, and the resulting network is produced from an evolutionary search by evaluating on the re-training validation set. This method performs poorly in machine translation, as shown in Table 1. We find that sampling-based methods favor large-kernel convolutions and that the resulting architectures tend to generate repetitive sentences.

We also experiment with increased split numbers. As shown in Table 2, an increased split number hurts the translation performance. The best results are all achieved by the smallest split. Also, the search process is harder to converge as the search space becomes too large. The re-training and inference speed will slow down when increasing the split number because more recurrence are introduced in the calculation as shown in Eq. (3).

In the following sections, we try the best search result (DARTSformer + search 2 layers + 2 split + max pooling) in various sequence-to-sequence tasks to see its generalization ability. We show this searched architecture in Figure 4.

4.2 Performance of DARTSformer on Other Datasets

First, we train DARTSformer with a base model size on three translation tasks in Section 3.1. We would like to see whether DARTSformer only performs well on the task used for architecture search or generalizes to related tasks. Second, we scale up the model size and the batch size to see whether the performance gain of DARTSformer still exists. We compare DARTSformer with standard Transformers and Evolved Transformers with similar model sizes. Following Vaswani et al. (2017), the parameter size is around 62.5M/214.7M for the base model and big model, respectively. To match the settings of So et al. (2019) when training big models, we increase the dropout rate to 0.3 and the learning rate to 1×10^{-3}. We also accumulate gradients for two batches.

Models	En-De	En-Fr	En-Cs
Transformer	27.7	40.0	27.0
ET (So et al., 2019)	28.2	**40.6**	27.6
DARTSformer	**28.4**	40.1	**27.9**

(a) Comparison for Base Model Size

Models	En-De	En-Fr	En-Cs
Transformer	29.1	41.2	28.1
ET (So et al., 2019)	29.3	**41.3**	28.2
DARTSformer	**29.8**	**41.3**	**28.5**

(b) Comparison for Big Model Size

Table 4: BLEU scores on WMT'14 translation tasks. ET is the Evolved Transformer. We use the best search result from different DARTSformer search setups.

Results are shown in Table 4. At the base model size, DARTSformer steadily outperforms standard Transformers. We achieved the same translation quality (28.4 BLEU, reported by Vaswani et al. (2017)) as the original big Transformer in WMT'14 En-De, with about 69% fewer parameters. Also, the maximum BLEU gain is 0.9 in WMT'14 En-Cs, which is not the dataset we conduct our architecture search on. As for Evolved Transformers, we surpass their performance in two out of three datasets, and our search algorithm is more computationally efficient. At the big model size, DARTSformer exceeds both standard Transformers and Evolved Transformers, which indicates the good generalization ability of DARTSformer.

4.3 Performance of DARTSformer vs. Parameter Size

In Section 4.2, DARTSformer consistently improves the performance with a model size comparable to the base and big Transformers. We are wondering whether the performance increase exists with smaller model sizes. We experiment with a spectrum of model sizes for standard Transformers and DARTSformer on WMT'14 En-De. Specifically, we use four embedding sizes for standard Transformers, [small:128, medium:256, base:512, big:1024], where its hidden size is identical to the embedding size. We also adjust the model size of DARTSformer accordingly. For base and big models, we use the results from Section 4.2. For small and medium models, we set the learning rate to 5×10^{-4}, the dropout probability to 0.1, and update the model parameters for 200,000 steps on the same 8 NVIDIA V100 hardware.

Figure 5 shows the results for both architectures. DARTSformer performs better than standard Transformers at all sizes. The BLEU increase is [1.3/0.9/0.7/0.7] for [small/medium/base/big] models. An interesting fact is that the performance gap between two models tends to be smaller as we increase the model size, which is also observed in So

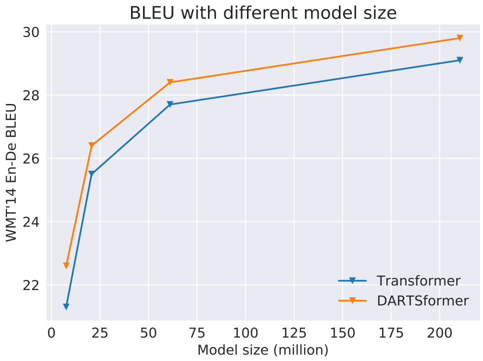

Figure 5: BLEU comparison between DARTSformer and standard Transformers with different model sizes.

Search Settings	e	d	**BLEU**
Tiny	128	120	24.2
Small	128	240	26.3
Medium	256	480	27.5
DARTSformer	256	960	**28.4**
DARTS + Transformer	320	320	27.7
Transformer	-	-	27.7

Table 5: BLEU scores of DARTS with different search hidden sizes on WMT'14 En-De test set. All searched architectures are re-trained with a parameter size similar to DARTSformer.

et al. (2019). Based on this observation, DARTSformer is more pronounced for environments with resource limitations, such as mobile phones. A possible reason for the decreased performance gap at larger model sizes is that the effect of overfitting becomes more important. We expect that some data augmentation skills (Sennrich et al., 2015; Edunov et al., 2018; Qu et al., 2020) might be of help.

4.4 The Impact of Search Hidden Size

The main motivation for our presented method is that we want to search in a large hidden size to reduce the performance gap between searching and re-training. However, whether this gap exists needs rigorous validation. Otherwise, it would suffice to instead use a small hidden size d in architecture search, and then increase d after search for training the actual model. We experiment with 4 search hidden sizes, namely, $e = 128, d = 120$ (tiny), $e = 128, d = 240$ (small), $e = 256, d = 480$ (medium), $e = 256, d = 960$ (DARTSformer). e is the word embedding size and d is the hidden size as described in Section 3.2. After obtaining the searched model, we set the model size to $e = 256, d = 960$, and re-train it on WMT'14 En-De.

The results are summarized in Table 5, which clearly shows that the translation quality is improving as the search hidden size gets larger. Also, note that when searching with tiny, small and medium settings, the final BLEU scores fall behind that of standard transformers. We argue that if one wants to evaluate the searched model in large model sizes, it is important to search with large hidden sizes. Further more, we directly apply DARTS with standard transformer as the backbone model. We set $e = 320, d = 320$. A larger search hidden size often causes memory failure due to the storage of many intermediate hidden states. As shown in Table 5, We can see that searching with a small hidden size yields no performance gain on the standard transformer.

5 Related Work

Architecture Search The field of neural architecture search (NAS) has seen advances in recent years. In the early stage, researchers focus on the reinforcement learning-based approaches (Baker et al., 2016; Zoph and Le, 2016; Cai et al., 2018a; Zhong et al., 2018) and evolution-based approaches (Liu et al., 2017; Real et al., 2017; Miikkulainen et al., 2019; So et al., 2019; Wang et al., 2020). These methods can produce architectures that outperform human-designed ones (Zoph et al., 2018; Real et al., 2019). However, the computational cost is almost unbearable since it needs to fully train and evaluate every candidate network found in the search process. Weight sharing (Brock et al., 2017; Pham et al., 2018) is a practical solution where a super network is trained, and its sub-graphs form the search space. Liu et al. (2018) proposed DARTS to use search parameters together with a super network, which allows searching with gradient descent. Gradient-based methods (Cai et al., 2018b; Xie et al., 2018; Chen et al., 2019; Xu et al., 2019; Yao et al., 2020) attracts researchers' attention since it is computationally efficient and easy to implement. We base our method on DARTS and take one step further to reduce the memory consumption of training the super network. Another recent trend is the one-stage NAS (Cai et al., 2019; Mei et al., 2019; Hu et al., 2020; Yang et al., 2020). Many NAS algorithms are in two stages. In the first stage, one searches for a good candidate network. In the second stage, the resulting network is re-initialized and re-trained. One-stage NAS tries to search and optimize the network weights simultaneously. After searching, one can have a ready-to-run network. We use a simple one-stage NAS algorithm (Guo et al., 2020) as a baseline in Section 4.1.

Reversible networks The idea of reversible networks is first introduced by RevNets (Gomez et al., 2017). Later on, Jacobsen et al. (2018); Chang et al. (2018); Behrmann et al. (2019) invented different reversible architectures based on the ResNet (He et al., 2016). MacKay et al. (2018) extended RevNets to the recurrent network, which is particularly memory-efficient. Bai et al. (2019, 2020) conducted experiments with reversible Transformers by fixed point iteration. Kitaev et al. (2020) combined local sensitive hashing attention with reversible transformers to save memory in training with long sequences. An important application of reversible networks is the flow-based models (Kingma and Dhariwal, 2018; Huang et al., 2018; Tran et al., 2019). For sequence tasks, Ma et al. (2019) achieved success in non-autoregressive machine translation.

6 Conclusion

We have proposed a memory-efficient differentiable architecture search (DARTS) method on sequence-to-sequence tasks. In particular, we have first devised a multi-split reversible network whose intermediate layer outputs can be reconstructed from top to bottom by the last layer's output. We have then combined this reversible network with DARTS and developed a backpropagation-with-reconstruction algorithm to significantly relieve the memory burden during the gradient-based architecture search process. We have validated the best searched architecture on three translation tasks.

Our method consistently outperforms standard Transformers. We can achieve the same BLEU score as the original big Transformer does with 69% fewer parameters. At a large model size, we surpass Evolved Transformers with a search cost lower by an order of magnitude. Our method is generic to handle other architectures, and we plan to explore more tasks in the future.

Abstract

Previous studies have shown that initializing neural machine translation (NMT) models with the pre-trained language models (LM) can speed up the model training and boost the model performance. In this work, we identify a critical side-effect of pre-training for NMT, which is due to the discrepancy between the training objectives of LM-based pre-training and NMT. Since the LM objective learns to reconstruct a few source tokens and copy most of them, the pre-training initialization would affect the copying behaviors of NMT models. We provide a quantitative analysis of copying behaviors by introducing a metric called *copying ratio*, which empirically shows that pre-training based NMT models have a larger copying ratio than the standard one. In response to this problem, we propose a simple and effective method named *copying penalty* to control the copying behaviors in decoding. Extensive experiments on both in-domain and out-of-domain benchmarks show that the copying penalty method consistently improves translation performance by controlling copying behaviors for pre-training based NMT models. Source code is freely available at `https://github.com/SunbowLiu/CopyingPenalty`.

1 Introduction

Self-supervised pre-training (Devlin et al., 2019; Song et al., 2019), which acquires general knowledge from a large amount of unlabeled data to help *better* and *faster* learning downstream tasks, has an intuitive appeal for neural machine translation (NMT; Bahdanau et al., 2015; Vaswani et al., 2017). One direct way to utilize pre-trained knowledge is initializing the NMT model with a pre-trained language model (LM) before training it on parallel data (Conneau and Lample, 2019; Liu et al., 2020). As a range of surface, syntactic and semantic information has been encoded in the initialized parameters (Jawahar et al., 2019; Goldberg, 2019), they are expected to bring benefits to NMT models and hence the translation quality.

Table 1: Training objective gap between Seq2Seq LM pre-training and NMT training. LM learns to reconstruct a few source tokens and copy most of them, while NMT learns more translation rather than copying. Underlines denote artificial noises, and highlights indicate expected copying tokens.

However, there is a discrepancy between the training objective of sequence-to-sequence LM pre-training and that of NMT training. As shown in Table 1, LM learns to reconstruct all source tokens with some noises, while NMT learns to translate most source tokens and copy few of them. Knowles and Koehn (2018) and Liu et al. (2020) show that LM pre-training requires to copy ~65% of tokens, while NMT training only needs to copy <10%. We believe that unexpected knowledge can be propagated to the NMT model via pre-training, which may bias NMT models to mistakenly copy source tokens to the target side. For example, the source word "Field Marshal" might be mistakenly copied to the target side by pre-training based NMT models, since such copying behaviors can be learned in

the pre-training stage.

In this paper, we first validate the change of copying behaviors in NMT models initialized with the pre-training weights. To this end, we propose a metric named *copying ratio* to quantitatively measure the extent of copying behaviors of NMT models. Experimental results on the WMT14 En-De data show that the NMT model with pre-training improves translation performance at the cost of introducing more copying predictions. Analyses on model training show that the NMT model with pre-training attempts to forget the copying behaviors transferred from pre-training, while the vanilla NMT model learns in the opposite way. Due to the dominating copying behaviors in the pre-training, the copying ratio of pre-training based NMT model (i.e., 10.8%) is much higher than that of the vanilla NMT model (i.e., 9.3%). Extensive analyses show that higher copying ratios severely hurt sentence fluency and word accuracy in translations, particularly for the translation of proper nouns, establishing the necessity for controlling the copying behaviors of NMT models.

To tackle this problem, we propose a simple and effective *copying penalty* to control the copying behaviors in inference, which requires no modification to model architectures and training algorithms. Specifically, we introduce a new regularizing term to the prediction at each time step, which guides the model to copy source tokens only when the model is highly confident. Experimental results on the WMT14 English-German and the OPUS German-English benchmark demonstrate that the proposed approach can significantly control copying behaviors in NMT models, making the model more accurately generate copying tokens.

Our contributions are summarized as follows:

- We reveal a critical side-effect of pre-training for NMT, where pre-training introduces more copying behaviors into NMT outputs.
- We propose a simple and effective *copying penalty* to further improve the performance of NMT models with pre-training by controlling copying behaviors in generated translation.
- We find that the domain containing a large number of copying tokens (e.g., the IT) benefits more from the proposed copying penalty.

2 Observing Copying Behavior Changes

The fact is that some source words are excessively copied by NMT models from the source to the target side instead of being translated, which leads to a high copying ratio in NMT outputs. In this section, we first propose a metric to measure the copying ratio of model predictions. Second, we quantitatively investigate the effect of pre-training on NMT in the perspective of copying behaviors. We expect to provide more evidence for controlling the copying behaviors of NMT models.

2.1 Experimental Setup

Data We conducted experiments on the widely-used WMT14 English-German benchmark. We used the processed data provided by Vaswani et al. (2017), which consists of 4.5M sentence pairs.[1] We used all the training data for model training. The validation set is newstest2013 of 3,000 examples and the test set is newstest2014 of 3,003 examples.

Models and Settings We implemented all the models by the open-sourced toolkit `fairseq` (Ott et al., 2019).[2] We used 8 V100 GPUs for the experiments. We mainly compared two models: 1) RANDOM, which is a vanilla NMT model whose weights are randomly initialized without pre-training; and 2) PRETRAINED, an NMT model using the weights of pre-trained `mBART.cc25`[3] for parameter initialization, which has shown its usability and reliability for translation tasks (Tran et al., 2020; Tang et al., 2020).

For the training of RANDOM, we used the Transformer *big* setting of Ott et al. (2018b) with a huge training batch size of 460K tokens.[4] For PRETRAINED, we fine-tuned on the pre-trained `mBART.cc25` with a training batch size of 131K tokens. The hyperparameters keep the same with RANDOM except the 0.2 label smoothing, 2500 warm-up steps, and 1e-4 maximum learning rate.

Evaluation For each model, we selected the checkpoint with the lowest perplexity on the validation set for testing. The beam size is 5 and the length penalty is 0.6. In addition to report-

Table 2: Translation from English to German. The words in color denote the copying tokens of which blue denotes right copies and *red* denotes copying errors.

ing the commonly-used 4-gram BLEU score (Papineni et al., 2002), we also report Translation Error Rate (TER) (Snover et al., 2006) to better capture the translation performance of unigrams, which more directly reflects the copying behaviors of NMT models. Both the scores are calculated by `sacrebleu` (Post, 2018) with de-tokenized text and unmodified references.[5,6]

2.2 Copying Ratio

Ratio To measure the extent of the copying behaviors in NMT models, we calculate the ratio of copying tokens in translation outputs:

$$\text{Ratio} = \frac{\sum_{i=1}^{I} \text{count}(\text{copying token})}{\sum_{i=1}^{I} \text{count}(\text{token})} \tag{1}$$

where I denotes the total number of sentences in the test set. We count the number of "copying token" by comparing each input and output sentence pair. The denominator is the total number of tokens in output sentences. In general, higher Ratio values indicate more copying behaviors produced by the NMT model, and vice versa.

Copying Error Rate (CER) To further analyze the copying problem in NMT models, we propose to calculate the rate of incorrect copying tokens among all copied ones:

$$\text{CER} = \frac{\sum_{i=1}^{I} \text{count}(\text{copying error})}{\sum_{i=1}^{I} \text{count}(\text{copying token})} \tag{2}$$

where we count the number of "copying error" by checking whether the copying tokens are included in its reference sentence. The CER is expected to be zero, which indicates that all copying tokens are correct. Table 2 gives an example. In experiments, Ratio and CER are computed based on words rather than sub-words. We further filter all punctuations, which are similar across different languages.

	Performance		Copying		
	BLEU	TER	Ratio	CER	#S
ORACLE	-	-	8.5%	-	9
RANDOM	28.3	60.7	9.3%	17.4	20
PRETRAINED	29.4	59.4	10.8%	27.6	50

Table 3: Results on the WMT14 En-De test set. ORACLE denotes the statistics on the reference. "#S" denotes the number of instances whose overlaps between the source and target exceeding 50% (Ott et al., 2018a). Although PRETRAINED gains better model performance than RANDOM, it also excessively copies tokens from the source.

Model Performance We compare the performance and copying behaviors of the final models in Table 3. The results show that although PRETRAINED improves the overall performance in terms of BLEU and TER scores, it tends to generate more copying errors, limiting its further improvement. In the following part, we probe into the essence of the copying behaviors via carefully designed experiments.

2.3 Learning Curves of Copying Behaviors

We analyze copying behaviors in learning dynamics. Specifically, we translate the test set using intermediate checkpoints at different training steps, and then compute corresponding Ratio and CER values. We compare RANDOM and PRETRAINED, and plot their learning curves in Figure 1.

Ratio Two models behave quite differently in the early stages of training. Taking Step 100 for instance, PRETRAINED copies 89% tokens while RANDOM does not generate any copying tokens. This demonstrates that the copying habit in the pretrained model is transferred to NMT models. As training proceeds, the copying behaviors of PRETRAINED are heavily suppressed, resulting in a rapid drop in Ratio. On the contrary, RANDOM is able to quickly learn copying from scratch, leading to an upward trend. After learning curves become stable, PRETRAINED performs more copying behaviors than RANDOM (10.8% vs. 9.3% Ratio).

CER In general, the results of CER show similar trends to those observed in Ratio. In the beginning, the CER of PRETRAINED is extremely high (i.e.,

[6] TER+lang.en-de+tok.tercom-nonorm-punct-noasian-uncased+version.1.4.14

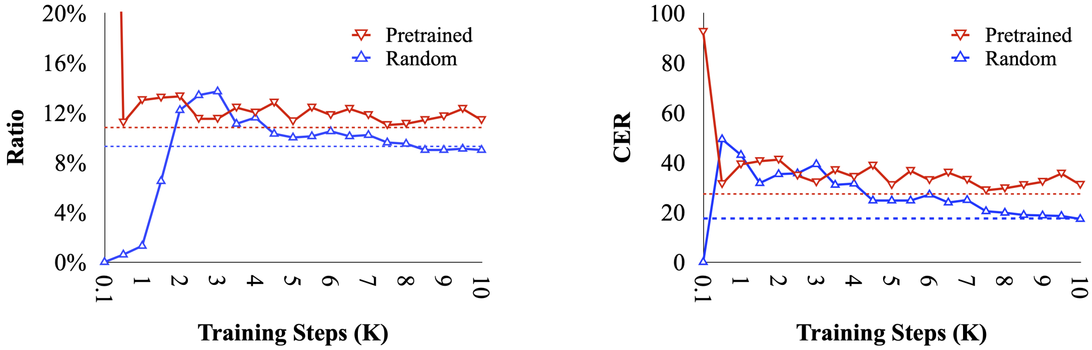

Figure 1: Copying ratio (left) and CER score (right) of RANDOM and PRETRAINED at different training steps. Reference lines report the values of the final models gaining the lowest validation perplexities. PRETRAINED gains 89.4% copying ratio at 0.1K step, which is omitted for better display clarity. PRETRAINED learns to forget its copying behaviors by reducing the copying ratio from 89.4% to 10.8% and CER from 92.4 to 27.6, while RANDOM learns copying from scratch by increasing the copying ratio and CER from 0 to 9.3% and 17.4, respectively.

	PPL	Rand>Pre		Rand<Pre	
		Ratio	CER	Ratio	CER
RANDOM	60.8	10.0%	18.5	8.7%	17.4
PRETRAINED	95.1	9.5%	14.9	12.5%	39.7

Table 4: Sentence perplexity on the test set. PRETRAINED's translation of worse perplexity (i.e., "Rand<Pre") also contains the higher Ratio (12.5%) and CER (39.7) scores.

92.4), revealing that most of the copying tokens are incorrect. The reason behind this phenomenon is that pre-trained models are accustomed to copying source words but the habit is overly transferred to the downstream translation models. The interesting finding is that RANDOM also makes more mistakes on copying at the early training stage. Finally, the error rate of PRETRAINED is much higher than that of RANDOM (27.6 vs. 17.4), showing that pre-trained models indeed expose harmful knowledge to NMT models.

Learning curves of two kinds of models perform in opposite ways: RANDOM learns copying from scratch while PRETRAINED tries to forget this behavior. As a result, PRETRAINED copies more source tokens than RANDOM and suffers severe copying errors. This motivates us to further investigate the effects of copying behaviors on NMT models in terms of translation quality.

2.4 Effect of Copying Ratio

Sentence Fluency The copying tokens from the source usually contain some tokens that do not belong to the target language, which might hurt the fluency of generated translations. Starting from this intuition, we use an external language model (Ng et al., 2019)[7] trained on in-domain data to evaluate the fluency of translation outputs. As shown in Table 4, Random achieves a much better perplexity than mBART (60.8 vs. 95.1 PPL), demonstrating that the NMT model with pre-training generates less fluent sentences than that trained from scratch.

To take a closer look at the fluency gap, we divide outputs of each model into two subsets: sentences with better or worse perplexity by comparing RANDOM and PRETRAINED. As seen, the fluency of translation is related to copying ratio and errors. The sentences with higher Ratio and CER scores tend to be less fluent. Taking PRETRAINED's worse subset for example (Rand<Pre), it gains a 12.5% Ratio and 39.7 CER scores, confirming that excessive copying behaviors lead to negative effects in terms of translation fluency.

Word Accuracy We also give a word-level analysis by bucketing copying tokens according to part-of-speech (POS) tags and calculate Ratio and CER in each type. In experiment, we employ Stanford POS tagger with the `german-ud.tagger` model to automatically label output sentences (Toutanova et al., 2003). Table 5 lists the results. The "Oracle" (Row 1) denotes the statistics by comparing the source input and its reference. As seen, most copying operations should occur in the type of proper noun (PROPN). This type occupies 5.7% Ratios, followed by adposition (ADP), numeral (NUM), noun (NOUN), and other types (Others).

Compared with RANDOM, we observe that the

	Total		PROPN		ADP		NUM		NOUN		Others	
	Ratio	**CER***	**Ratio**	**CER***	**Ratio**	**CER***	**Ratio**	**CER***	**Ratio**	**CER***	**Ratio**	**CER***
Oracle	8.5%	-	5.7%	-	1.1%	-	0.8%	-	0.5%	-	0.3%	-
Random	9.3%	17.4	6.3%	14.5	1.3%	25.8	0.9%	14.2	0.5%	21.3	0.3%	44.4
Pretrained	10.8%	27.6	7.5%	27.3	1.3%	24.9	0.9%	14.0	0.6%	21.0	0.5%	63.8
Δ	**+1.5%**	**+10.2**	**+1.2%**	**+12.8**	0%	-0.9	0%	-0.2	+0.1%	+0.3	+0.2%	**+19.4**

Table 5: Copying behaviors by part-of-speech (POS) bucket on the WMT14 En-De task. "Oracle" denotes the statistics in the reference. "CER*" denotes only using the copying tokens belonging to each POS category for the CER calculation. Δ denotes the changes from the Random to Pretrained, in which the significant ones are **bold**. Most of the copying tokens are found in translating proper nouns (PROPN) in Pretrained.

increase of Ratio for Pretrained mainly attributes to copying PROPN words (+1.2%). In addition, Pretrained generates more copying errors (+10.2), especially on PROPN and Others types (+12.8 and +19.4). These results reveal that it is necessary to pay more attention to proper nouns on controlling copying behaviors for NMT.

3 Controlling Copying Behaviors

Based on the above experiments, we prove that pre-training indeed changes the copying behaviors of NMT models, hurting the sentence fluency and word accuracy of generated translations. To alleviate this issue, we propose a simple and effective method *copying penalty* to make the copying behaviors in NMT controllable.

3.1 Copying Penalty (CP)

To control copying behaviors in NMT, an intuitive way is generating copying tokens only when the model is of high confidence. To this aim, we propose to modify the probability distribution predicted by the NMT model, decreasing the predicting probability of the tokens also occurred in the source (i.e., weakening the model confidence of making copying predictions). In this way, for those predictions are wavering between copying and translating, the model is more likely to translate them, and thus only those confident copying tokens will be retained. Specifically, during inference, the predicting probability of t-th time step is as follows:

$$P(y_j|y_{<j}, \mathbf{x}) \in \mathbb{R}^{\mathcal{V}} = \text{softmax}(\mathbf{y}_t) \tag{3}$$

where $P(y_j|y_{<j}, \mathbf{x})$ denotes the probability over the whole target vocabulary and $\mathbf{y}_t$ denotes the decoder output of t-th time step. The search algorithm (e.g., beam search) will take this probability distribution as a candidate to find the final translation of the source sentence.

Copying penalty regularizes the prediction probability of each time step by element-wisely multiplying a new constraint $\text{CP} \in \mathbb{R}^{\mathcal{V}}$:

$$\text{CP} = \begin{cases} 1, & y_j \notin \mathbf{x}/\mathcal{C}_{\text{punc}} \\ \alpha, & y_j \in \mathbf{x}/\mathcal{C}_{\text{punc}} \end{cases} \tag{4}$$

where α is a hyperparameter to control the penalty which can be tuned on the development set, similar to length penalty (Wu et al., 2016). $\mathbf{x}/\mathcal{C}_{\text{punc}}$ denotes the set of sources tokens excluding punctuation and `eos`, which means that the prediction probabilities of punctuation and `eos` will not be penalized. For those predictions not belonging to the source, their probabilities keep the same. But for those predictions that are copied from the source, their probabilities will be α times as large/small as before and the model will be more/less likely to choose them as candidates for searching.

The proposed method is simple and effective: 1) It does not change the model architecture and does not need any additional model training, thus no parameters needed to be newly introduced; 2) Its implementation only requires some low-cost matrix operations during model inference, slightly slowing the decoding speed; and 3) It can significantly control the overall copying ratio of the model predictions, making the model accurately generate copying tokens, as shown in the following sections.

Effect of Copying Penalty Figure 2 depicts the changes of the copying ratio and CER scores when setting CP to different values on the test data. When setting CP smaller than 1 (i.e., punishing copying tokens), only those confident copying predictions will be made, and thus reducing both the copying ratio and CER scores. Conversely, setting CP larger than 1 makes the model generate more copying tokens even some of them are of low confidence, thus both the copying ratios and CER scores increase. Similar to length penalty (Wu et al., 2016), we also

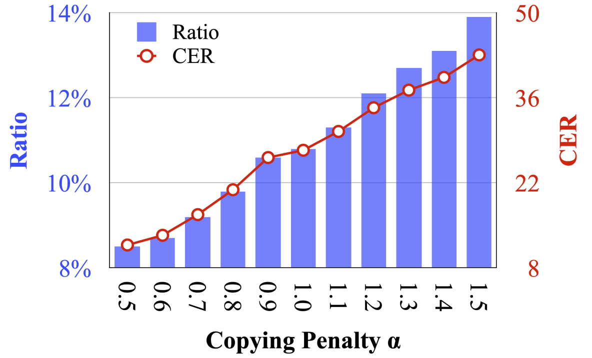

Figure 2: Copying ratios and CER scores by different copying penalties in Pretrained. When setting CP smaller than 1 (i.e., penalizing copying), both the copying ratios and CER scores decrease, and vice versa.

tuned CP on the development data and found that setting CP to 0.7 wins the best BLEU score. Therefore, we used this value for decoding test data in the following experiments.

Empirical results also show that the copying penalty is very efficient. When evaluated by a single 32GB V100 GPU card, the inference speed of Pretrained is about 612 token/s, and that of the model with CP is 607 token/s. The extra latency of the copying penalty is negligible.

3.2 Main Results

Table 6 lists the overall results of the model performance and copying behavior. By looking at the part of evaluating the all test data of 3,003 sentences, the results first confirm the effectiveness of Pretrained that can consistently improve the model performance in terms of BLEU and TER scores. However, the introduction of pre-trained knowledge also brings more copying properties to the model that increases the copying ratio, copying errors, and the number of copying sentences at the same time. Thanks to the introduction of the copying penalty, the model successfully alleviates the copying errors (i.e., reducing the CER score from 27.6 to 16.8), making them be on par with Random, and thus further improve the BLEU and TER scores over the strong Pretrained.

To better understand how copying behaviors affect model performance, we split the test data into two subsets: HasCopy and NoCopy. One intuitive assumption is that copying errors would significantly hurt the performance of the NoCopy data since every copying token in the translation is a copying error. The results confirm our assumption that Pretrained can only improve limited model performance on the NoCopy data (e.g., improving the TER scores from 62.9 to 62.7), but with the copying penalty, the copying errors less occur in Pretrained (i.e., reducing the copying ratio from 2.7 to 1.2 and copying sentences from 18 to 3) and thus, better model performance.

	Performance		**Copying**		
	BLEU	**TER**	**Ratio**	**CER**	**#S**
All (3,003 sentences)					
Oracle	-	-	8.5%	-	9
Random	28.3	60.7	9.3%	17.4	**20**
Pretrained	29.4	59.4	10.8%	27.6	50
+CP	**29.6**	**59.0**	**9.2%**	**16.8**	**20**
HasCopy (1,774 sentences)					
Oracle	-	-	12.5%	-	9
Random	29.7	59.4	13.4%	13.8	**15**
Pretrained	30.9	57.8	14.8%	20.7	32
+CP	**31.0**	**57.5**	**13.0%**	**13.2**	17
NoCopy (1,229 sentences)					
Oracle	-	-	0%	-	0
Random	25.4	62.9	**1.2%**	-	5
Pretrained	26.2	62.7	2.7%	-	18
+CP	**26.7**	**62.0**	**1.2%**	-	**3**

Table 6: Overall results on the WMT14 En-De test set. "Oracle" denotes the statistics on the reference. "+CP" denotes using the proposed copying penalty method for inference. "#S" denotes the number of instances whose overlaps between the source and target exceeding 50%. "HasCopy" denotes evaluating on the sampled test set containing copies between the source and target, while "NoCopy" denotes evaluating on the remained set without any copying. CER score is not applicable in NoCopy as all the copying tokens are copying errors.

Sentence Fluency The copying penalty improves sentence fluency. In §2.4, we show that the perplexity of Pretrained (95.1) is worse than that of Random (60.9). However, after introducing the copying penalty into Pretrained, the perplexity gets a significant drop from 95.1 to 62.3, which can be on par with Random. This confirms our hypothesis that more copying behaviors hurt NMT in terms of translation fluency, and controlling copying behaviors can make the model generate fluent outputs.

Word Accuracy The copying penalty enhances the translation of PROPN. As shown in Table 7, the copying penalty improves the translations of proper nouns, reducing the copying ratio from 7.5%

	#Num	Total		PROPN	
		Ratio	CER	Ratio	CER*
All	3,003	10.8%	27.6	7.5%	27.3
+CP		9.2%	16.8	6.3%	15.1
Tgt-Ori	1,500	10.1%	17.5	6.6%	15.6
+CP		9.4%	12.6	6.1%	10.1
Src-Ori	1,503	11.4%	34.4	8.3%	34.8
+CP		9.1%	20.3	6.4%	18.9

Table 7: Copying behaviors of the source original and target original text in PRETRAINED. “#Num” denotes the total number of sentences in each test set. The translation of source original text contains more copying tokens, and CP can reduce the copying ratio.

to 6.3% and the CER score from 27.3 to 15.1.

To make headway into the translation of proper nouns, we further investigate the translations from various sources that usually show the large difference in the number of proper nouns (Lembersky et al., 2011). Specifically, we investigate the two kinds of sentence pairs in the WMT14 En-De test set: 1) the *source original text* (Src-Ori) that originated in English and was human-translated into German; 2) the *target original text* (Tgt-Ori) was translated in the opposite direction, originating in German with manual translation into English.

Zhang and Toral (2019) conclude that Tgt-Ori is artificially easier to translate, resulted in inflated scores for NMT models. Our results of PRETRAINED positively support this conclusion that translating Tgt-Ori makes fewer copying errors and this might be a reason why it can win a better translation performance. However, by looking at the last row, Src-Ori suffers from serious copying errors especially in translating proper nouns, making it harder to translate. Encouragingly, the copying penalty nicely reduces the copying ratios and copying errors in translating both Src-Ori and Tgt-Ori. These results further reveal the importance of controlling copying behaviors in NMT models since translating source original text is the core task of most NMT systems (Graham et al., 2020).

The above results have shown that copying errors worsen the translation of Src-Ori. To support the claim, we further investigate the effects of varying degrees of copying errors in the translations of Src-Ori and Tgt-Ori. Figure 3 shows the change of BLEU scores with different copying penalties. Clearly, the translation of Src-Ori is more sensitive to copying errors and thus the BLEU scores get a sharp degradation when setting the copying penalty greater than 1, which verifies our claim.

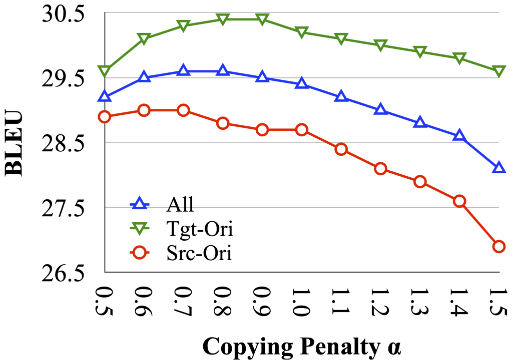

Figure 3: BLEU scores of different copying penalties in PRETRAINED. Penalizing copying (i.e., $\alpha < 1$) brings benefits to the translations of various sources. Translating source original sentences is more sensitive to copying behaviors, leading to a larger score degradation when encouraging copying (i.e., $\alpha > 1$).

3.3 Out-of-domain Robustness

Improving out-of-domain (OOD) robustness is one of the benefits of pre-training for NLP tasks (Hendrycks et al., 2020; Tu et al., 2020), but the OOD sentences usually contain some low-frequency proper nouns which are hard to translate (Ding et al., 2021). In this part, we take the first step towards understanding how pre-training affects the OOD robustness of NMT models.

Setup We followed Müller et al. (2020) to preprocess all the used data sets.[8] We served the medical domain as the training domain (i.e., using the data from the medical domain for model training and validation), which consists of 1.1M training examples and 2,000 validation examples. The test set of the medical domain contains 1,691 examples, while the test sets of the IT, Koran, law, and subtitle domains are with 2,000 examples respectively. For training RANDOM, we used the Transformer *base* setting with 32K batch size. The model dropout is set to 0.3, while the dropouts for attention and inner-FFN activation are set to 0.2. For PRETRAINED, apart from using 32K batch size, the other hyperparameters follow the training of the WMT14 English-German task. The beam size is set to 5 and the length penalty is set to 1.4. We evaluated the model performance on the OOD test sets from IT, Koran, Law, and Subtitles domains,

	InD	OutD				
	Med.	Avg.	IT	Kor.	Law	Sub.
EXISTING	61.5	11.7	17.1	1.1	25.3	3.4
+REG.	60.8	13.1	-	-	-	-
RANDOM	60.5	11.4	20.5	1.1	20.5	3.4
PRETRAINED	63.1	17.6	29.8	2.4	31.0	7.3
+CP	**63.2**	**18.3**	**31.5**	**2.5**	**31.1**	**7.9**

Table 8: BLEU scores on the OPUS De-En translation task trained on the in-domain medical data. "Existing" and "+Reg." denote the results of baseline and regularization method from Müller et al. (2020). CP can significantly improve the translation performance of the IT domain that needs to copy more tokens from the source.

and the averaged BLEU scores can be seen as the OOD robustness of each NMT model.

Results Table 8 lists the results. Clearly, PRETRAINED substantially improves the performances of in-domain translation and OOD robustness, increasing the in-domain BLEU scores from 60.5 to 63.1 and the OOD BLEU scores from 11.4 to 17.6 respectively. The copying penalty can further improve the OOD robustness of PRETRAINED that consistently improves the model performance of each OOD test set. The copying penalty can even remarkably enhance PRETRAINED in translating the sentences from the IT domain (when setting CP to 1.2). One possible reason is that the IT domain needs to copy more tokens from the source sentence than translating sentences from other domains, thus the copying penalty can play a greater role and bring a significant performance boost. This also verifies the effectiveness of the copying penalty.

4 Related Work

4.1 Pre-Training for NMT

Recently, pre-training has been shown useful for transferring general knowledge to specific downstream tasks, including text classification, question answering and natural language inference (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019). Compared with training from scratch, fine-tuning a pre-trained model on downstream datasets usually pushes state-of-the-art performances, while reducing computational and labeling costs.

Previous studies mainly investigate the effect of pre-training on NMT from two perspectives: 1) *knowledge extraction*, where a fixed pre-trained model is used to encode input sequences into features which are then fed into NMT models; and 2) *parameter initialization*, where part/all of the parameters of an NMT model are initialized by a pre-trained model and then training the model on downstream datasets (i.e., parallel corpus).

About knowledge extraction, Yang et al. (2020a) and Zhu et al. (2020) explore enhancing encoder and decoder representations by leveraging pre-trained BERT models (Devlin et al., 2019). In addition, Chen et al. (2020) distill the soft labels from BERT to improve predictions for NMT. These methods are effective but costly because the novel NMT architecture needed to be carefully designed and the computation graph has to store the parameters of both the pre-trained model and NMT model.

About parameter initialization, pre-trained models in different architectures have been studied. For the pre-trained model whose architecture is similar to Transformer encoder (e.g., BERT) or decoder (e.g., GPT (Radford et al., 2018)), the parameters of encoder and decoder can be independently initialized (Conneau and Lample, 2019; Rothe et al., 2020). For the pre-trained model building upon the encoder-decoder architecture (Sutskever et al., 2014), all the model parameters can be directly inherited by NMT, which is easy to use and effective (Song et al., 2019; Lewis et al., 2020; Lin et al., 2020; Yang et al., 2020b).

In general, most previous works focus on designing novel pre-training methods and architectures to boost the model performance of NMT, but the understanding of pre-training for NMT is still limited. This paper improves pre-training for NMT by first understanding its weakness in copying behavior, revealing the importance of further identifying the side-effect from pre-training.

4.2 Copying Behaviors of NMT

It is a common behavior in Seq2Seq models to copy source tokens to the target sentences, especially in monolingual generation tasks. For example, Gu et al. (2016) propose a copying mechanism to explicitly help model learn copying predictions, showing its effectiveness in the tasks of dialogue and summarization.

The copying behaviors also exist in NMT, particularly in languages that share some alphabets (e.g., English and German). Koehn and Knowles (2017) observe that subword-based NMT (Sennrich et al., 2016) outperforms statistical machine translation when translating/copying unknown words.

Knowles and Koehn (2018) find that NMT is able to translate source words in specific contexts via copying (e.g., personal names followed by "Mrs."), and even these are unknown words. However, too many copying signals (i.e., source and target sentences are identical) in training data may lead to one potential threat: NMT models prefer copying source tokens instead of translating them, resulting in performance degradation (Ott et al., 2018a; Khayrallah and Koehn, 2018).

This paper broadens the understanding of copying behaviors in NMT models. We observe that the translation of proper nouns in the source original text contains more copying tokens, which sheds light upon future works.

5 Conclusion and Future Work

We find that NMT models with pre-training are prone to generate more copying tokens. We introduce a copying ratio and a copying error rate to quantitatively analyze copying behaviors in NMT evaluation. In addition, a simple and effective copying penalty is proposed to enhance the copying behaviors during model inference. Experimental results prove the effectiveness of the copying penalty, which can effectively control copying behaviors and improve the overall model performance, especially for the domains (e.g., the IT) where much copying is needed. Extensive analyses reveal that translating proper nouns in source original text generates more copying tokens, providing a direction for the following works on controlling copying behaviors of NMT models.

In the future, we would like to test the effectiveness of the copying penalty on the NMT models with other powerful pre-trained models, and explore more kinds of discrepancies between LM pre-training and NMT training which can be investigated to improve the performance of NMT models. It is also worthwhile to adapt it to other Seq2Seq tasks that need to make a large number of copying predictions, e.g., text summarization and grammar error correction (Liu et al., 2021).

Abstract

Recent advancements in transformer-based models have greatly improved the ability of Question Answering (QA) systems to provide correct answers; in particular, answer sentence selection (AS2) models, core components of retrieval-based systems, have achieved impressive results. While generally effective, these models fail to provide a satisfying answer when all retrieved candidates are of poor quality, even if they contain correct information. In AS2, models are trained to select the best answer sentence among a set of candidates retrieved for a given question. In this work, we propose to generate answers from a set of AS2 top candidates. Rather than selecting the best candidate, we train a sequence to sequence transformer model to generate an answer from a candidate set. Our tests on three English AS2 datasets show improvement up to 32 absolute points in accuracy over the state of the art.

Q: How a **water** **pump** works?

$\mathbf{c_1}$: A small, electrically powered **pump**.

$\mathbf{c_2}$: A large, electrically driven **pump** (electropump) for **waterworks** near the Hengsteysee, Germany.

$\mathbf{c_3}$: A **pump** **is a device** that **moves fluids** (liquids or gases), or sometimes slurries, by **mechanical action**.

$\mathbf{c_4}$: **Pumps** can be classified into three major groups according to the method they use to **move the fluid**: direct lift, displacement, and gravity **pumps**.

$\mathbf{c_5}$: **Pumps** operate by some mechanism (typically reciprocating or rotary), and consume energy to perform **mechanical work** by **moving the fluid**.

G: A **water** **pump** **is a device** that **moves fluids** by **mechanical action**.

Table 1: An example of a question Q and five answer candidates $c_1, \ldots, c_5$ from WikiQA (Yang et al., 2015) ranked by an AS2 system. Answer G generated by our best system is significantly more natural and concise than any extracted candidates.

1 Introduction

Question answering systems are a core component of many commercial applications, ranging from task-based dialog systems to general purpose virtual assistants, e.g., Google Home, Amazon Alexa, and Siri. Among the many approaches for QA, AS2 has attracted significant attention in the last few years (Tymoshenko and Moschitti, 2018; Tian et al., 2020; Garg et al., 2020; Han et al., 2021). Under this framework, for a given question, a retrieval system is first used to obtain and rank a set of supporting passages; then, an AS2 model is used to estimate the likelihood of each sentence extracted from passages to be a correct answer, returning the one with the highest probability. This approach is favored in virtual assistant systems because full sentences are more likely to include the right context and sound natural, both of which are characteristics users value (Berdasco et al., 2019).

AS2 models have shown great performance on academic benchmarks. However, these datasets fail to consider many essential qualities of a QA system which interacts directly with users, such as a virtual assistant. In some cases, extracted answer sentences contain the correct information, but the focus of the answer doesn't match the question; in others, the answer requires reasoning or contextual knowledge from the user or is very long and contains extraneous information. For example, in WikiQA (Yang et al., 2015), a widely used AS2 dataset, the answer *"Wind power is the conversion of wind energy into a useful form of energy, such as using wind turbines to make electrical power, windmills for mechanical power, wind pumps for water pumping... "* is considered a good answer for *"What can be powered by wind?"*, even though its formulation is burdensome to a user.

In this work, we explore a fundamentally differ-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4276–4282
August 1–6, 2021.

ent approach to AS2. Rather than *selecting* the best candidate, we propose using a model to *generate* a suitable response for a user question. In so doing, we extend the traditional AS2 pipeline with a final generation stage that can recover correct and satisfying answers in cases where a ranking AS2 model fails to place an acceptable candidate at the top position or where a top candidate with the desired information is not a natural-sounding response to the query. Table 1 shows an example of our system: given the question, Q, and a list of candidates, $C_k = \{c_1, \ldots, c_5\}$ sorted by a state-of-the-art AS2 system, we use a sequence-to-sequence model to produce an answer G given Q and C_k as input. This approach, which we refer to as GenQA, addresses the limitations of AS2 systems by composing concise answers which may contain information from multiple sources.

Recent works have shown that large, transformer-based conditional generative models can be used to significantly improve parsing (Chen et al., 2020; Rongali et al., 2020), retrieval (De Cao et al., 2020; Pradeep et al., 2021), and classification tasks (Raffel et al., 2019). Our approach builds on top of this line of work by designing and testing generative models for AS2-based QA systems. In recent years, the use of generative approaches has been evaluated for other QA tasks, such as machine reading (MR) (Izacard and Grave, 2021; Lewis et al., 2020b) and question-based summarization (QS) (Iida et al., 2019; Goodwin et al., 2020; Deng et al., 2020). However, while related, these efforts are fundamentally different from the experimental setting described in this paper. Given a question, generative MR models are used to extract a short span (1-5 tokens) from a passage that could be used to construct an answer to a question. In contrast, AS2 returns a complete sentence that could be directly returned to a user.

QS systems are designed to create a general summary given a question and one or more related documents. Unlike QS, AS2-based QA systems need to provide specific answers; thus, the presence of even a small amount of unrelated information in a response could cause the answer sentence to be unsuitable. In contrast, we show that our approach can succinctly generate the correct information from a set of highly relevant sentence candidates.

In summary, our contribution is four-fold: (*i*) we introduce a new approach for AS2-based QA systems, which generates, rather than selects, an answer sentence; (*ii*) we illustrate how to adapt state-of-the-art models such as T5 (Raffel et al., 2019) and BART (Lewis et al., 2020a) for answer generation; (*iii*) we show[1] that our GenQA system improves over the state-of-the-art AS2-based systems by up to 32 accuracy points, as evaluated by human annotators; finally, (*iv*) we briefly explain why traditional generation metrics are not suited for evaluating AS2-based systems.

2 Datasets

We use four English datasets in our work, one related to generative QA and three to AS2. For a fair comparison between selector and generation methods, we re-evaluate the top answers returned by all models using a fixed set of annotators. All annotations were completed by company associates who are not part of our research group and had no knowledge of the systems. Annotators were required to mark an answer as correct if it was: (*i*) factually correct; (*ii*) natural-sounding; and (*iii*) required no additional information to be understood. All QA pairs were single annotated, as we determined sufficient agreement for this task in previous campaigns.

WikiQA by Yang et al. (2015) contains queries from Bing search logs and candidate answer sentences extracted from a relevant Wikipedia page. For evaluation, we used the dev. and test sets, which contain 126 and 243 unique questions and we re-annotated all of the resulting 569 QA pairs.[2]

Answer Sentence Natural Questions (ASNQ) introduced by Garg et al. (2020) was derived from the NQ dataset (Kwiatkowski et al., 2019) and consists of the questions which have a short answer span within a single sentence in a long answer span. The sentences containing the short answer are marked as correct and the other sentences in the document are marked as incorrect. We use the dev. and test splits introduced by Soldaini and Moschitti (2020) which contain 1,336 questions each. We re-annotated a total of 5,344 QA pairs.

WQA is an internal AS2 dataset created from a non-representative sample of questions asked by

---

[1] Our models, source code, and annotated data are available at: `https://github.com/alexa/wqa-cascade-transformers`.

[2] Due to time and annotation constraints, we were only able to annotate results for 100 queries from each of the dev. and test sets for our UQAT5 model

users of a virtual personal assistant in 2019[3]. For each question, we retrieved 500 pages from an index containing over 100M web documents. We then ranked candidate answers using a state-of-the-art AS2 system, and annotated up to 100 of them. In total, the training and dev. sets contain 3,074 queries and 189k QA pairs, while the test set contains 808 queries. For this effort, we re-annotated 4,847 QA pairs from the test set.

MS MARCO QA NLG (MSNLG) by Nguyen et al. (2016) is a subset of the MS MARCO dataset focused on generating natural language answers to user queries from web search result passages. It consists of 182k queries from Bing search logs, the ten most relevant passages retrieved for each query, and a well-formed answer synthesized by an annotator. This dataset is not designed for AS2, but it represents a large resource of succinct and clear answers, thus making it close to our AS2 task.

3 Generative QA Model (GenQA)

The AS2 task is defined as follows: Let q be an element of the question set, Q, and $C_q = \{c_1, \ldots, c_n\}$ be a set of candidates for q, e.g., sentences retrieved by a search engine, where $c_i \in C$, and C is a set of candidates. We model a selector $\mathcal{S} : Q \times C^n \to C$, such that $\mathcal{S}(q, C_q) = \text{argmax}_i\,(p(q, c_i))$, where $p(q, c_i)$ is the probability that c_i is a good answer. We also define $\mathcal{S}_k : Q \times C^n \to C^k$, such that, $\mathcal{S}_k$ selects the top k answers in descending order of $p(q, c_i)$.

State of the Art Throughout our experiments, we use TANDA (Garg et al., 2020) as our state-of-the-art selector $\mathcal{S}$. This AS2 model was trained as a binary classifier on (q, c_i) pairs using a sequential fine-tuning approach starting with ASNQ and finishing on a target dataset, e.g., WikiQA. Specifically, we use their pretrained RoBERTa Large model (Liu et al., 2019), as it achieved the best results on all datasets it was tested on.

3.1 Our Generative Approach

Instead of selecting the best candidate, we generate a new answer using the information from the top k answer candidates. Thus, our model is a function $\mathcal{G} : Q \times C^k \to G$, where G is the text that can be generated by the generator $\mathcal{G}$ from the question, any fragment of the retrieval set, the model's vocabulary, and knowledge stored in the model's parameters. Formally:

$$\mathcal{G}(q, C_q) = \mathcal{G}(q, C_k) = \mathcal{G}(q, \mathcal{S}_k(k, C_q)). \quad (1)$$

The example in Table 1 shows that we can generate a correct answer from a set of candidates which, as a whole, contain enough information to formulate a correct answer. We propose that a valid answer can be built by composing the *most promising* constituents coming from the different candidates in C_k. Intuitively, information repeated across multiple candidates is more *promising*; therefore, we hypothesize that a model trained on the same or similar generation task should be able to effectively exploit this form of repetition, even in cases where the same information is presented in a similar, but not identical manner. Further, recent works have shown that large transformer models hold a substantial amount of commonsense knowledge in their parameters (Roberts et al., 2020), which our model could leverage to perform inference across sentences in C_k, *e.g.*, associate *water* with *fluid* in the example in Table 1.

3.2 Fine-tuning GenQA

Given a pre-trained transformer seq2seq model, e.g., T5 (Raffel et al., 2019) or BART (Lewis et al., 2020a), we obtain $\mathcal{G}$ by fine-tuning on a large AS2 or QA generation dataset. For this purpose, we format our training data as a standard sequence-to-sequence/text-to-text task, where the source text is the question concatenated with the top five answer candidates, $(q, \mathcal{S}_{k=5})$, joined by newlines. When an answer composed by a human is available, such as in MSNLG, we use it as the output target. For cases where there is no composed answer, we randomly select a known-good candidate to be the target, remove it from the inputs and replace it with another candidate if one is available. We truncate the input text to 512 tokens and, at test time, we use beam search with a beam size of four and a maximum output length of 100 tokens.

4 Experiments

In this section, we first report on our experimental setup, then we show the results on fine-tuning GenQA, and finally, we report on the comparative results between AS2 and GenQA.

4.1 Setup

Models and Parameterization Our GenQA model is based on the T5 (Raffel et al., 2019) vari-

---

[3] The public version of WQA will be released in the short-term future. Please search for a publication with title *WQA: A Dataset for Web-based Question Answering Tasks* on arXiv.

ant of the UnifiedQA (UQAT5) model by Khashabi et al. (2020). We use the Large version of UQAT5, which has 770M parameters for all of our experiments. We compute training loss as the mean of the cross-entropy between the softmax probabilities over the output vocabulary and the one-hot encoded target answer. We fine-tune UQAT5 with a learning rate of $5E^{-5}$. We also experiment with the Large variant of BART (Lewis et al., 2020a), which is comprised of 400M parameters. This model was trained using same loss with learning rate $5E^{-6}$.

Evaluation We used accuracy as our primary metric for all our experiments and models. This is computed as the average number of questions a model answers correctly; for a selector $\mathcal{S}$, it is equivalent to Precision at 1. For $\mathcal{S}$, we also report Hit Rate at 5, which is the fraction of queries with at least one good candidate ranked five or less.

Beside human evaluation, we also experimented with automatic evaluation metrics such as BLEU (Papineni et al., 2002) and ROUGE-L (Lin, 2004) for GenQA. Such metrics have found little success in evaluating QA tasks (Chaganty et al., 2018; Chen et al., 2019), so we investigate whether that is the case for AS2 as well.

4.2 Results

How to Fine-tune GenQA? As described in Section 4.1, we tested two GenQA variants: one uses a UnifiedQA T5 (UQAT5) (Khashabi et al., 2020) as base model, while the other leverages BART-Large (Lewis et al., 2020a). Of the datasets used in this work, MSNLG and WQA are large enough for fine-tuning GenQA. Therefore, based on preliminary results, we tested four different strategies for training UQAT5: fine tuning on (*i*) WQA or (*ii*) MSNLG alone, (*iii*) combine the two datasets by alternating mini-batches during training, or (*iv*) follow the *transfer-then-adapt* strategy proposed by Garg et al. (2020): first fine-tune on MSNLG, then adapt to a AS2 using WQA.

Table 2 reports the results on the WQA test set, which are all relative to the performance of the state-of-the-art model (TANDA). First, we observe that all GenQA models reported in this table considerably outperform the best selector model, TANDA. This result shows that our generative approach can improve system based on AS2.

Comparing the accuracy of different training strategies applied to UQAT5, we achieve the best results when the model is trained on MSNLG alone (+19.9% over TANDA baseline). While we were initially surprised by this result, as MSNLG is not designed for AS2, error analysis suggests that GenQA benefits from the high quality training data (concise answers written by annotators). Conversely, when training with WQA, we observed that GenQA tends to produce answers that, while correct, are not as natural-sounding. We plan to explore how to best leverage existing AS2 datasets for generative model training in future work. We also note that a GenQA BART-Large achieves comparable results to GenQA UQAT5 on WQA; in preliminary experiments, we found training strategies reported on UQAT5 to have similar effect on BART-Large.

Model	Accuracy	BLEU	ROUGE-L
TANDA (Garg et al., 2020)	*baseline*	-	-
UQAT5 (AS2D)	+5.3%	40.8	55.7
UQAT5 (MSNLG)	**+19.9%**	20.2	39.7
UQAT5 (MSNLG+AS2D)	+13.6%	35.3	50.6
UQAT5 (MSNLG→AS2D)	+7.9%	40.6	54.8
BART-Large (MSNLG)	**+20.7%**	21.5	41.1

Table 2: Relative accuracy of different GenQA models and training configurations on the WQA dataset; both UQAT5 and BART perform best when finetuned on MSNLG only. As shown in previous work, automatic metrics (BLEU, ROUGE-L) do not correlate with human annotations (accuracy).

When manually annotating results of our early tests, we found that BART was more likely to be extractive and copy input passages in their entirety while UQAT5 was more likely to compose new text and produce answers with textual overlap from multiple input candidates but was more likely to hallucinate content. We found that through hyperparameter tuning we could largely eliminate the hallucination from UQAT5 answers but we were unable to make BART more abstractive.

Similar to what has been observed in other QA tasks (Chaganty et al., 2018; Chen et al., 2019), we find that automatic metrics do not correlate with assessments from human annotators. This is due to the fact that neither BLEU nor ROUGE-L are designed to estimate whether an answer is clear and natural-sounding, instead rewarding candidates that have high overlap with reference answers. Most importantly, such overlap is a poor indicator of factual correctness.

	TANDA			GenQA UQAT5	
Dataset	**Acc.**	**Hit@5**	**Length**	**Acc.**	**Length**
WikiQA$_{\text{DEV}}$	59.5	99.2	31.7 ± 13.7	**92.1**	14.9 ± 9.3
WikiQA$_{\text{TEST}}$	61.0	99.2	30.1 ± 12.4	**88.5**	14.6 ± 8.3
ASNQ$_{\text{DEV}}$	75.5	87.7	41.0 ± 122.4	**90.2**	13.9 ± 5.9
ASNQ$_{\text{TEST}}$	69.0	87.9	37.9 ± 51.5	**90.5**	13.9 ± 5.6

Table 3: Accuracy of our GenQA UQAT5 model compared to a state-of-the-art AS2 model by Garg et al. (2020). All answer candidates returned by the two models were re-annotated to ensure a fair comparison. Length is the average number of tokens in the answer.

Comparison between AS2 and GenQA Table 3 reports the results of TANDA and GenQA on two standard AS2 datasets, evaluated with manual annotation. We note that there is an impressive gap of over 20 absolute accuracy points on both development and test sets. This result is produced by two important properties of GenQA. First, it builds correct answers from a pool of correct and incorrect answers, and it can generate a good answer so long as the relevant information can be found anywhere in the top $k = 5$ candidates. This is a clear advantage over using TANDA alone, as Hit-Rate@5 of 99.2%, and 87.9% for WikiQA and ASNQ, respectively, ensures that GenQA often receives at least one correct answer as input.

Second, GenQA exhibits the ability to rewrite *unnatural* answers from a text snippet into an answer suitable for a conversation. For example, for the question *"What year did Isaac Newton die?"*, TANDA returns candidate *"Sir Isaac Newton (25 December 1642–20 March 1727) was an English physicist and mathematician"*. Although correct, no human would provide it in such a form. In contrast, GenQA composes a concise answer: *"Isaac Newton died in 1727"*.

Finally, Table 3 shows that the size of GenQA answers, in terms of words, is only 14 tokens, which is 2.7 times less than the 30-40 tokens from TANDA. This further suggests that GenQA can provide more concise and direct answers, which are preferable in a conversational context.

5 Conclusions

In this work we present GenQA, a generative approach for AS2-based QA systems. The main difference with recent MR-based generative systems is the capacity of our models to generate long answers. This comes from the use of AS2 candidates (complete sentences) as input to our generative approach. In contrast, MR systems, being mainly trained with short answers, e.g., noun phrases and named entities, mostly generate short answers.

We show that GenQA significantly outperforms state-of-the-art selector models for AS2 by up to 32 accuracy points by combining different pieces of information from the top k answer candidates. These results suggest promising directions for generative retrieval-based systems.

Grounding *'Grounding'* in NLP

Khyathi Raghavi Chandu, Yonatan Bisk, Alan W Black
Language Technologies Institute
Carnegie Mellon University
`{kchandu, ybisk, awb}@cs.cmu.edu`

Abstract

The NLP community has seen substantial recent interest in grounding to facilitate interaction between language technologies and the world. However, as a community, we use the term broadly to reference *any* linking of text to data or non-textual modality. In contrast, Cognitive Science more formally defines "grounding" as **the process of establishing what mutual information is required for successful communication between two interlocutors** – a definition which might implicitly capture the NLP usage but differs in intent and scope.

We investigate the gap between these definitions and seek answers to the following questions: *(1) What aspects of grounding are missing from NLP tasks?* Here we present the dimensions of coordination, purviews and constraints. *(2) How is the term "grounding" used in the current research?* We study the trends in datasets, domains, and tasks introduced in recent NLP conferences. And finally, *(3) How to advance our current definition to bridge the gap with Cognitive Science?* We present ways to both create new tasks or repurpose existing ones to make advancements towards achieving a more complete sense of grounding.
github.com/khyathiraghavi/Grounding-Grounding

1 Introduction

We as humans communicate and interact for a variety of reasons with a goal. We use language to seek and share information, clarify misunderstandings that conflict with our prior knowledge and contextualize based on the medium of interaction to develop and maintain social relationships. However, language is only one of the enablers of this communication reliant on several auxiliary signals and sources such as documents, media, physical context etc., This linking of concepts to context is *grounding* and within NLP context is often a knowledge base, images or discourse.

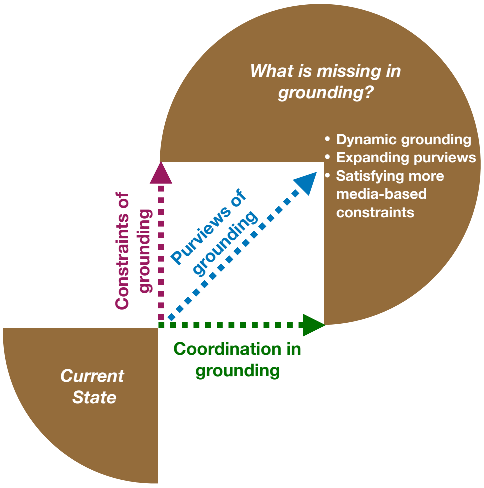

Figure 1: Dimensions of grounding – required to bridge the gap between current state of research and what is missing from a more complete sense of grounding.

In contrast, research in cognitive science defines grounding as the process of building a common ground based on shared mutual information in order to successfully communicate (Clark and Carlson, 1982; Krauss and Fussell, 1990; Clark and Brennan, 1991; Lewis, 2008). We argue that this definition subsumes NLP's current working definition and provides concrete guidance on which phenomena are missing to ensure the naturalness and long term utility of our technologies.

In Section 2, we formalize 3 dimensions key to grounding: Coordination, Purviews and Constraints, to systematize our analysis of limitations in current work. Section 3 presents a comprehensive review of the current progress in the field including the interplay of different domains, modalities, and techniques. This analysis includes understanding when techniques have been specifically designed for a single modality, task, or form of grounding. Finally, Section 4 outlines strategies to repurpose existing datasets and tasks to align with the new

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4283–4305
August 1–6, 2021.

richer definition from cognitive science literature. These introspections, re-formulations, and concrete steps situate NLP ‘grounding’ in larger scientific discourse, to increase its relevance and promise.

2 Dimensions of grounding

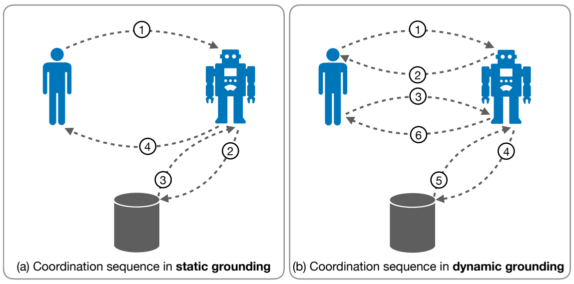
Defining grounding loosely as *linking* or tethering concepts is insufficient to achieve a more realistic sense of grounding. Figure 1 presents the research dimensions missing from most current work.

2.1 Dimension 1: Coordination in grounding

The first and the most important dimension that bridges the gap between the two definitions of grounding is the aspect of coordination – alternatively viewed as the difference between *static* and *dynamic* grounding (Fig 2).

Static grounding is the most common type and assumes that the evidence for common ground or the gold truth for grounding is given or attained pseudo-automatically. This is demonstrated in Figure 2 (a). The sequence for this form of interaction includes: (1) human querying the agent, (2) agent querying the data or the knowledge it acquired, (3) agent retrieving and framing a response and (4) agent delivering it to the human. In this setting the common ground is the ground truth KB/data. The human and the agent have common ground by assuming its universality (i.e. no external references). Therefore, successfully grounding the query in this case relies solely on the agent being able to link the query to the data. For instance, in a scenario where a human wants to know the weather report, the accuracy of the database itself is axiomatic and we build a model for the agent to accurately retrieve the queried information in natural language.

Most current research assumes static grounding so progress is measured by the ability of the agent to *link* more concepts to more data. However, the axiomatic common ground often does not exist and needs to be established in real world scenarios.



(a) Coordination sequence in **static grounding** (b) Coordination sequence in **dynamic grounding**

Figure 2: Coordination sequence in grounding

Dynamic grounding posits that common ground is built via interactions and clarifications. The mutual information needed to communicate successfully is built via interactions including: Requesting and providing clarifications, Acknowledging or confirming the clarifications, Enacting or demonstrating to receive confirmations, and so forth. This dynamically-established-grounding guides the rest of the interaction by course-correcting any misunderstandings. The sequence of actions in dynamic grounding is demonstrated in Figure 2 (b). The steps for establishing grounding is a part of the interaction that includes: (1) The human querying the agent, (2) The agent requesting clarification or acknowledging, (3) The human clarifying or confirming. These three steps loop until a common ground is established. The remaining steps of (4) querying the data, (5) retrieving or framing a response, and (6) delivering the response, are same as that of static grounding. The agent and the human may not be on the same common ground but steps 2 and 3 loop as the conversation progresses to build this common ground. The process of successfully grounding the query not only relies on the ability of the agent to *link* the query but also to *construct the common ground from the mutually shared information* with respect to the human. Although there are efforts about clarification questioning (), the coverage of phenomena are still far from comprehensive (Benotti and Blackburn, 2021b).

Cognitive sciences in the perspective of language acquisition (Carpenter et al., 1998) present two ways of dynamic grounding via joint attention (Kolева et al., 2015; Tan et al., 2020): Dyadic joint attention and Triadic joint attention. In our case, dyadic attention describes the interaction between the human and the agent and any clarification or confirmation is done strictly between the both of them. Triadic attention also includes a tangible entity along with the human and the agent. The human can provide clarifications by gazing or pointing to this additional piece in the triad.

> *Summary: The community should prioritize dynamic grounding as it is more general and more accurately matches real experiences.*

2.2 Dimension 2: Purviews of grounding

Next, we present the different stages behind reaching a common ground, known as purviews. Most of the current approaches and tasks address these purviews individually and independently, while they are often co-dependent in real world scenarios.

Stage 1: Localization: The first stage is the localization of the concept either in the physical or mental contexts. This step is idiosyncratic and relates to the ability of the agent alone to localize the concept. These concepts often are also linked in a *compositional* form. For instance, consider a scenario in which the agent is to locate a 'blue sweater'. The agent needs to understand each of the concepts of 'blue' and 'sweater' individually and then locate the composition of the whole unit. Clark and Krych (2004) from cognitive sciences demonstrate how *incremental* grounding (Schlangen and Skantze, 2009; DeVault and Traum, 2013; Eshghi et al., 2015) is performed with these compositions and show how recognition and interpretation of fragments help in this by breaking down instructions into simpler ones. This localization occurs at word, phrase and even sentence level in the language modality and pixel, object and scene level in the visual modality.

Stage 2: External Knowledge: After localizing the concept, the next step is to ensure consistency of the current context of the concept with existing knowledge. Often times, the references of grounding either match or contradict the references from our prior knowledge and external knowledge. This might lead to misunderstandings in the consequent rounds of communication. Hence, in addition to localizing the concept, it is also essential to make the concept and its attributes consistent with the available knowledge sources. Most of the current research is focused on localizing with few efforts towards extending it to maintain a consistency of the grounded concept with other knowledge sources.

Stage 3: Common sense: After establishing consistency of the concept, a human-like interaction additionally calls for grounding the common sense associated with the concept in that scenario. In addition to the basic level of practical knowledge that concerns with day to day scenarios Sap et al. (2020), the concept should also be reasoned based on that particular context. This contextual common sense moves the idiosyncratic sense towards a sense of collective understanding. For instance, if the human feels cold and asks the agent to get a blue coat, the agent needs to understand that the coat in this instance is a sweater coat and not a formal coat. This implicit common sense minimizes the effort in building a common ground reducing articulation of meticulous details. Therefore it is essential to incorporate this explicitly in our modeling as well.

Stage 4: Personalized consensus: As a part of the evolving conversations, the references in the language evolve as well. The grounded term might have different meanings for the agent in the context with access to the history as opposed to a fresh agent without access to the history. This multi-instance multi-turn process to achieve consensus makes this collective or a shared stage continually adapting to personalization leading to better engagement (Bohus and Horvitz, 2014). In such settings, it is sufficient that the human and the agent are in consensus with the truth value of the grounded term, which need not be the same as the ground truth. This shift in the truth value of the meanings of the grounded terms often arise due to developing short-cuts for ease of communication and personalization, which is an acceptable shift as long as the communication is successful.

> *Summary: Common ground requires expanding to verticals of local, general, common-sense and personalized contextual knowledge.*

2.3 Dimension 3: Constraints of grounding

The medium and mode of communication constrain communicative goals in practical scenarios. The number and availability of such media have increased and facilitated ubiquitous communication around the world, presenting a diversity in the mode of interaction. Motivated by this, we resurface and adapt the constraints of grounding with respect to media of interaction as defined by Clark and Brennan (1991). Here are the definitions of these constraints in the context of grounded language processing and the corresponding categorization of the majority of the representative domains in grounding satisfying different constraints.

- *Copresence:* Agent and human share the same physical environment of the data. Most of the current research in the category of embodied agents satisfy this constraint.
- *Visibility:* The data is visible to the agent and/or human. The domains of images, images & speech, videos, embodied agents satisfy this constraint.
- *Audibility:* Agent and human communicate by speaking about the data. Domains like speech, spoken image captions and videos satisfy this.
- *Cotemporality:* The agent/human receives at roughly the same time as the human/agent pro-

duces. The lag in the domains like conversations or interactive embodied agents is considered negligible and satisfy this constraint.

- *Simultaneity:* The agent and the human can send and receive at once simultaneously. Most media are cotemporal but do not engage in simultaneous interaction. This often disrupts the understanding of the current utterance and the participant may have to repeat it to avoid misunderstandings, which is commonly observed in real world scenarios.
- *Sequentiality:* The turn order of the agent and the human cannot get out of sequence. Face-to-face conversations usually follow this constraint but an email thread with active participants and the comments sections in online portals (such as Youtube, Twitch etc.,) do not necessarily follow a sequence. In such cases a reply to the message may be separated by arbitrary number of irrelevant messages. These categories are usually understudied but are commonly observed online.
- *Reviewability:* The agent reviews the common ground to the human to adapt to imperfect human memories. For instance, we reiterate full references instead of adapting to short cut references when the conversation resurfaces after a while. This is to develop a personalized adaptation between the interlocutors based on the media to enable ease of communication.
- *Revisability:* The interaction between the agent and the human indexes to a specific utterance in the conversation sequence and revise it, therefore changing the course of the interaction henceforth. Human errors are only natural in a conversation and the agent needs to be ready to rectify the previously grounded understanding.

There has been a good and continual effort in formulating tasks and datasets that satisfy the constraints of visibility, audibility and cotemporality. Contemporary efforts also see an increased interest in addressing copresence in grounded contexts. Very recently, (Benotti and Blackburn, 2021a) highlights the importance of recovering from mistakes while establishing the collabrative nature of grounding, contributing to the ability of revisability.

> *Summary: Key to progress is to focus on largely a blind spot in grounding: simultaneity, sequentiality & revisability to revive from mistakes.*

3 Grounding '*Grounding*'

Having covered a more formal definition of grounding adapted to NLP, we turn our attention to cataloging the precise usage of 'grounding' in our research community. We present an analysis on the various domains and techniques NLP has explored.

3.1 Data and Annotations

To this end, since our aim is to investigate how the community understands the loosely defined term 'grounding', we subselected all the papers that mention terms for 'grounding' in the title or abstract from the S2ORC data (Lo et al., 2020) between the years 1980-2020. In this way, we grounded the term *'grounding'* in literature [1] to collect the relevant papers. We acknowledge that the papers analyzed here are not exhaustive with respect to concept of 'grounding'.

Each of the paper is annotated with answers to the following questions: (i) is it introducing a new task? (ii) is it introducing a new dataset? (iii) what is the world scope (iv) is it working on multiple languages? (v) what are the grounding domains? (vi) what is the grounding task? (vii) what is the grounding technique?

3.2 Domains of grounding

Real world contexts we interact with are diverse and can be derived from different modalities such as textual or non-textual, each of which comprises of domains. Our categorization of these is inspired from the constraints of grounding as described in §2.3. Based on this, the modality based categorization include the following domains:

- *Textual modality comprising plain text, entities & events, knowledge bases and knowledge graphs.*
- *Non-textual modality comprising images, speech, images & speech and videos.*

Numerous other domains including *numbers and equations, colors, programs, tables, brain activity signals* etc., are studied in the context of grounding at relatively lower scale in comparison to the aforementioned ones. Each of these can further be interacted with along the variation in the coordination dimension of grounding from §2.1, that give rise to the following settings including *conversations, embodied agents and face-to-face interactions*.

3.3 Approaches to grounding

This section presents a list of approaches tailored to grounding. The obvious solution is to expand the datasets to promote a research platform. The

---

[1] Please note that this is not an exhaustive list of papers working on grounding as there are several others that do mention this term and still work on some form of grounding.

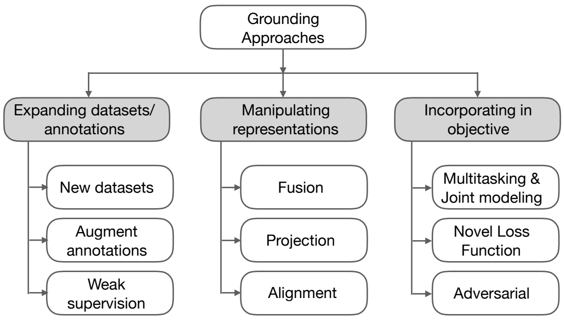


Figure 3: Categorical approaches to grounding

second is to manipulate different representations to *link* and bring them together. Finally the learning objective can leverage grounding. The subcategories within each are presented in Figure 3.

1. Expanding datasets / annotations: The first step towards building an ecosystem for research in grounding is to curate the necessary datasets which is accomplished with expensive human efforts, augmenting existing annotations and automatically deriving annotations with weak supervision.

1a) New datasets: There has been an increase in efforts for curating new datasets with task specific annotations. These are briefly overlaid in Table 1 along with their modalities, domains and tasks.

1b) Augment annotations: These curated datasets can also be used subsequently to augment with task specific annotations instead of collecting the data from scratch, which might be more expensive.

- *Non-textual Modality:* Static grounding here includes using adversarial references to ground visual referring expressions (Akula et al., 2020), narration (Chandu et al., 2019b, 2020a), language learning (Suglia et al., 2020; Jin et al., 2020) etc.,
- *Textual Modality:* Static grounding includes entity slot filling (Bisk et al., 2016).
- *Interactive:* Though not fully dynamic grounding, some efforts here are amongst tasks like understanding spatial expressions (Udagawa et al., 2020), collaborative drawing (Kim et al., 2019) etc.,

1c) Weak supervision: While the above two are based on human efforts, we can also perform weak supervision to use a model trained to derive automatic soft annotations required for the task.

- *Non-Textual Modality:* In the visual modality, weak supervision is used in the contexts of automatic object proposals for different tasks like spoken image captioning (Srinivasan et al., 2020), visual semantic role labeling (Silberer and Pinkal, 2018), phrase grounding (Chen et al., 2019), loose temporal alignments between utterances and a set of events (Koncel-Kedziorski et al., 2014) etc.,
- *Textual Modality:* In the contexts of text, Tsai and Roth (2016a) work towards disambiguating concept mentions appearing in documents and grounding them in multiple KBs which is a step towards Stage 3 in §2.2. Poon (2013) perform question answering with a single database and (Parikh et al., 2015) with symbols.

Table 1: Example datasets introduced for *grounding*.

> *Summary: While augmentation and weak supervision can be leveraged for dimensions of coordination and purviews, curating new datasets is the need of the hour to explore various constraints.*

2. Manipulating representations: Grounding concepts often involves multiple modalities or representations that are *linked*. Three major methods to approach this are detailed here.

2a) Fusion and concatenation: Fusion is a very common technique in scenarios involving multiple modalities. In scenarios with a single modality, representations are often concatenated.

- *Non-textual modality:* Fusion is applied with images for tasks like referring expressions (Roy et al., 2019), SRL (Yang et al., 2016) etc., For videos, some tasks are grounding action descriptions (Regneri et al., 2013), spatio-temporal QA (Lei et al., 2020), concept similarity (Kiela and Clark, 2015), mapping events (Fleischman and Roy, 2008) etc.,

- *Textual Modality:* With text, this is similar to concatenating context (Prabhumoye et al. (2019) perform content transfer by augmenting context).
- *Interactive:* In a conversational setting, work is explored in reference resolution (Takmaz et al., 2020; Haber et al., 2019), generating engaging response (Shuster et al., 2020), document grounded response generation Zhou et al. (2018b), etc.,
- *Others:* Nakano et al. (2003) study face-to-face grounding in instruction giving for agents.

2b) Alignment: An alternative to combining representations is aligning them with one another.

- *Non-textual modality:* Wang et al. (2020) perform phrase localization in images and Hessel et al. (2020) study temporal alignment in videos.
- *Interactive:* Han and Schlangen (2017) align GUI actions to sub-utterances in conversations and Jänner et al. (2018) align local neighborhoods to the corresponding verbalizations.

2c) Projecting into a common space: A widely used approach is to also bring the different representations on to a joint common space.

- *Non-textual modality:* Projection to a joint semantic space is used in spoken image captioning (Chrupala et al., 2017; Alishahi et al., 2017; Havard et al., 2019), bicoding for learning image attributes (Silberer and Lapata, 2014), representation learning of images (Zarrieß and Schlangen, 2017) and speech (Vijayakumar et al., 2017).
- *Textual modality:* Tsai and Roth (2016b) demonstrate cross-lingual NER and mention grounding model by activating corresponding language features.Yang et al. (2019) perform imputation of embeddings for rare and unseen words by projecting a graph to the pre-trained embeddings space.

> *Summary: Modeling different representations effectively aid in improving both consistency across purviews and media based constraints.*

3. Learning Objective: Grounding is often performed to support a more defined end purpose task. We identified 3 ways that are broadly adopted to incorporate grounding in objective functions.

3a) Multitasking and Joint Modeling: The *linking formulation* of grounding is often used as an auxiliary or dependent to model another task.

- *Non-textual Modality:* Multitasking with images is used to perform spoken image captioning (Chrupala, 2019) and grammar induction (Zhao and Titov, 2020). Joint modeling was used in multiresolution language grounding Koncel-Kedziorski et al. (2014), identifying referring expressions Roy et al. (2019), multimodal MT (Zhou et al., 2018c), video parsing Ross et al. (2018), learning latent semantic annotations (Qin et al., 2018) etc.,
- *Interactive:* In a conversational setting, multitasking is used to compute concept similarity judgements (Silberer and Lapata, 2014), knowledge grounded response generation (Majumder et al., 2020), grounding language instructions Hu et al. (2019). Joint modeling is used by Li and Boyer (2015) to address dialog for complex problem solving in computer programs.

3b) Loss Function: It is crucial to utilize appropriate loss designed for the specific grounding task. The main difference between multitasking and a loss function adaptation is that while multitasking reweights combinations of existing loss functions, novel loss functions are informed by the data/task at hand, adapting to a novel use case.

- *Non-textual Modality:* Grujicic et al. (2020) design soft organ distance loss to model inter and intra organ interactions for relative grounding. Ilharco et al. (2019) improve diversity in spoken captions with a masked margin softmax loss.

3c) Adversarial: Leveraging deceptive grounded inputs in an attempt to fool the model is capable of making it robust to certain errors.

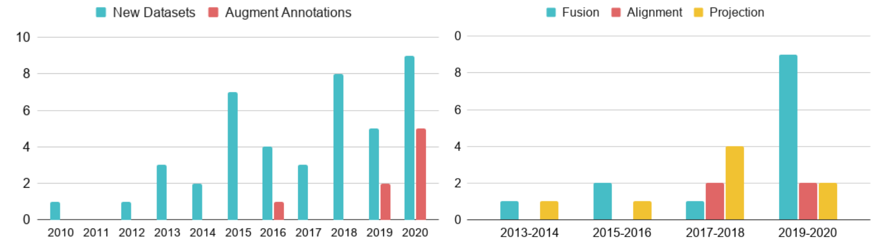
- *Non-textual Modality:* Chen et al. (2018); Akula et al. (2020) present an algorithm to craft visually-similar adversarial examples.
- *Textual Modality:* Zellers et al. (2018) perform adversarial filtering and constructs a de-biased dataset by iteratively training stylistic classifiers.

> *Summary: Manipulating learning objective is a modeling capability aiding as an additional component in bringing grounding adjunct to several other end tasks across all the dimensions.*

3.4 Analysis of trends

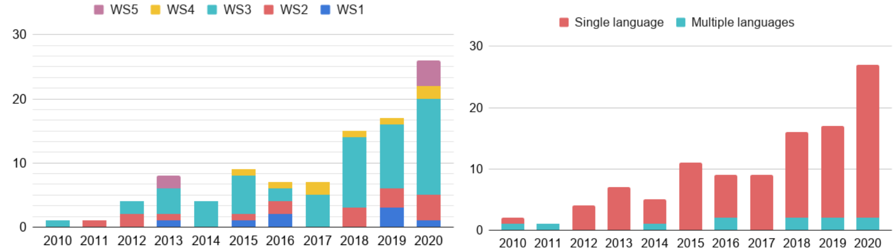
Based on the categories of approaches and different datasets from §3.3, we presented a representative set of analyses that highlight the major avenues that addressing the key missing pieces of work on grounding to advance future research.

Figure 4 presents the trends in the development of grounding over the past decade including: specific approaches (a,b) that presents new tasks/challenges; world scopes (Bisk et al., 2020) (c) contributing to grounding language in different



a) Trends in curating new datasets and augmenting annotations

(b) Trends in manipulation of representations



(c) Trends in world scopes

(c) Trends in multilingual datasets and tasks

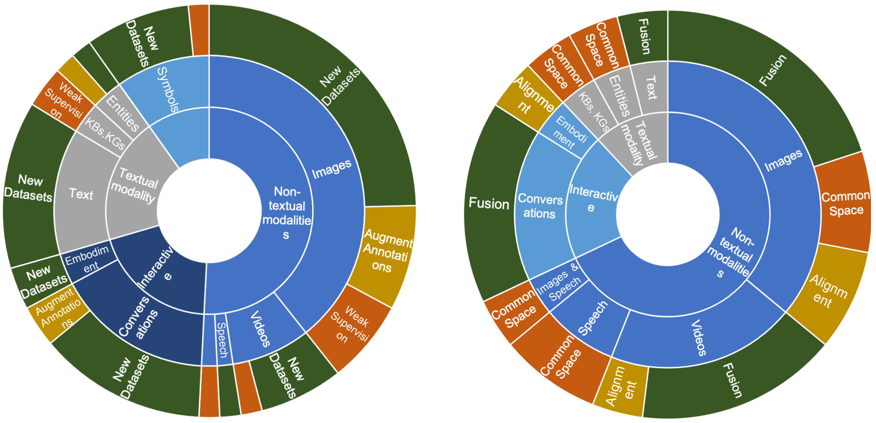
Figure 4: Analysis on the trends in grounding

data types; and multilinguality (d) contributing to a part of linguistic diversity. We also present hierarchical pie charts in Figure 5 and in Appendix to analyze the compositions of modalities and domains for these approaches.While we believe our analysis targets several of the most critical dimensions paving way for future research directions, it is not exhaustive and welcome suggestions from the community for additional analysis. For example, it is also interesting to study domain diversity, task formulation/usefulness, etc., in future.

Trends in datasets expansion: The introduction of new datasets has seen a rapid increase over the years, while there is also a subtle increasing trend in augmenting annotations to the existing datasets, as observed in Figure 4 (a). As we can see from Figure 5 (a), across all the domains, gathering new datasets seem to be prominent than augmenting them with additional annotations to repurpose the data for a new task. There seems to be a higher emphasis of expansion of datasets in the non-textual modalities, particularly in the domain of images. A similar rise is not observed in interactive settings including conversational data and interaction with embodied agents; which is the propitious way to bridge the gap towards real sense of grounding. It is indeed encouraging to see an increasing trend in the efforts for expanding datasets but *the need of the hour is to redirect some of these resources to address dynamic grounding in the coordination dimension which is scarcely studied in existing datatsets.*

Trends in manipulating representations: From Figure 4 (b), we note that the fusion technique has and is increasingly becoming popular in grounding through manipulating representations in comparison to alignment and projection. This is also observed in Figure 5 (b) with the dominance of non-textual modality. In the context of textual modality, this technique is equivalent to concatenation of the context or history in a conversation. Projecting onto a common space is the next popular technique in comparison to alignment. Similarly, we observe that the non-textual modality overwhelmingly occupies the space of manipulating representations with exceeding prominence of fusion. *Fusion and projecting onto common space currently are exceedingly used methodologies to ground within a single purview. They demonstrate a promising direction to manipulate representations across different stages to maintain consistency along the purviews.*

Trends in World Scopes: We also study the development of the field based on the definitions of the world scopes presented by Bisk et al. (2020). Based on this, last decade has seen an increasing dominance in research on world scope 3 (world of sights and sounds). However, this is limited to this scope and the same trend is not clear in world scope 4 (world of embodiment and action). An encouraging observation is the focus of the field in world scope 5 (social world) which is closer to real interactions in the last year. *We need to accelerate development of datasets and tasks in world scopes 4 and 5. It is highly recommended to take dynamic grounding scenario into account in the efforts for*



(a) Expanding datasets/annotations

(b) Manipulating Representations

Figure 5: Analysis of Domains and Techniques

curating datasets in these scopes.

Inclusivity of multiple languages: Figure 4 (c) shows that research into grounding in multiple languages is still incredibly rare. As noted by Bender (2011), improvements in one language do not necessarily mandate comparable performances in other languages. *The norm for benchmarking large scale tasks still remains anglo-centric and we need serious efforts to drift this trend to identify challenges in grounding across languages. As a first step, a relatively less expensive way to navigate this dearth is to augment the annotations of existing datasets with other languages.*

4 Path Ahead: Towards New Tasks and Repurposing Existing Datasets

We presented the dimensions of grounding that require serious attention to bridge the gap between the definitions in cognitive sciences and language processing communities in §2. Based on this, we analyzed the language processing research to understand where we stand and where we fall short with the ongoing efforts in trends in grounding in §3. While we strongly advocate for efforts in building new datasets and tasks considering progress along these dimensions, we believe in a smoother transition towards this goal. Hence we present strategies to repurpose existing resources to maximum utility as we stride towards achieving grounding in real sense. In this section, we focus on concrete suggestions to improve along each of the dimensions.

Coordination: This is based on simulating interaction for dynamic grounding. As establishing a common ground is not integrated within datasets, we propose an iterative paradigm to explicitly settle on a common ground based on our priors.

The first family of methods to perform this is human-in-the-loop interactions. The traditional methods of data collection do not cater to human feedback or generation. Some recent approaches to incorporate human feedback are during data collection (Wallace et al., 2019), training (Stiennon et al., 2020), inference (Hancock et al., 2019). While the feedback in a human in the loop setting can be via scores, we argue for natural language feedback (Wallace et al., 2019) loop, which resembles human-human grounding via communication.

The second family of methods are inspired from the theory of mind (Gopnik and Wellman, 1992) to iteratively or progressively ask and clarify to establish a common ground (Roman et al., 2020). de Vries et al. (2017); Suglia et al. (2020) disambiguate or clarify the referenced object through a series of questions in a guessing game. This iterative paradigm can be related to work by Shwartz et al. (2020) that generates clarification questions and answers to incorporate in the task of question answering. This loop of semi-automatic generation of clarifications establishes a common ground. This is also in spirit similar to generating an explanation or a hypothesis for question answering (Latcinnik and Berant, 2020). The process of generating an acceptable explanation to human before acts as establishing a common ground.

We believe that datasets and tasks along the following 3 directions encourage dynamic grounding: (1) conversational language learning (Chevalier-Boisvert et al., 2019) or acquisition, and (2) clarification questioning and ambiguity resolution (Shwartz et al., 2020) (3) mixed initiative for grounding in conversations (Morbini et al., 2012). The need of the hour that can revolutionize this paradigm is the *development of evaluation strategies to monitor evolution of the common ground.* This dynamic grounding data helps improve performance/robustness and encourages human's trust while using these interactive systems.

Purviews: This is based on establishing consistency across stages of grounding with an incremental paradigm. A simple solution is a modular approach where the purviews flow into the next stage after reasonably satisfying the previous stage. The current benchmarking approaches are mostly lateral i.e., our current strategies collate multiple datasets of a single task to benchmark. This approach implicitly establishes boundaries between the purviews. In contrast, *we advocate for a longitudinal approach for benchmarking* i.e in addition to collating different datasets for a task, we also extend the purviews of the task such that the output from the previous purview flows into the next purview. An example of establishing a longitudinal benchmark for visual dialog. The tasks flow from object detection (stage 1: localization) to knowledge graphs (stage 2: external knowledge) to common sense understanding (stage 3: common sense) to empathetic dialogue (stage 4: personalization) for the *same* dataset. This helps us dissect which aspect of grounding is the model good and bad at to understand the weak areas.

Constraints: With media imposed constraints, there is a need for paradigm shift in the way these datasets are curated. The optimal way to navigate this problem is curating new datasets to *specifically focus on the less studied constraints of simultaneity, sequentiality and revisability.* At the heart of revisability in a collaborative dialog is clarification questioning and resolving ambiguities (Boni and Manandhar, 2003; Rao and III, 2018; Braslavski et al., 2017; Kumar and Black, 2020; Aliannejadi et al., 2020; Benotti and Blackburn, 2021b) However, they are rarely explored and are not systematically standardized across modalities. Transferring knowledge for shared constraints across tasks is a promising way to leverage the existing datasets.

Augment with multilingual annotations: Different languages also bring novel challenges to each of these issues (e.g. pronoun drop dialogue in Japanese, morphological alignments, etc). However, as observed in §3.4, the increase in expanding datasets is not proportionally reflected to include multiple languages. We recommend a relatively less expensive process of translating the datasets for grounding into other languages to kick start this inclusion. The research community has already seen such efforts in image captioning with human annotated German captions in Multi30k (Elliott et al., 2016) extended from Flick30k (Plummer et al., 2015) and Japanese captions in STAIR (Yoshikawa et al., 2017) based on MS-COCO images (Lin et al., 2014). Instead of using human annotations, some efforts have also been made to use automatic translations such as the work by Thapliyal and Soricut (2020) and denoising (Chandu et al., 2020b) extending from (Sharma et al., 2018). Not just augmentation, but there are also ongoing efforts in gathering datasets in multiple languages (Ku et al., 2020) extending (Anderson et al., 2018).

5 Conclusions

We discussed the missing pieces and dimensions that bridge the gap between the definitions of grounding in Cognitive Sciences and NLP communities. Thereby, we chart out executable actions in steering existing resources along 3 dimensions to achieve a more realistic sense of grounding. Specifically: (1) Static grounding still remains the central tenet for existing tasks and datasets. However, dynamic grounding is key moving forward. (2) Current benchmarking strategies evaluate model generalization. In tandem, we also need to steer towards longitudinal benchmarking to naturally proliferate across purviews of grounding that is closer to human interactions. (3) Constraints imposed by the interaction medium present nuanced categories of communicative goals. While discerning learning from shared constraints, we also urge the community to invest resources on revisability as a way to recover from contextually mistaken groundings. While ruminating on the above phenomena, the challenge of expanding them to multiple languages and domains still persists. We also recommend systematic evaluation of grounding along these dimensions in addition to the existing linking capabilities.

Ethical Considerations

The analytical and ontological discussion here focuses exclusively on the question of *grounding* and common ground and does not address the harmful biases inherent in these datasets. Further, the common ground for which we are advocating is culturally specific and future work that introduces tasks and data for these purposes must be explicit about who they serve (culturally and linguistically).

A Examples for dimensions of grounding

Static Grounding: In static grounding, when you ask an agent *"Can you place the dragon fruit on the rack"?*, the agent links the entities and places the dragon fruit on the rack. The challenge here is mainly the linking part which is crucial to ensure it accurately understood the instruction.

Dynamic Grounding: The same is not true for dynamic grounding. There are primarily 2 ways to materialize this. First, with respect to language learning: What if the agent does not know dragon fruit? The agent needs to first ask *"What is a dragon fruit?"*, and the human provides an answer. Lets say the human responded by describing the physical attributes such as *reddish pink fruit* and/or a spatial reference by refering to it as *the fruit on the bottom left*. The important aspect here is that the agent asks and learns what a dragon fruit is and use this knowledge later.

The second is ambiguity resolution. Consider a scenario where there are multiple racks. It is very natural for a human to ask the agent which rack to resolve ambiguity.We expect the same from the agent to ask a clarifying question to resolve ambiguity and then place it on the second rack.

Purviews - Localization: Consider this example of a conversation between an agent and a human.

***Human**: What is the name of the role Robert Downey Jr played in Avengers?*
***Agent**: He played the role of Tony Stark, and sometimes is also referred to as Iron Man.*

The agent begins by localizing and linking Robert Downey Jr to Tony Stark and Iron Man to provide the appropriate answer to the query.

Purviews - External Knowledge: However, natural conversations also extend beyond the purview of localization to discuss a broadened scope involving external knowledge of the context including entities, actions etc., For example, consider this conversation which seems to be a natural continuation to the earlier one.

***Human**: Is he the head of SHIELD?*
***Agent**: Tony Stark has never been the head of SHIELD in the movies but has been the acting head upon Maria Hill's suggestion in the Comics.*

Once we localized Tony Stark, asking additional information like whether he is the head of SHIELD is natural in conversations; However, access to required external knowledge is rarely present in the datasets as well as evaluated. Here, we need to refer to external sources spanning from movies to comics to conclude that he has been the acting head in the comics but was never in the movies.

Purviews - Common sense: One of the branches of natural progression to this context can extend to the following turns:

***Human**: How long was the contract between Tony Stark and Marvel?*
***Agent**: Tony Stark is the name of the character in Marvel. Would you like to know the contract length for Robert Downey Jr who played the role?*

Here, the agent needs to understand that Tony Stark is not a real person, but is a character in Marvel. Hence, any contract is with the actor but not the character who played the role. The agent needs to have the common sense to understand this and clarify the question.

Purviews - Personalization: Upon a continous exchange regarding this topic (and perhaps a few other times earlier), the agent needs to adapt and personalize to the interacting human over time.

***Human**: Can you give me any movie suggestions?*
***Agent**: Yes, since you like Disney movies and seem interested in Robert Downey Jr, would you like to watch "Dolittle"?*

Having discussed about Robert Downey Jr in prior contexts and retaining from the prior interactions that the human likes Disney movies, when the human asks about a movie recommendation, the agent continually learns and contextually suggests Robert Downey Jr's Disney movie "Dolittle" as a recommendation.

Constraints - Copresence: Modality is an important medium that affects communicative goals and the nature of interaction. Here is an example in a copresent environment.

***Human**: I want to play with my cat. Can you get me the ball on your right?*

In the above example, the human and the agent

	Modality			Cue				
	Copresence	**Visibility**	**Audibility**	**Cotemporality**	**Simultaneity**	**Sequentiality**	**Reviewability**	**Revisabiility**
Face-to-face	✓	✓	✓	✓	✓	✓		
Telephone			✓	✓	✓	✓		
Video Teleconference		✓	✓	✓	✓	✓		
Terminal Teleconference				✓		✓	✓	
Answering Machines			✓				✓	
E-mail							✓	✓
Letters							✓	✓

Table 2: Constraints of grounding along with their medium of communication (Clark and Brennan, 1991)

are copresent in the same environment. The above utterance for instance, includes executable actions in the environment along with references being either person-centric or agent-centric.

Constraints - Visibility: Certain communications like in the cases of visual question answering or visual dialog only presents a visible medium to interact *about*. The interaction requires information from an image or a video, but does not necessarily include executable actions or cater to external knowledge of the information. For example, with an access to an image a human can ask a question like the following:

***Human**: How many peaks are there in those mountain ranges?*

Constraints - Audibility: This modality constrains the information scope to be within speech signals that are only heard and do not contain any visual or copresent information.

Table 2 presents the constrainst of grounding.

B Further survey and categories

Here is a brief elaboration of the datasets presented in Table 1.

New datasets: The first solution to curate the entire dataset with annotations designed for the task.

- *Non-textual Modality:* For images, new datasets are curated for a variety of tasks including caption relevance (Suhr et al., 2019), multimodal MT (Zhou et al., 2018c), soccer commentaries (Koncel-Kedziorski et al., 2014) semantic role labeling (Silberer and Pinkal, 2018), instruction following (Han and Schlangen, 2017), navigation (Andreas and Klein, 2014), understanding physical causality of actions (Gao et al., 2016), understanding topological spatial expressions (Kelleher et al., 2006), spoken image captioning (Alishahi et al., 2017), entailment (Vu et al., 2018), image search (Kiros et al., 2018), scene generation (Chang et al., 2015), etc., Coming to videos, datasets have become popular for several tasks like identifying action segments (Regneri et al., 2013), sematic parsing (Ross et al., 2018), instruction following from visual demonstration (Liu et al., 2016), spatio-temporal question answering (Lei et al., 2020), etc.,

- *Textual Modality:* Within text, there are several datasets for tasks like content transfer (Prabhumoye et al., 2019), commonsense inference (Zellers et al., 2018), reference resolution (Kennington and Schlangen, 2015), symbol grounding (Kameko et al., 2015), studying linguistic and non-linguistic contexts in microblogs (Doyle and Frank, 2015), bilingual lexicon extraction (Laws et al., 2010), universal part-of-speech tagging for low resource languages (Cardenas et al., 2019), entity linking and reference (Nothman et al., 2012) etc.,

- *Other:* More static grounding datasets correspond to tasks like identifying phrases representing variables (Roy et al., 2016), conceptual similarity in olfactory data (Kiela et al., 2015), identifying colors from descriptions (Monroe et al., 2017), correcting numbers (Spithourakis et al., 2016) etc.,

- *Interactive:* Coming to an interactive setting, the datasets span tasks like conversations based on negotiations (Cadilhac et al., 2013), referring expressions from images (Haber et al., 2019; Takmaz et al., 2020), emotions and styles (Shuster et al., 2020), media interviews (Majumder et al., 2020), documents (Zhou et al., 2018b), improvisation (Cho and May, 2020), problem solving (Li and Boyer, 2015), spatial reasoning in a simulated environment (Jänner et al., 2018), navigation (Ku et al., 2020) etc.,

In addition, there are several other techniques used to ground phenomenon in real world contexts.

In addition to the techniques dicscussed in the paper, we also studied the categorization based on stratification, which is explained here.

Stratification: The stratification technique characterizes the input or the model to explicitly cater to the compositionality property. This can be done by either breaking down the input to meaningful compositions or building the model to compose the representations. Utilizing grammatical rules need not necessarily lead to compositions, although there is an overlap between these two techniques.

A common strategy when language is involved is leveraging **syntax and parsing**. In the domain of images, Udagawa et al. (2020) design an annotation protocol to capture important linguistic structures based on predicate-argument structure, modification and ellipsis to utilize linguistic structures based on spatial expressions. Becerra-Bonache et al. (2018) study linguistic complexity from a developmental point of view by using syntactic rules to provide data to a learner, that identifies the underlying language from this data. Shi et al. (2019) use image-caption pairs to extract constituents from text, based on the assumption that similar spans should be matched to similar visual objects and these concrete spans form constituents. Kelleher et al. (2006) use combinatory categorial grammar (CCG) to build a psycholinguistic based model to predict absolute proximity ratings to identify spatial proximity between objects in a natural scene. Ross et al. (2018) employ CCG-based parsing to a fixed set of unary and binary derivation rules to generate semantic parses for videos.

- *Textual Modality:* Johnson et al. (2012) study the modeling the task of inferring the referred objects using social cues and grammatical reduction strategies in language acquisition. Eckle-Kohler (2016) attempt to understand meaning in syntax by a multi-perspective semantic characterization of the inferred classes in multiple lexicons. Chen (2012) develop a context-free grammar to understand formal navigation instructions that correspond better with words or phrases in natural language. Börschinger et al. (2011) study the probabilistic context-free grammar learning task using the inside-out algorithm in game commentaries. CCG parsers are also used to perform entity slot filling task (Bisk et al., 2016). When applied to question answering over a database, dependency rules are used to model the edge states as well as transitions such as the work done by using a treeHMM (Poon, 2013).

- *Other:* Roy et al. (2016) perform equation parsing that identifies noun phrases in a given sentence representing variables using high precision mathematical lexicon to generate the correct relations in the equations. Parikh et al. (2015) perform prototype driven learning to learn a semantic parser in tables of nested events and unannotated text.

- *Interactive:* Luong et al. (2013) use parsing and grammar induction to produce a parser capable of representing full discourses and dialogs. Steels (2004) study games and embodied agents by modeling a constructivist approach based on invention, abduction and induction to language development.

Another frequently used technique when language is involved is by leveraging the principle of **compositionality**. This implies that the meaning of a complex expression is determined by the meanings of its constituents and how they interact with one another.

- *Non-textual Modality:* In the domain of images, Suhr et al. (2019) present a new dataset to understand challenges in language grounding including compositionality, semantic diversity and visual reasoning. Shi et al. (2019), discussed earlier also use grammar rules to compose the inputs. Koncel-Kedziorski et al. (2014) leverage the compositional nature of language to understand professional soccer commentaries. In the domain of videos, Nayak and Mukerjee (2012) study language acquisition by segmenting the world to obtain a meaning space and combining them to get a linguistic pattern.

- *Textual Modality:* With ontologies, Pappas et al. (2020) perform adaptive language modeling to other domains to get a fully compositional output embedding layer which is further grounded in information from a structured lexicon.

- *Interactive:* Roy et al. (2003) work on grounding word meanings for robots by composing perceptual, procedural, and affordance representations.

Hierarchical modeling is also applied to show effect of introducing phone, syllable, or word boundaries in spoken captions (Havard et al., 2020) and with a compact bilinear pooling in visual question answering (Fukui et al., 2016).

There is some work that presents a bayesian probabilistic formulation to learn referential grounding in dialog (Liu et al., 2014), user preferences (Cadilhac et al., 2013), color descriptions (McMahan and Stone, 2015; Andreas and Klein, 2014).

A huge chunk of work also focus on leveraging attention mechanism for grounding multimodal phenomenon in images (Srinivasan et al., 2020; Chu et al., 2018; Huang et al., 2019; Fan et al., 2019; Vu et al., 2018; Kawakami et al., 2019; Dong et al., 2019), videos (Lei et al., 2020; Chen et al., 2019) and navigation of embodied agents (Yang et al., 2020), etc.,

Some approach this using data structures such as graphs in the domains of grounding images (Chang et al., 2015; Liu et al., 2014), videos (Liu et al., 2016), text (Laws et al., 2010; Chen, 2012; Massé et al., 2008), entities (Zhou et al., 2018a), knowledge graphs and ontologies (Jauhar et al., 2015; Zhang et al., 2020) and interactive settings Jauhar et al. (2015); Xu et al. (2020).

Here is the technique wise representation of these categories of models in the literature.

Figure 6: Papers addressing stratification in grounding

C Prevelance of modailties and constraints

Here is the distribution of the papers studying various tasks based on the constraints imposed by the medium.

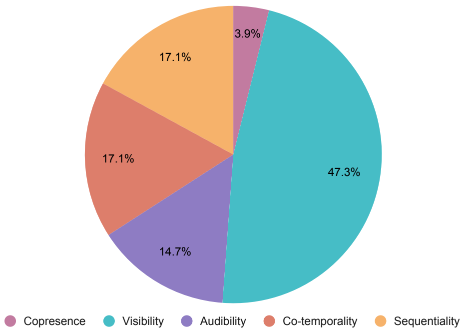

Figure 7: Papers addressing different constraints of grounding

As we can see, a major concentration of these efforts lie in grounding visual and textual media, while a few cater to audibility i.e speech signals. Papers studying dialog are the main representatives of the constraints for sequentiality and co-temporality.

D Nuanced modeling variations for grounding

Here is a more nuanced and finer grained categorization of the various modeling techniques used in literature for grounding. Figure 8 presents these categories in depth.

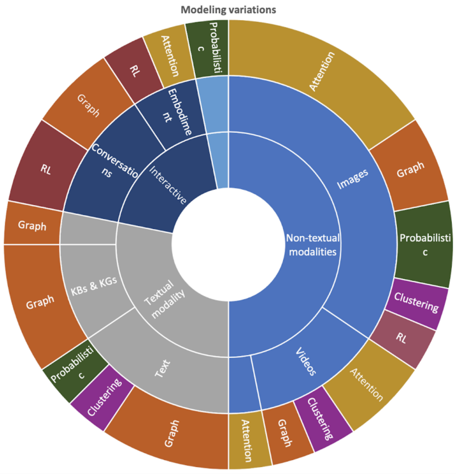

Figure 8: Modeling variations in papers studying grounding

As discussed in the paper, most of the literature is focused on grounding in static visual modality. Attention based methods dominate the rest of the methods in both textual and non-textual modalities closely followed by graph based methods as observed in these trends.

This is not an exhaustive study of all the techniques that present grounding, but are some of the representative categories. Here are more studies that perform grounding with various techniques such as clustering (Shutova et al., 2015; Cardenas et al., 2019) regularization (Shrestha et al., 2020), CRFs (Gao et al., 2016), classification (Pangburn et al., 2003; Monroe et al., 2017), linguistic theories (Strube and Hahn, 1999), iterative refinement (Li et al., 2019; Chandu and Black, 2020), language modeling (Spithourakis et al., 2016; Cho and May, 2020), nearest neighbors (Kiela et al., 2015), contextual fusion (Chandu et al., 2019a), mutual information (Oates, 2003), cycle consistency (Zhong et al., 2020) etc.,

Federated Chinese Word Segmentation with Global Character Associations

Abstract

Chinese word segmentation (CWS) is a fundamental task for Chinese information processing, which always suffers from out-of-vocabulary word issues, especially when it is tested on data from different sources. Although one possible solution is to use more training data, in real applications, these data are stored at different locations and thus are invisible and isolated among each other owing to the privacy or legal issues (e.g., clinical reports from different hospitals). To address this issue and benefit from extra data, we propose a neural model for CWS with federated learning (FL) adopted to help CWS deal with data isolation, where a mechanism of global character associations is proposed to enhance FL to learn from different data sources. Experimental results on a simulated environment with five nodes confirm the effectiveness of our approach, where our approach outperforms different baselines including some well-designed FL frameworks.[1]

1 Introduction

Chinese word segmentation (CWS) is a preliminary and vital task for natural language processing (NLP). This task aims to segment Chinese character sequence into words and thus is generally performed as a sequence labeling task (Tseng et al., 2005; Levow, 2006; Song et al., 2009a; Sun and Xu, 2011; Song and Xia, 2012, 2013; Mansur et al., 2013). Although recent neural-based CWS systems (Pei et al., 2014; Chen et al., 2017; Ma et al., 2018; Higashiyama et al., 2019; Qiu et al., 2019; Ke et al., 2020; Huang et al., 2020a; Tian et al., 2020e) have achieved very good performance on benchmark datasets, it is still an unsolved task (Fu et al., 2020), because it is challenging to handle out-of-vocabulary words (OOV), especially in real applications where the test data may come from different sources. Although leveraging extra labeled data from other sources or domains could alleviate this issue, in real applications, such data are always located in different nodes and thus are inaccessible to each other because of the privacy or legal concerns (e.g., clinical or financial reports from different hospitals or companies).

To address the data isolation issue, federated learning (FL) (Shokri and Shmatikov, 2015; Konečný et al., 2016) is proposed and has shown its great promises for many machine learning tasks (Aono et al., 2017; Sheller et al., 2018; He et al., 2020). In many cases, data in different nodes are encrypted and aggregated to the centralized model, and they are invisible to each other during the training stage. This property allows FL to be an essential technique for real applications with privacy and security requirements. However, conventional FL techniques are more suitable for nodes sharing homogeneous data, which is seldom the case for NLP tasks. Particularly for CWS, the appropriate segmentation is sensitive to the data source, where the text and vocabularies used in different datasets contain various expressing patterns. For example, in real applications such as Input Method Editors (IME, such as pinyin input environment), there are millions of individual users with their data stored in isolated nodes, where the different nodes could have diverse segmentation requirement due to the users' preference. Therefore, the restricted data access of traditional FL approaches could result in inferior performance for CWS since they cannot update the model to facilitate localized prediction. Unfortunately, limited attentions have been paid to address this issue. Most existing approaches (Liu et al., 2019; Huang et al., 2020b; Sui et al., 2020) with FL on NLP (e.g., for language modeling

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4306–4313
August 1–6, 2021.

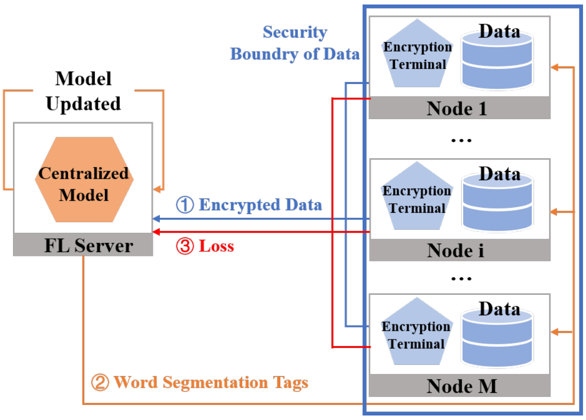

Figure 1: The server-node architecture of our approach. The encrypted information (i.e., encrypted data, word segmentation tags, and loss) communicates between a node and the server, where the locally stored data is inaccessible to other nodes during the training process.

(Hard et al., 2018; Chen et al., 2019), named entity recognition (Ge et al., 2020), and text classification (Zhu et al., 2020)) mainly focus on optimizing the learning process and ignore domain diversities.

In this paper, we propose a FL-based neural model (GCA-FL) for CWS, which is enhanced by global character association (GCA) mechanism in a distributed environment. The GCA mechanism is designed to capture contextual information (patterns) in a particular input for localized predictions and to handle the difficulties in identifying text sources caused by data inaccessibility. Specifically, GCA is served as a server-side component to associate global character n-grams with different inputs from each node and responds with contextual information to help the backbone segmenter. Experimental results on a simulated environment with isolated data from five domains demonstrate the effectiveness of our approach, where GCA-FL outperforms different baselines including the ones with well designed FL framework.

2 The approach

Figure 1 illustrates the overall server-node architecture for applying our approach. The centralized model is stored in the FL server and data from multiple sources (domains) are stored at different nodes (the i-th node is denoted by $\mathcal{N}_i$), respectively. Encrypted information (e.g., data, vectors, and loss) communicates between each node $\mathcal{N}_i$ and the FL server. In this way, the original data stay in the local node and is not accessible to the other nodes. To encode contextual information (patterns) to facilitate localized prediction, we enhance FL by introducing GCA into the centralized model (Figure 2), which follows the character-based sequence labeling paradigm for CWS. Herein, GCA encodes the contextual information from the encrypted input and uses the resulted information to guide the centralized model to make a localized prediction. In the following, we introduce FL for CWS and then the centralized model with GCA.

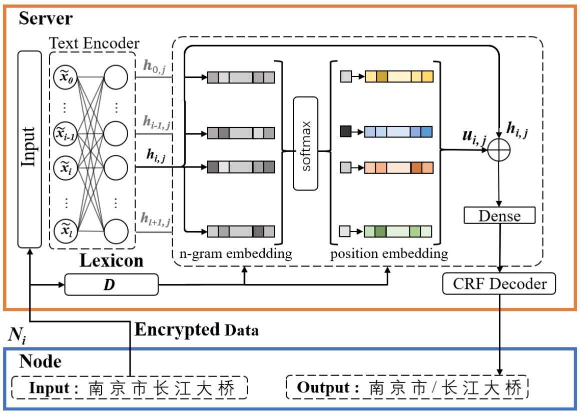

Figure 2: An overview of GCA-FL, where centralized model is illustrated on the top and the example input sentence “南京市长江大桥” (*Nanjing Yangtze River Bridge*) from $\mathcal{N}_i$ is shown on the bottom. “/” in the output represents the delimiter for the word boundaries.

2.1 Federated Learning

In the training process of FL, the node $\mathcal{N}_i$ firstly encrypts the original input character sequence $\mathcal{X}_i$ into $\widetilde{\mathcal{X}}_i = \widetilde{x}_{i,1} \cdots \widetilde{x}_{i,j} \cdots \widetilde{x}_{i,l}$, where $\widetilde{x}_{i,j}$ denotes the j-th character in $\widetilde{\mathcal{X}}_i$. Next, $\mathcal{N}_i$ passes $\widetilde{\mathcal{X}}_i$ to the server. Then, the centralized model on the server processes $\widetilde{\mathcal{X}}_i$ and predicts the corresponding label sequence $\widehat{\mathcal{Y}}_i = \widehat{y}_{i,1} \cdots \widehat{y}_{i,j} \cdots \widehat{y}_{i,l}$ by

$$\widehat{\mathcal{Y}}_i = \text{GCA-FL}\left(\widetilde{\mathcal{X}}_i\right) \tag{1}$$

where $\widehat{y}_{i,j} \in \mathcal{T}$ ($\mathcal{T}$ is the label set) is the segmentation label for $\widetilde{x}_{i,j}$. Afterwards, $\widehat{\mathcal{Y}}_i$ is passed back to $\mathcal{N}_i$ and compared with the gold label sequence $\mathcal{Y}_i^*$, after which the loss $\mathcal{L}_i$ for that training instance is obtained locally. Finally, $\mathcal{L}_i$ is passed to the server and the parameters in the centralized model are updated accordingly.

2.2 Centralized Model with GCA

In standard FL framework, the backbone centralize model works following the encoding-decoding paradigm, where $\widetilde{\mathcal{X}}_i$ is encoded[2] into a sequence of hidden vectors ($\mathbf{h}_{i,j}$ denotes the hidden vector for $\widetilde{x}_{i,j}$), which are then sent to a decoder (e.g.,

---

[2] One can use any encoder, e.g., biLSTM, for this process.

Rule	$v_{i,j,k}$
$x_{i,j}$ is the beginning of the n-gram $s_{i,j,k}$	V_B
$x_{i,j}$ is inside the n-gram $s_{i,j,k}$	V_I
$x_{i,j}$ is the ending of the n-gram $s_{i,j,k}$	V_E
$x_{i,j}$ is the single-character n-gram $s_{i,j,k}$	V_S

Table 1: The rules for assigning different position patterns to $x_{i,j}$ based on its position in an n-gram $s_{i,j,k}$.

CRF) to obtain the prediction $\widehat{\mathcal{Y}}_i$. However, data from different nodes (sources) always contains heterogeneous vocabularies and expressing patterns, where standard FL may obtain inferior results for localized prediction because it cannot distinguish the contextual information from the isolated data. Therefore, motivated by previous studies that leverage n-grams to capture local contextual information (Song et al., 2009b; Pei et al., 2014; Chen et al., 2017; Higashiyama et al., 2019), we propose GCA to enhance standard FL by exploring the contextual information carried by n-grams in the running text and use it to guide the centralized model for making localized prediction.

Specifically, GCA contains three components, namely, a lexicon ($\mathcal{D}$) that contains global character n-grams, an n-gram embedding matrix that maps an n-gram in $\mathcal{D}$ to its embedding, and a position embedding matrix that maps a position pattern, i.e., the position (e.g., beginning, ending, and inside) of a character in an n-gram, to its embedding. For each character $\widetilde{x}_{i,j}$, GCA encodes the contextual information and uses it to enhance the centralized model in the following process. First, GCA extracts all m n-grams $s_{i,j,k}$ $(1 \leq k \leq m)$ associated with $\widetilde{x}_{i,j}$ from $\mathcal{D}$, where $s_{i,j,k}$ satisfies the conditions that it contains $\widetilde{x}_{i,j}$ and it is a sub-string of $\widetilde{\mathcal{X}}_i$. Next, according to the position of $\widetilde{x}_{i,j}$ in $s_{i,j,k}$, GCA finds the position pattern $v_{i,j,k}$ associated with $s_{i,j,k}$ and $\widetilde{x}_{i,j}$ based on the rules specified in Table 1. For example, if $\widetilde{x}_{i,j}$ =“市” (*city*) and $s_{i,j,k}$ =“市长” (*mayor*), the position pattern $v_{i,j,k}$ will be “V_B” according to the rules in Table 1, because $\widetilde{x}_{i,j}$ is at the beginning of $s_{i,j,k}$. Third, GCA applies n-gram embedding matrix and position embedding matrix to $s_{i,j,k}$ and $v_{i,j,k}$, respectively, and obtains the n-gram embedding $\mathbf{e}^s_{i,j,k}$ and the position embedding $\mathbf{e}^v_{i,j,k}$. Then, GCA computes the weights $p_{i,j,k}$ for position patterns $v_{i,j,k}$ by

$$p_{i,j,k} = \frac{\exp(\mathbf{h}_{i,j} \cdot \mathbf{W} \cdot \mathbf{e}^s_{i,j,k})}{\sum_{k=1}^{m} \exp(\mathbf{h}_{i,j} \cdot \mathbf{W} \cdot \mathbf{e}^s_{i,j,k})} \qquad (2)$$

Genres		Sent. #	Token #	OOV Rate
BC	Train	7,301	628K	-
	Dev	2,368	237K	7.6
	Test	2,383	235K	6.1
BN	Train	5,867	1,108K	-
	Dev	2,151	394K	2.7

	Test	2,001	243K	8.2

Table 2: The number of sentences, word tokens, and the out-of-vocabulary (OOV) rate (in dev and test sets) with respect to the training set of five genres in CTB7.

where $\mathbf{W}$ is a trainable matrix that maps $\mathbf{e}^s_{i,j,k}$ to the same dimension as $\mathbf{h}_{i,j}$ to facilitate the inner production “$\cdot$”. GCA further applies $p_{i,j,k}$ to all position embeddings and obtain the representation of contextual information $\mathbf{u}_{i,j}$ for $\widetilde{x}_{i,j}$ by

$$\mathbf{u}_{i,j} = \sum_{k=1}^{m} p_{i,j,k} \cdot \mathbf{e}^v_{i,j,k} \qquad (3)$$

Afterwards, $\mathbf{u}_{i,j}$ is added $(+)$ to $\mathbf{h}_{i,j}$ to guide the backbone model for localized prediction, where the resulted vector is mapped into the output space by a trainable matrix $\mathbf{W}_o$ and bias $\mathbf{b}_o$ by

$$\mathbf{o}_{i,j} = \mathbf{W}_o \cdot (\mathbf{u}_{i,j} + \mathbf{h}_{i,j}) + \mathbf{b}_o \qquad (4)$$

Finally, $\mathbf{o}_{i,j}$ is fed into a CRF decoder to obtain the predicted segmentation label $\widehat{y}_{i,j}$ for $\widetilde{x}_{i,j}$.

3 Experimental Settings

3.1 Simulations

To test the proposed approach, we follow the convention of recent FL-based NLP studies (Liu et al., 2019; Huang et al., 2020b; Zhu et al., 2020; Sui et al., 2020) to build a simulated environment where isolated data are stored in five nodes. Each node contains one of the five genres (i.e., broadcast conversation (BC), broadcast news (BN), magazine (MZ), newswire (NW), and weblog (WEB)) in CTB7 (LDC2010T07)[3] for CWS. Therefore, data from different genres are distributed to the five nodes without overlapping (i.e., the data sources in

our simulation are heterogeneous), which is similar to the simulation setting of aforementioned previous studies. We split each genre into train/dev/test splits following Wang et al. (2011) and report the statistics (in terms of the number of sentences, word tokens, and OOV rate) in Table 2.

3.2 Baselines and Reference Models

To show the effectiveness of our approach with GCA, we compare it with a baseline model that follows the FL framework without using it. In addition, we also run two reference models without both FL and GCA, where all training instances are not isolated and are accessible to each other. Specifically, the first reference model (denoted by Single) is trained and evaluated on the data from a single node (genre). The second (denoted by Union) is trained on the union of training instances from all five nodes (genres) and evaluated on a single node. Herein, the Union reference model can be optimized on a particular local node to achieve the best localized prediction; on the contrary, models under the FL setting is stored on the server and shared by all nodes, so that optimizing the model on a particular node could significantly hurt the performance on others. Therefore, the setting of the Union reference model is the ideal situation which is hard to happen in real-applications and it thus provides a potential upper-boundary of model performance for FL-based approaches.

3.3 Implementation

A good text representation is generally a prerequisite to achieve outstanding model performance (Pennington et al., 2014; Song and Shi, 2018; Peters et al., 2018). To obtain a high qulity of text representation, in our experiments, we try two types of encoder in the centralized model, i.e., the Chinese version of BERT (Devlin et al., 2019)[4] and the large version of ZEN 2.0 (Song et al., 2021)[5], because they are pre-trained language models that have been demonstrated to be effective in many NLP tasks (Nie et al., 2020; Huang et al., 2020a; Song et al., 2020; Chen et al., 2020; Fu et al., 2020; Tian et al., 2020a,b,c,d, 2021a,b; Chen et al., 2021; Qin et al., 2021). For both BERT and ZEN 2.0, we use the default settings (i.e., 12 layers of multi-head attentions with 768 dimensional hidden vectors for BERT and 24 layers of multi-head attentions with 1024 dimensional hidden vectors for ZEN 2.0). We use the vocabulary in Tencent Embedding[6] (Song et al., 2018) to initialize our lexicon $\mathcal{D}$ and the n-gram embedding matrix, where n-grams whose character-based length higher than five are filtered out[7]. During the training stage, we fix the n-gram embedding matrix and update all other parameters (including BERT). For evaluation, we follow previous studies to use the F1 scores (Chen et al., 2017; Ma et al., 2018; Qiu et al., 2019). For other hyper-parameter settings, we report them in Table 3. We test all combinations of them for each model on the development set, where models achieve highest F1 score on the development set is evaluated on the test set (the best hyper-parameter setting in our experiments is highlighted in boldface).

4 Results and Analysis

4.1 Overall Results

Table 4 illustrates the experimental results (i.e., F1 scores) of our GCA-FL models and all the aforementioned baselines (i.e., FL) and reference models (i.e., Single and Union) with BERT (a) and ZEN 2.0 (b) encoders on the test set of BC, BN, MZ, NW, and Web from CTB7.

There are several observations from the test set results. First, models under the FL framework (i.e., FL and GCA-FL) outperform the reference model (Single) trained on the single node for both BERT and ZEN 2.0 encoder, which confirms that FL works well to leverage extra isolated data. Second, our GCA-FL model consistently outperforms the FL baseline on all nodes (genres), although the FL baseline with BERT and ZEN 2.0 has already achieved very good performance. This observation demonstrates the effectiveness of the proposed GCA mechanism to leverage contextual information to facilitate localized prediction. Third, it is

Union	97.88	97.79	97.23	98.61	96.38	97.58
FL	97.62	97.56	96.88	98.44	95.88	97.28
GCA-FL	**97.83**	**97.76**	**97.01**	**98.50**	**95.94**	**97.41**

(b) ZEN 2.0

Table 4: Experimental results (i.e., F1 scores) of different models with BERT (a) and ZEN 2.0 (b) on the development sets of the five nodes (genres) of CTB7.

observed that GCA-FL achieves competitive results compared with the Union reference model in most cases. This observation is promising because the Union model has all training data available without suffering from the data isolation problem, which could provide a potential upper boundary for FL-based models. The results obtained from GCA-FL thus further confirm the effectiveness of GCA.

4.2 Effect of GCA

To analize the effect of GCA to leverage isolated extra data to facilitate localized prediction, especially for OOV, we illustrate the recall of OOV of different models (i.e., Single, Union, FL, and GCA-FL) on five nodes (genres) with BERT encoder in Figure 3. Similar to the experimental results in the main experiments, it is observed that FL and GCA-FL outperform Single model in identifying unseen words (OOV). Further, GCA-FL can outperform the FL baseline on the test data in all nodes, where the highest improvement is observed on the node storing data from newswire. One possible explanation could be that BC and BN contains similar texts to NW. GCA-FL can better learn from the similar data on these nodes and thus improves localized prediction, especially for OOV.

5 Conclusion

In this paper, we apply FL to CWS to leverage isolated data stored in different nodes and propose GCA to enhance the CWS model stored in the server. Specifically, our approach encodes the contextual information by associating the input characters with global character n-grams, and uses that information to guide the backbone model to make localized predictions. Experimental results under a

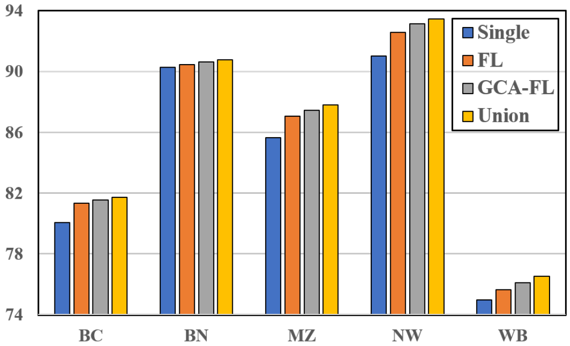

Figure 3: The recall of out-of-vocabulary words (OOV) of different BERT-based models (i.e., Single, FL, GCA-FL, and Union) on the test set of five nodes (genres).

simulated environment performed on five isolated nodes on CTB7 demonstrate the effectiveness of the proposed approach. Our approach outperforms the baseline model trained under the FL framework and achieves competitive results compared with the reference model that is trained on the union of the data from all nodes. Further analyses on identifying OOV justify the validity of the GCA mechanism to leverage the data on other nodes to facilitate localized prediction and demonstrate its great potential to be applied to real-world applications.

Abstract

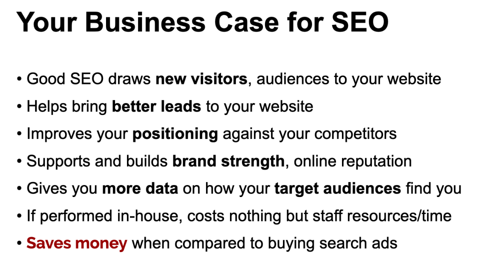
Emphasizing words in presentation slides allows viewers to direct their gaze to focal points without reading the entire slide, retaining their attention on the speaker. Despite many studies on automatic slide generation, few have addressed helping authors choose which words to emphasize. Motivated by this, we study the problem of choosing candidates for emphasis by introducing a new dataset containing presentation slides with a wide variety of topics. We evaluated a range of state-of-the-art models on this novel dataset by organizing a shared task and inviting multiple researchers to model emphasis in slides.

1 Introduction

Presentation slides have become so commonplace that researchers have developed resources for designing effective slides (Alley and Robertshaw, 2004; Alley and Neeley, 2005; Jennings, 2009). These guidelines cover advice on the overall style, such as choosing colors and font size to ensure readability from a distance, as well as ways to help the content stand out more distinctly. However, recommendations to enhance the slides' communication power could improve authoring even more.

Our goal is predicting emphasis words in presentation slides. Emphasis uses special formatting like **boldface** or *italics* to make words stand out. Well-designed emphasis can significantly increase the viewers' retention by guiding their focus to a few words (Alley and Robertshaw, 2004). Instead of reading the entire slide, they can read only the emphasized parts, keeping their attention on the speaker and their speech, as Figure 1 illustrates.[1]

The Emphasis Selection (ES) task was initially introduced by Shirani et al. (2019) with a focus on short written text in social media, and later became a SemEval 2020 task (Shirani et al., 2020b). In this paper, we focus on presentation slides, introducing a new corpus as well as automated emphasis prediction approaches. We are among the first to use the content of the slides to provide automated design assistance.



Your Business Case for SEO

- Good SEO draws **new visitors**, audiences to your website
- Helps bring **better leads** to your website
- Improves your **positioning** against your competitors
- Supports and builds **brand strength**, online reputation
- Gives you **more data** on how your **target audiences** find you
- If performed in-house, costs nothing but staff resources/time
- **Saves money** when compared to buying search ads

Figure 1: The slide uses special formatting to emphasize salient content.

Task Characteristics Emphasis selection poses new challenges specific to presentation slides. They can have different structures, and authors may follow traditional styles, or modern styles with more visual content. Slides cover a wide range of topics, from technical, marketing, and legal presentations to children's illustrations. The requirement to generalize to different domains and cover a variety of topics poses new challenges and encourages developing robust language understanding models. We rely only on input text without additional context from the user or the rest of the design. The task is highly subjective, but the goal is straightforward: use natural language understanding techniques to discover the most most common interpretation of a slide page and to generate emphasis that makes the page easier to understand quickly.

Benchmarking The Task Instead of providing baselines for the proposed dataset, we organized a shared task and invited researchers to work on the new corpus. Section 6 describes the top-performing methods. By examining the challenges of the

dataset, we provide different analysis components.

2 Related Work

Prior work explored automatically generating presentation slides from documents such as scientific articles (Beamer and Girju, 2009; Wang et al., 2017; Hu and Wan, 2013; Shibata and Kurohashi, 2005; Sravanthi et al., 2009). These projects assume that a slide page is a summarization of some part of the paper, and many summarization methods have been proposed to improve the effectiveness.

Other studies provide guidelines or alternatives to traditional designs to communicate a presentation's content more effectively (Alley and Robertshaw, 2004; Jennings, 2009; Alley et al., 2006; Atkinson, 2005; Doumont, 2005). These create slides with sentence headlines and visual elements to reinforce ideas and increase the audience's retention of the information during presentation.

Many applications provide design assistance for images and text, but most use only basic heuristics. Recent work uses AI-based models to recommend design attributes based on the content (Zhao et al., 2018b,a; Shirani et al., 2020a).

Shirani et al. (2019) introduced Emphasis Selection for written text in visual media. The proposed model with an end-to-end sequence tagging architecture utilizes label distribution learning (LDL) (Geng, 2016) to handle the task's subjectivity, and predicts emphasis scores for short written texts. They trained and evaluated the model against a collection of social media short texts from Adobe Spark[2]. Later on in SemEval 2020 (Shirani et al., 2020b), 31 teams proposed novel approaches to model emphasis more effectively. The organizers augmented the social media dataset with a large dataset of short quotations. Top-performing teams (Huang et al., 2020; Morio et al., 2020; Singhal et al., 2020) used rich contextualized pre-trained language models such as ERNIE 2.0 (Sun et al., 2020), XLMRoBERTa (Conneau et al., 2019), XLNet (Yang et al., 2019), and T5 (Raffel et al., 2019).

This study focuses on a new domain, presentation slides, where emphasis serves a different purpose than in social media. For social media the main purpose is to draw the audience's attention, while for presentations, the main purpose is to help the audience better understand the content. Identifying emphasis in presentations brings unique challenges due to differences in topic, length, and document structure.

3 Task Definition

Given a sequence of tokens in a slide page, $C = \{x_1, ..., x_n\}$, the task is to compute a real value $y_i \in [0, 1]$ for each x_i in C, indicating the degree to which the token needs to be emphasized.

4 Data Collection

The Presentation Slides Emphasis Dataset (PSED)[3] is a collection of presentation slides covering a wide range of topics, from technical slides on various topics to non-technical ones such as children's material. Each instance in PSED represents one slide page along with eight annotations. We only focused on English slides. To cover a wide range of topics and areas, we collected data from different sources such as websites with .ORG and .GOV domains and slides from the ACL anthology.[4] We pre-processed all slide pages to make sure they included clean pieces of text. We removed slides that only had equations, mathematical formulas, tables, or figures and used the PDFMiner Python library[5] to extract the text. Quality control steps ensured the text and the slide matched.

4.1 Annotation Process

In an MTurk experiment, we asked nine annotators to label each page. We showed the image of the slide as well as the corresponding text and asked workers to select words to emphasize as if they were preparing the slides for their own presentation. Ten percent of the hits included quality questions to make sure the annotators read the slides.

We observed a low Fleiss' Kappa score (Shrout and Fleiss, 1979) of 0.1414 on the dataset. A closer examination revealed that the dataset included some technical and domain-specific slides that were not entirely understandable to a general audience. Therefore, we removed slides with a score below -0.05 and the overall score increased to 0.1797. We also noticed that many cases included at least one annotator with a very different selection. To provide a more consistently-annotated data

---

[5] `https://github.com/pdfminer/pdfminer.six`

set for training, we removed the annotator for each slide with the lowest agreement to the other annotators. The final dataset contains annotations from eight annotators and has a Fleiss' Kappa score of 0.2092. Such a score is similar to the score reported in (Shirani et al., 2020b) and indicates the existence of multiple points of view about emphasis in the dataset. Table 1 shows an example of a bullet point annotated with BIO annotation data. It shows that there is more agreement selecting words such as "risk" and "management" compared to the others.

Table 1: An example bullet point along with emphasis probabilities. "B" indicates the beginning of the emphasis, "I" the inside, and "O" non-emphasis words. "Freq." shows the frequencies of "B", "I" and "O". "Emphasis Probs.", shows the emphasis probability ("B+I") over eight annotations.

Words	Freq. [B,I,O]	Emphasis Probs. [B+I]
•	[0,0,8]	0.0
Demonstrate	[1,0,7]	0.125
how	[0,0,8]	0.0
operational	[1,0,7]	0.125
agencies	[1,0,7]	0.125
are	[0,0,8]	0.0
using	[0,0,8]	0.0
NASA	[2,0,6]	0.25
data	[0,1,7]	0.125
for	[0,0,8]	0.0
risk	[3,0,5]	0.375
management	[3,3,2]	0.75

5 Data Analysis

Table 2 provides more information on the number of slides, sentences, and words in the PSED dataset. The dataset contains 1,776 high-quality slides, randomly divided among training, development and test sets of 1,241, 180, and 355 instances respectively.

Table 2: Dataset Statistics

Section	#Slides	#Sentences	#Words
Train	1241	9645	96934
Dev	180	1251	12822
Test	355	2754	28108
Total	1776	13650	137864

Table 3 describes the length of instances in the PSED dataset, giving the minimum, mean, and maximum number of words in slides for each split.

Table 3: Statistics on the length of the samples computed in words

Section	Min	Mean	Max
Train	13	78	180
Dev	15	71	164
Test	17	79	181

As previous research has suggested, word types have a significant role in the selection of appropriate emphasis. Therefore, in this section, we examine the role of part-of-speech tags (POS) in this task. Specifically, we choose the top 20 POS tags, which frequently occur in the training and development sets, to analyze the feature's effectiveness. We used spaCy library[6] to obtain POS tags for all tokens. To examine how the emphasis probabilities are distributed, we divided them evenly into four intervals. Figure 2 shows the occurrence of the top 20 POS tags for all token labels in our training and development sets. POS tags such as "IN", ",", ".", and ":" are more favored to have low emphasis probabilities (0–0.25). Interestingly, some POS tags like "DT", "CD," and "VBZ" have zero words in the highest emphasis probability interval (0.75–1.0). Overall, most POS tags fall into the lowest emphasis probability, and the difference lies in the (0.25–0.5) interval, where POS tags like "NN", "NNS," and "VBG" mostly appear. Similar to POS tags, other hand-crafted features such as punctuation and upper-case tokens helped improve the results of some models. This motivated us to examine the degree of emphasis probability for different lexical features. Figure 3 shows the average emphasis scores for each category in the training and development sets. Comparing all lexical features, "Uppercase_start" has the highest average emphasis score, and "Contain_numbers" and "Punctuation" have the lowest. This indicates some general trends for emphasis with respect to word categories.

We also performed an error analysis to examine how the length of slides can affect the prediction. The results show that longer slides are more challenging due to having more options to select.

5.1 Evaluation Metric

For better comparison with previous work in ES, we followed an evaluation method similar to Shirani et al. (2020b). This metric is specifically designed to meet the subjectivity of the task.

Cisco	Ensemble of XLNet, RoBERTa + POS Tags	0.518	0.330 (2)	0.675 (2)	0.551 (3)
Baseline	BiLSTM+ELMo	0.475	0.301 (3)	0.634 (5)	0.489 (5)
Zouwuhe	N/A	0.474	0.285 (4)	0.638 (4)	0.500 (4)

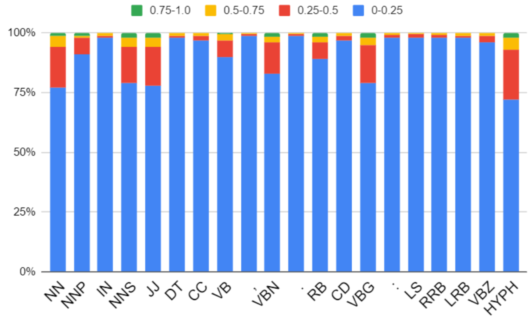

Figure 2: Frequencies of the top 20 POS tags in the 0–0.25, 0.25–0.5, 0.5–0.75, 0.75–1.00 probability intervals. Vertical values correspond to the percentage of tag counts over the total number of words in the training and development sets.

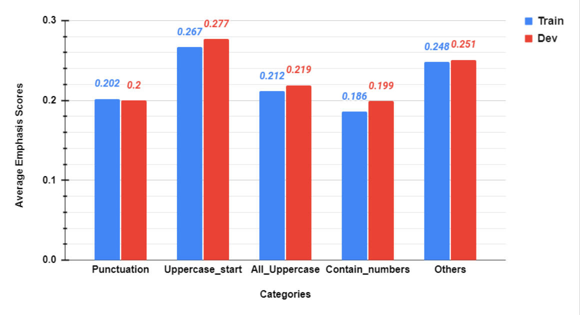

Figure 3: The figure shows average emphasis scores on the training and development sets for four different lexical features.

Match$_m$ For each slide page x in the test set D_{test}, we select a set $S_m^{(x)}$ of $m \in \{1, 5, 10\}$ words with the top m probabilities according to the ground truth. Similarly, we select a prediction set $\hat{S}_m^{(x)}$ for each $m \in \{1, 5, 10\}$, based on the prediction probabilities. Match$_m$ is defined as:

$$\text{Match}_m := \frac{\sum_{x \in D_{test}} |S_m^{(x)} \cap \hat{S}_m^{(x)}| / m}{|D_{test}|}$$

To rank models, we compute the average value of Match$_m$ for all m values and call this averaged value (*RANK*). We treat words in the ground truth with the same probability equally, so if the model predicts either of the tokens, we consider it as a correct answer.

6 Performance Benchmarks

To better examine the challenges of the dataset and benchmark the task, we organized a shared task and invited the community to participate in modeling emphasis in this new domain.[7]

Different novel and interesting solutions for this particular task were proposed. Table 4 shows the scores and the best methods for the top three teams. The most popular approach was ensemble Transformer-based models. Many hand-crafted features such as Part-of-speech (POS) tags, keywords, and lexical features (such as words with capital letters and punctuation) were explored to improve the models' performance. We describe and compare top-performing approaches next.

The top-performing team, *UBRI-604* (Hu et al., 2021), by proposing end-to-end Transformer-based approach, ranked in the first place with *RANK* score of (0.525). Different rich Transformer-based pre-trained language models were explored during the experiment, such as ALBERT (Lample and Conneau, 2019), GPT-2 (Radford and Wu, 2019), RoBERTa (Liu et al., 2019), ERNIE 2.0 (Sun et al., 2020), XLNet(Yang et al., 2019), XLMRoBERTa and BERT (Devlin et al., 2019). Comparing the results of all seven models, XLMRoBERTa performed the best. Besides pre-trained language models, *UBRI-604* leveraged lexical features such as capitalized words and punctuation, for further improvement.

DeepBlueAI team stood in second place (0.519), a *RANK* score that was 0.006 lower than the first team's. *DeepBlueAI* introduced an ensemble Transformer-based model with two fully-connected layers combined with POS tags embedding and hand-crafted features. The ensemble model takes advantage of BERT, SciBERT (Beltagy et al., 2019) and ERNIE 2.0 pre-trained language models by taking the average of the scores predicted by these models.

---

[7] CAD21 shared task: `https://competitions.codalab.org/competitions/27419`

Lastly, *Cisco* (Ghosh et al.), with a score 0.001 lower than the second team, ranked third. *Cisco* explored two approaches based on BiLSTM+ELMo (Shirani et al., 2019) architecture and Transformer-based pre-trained models with the base model of RoBERTa and XLNet. They enriched the ELMo contextual embedding in BiLSTM+ELMo model by incorporating a character-level BiLSTM Network. Their results show an increase of 0.026 when POS tags and keyphrases are added to the model, showing the effectiveness of these two features for this task. *Cisco*'s best score on the evaluation phase used an ensemble of XLNet and RoBERTa, giving them third place. They boosted the model further in the Post Evaluation phase by ensembling XLNet and BiLSTM+ELMo models and incorporating hand-crafted features like POS and Keyphrase.

We used the same baseline model (DL-BiLSTM+ELMo) introduced in Shirani et al. (2019) to better show the challenges of PSED dataset. This model achieved *RANK* score of 0.475 (Table 4) which is 0.275 lower than the reported score by Shirani et al. (0.75).[8] With a sequence-labeling architecture, this model utilizes ELMo contextualized embeddings (Peters et al., 2018) and two BiLSTM layers to label emphasis. The Kullback-Leibler Divergence (KL-DIV) (Kullback and Leibler, 1951) is used as the loss function during the training phase.

7 Discussion

The PSED dataset contains slides with different lengths. To better examine how the length of slides can affect the prediction, we performed an error analysis to examine this relationship. We divided the test set into three groups based on the instances' lengths, namely <60, 60–90, and >90 tokens. Then we computed the average Match_m scores over all shared task submissions, four in total, for every example in each group. As shown in Table 5, short slides always achieve better scores compared to medium and long slides. This indicates that predicting emphasis in longer instances is more challenging. This is due there being more options (words) to select for emphasis.

Many slides in the PSED dataset contain scientific words. Besides using pre-trained models, trained on a general domain, some teams decided to handle scientific words differently. For example, *DeepBlueAI* explored using the SciBERT (Beltagy et al., 2019) model, which is pre-trained on scientific articles. On the other hand, *Cisco* explored training a scientific keyword predictor and used the output as a feature to the model. Extending the proposed approaches to more efficiently address the diverse vocabulary of the dataset is an important future direction.

Table 5: Length vs. Performance on the test set. The average scores over all submissions are used for computing the performance. Short: (<60 tokens, 112 slides), Medium: (60–90 tokens, 126 slides), Long: (>90 tokens, 116 slides)

Length/Scores	*RANK*	Score 1	Score 5	Score 10
Short	**0.601**	**0.42** (1)	**0.634** (1)	**0.75** (1)
Medium	0.55	0.349	0.589	0.713
Long	0.485	0.293	0.526	0.635

8 Conclusion

We presented a new dataset for emphasis selection on presentation slides, posing new challenges for modeling emphasis. We created a shared task and invited researchers to model emphasis for presentation slides. We provided different data analyses on the dataset and summarized the insights gained from the shared task. A future extension could explore more robust techniques to address the challenges in the PSED dataset because of its diversity in topic, structure, and length.

9 Ethics

The proposed data in this work is collected from public domain sources and do not intrude on user privacy. For the manual work in annotation process, crowd workers were fairly compensated ($0.55 reward per response, which is over the US minimum wage).

Acknowledgments

We thank the reviewers for their thoughtful comments and efforts towards improving our work. We also thank Andrew Greene for his help in creating the corpus.

MLMLM: Link Prediction with Mean Likelihood Masked Language Model

Louis Clouatre[*][†]**, Philippe Trempe**[*]**, Amal Zouaq**[*]**, Sarath Chandar**[*] [†] [∇]

Abstract

Knowledge Bases (KBs) are easy to query, verifiable, and interpretable. They however scale with man-hours and high-quality data. Masked Language Models (MLMs), such as BERT, scale with computing power as well as unstructured raw text data. The knowledge contained within these models is however not directly interpretable. We propose to perform link prediction with MLMs to address both the KBs scalability issues and the MLMs interpretability issues. By committing the knowledge embedded in MLMs to a KB, it becomes interpretable. To do that we introduce MLMLM, **M**ean **L**ikelihood **M**asked **L**anguage **M**odel, an approach comparing the mean likelihood of generating the different entities to perform link prediction in a tractable manner. We obtain State of the Art (SotA) results on the WN18RR dataset and SotA results on the Precision@1 metric on the WikidataM5 inductive and transductive setting. We also obtain convincing results on link prediction on previously unseen entities, making MLMLM a suitable approach to introducing new entities to a KB.

1 Introduction

1.1 Context

KBs have many desirable properties. They are easy to query, verifiable, and perhaps most importantly interpretable by humans. They however have one critical shortcoming, they are expensive to build, making them harder to scale. Indeed, modern KBs scale with high-quality data, manual labor, or a mix of both. Approaches that scale with available computation and the massive amounts of unstructured data that are being created and accumulated have proven invaluable in the recent deep learning boom.

Large pretrained MLMs (Devlin et al., 2018; Liu et al., 2019) have been shown to scale well with large amounts of unstructured text data as well as with computing power. They also have displayed some interesting emergent abilities, such as the ability to perform zero-shot question answering (Radford et al., 2019; Brown et al., 2020). This ability implies that the model parameters contain a large amount of factual knowledge that it can leverage to answer a wide variety of questions. However, that knowledge is hardly interpretable by humans, as it is hidden within the millions to billions of parameters of the language model.

By using MLMs to completes KBs, we can address both the issue of scalability of KBs and the issue of the interpretability of MLMs by committing knowledge of the latter to an interpretable format in the former. The MLM can learn new knowledge from the large amount of unstructured textual data that keeps being added to the World Wide Web and then be used to continually complete and update the KB. This has the very desirable effect of making the link prediction approach scale with both computational power and a large quantity of unstructured data, both of which show no sign of slowing down.

1.2 Problem Definition

Given an entity and a relation, we want to train an MLM to generate all entities completing the KB triple.

Several technical challenges had to be addressed to achieve proper link prediction with pretrained MLMs. The first one is tractability. It is well known that inference in the task of Link Prediction is extremely costly, to the point where validation and test sets are purposefully kept small and most datasets will shy away from containing millions of different entities (Wang et al., 2019). While smaller Link Prediction datasets (Dettmers et al., 2017; Toutanova and Chen, 2015) are limited to a few thousand entities, a dataset more representative of full sized KBs (Wang et al., 2019) would contain upwards of a million potential entities. A

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4321–4331
August 1–6, 2021.

model that would be used on such a dataset could not realistically require an inference step through an MLM for every potential entity completing a triplet. It is necessary to enable link prediction with as little inference to the model as possible, as performing inference on pretrained models is expensive. Otherwise, it could result in a model with no practical purposes, even if it obtained better leaderboard scores.

The second challenge has to do with the inference outputs format of the MLMs. The length of the output needs to be known at inference time (Devlin et al., 2018; Vaswani et al., 2017), making it hard to sample entities of varying lengths from it. The example ”Horses like _” could be completed with the word ”carrot” and ”long runs”, but those two answers require varying length of masked inputs to be filled. Work like Petroni et al. (2019) is limited to single token outputs, which is useful to probe the model for the presence of embedded knowledge, but is not usable in practice for tasks such as link prediction, as the missing entities will have variable lengths. Solutions have to be able to sample an MLM for entities of varying lengths to have practical applications.

Finally, the use of MLMs opens the door to performing link prediction on entities that have not been previously seen by the model or the KB. This permits the addition of new entities to a KB on top of the link prediction capacities. Some capability of such an approach with MLMs was previously demonstrated (Petroni et al., 2019) and other works have approached the task by generating and comparing entities embedding (Daza et al., 2020; Gupta et al., 2017; Wang et al., 2019) for different KB tasks. By generating entity embeddings from text, they permit apt representation for previously unseen entities that can then be compared to other, previously seen entities. Unlike previous approaches we forgo the entity embedding step and let the model directly output the entity. We show that our approach yields strong results with unseen entities of arbitrary lengths in this task and should be explored further.

1.3 Contribution

Our main contributions are summarized here:

- We propose MLMLM, a mean likelihood method to compare the likelihood of different text of different token lengths sampled from an MLM.
- We demonstrate the tractability of our approach, requiring only one inference step through the model to perform link prediction on any numbers of possible entities, something which was not previously possible with an MLM.
- We achieve SotA results on the WN18RR benchmark and the best Precision@1 on both the inductive and transductive setting of the WikidataM5 dataset.
- We demonstrate that our approach can generalize to previously unseen entities on all benchmarks.

2 Background and Related Work

2.1 Masked Language Models

Pretrained MLMs, popularized by BERT (Devlin et al., 2018), have seen tremendous success when applied to Natural Language Understanding (NLU) problems. They are pretrained on massive amount of unsupervised text data. Those models incorporate enormous amounts of language knowledge and world knowledge within their weights. This lets them be further tuned on challenging NLU tasks with great success. Being based on the transformer (Vaswani et al., 2017) encoder architecture, the output length of the model is equal to the input length. This makes it challenging to sample text of arbitrary length when using MLMs without knowing the length of the desired sample in advance.

2.2 Sampling from MLM

Sampling single words from an MLM is trivial. By adding a mask to the input, we can sample likelihoods for the whole vocabulary. This feature is used by several pieces of work to complete sentences, answer questions and more (Guu et al., 2020; Lewis et al., 2020; Petroni et al., 2019). Work to generate and evaluate multi-token spans from MLM has also yielded interesting results (Wang and Cho, 2019; Salazar et al., 2020). We are however unaware of any other approach to sampling and evaluating multi-token spans of variable length, which is necessary to properly accomplish the task of link-prediction in a single pass through the model.

2.3 A Re-evaluation of Knowledge Graph Completion Methods

Recently, Sun et al. (2020) has found that many of the SotA approaches to link prediction have used an inappropriate evaluation protocol. They have shown that the evaluation protocol typically used in the link prediction approaches assigns a perfect score to a constant output, by putting the correct entities on top during a tiebreaker. In essence, under this evaluation protocol, assigning a likelihood of 0 to all entities would yield a perfect reranking score, since the tiebreaker would put the target entity as the first prediction. This was shown to yield very inflated scores for many neural network based link prediction approaches (Nathani et al., 2019; Vu et al., 2019; Nguyen et al., 2017), as several of them output a large number of tied scores for the various entities. Entity-embedding based approaches (Balažević et al., 2019; Sun et al., 2019; Dettmers et al., 2018) do not suffer from this issue. While we have found that our approach does not suffer from this issue despite not being an entity-embedding approach, we will use the random evaluation protocol proposed by Sun et al. (2020) for all evaluations and compare against approaches that used a similar protocol to ensure the validity of the comparisons. This protocol is similar to the filtered setting (Bordes et al., 2013), with the difference that the rank among entities with tied scores is randomly assigned.

2.4 KG-BERT

KG-BERT (Yao et al., 2019) is an approach to KB tasks based on MLM. It successfully demonstrates the potential of leveraging these models' internal knowledge on KB tasks. They train a BERT model to classify whether an individual triple fed to the model is correct or not. In essence, they feed every single possible (h, r, ?) or (?, r, t) triple in a string format to the model to obtain all scores to be reranked. This can result in millions of inference steps on the MLM for a single triple completion depending on the size of the KB. KG-BERT has many advantages over our proposed approach. It uses the target entity in the input, thus giving the model more information to use at inference time. The problem that it solves is much simpler, reducing it to a simple sequence classification problem. With a similar setup, it is even likely that KG-BERT would yield better results than our proposed approach since it has access to more information and has a more straightforward training setup. Unfortunately, KG-BERT is not tractable on any reasonably large KB (see Figure 1). For a KB containing millions of entities, KG-BERT would require millions of inference step through the MLM model for every triple completion. In contrast, our approach requires only one inference step through the MLM model for every triple completion, by generating all logits required to obtain the likelihood of any potential entity at once. Modern KBs can contain millions of entities (Wang et al., 2019), which would translate in KG-BERT requiring hours to complete a single triplet on a GPU.

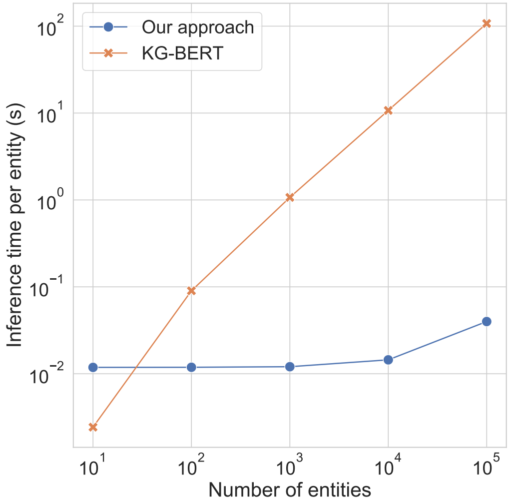

Figure 1: Approach Inference Time. This figure shows the per-entity inference time based on the total number of entities to be re-ranked, of MLMLM and KG-BERT, the most comparable approach.

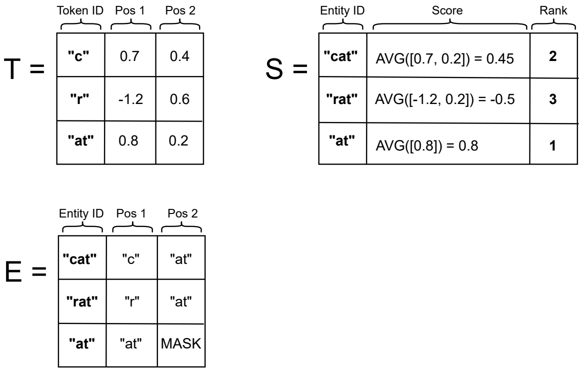
3 Methodology

3.1 Overview

Our system performs link prediction. It uses MLM to generate all possible logits of all tokens required to generate all entities, and mean likelihood sampling to rerank all possible entities to complete the triple and perform link prediction. It can also be used to sample likelihoods for previously unseen entities.

Figure 2 shows a toy example of our inference setup. Our model outputs logits for the whole vocabulary of the RoBERTa-Large model. The outputs are simply the logits for all words and subwords from that vocabulary. This vocabulary is expressive enough to generate any English text.



T =

Token ID	Pos 1	Pos 2
"c"	0.7	0.4
"r"	-1.2	0.6
"at"	0.8	0.2

S =

Entity ID	Score	Rank
"cat"	AVG([0.7, 0.2]) = 0.45	2
"rat"	AVG([-1.2, 0.2]) = -0.5	3
"at"	AVG([0.8]) = 0.8	1

E =

Entity ID	Pos 1	Pos 2
"cat"	"c"	"at"
"rat"	"r"	"at"
"at"	"at"	MASK

Figure 2: Ranking Example. The figure contains a minimal example of the ranking system. It represents the system in a KB containing 3 subwords in its vocabulary ['c', 'r', 'at'], 3 entities to rank ['cat', 'rat', 'at'] and a maximum entity length of 2.

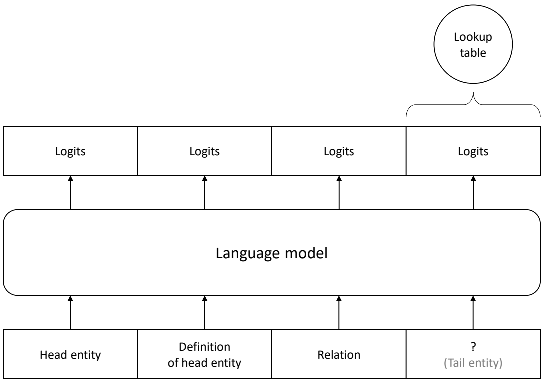


Figure 3: Lookup Table Generation For Tail Entity Prediction. The figure shows how the lookup table for tail entity prediction is generated. A string representation of the head entity and the relation are fed to the masked language model which outputs logits that represent the likelihood of finding each token at each possible position of the tail entity.

We decide in advance on a maximum length n for the maximum length of English text to generate. With a vocabulary of roughly 50,000 logits, the model would output a vector of logits of shape [50,000 x n]. Knowing in advance the tokens that would build the string for all possible entities, we can obtain a score for the likelihood of those entities completing a triplet by averaging the logits of those tokens. To evaluate the likelihood of the entity ”brown dog”, we would average the logits for the word ”brown” on the first column of the matrix with the logits of the word ”dog” on the second column of the matrix, ignoring all other columns of our logit matrix. Even if the model would never have encountered the entity ”brown dog” it could still produce a score for said entity.

3.2 Data Pre-processing

The data pre-processing pipeline takes a link prediction dataset and transforms it into a generic format usable by the model. It is required that both the entity and relations have string representations. For every entity in the dataset, we extract an entity string, which uniquely identifies the entity, and a definition string, which is a textual description of the given entity. For every relation, we extract a relation string, which uniquely identifies and describes the relation.

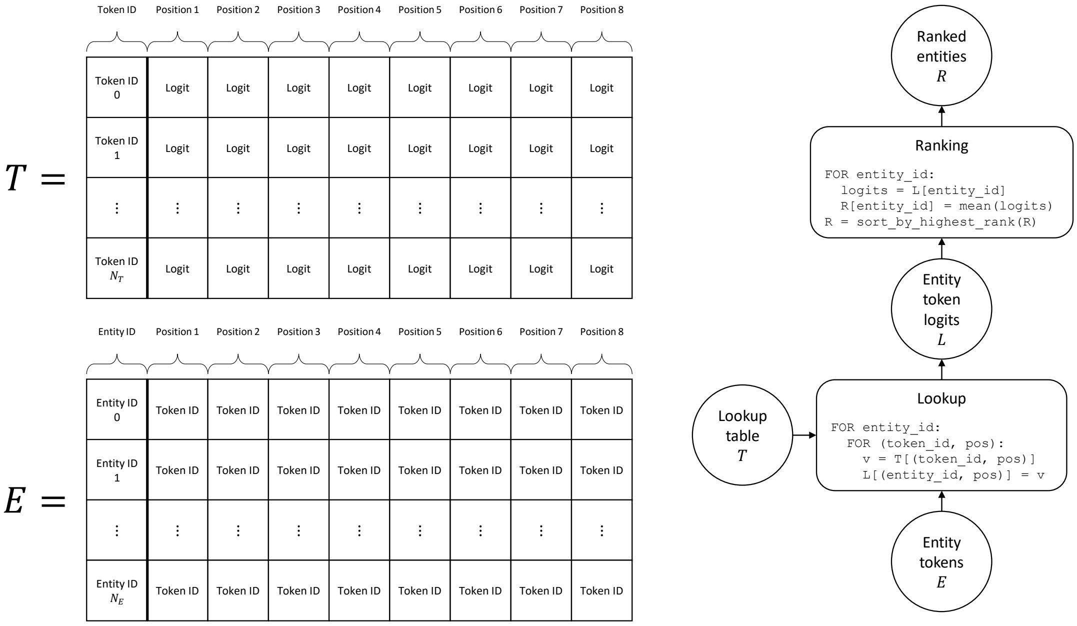
We tokenize all strings through the pretrained RoBERTa tokenizer (Sennrich et al., 2016) and further transform the entity string by adding padding to match the longest tokenized entity within the dataset. Concretely, in a dataset where the longest entity has a length of 4 token ids, the entity string “dog” would be padded to have the representation “dog _ _ _” and the entity string ”cat and dog” would have the representation “cat and dog _” where “_” is the padding token. The purpose of this padding is to standardise the masked representation of all entities, therefore letting the model treat all entities in the same manner.

3.3 Model

Our approach uses the RoBERTa-Large model (Liu et al., 2019) for all experiments. We finetune the pretrained model on the link prediction datasets to generate the logits of the unknown entities. As our approach does a single call to the model to rerank all possible entities, it is acceptable to use the larger model for better performance. Figure 3 shows the inference process for tail entity prediction. Similarly, the head entity prediction takes as input the head entity mask, the relation, the tail entity and the tail entity definition. We use the relation string, the known entity string and the entity definition of the known entity string to make the model generate the logits representing the unknown entity string.

3.4 Ranking System

The ranking system pictured in Figure 4 performs link prediction on a given triple. The MLM outputs logits for all possible token ids and positions for the missing entity to complete the triple. This forms the lookup table T. The link prediction dataset contains a list of all possible entities. The token ids forming those entities make up E. We obtain



Token ID	Position 1	Position 2	Position 3	Position 4	Position 5	Position 6	Position 7	Position 8
Token ID 0	Logit	Logit	Logit	Logit	Logit	Logit	Logit	Logit
Token ID 1	Logit	Logit	Logit	Logit	Logit	Logit	Logit	Logit
⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮
Token ID N_T	Logit	Logit	Logit	Logit	Logit	Logit	Logit	Logit

Entity ID	Position 1	Position 2	Position 3	Position 4	Position 5	Position 6	Position 7	Position 8
Entity ID 0	Token ID	Token ID	Token ID	Token ID	Token ID	Token ID	Token ID	Token ID
Entity ID 1	Token ID	Token ID	Token ID	Token ID	Token ID	Token ID	Token ID	Token ID
⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮
Entity ID N_E	Token ID	Token ID	Token ID	Token ID	Token ID	Token ID	Token ID	Token ID

```
FOR entity_id:
  logits = L[entity_id]
  R[entity_id] = mean(logits)
R = sort_by_highest_rank(R)
```

```
FOR entity_id:
  FOR (token_id, pos):
    v = T[(token_id, pos)]
    L[(entity_id, pos)] = v
```

Figure 4: Ranking System. The figure details the inner workings of the ranking system which uses the lookup table generated by the masked language model to compute the score associated with each possible entity. The scored entities are then ranked by highest score.

the entity token logits L by matching all token ids in E with their corresponding values in T. L represents how likely every token of the entity is to be generated by the MLM at that specific position. The mean likelihood[1] of each entity is computed by averaging L over *non-padded* token logits.[2] This value is used to determine the ranking of the entity. It provides a proper comparison between entities of different lengths.

Concretely, in our previous "cat and dog _" example, we average the output logits for the "cat and dog" token ids and positions while ignoring the final padded logit. This averaging is done on all entities in the dataset completing the triple, yielding the average likelihood assigned by the model to all entities.

Entities are then sorted by highest rank using the randomized setting (Sun et al., 2020). For equal scores the tie-breaking is done randomly, to produce the ordered list of ranked entities R. We use the filtered setting (Bordes et al., 2013) for evaluation and remove corrupted triples from the list of ranked entities, corrupted triples being all other known correct triples.

4 Experimentation

4.1 Datasets

The two datasets used are WN18RR and WikidataM5 (Dettmers et al., 2017; Fellbaum, 1998; Bollacker et al., 2008; Wang et al., 2019), a commonly used link prediction benchmark and a new, large scale, link prediction benchmark. Summary stats are shown in Table 1.

Table 1: Datasets statistics.

	WN18RR	WikidataM5
#Entities	40,943	4,594,585
#Relations	11	822
#Training	86,835	20,614,279
#Validation	3034	5163
#Test	3134	5133
Mean in-degree	2.12	1
Median in-degree	4.49	0

WN18RR is a dataset composed of WordNet synsets. We use the cleaned synset as the entity string. The synset "dog.n.01" would have a string representation of "dog noun 1" which should be more interpretable by the model while remaining a unique identifier. The entity definition is the definition of the entity given by WordNet. The relation string is a cleaned representation of the relation

---

[1] Because the length of non-padded tokens is variable, using the mean of the logits is the chosen comparison metric for re-ranking.

[2] By far, the token the model sees most is the padding token. Counting it would most likely yield a heavy skew towards shorter entities with more padding.

string. The relation "_member_of_domain_usage" would be represented with the string "member of domain usage". Full examples of inputs and outputs are shown in Listing 1 and Listing 2.

WikidataM5 is composed of triples based on Wikidata and the English Wikipedia with aligned descriptions for each entity. We use the entity string and definitions provided in the benchmark.

4.2 Metrics

We use the Mean Reciprocal Rank (MRR) metric to validate our model and select the best model. For all experiments, we also report the Mean Rank (MR), the Mean Precision at 1 (MP@1), the Mean Precision at 3 (MP@3), and the Mean Precision at 10 (MP@10).

4.3 Training

The training setup is a modified MLM training, where we let the model generate the missing entity. The previously mentioned padding lets us deal with the generation of entities of varying sizes. The input fed to the model for tail entity prediction, depicted in Figure 3, consists of the concatenated token ids of the head entity, the head entity definition, the relation and the tail entity mask. The model will then generate, in the place of the mask, the missing entity. The input fed to the model for head entity prediction is similar. An example of the input for head entity prediction is found in Listing 1 and an example for tail entity prediction is found in Listing 2.

We use the categorical cross-entropy loss to train the language model. The loss only depends on the non-padded token of the generated entity, ignoring all other outputs. The target is the actual entity completing the triple, aligned with the mask in the input. We retain the model with the best validation MRR. All experiments are run for 5 random seeds and the mean and standard deviation of the results are reported.

For all experiments, we use the hyperparameters and training setup described in Liu et al. (2019), with a total of 25 epochs for the WN18RR dataset and 1 epoch for the WikidataM5 dataset.

4.4 Unseen Entities

An alternative version of the dataset is made to test the generalization capacity of our methodology to unseen entities. For WN18RR we start by randomly sampling 5% of the entities for the validation entities and 5% of the entities for the testing entities. Our training set consists of all triples not containing any of the validation or testing entities. Our validation set consists of all triples containing the validation entities. Finally, our test set consists of all triples containing the test entities, but not containing any of the validation entities. The training is done in the same fashion. The validation and testing are only done on entities present in the validation or test entity list, but are still reranked against all other possible entities. While WN18RR would only have 2047 test entities in this setting, the reranking would still involve 40,943 entities. If the tail entity is the one present in the test entity list, we will complete the link $(h, r, ?)$ and not the link $(?, r, t)$. The reported results are therefore only on the performance of previously unseen entities in the KB, compared to all other possible entities. The validation and test set are rebuilt for every random seed, to evaluate our approach on a wider array of unseen entities.

WikidataM5 has an inductive setting which closely resembles our unseen entities setting. The main difference is that the reranking step in the validation and test only compares with other previously unseen entities. While there is upwards of 4 million training entities, the validation and testing would only consider roughly 7000 entities. For the purpose of proper comparison, the M5 results are however done within their specific setting.

5 Results and Analysis

5.1 WN18RR

We achieve SotA results on the WN18RR dataset on all tested metrics with the exception of MR, as shown in Table 2. The WN18RR dataset is sparse in terms of the KG in-degree connections, see Table 1. Sparseness lends itself naturally to leveraging a pretrained model. The amount of information that can be extracted from the dataset on any given entity is then limited, which makes outside information all the more valuable.

We can observe that the MR metric is relatively much weaker for our model, compared to its other metrics. This implies that while the model will often rerank the correct entities to the top, it will also sometimes forget certain entities completely, given them ranks in the thousands. This could be explained by an issue of disambiguation in the name of the entity. While approaches using entity embeddings (Balažević et al., 2019; Sun et al., 2019; Dettmers et al., 2018) will have no issue separating

them. An example of such an error is shown in Listing 2, where the model confuses `aid.n.01` and `aid.n.03`. Follow up work on better representations for entity names could yield stronger results.

Our model generally has a much easier time predicting the tail entity than the head entity. It has an MRR of 60.15 on tail entities and an MRR of 40.09 on head entities. By observing the instances where our model gives the worst rank to the correct answer, we can understand why. A large number of those cases are hypernyms on the head entity. An example of a hypernym relationship would be: "animal is an hypernym of dog, since all dogs are animals." Correctly ranking all possibilities for "X is an hypernym of dog." is more straightforward for the model than correctly ranking all possibilities for "Animal is an hypernym of Y.". An example of such failure is shown in Listing 1, where we look for the hypernym of the term `mediator`. It is clear that the model understands the concept and outputs plausible answers in its top 3. A large amount of the model's severe failure cases are similar to this one, where the model will output a plausible hypernym of the tail entity, while completely missing the targeted hypernym. This seems to be the likely cause for the weak MR of the approach.

5.2 WikidataM5

The results on WikidataM5 are shown in Table 3. MLMLM boasts the best Precision@1 metric by a fair margin. Once again, we observe the weakness in the MR metric. The implications are that there are many possible correct entities that are given no weights by the approach.

5.3 Unknown Entities Experiments

We demonstrate the capacity of our approach to generalize to unknown entities. Results for the WN18RR datasets are shown in Table 4.

For baselines, we use a random baseline, reranking the entities randomly, as well as a non-finetuned RoBERTa-large model, that simply generates the entity tokens without being finetuned on the dataset first. We can notice that while our approach outperforms a non-finetuned benchmark, the non-finetuned RoBERTa model still far outperforms the random baseline, supporting some of the findings of Petroni et al. (2019) in the capacity of MLM to perform unsupervised link prediction.

The M5 inductive settings are reported in Table 5. We obtain the best Precision@1 metric. The weakness in MR is once again visible, supporting the intuition that while the model might generate the correct entity with high conviction, it will often not give positive score to all plausible entities, yielding a much worst average rank.

We believe that leveraging MLMs could eventually lead to automatically populating KBs with new entities, as new knowledge and new facts are created and added to the web.

5.4 Limitations

MLMLM comes with several limitations. Our approach to padding limits the size of an unknown entity to the size of the longest known entity. While it is unlikely to be limiting in practice, it is still a weakness of our approach to sampling. The model size can be very prohibitive and specialized hardware such as GPUs is required to run it in a timely fashion. The approach however remains tractable as it can provide likelihoods for all possible entities in a single inference call. Compared to entity-embedding based methods, our approach needs additional information in the form of meaningful string representations for both entities and relations. The lack of entity disambiguation is also a limiting factor that does not affect other approaches. Finally, our approach is liable to *forgetting* some entities, leading to comparatively much worst MR than prior approaches.

6 Conclusion

We have developed a methodology for training masked language models to perform link prediction. By leveraging the natural language understanding abilities of these models and the factual knowledge embedded within their weights, we have achieved a tractable approach to link prediction that yields state of the art results on a standard benchmark and the best Precision@1 on another competitive benchmark. We have also demonstrated the ability of our model to perform link prediction of previously unseen entities, making our approach suitable to introduce new entities to knowledge bases. More generally, we have introduced an approach to sampling text from a masked language model of varying lengths, which can have a wider use case.

Abstract

Generating context-aware language that embodies diverse emotions is an important step towards building empathetic NLP systems. In this paper, we propose a formulation of modulated layer normalization—a technique inspired by computer vision—that allows us to use large-scale language models for emotional response generation. In automatic and human evaluation on the MojiTalk dataset, our proposed modulated layer normalization method outperforms prior baseline methods while maintaining diversity, fluency, and coherence. Our method also obtains competitive performance even when using only 10% of the available training data.

1 Introduction

Building interactive systems that can understand and express human emotions has been a long-term goal of artificial intelligence (Shen and Feng, 2020; Huang et al., 2018; Salovey and Sluyter, 1997). Given a context, an intelligent agent ought to be able to generate responses that not only consider the context but also reflect a specified emotion, a task called *emotional response generation*. One common representation of emotions is through *emojis*, which often convey the underlying emotions in an utterance (Zhou and Wang, 2018). Table 1 shows an example generation in this formulation.

To tackle this problem, prior work has proposed a number of different models, including variants of sequence-to-sequence (Seq2Seq) models (Serban et al., 2016; Li et al., 2016a), variational autoencoders (VAE) (Gu et al., 2019; Shen et al., 2017; Zhao et al., 2017) and adversarial networks (Kong et al., 2019; Li et al., 2017). Their generated responses are often dull or generic, partially due to the limited training data for diverse emotions (Li et al., 2017). More recent studies have tried to pre-train language models (LMs) on specific domain data to pivot generation towards certain direction (Gao et al., 2020; Zhang et al., 2020; Yang et al., 2020; Keskar et al., 2019). However, training a LM from scratch can be costly, and collecting sufficient pre-training data in diverse emotions is also challenging, especially for low-resource emotions (Yang et al., 2019a).

Context: good game start morning off tigers v eagles.

Emotion	**Response**
😃	*good luck to all the eagles*
🙏	*i m not a tigers fan but we ve got a win*
💔	*we ve got to wait for tommorrow for the game*
👌	*hope you enjoyed the match with your team*

Table 1. Example generation of our method for four different emojis. Context is an actual random tweet, and emotion is specified by emojis.

In this work, we present a simple and easy-to-deploy technique that can enable pre-trained large-scale LMs to generate fine-grained emotional responses. Specifically, we inject emotional signals specified by 64 commonly used emojis via Modulated Layer Normalization (Mod-LN), a technique widely adopted in computer vision but whose potential has not been well studied yet in NLP. The main advantages of our method are:

- Instead of designing or re-training models from scratch, our method is plug-and-play. In this work, we show its effectiveness on BERT (2019) and GPT-2 (2019), but one can easily extend our method to other Transformer-based LMs.
- By fully exploiting the transfer learning ability of pre-trained LMs, we achieve comparable emotional response generation performance as prior best-performing work with only 10% of the training data, which is especially beneficial for low-resource scenarios.

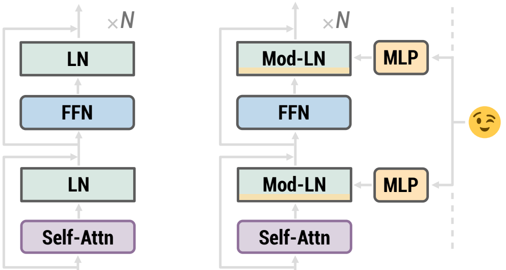
2 Approach

Given a context text and a specified emoji as a target emotion, we aim to generate responses that both reflect the emotion associated with the emoji and the semantic information in the context. In this work, we demonstrate how to inject target emotions through a modulation module of layer normalization (§2.1). We also provide data preparation and model adaptation strategies on two typical LMs (BERT and GPT-2) to aid reproduction and extension (§2.2).

2.1 Modulated Layer Normalization

Layerwise-normalization (LN) is commonly used in Transformer-based (Vaswani et al., 2017) language models (LMs) (Devlin et al., 2019; Radford et al., 2019; Yang et al., 2019b) to stabilize hidden state dynamics and reduce training time (Ba et al., 2016). In the vanilla implementation (Figure 1(a)), data are normalized by their own mean μ and standard deviation σ without relying on external inputs.



(a) Vanilla LayerNorm **(b)** Modulated LayerNorm

Figure 1: Overview of (a) Vanilla Layer Normalization (LN) and (b) Modulated Layer Normalization (Mod-LN) in Transformer-based LMs. The modulation module in Mod-LN uses two Multi-Layer Perceptrons (MLPs) that each have two sets of dense layers. It uses the external emotion input to modulate regularization towards a certain emotion c. FFN: Feed-Forward Network. Self-Attn: Multi-head Self-Attention blocks.

In contrast to vanilla LN that only regularizes data itself, Mod-LN introduces an external modulation module shared across the whole dataset, which is independent of the individual data samples and able to modulate the regularization towards external inputs c (Figure 1 (b)). Specifically, for an input hidden state tensor x in layer l, it is normalized by Mod-LN as

$$x = \text{MLP}_{\gamma}^{(l)}(c) \cdot \frac{x-\mu}{\sigma+\epsilon} + \text{MLP}_{\beta}^{(l)}, \quad (1)$$

where ϵ is the smoothing parameter to avoid dividing by zero. $\text{MLP}_{\gamma}^{(l)}$ and $\text{MLP}_{\beta}^{(l)}$ are two trainable modulation modules for a certain layer l. They are computed by

$$\text{MLP}_{\gamma}^{(l)}(c) = W_{\gamma}^{(l,2)} \cdot \text{Swish}(W_{\gamma}^{(l,1)} c), \quad (2)$$

$$\text{MLP}_{\beta}^{(l)}(c) = W_{\beta}^{(l,2)} \cdot \text{Swish}(W_{\beta}^{(l,1)} c + b), \quad (3)$$

where $W^{(l,1)}$ and $W^{(l,2)}$ are dense layers belonging to layer l, with weights size of $[64, \frac{1}{2} \cdot \text{dim}_h]$ and $[\frac{1}{2} \cdot \text{dim}_h, \text{dim}_h]$ respectively[1]. Dense layers connect 64 emoji classes to the output hidden states of the language model, and b is a bias added to γ. We use the Swish activation (Ramachandran et al., 2017), which has been shown to outperform ReLU (Xu et al., 2015) on several challenging datasets. Though conceptually simple, such MLP based modules have been shown to be a faster and more efficient alternative to vanilla dot product self-attention in NLP (Tay et al., 2021) and CV (Tolstikhin et al., 2021). Our work uses MLPs as a plug-and-play modulator rather than a replacement for self-attentions, allowing us to shift the hidden states towards a given target emotion.

2.2 Data Preparation and Model Adaptation

For the text input, we concatenate ground-truth context with corresponding response as a whole input to feed into LMs. We add a pre-defined separator token (`[SEP]` for BERT and `[UNK]` for GPT-2) between context and response, to make LMs aware of the range of each part. We also pad both context and response to a max sequence length with the padding token.

Encoder-Decoder models have been successful in many text-to-text generation tasks, such as question answering (Chen et al., 2017; Seo et al., 2017), news summarization (Chopra et al., 2016; Rush et al., 2015), and style transfer (Li et al., 2018; Liu et al., 2021). For the response generation task, the encoder encodes the context text into a fixed-length vector in latent space, while the decoder decodes the generated response tokens step-by-step, given the encoded context vector and the ground truth token from the previous step; this method is also known as teacher-forcing (Zhang et al., 2019c; Cho et al., 2014).

In this work, we consider leveraging the transfer learning power of large-scale LMs—using LMs

---

[1] The hidden size dim_h of bert-large-uncased and GPT-2 medium model are both 1024.

as encoder and decoder—to better capture the complicated relationship between context and response (Rothe et al., 2020). Auto-regressive LMs (ARLMs), such as GPT-2 are trained to iteratively predict the next step token given the past, while Masked Language Models (MLM), such as BERT, are trained to predict missing tokens given both the preceding and subsequent text. In contrast to the uni-directional attention flow in ARLM, the attention flow of MLM is bi-directional, and thus if we directly use MLM as decoder, the prediction of tokens in the response will also attend to (i.e., have the context of) future tokens; this could potentially lead to exposure bias (Schmidt, 2019). Inspired by recent text-to-text LMs such as T5 (Raffel et al., 2020) and BART (Lewis et al., 2019), for MLM decoder, we modify the original bi-directional attention mask to make it uni-directional.

We experiment with two encoder-decoder models built on MLM and ARLM: 1) BERT-to-BERT: using bi-directional BERT as both encoder and decoder, but forcing the decoder BERT to attend to past context with uni-directional mask, and 2) GPT2-to-GPT2: using uni-directional GPT-2 as both encoder and decoder.

3 Experimental Setup

Dataset. For all the experiments, we use the MojiTalk (Zhou and Wang, 2018) dataset, a large Twitter conversation corpus ($N \approx 700k$) of responses that each contain one or more of 64 popular emojis. Following the original paper, we split the corpus into training, validation, and test sets of 596,959, 32,600, and 32,600 conversation pairs, respectively. We fine-tune the two LM-based encoder-decoder models on this dataset and generate responses given contexts and all possible emotions using top-k random decoding (Fan et al., 2018) on a machine with four RTX 2080 GPUs [2].

Models. We evaluate three models in total. We take the Reinforced Conditional Variational AutoEncoders (R-CVAE) model from Zhou and Wang (2018) as **Baseline** (current best-performing model on 64-emoji controlled response generation), **Mod-LN MLM**: BERT-to-BERT (large, uncased) + Mod-LN, and **Mod-LN ARLM**: GPT2-to-GPT2 (large) + Mod-LN.

Model	Emoji Acc (%)		
	Hits@1	Hits@3	Hits@5
Baseline: R-CVAE			
w/. 10% train data	13.4	27.1	33.6
w/. 100% train data	26.2	44.2	53.4
Mod-LN MLM			
w/. 10% train data	20.5	47.4	59.1
w/. 100% train data	33.6	56.8	72.2
Mod-LN ARLM			
w/. 10% train data	27.9	43.4	64.1
w/. 100% train data	34.4	60.3	82.5

Table 1: Accuracy of emotional response judged by DeepMoji on classifying emotions in responses generated by R-CVAE, MLM (BERT) with Mod-LN, and ARLM (GPT-2) with Mod-LN.

4 Evaluation

Good emotional responses should accurately reflect the intended emotion, be diverse, and have coherent language. We thus evaluate three aspects of generated responses: emotion control (§4.1), response diversity (§4.2), and coherence and fluency (§4.3). We also use Amazon Mechanical Turk (MTurk) to run a manual evaluation of emotion control and readability in generated responses (§4.4).

4.1 Emotion Control

First, we evaluate whether intended emotions were reflected in the responses generated by various models. We choose DeepMoji (Felbo et al., 2017)[3] as the judgment classifier. DeepMoji was trained on a large-scale emoji dataset containing 1,246 million tweets and 64 distinct emojis, and as far as we know, is state-of-the-art for 64-emoji classification tasks. Since the meanings of different emojis can overlap with subtle differences, we compute Hits@k ($k = \{1, 3, 5\}$) classification accuracy (Gao et al., 2020) to describe the performance of models in different criteria. As shown in Table 1, our proposed models outperform R-CVAE with a large margin. Of note, LM-based models reveal more robust performance in extreme data scarcity cases: our models achieve comparable performance with R-CVAE even when using only 10% of the training data. Between BERT and GPT-2, GPT-2 shows superior performance, partially because its weights are from auto-regressive pre-training.

---

[2] We choose $k = 10$ for a balance of generation diversity and readability through empirical observation.

[3] We chose the official implementation by huggingface: https://github.com/huggingface/torchMoji.

Model	TTR-1	TTR-2	Avg. len	%stop
Human Reference	0.059	0.43	11.7	50.4
Baseline: R-CVAE				
w/. 10% train data	0.034	0.24	8.6	60.1
w/. 100% train data	0.051	0.33	9.2	59.3
Mod-LN MLM				
w/. 10% train data	0.054	0.43	18.2	49.3
w/. 100% train data	0.059	0.39	14.3	49.2
Mod-LN ARLM				
w/. 10% train data	0.056	0.38	15.9	48.7
w/. 100% train data	0.057	0.40	12.5	48.5

Table 2: Lexical diversity of generated responses from various models. TTR-1/TTR-2: unigram/bigram type-token ratio; Avg. len: average number of tokens in generated responses; %stop: average percent of stop words among all tokens in the generated responses.

4.2 Generation Diversity

As shown in Table 2, we evaluate the diversity of responses generated by each model in terms of unigram and bigram type-token ratios, average length, and percent of stop words in generated responses, with values for the human-generated responses shown for reference. As measured by the type-token ratio for both uni- and bi-grams, our proposed models generate more diverse responses. In addition, compared with the R-CVAE, the responses generated by our models are longer and use fewer stop words. The advance can be attributed to the using of large-scale language models as base models.

4.3 Fluency and Coherence

Moreover, we evaluate the fluency and coherence of machine-generated text. For fluency, we trained a standalone language model on the human-generated responses using KenLM (Heafield, 2011) to measure the perplexity of generated texts. To evaluate coherence between the context and the generated responses, we compute the similarity between the generated text and human-generated responses using BERTScore (Zhang et al., 2019b), with the human-generated responses as reference. We configure the BERTScore using 24-layer RoBERTa-large (Liu et al., 2019) as for English tasks. Table 3 shows these results. For perplexity and BERTScore, our Mod-LN models outperform the R-CVAE in both 10% and 100% training data cases.

Model (vs Ref.)	PPL	BERTScore (%)		
		Precision	Recall	F1
Baseline: R-CVAE				
w/. 10% train data	121.18	74.9	83.0	76.7
w/. 100% train data	92.64	80.8	80.8	80.8
Mod-LN MLM				
w/. 10% train data	79.24	78.4	80.1	78.8
w/. 100% train data	50.72	82.9	84.1	83.5
Mod-LN ARLM				
w/. 10% train data	51.55	83.7	80.7	83.2
w/. 100% train data	36.31	84.7	86.2	85.4

Table 3: Fluency as measured by perplexity (PPL) and coherence as measured by BERTScore of generated responses from various models. Ref.: Human-generated responses.

4.4 Human Evaluation

In total 120 MTurk participants manually evaluated the emotion control and readability of responses from our proposed models and the original human-generated reference data. The average age of participants was 38.40 years-old (SD = 12.26, Median=34.50). More than half (65.8%) of participants were male, and 34.2% were female. The average completion time of each survey was 4.53 minutes. Participants were paid $1 per survey, averaging to more than $13 per hour wage for each participant, significantly above the U.S. federal minimum wage.

Procedure Each participant was assigned to read five randomly selected context-response pairs without being informed of the sources of the responses. They were asked to rate 1) emotion control: "*How well the emotion conveyed in the response agrees with the specified emoji?* (1-very well to 7-not at all)", and 2) readability: "*Please rate the readability of the response on a 7-point scale.* (1-very low to 7-very high)". The readability measure included five items adapted from a previous study (Graefe et al., 2018), specifically, well-written, concise, comprehensive, coherent, and clear. Since the five measures had very high agreement (Cronbach's[4] α = .91), we average the five measures into one as a general readability index.

Results The participant's averaged ratings (μ) and Standard Errors (SE) are reported in Table 4.

---

[4] Cronbach's alpha is a measure of internal consistency between sets of items.

Response Source	**Annotator Ratings**: μ (SE)	
	EMO CTRL.	READABILITY
Human Reference	5.62 (0.10)	5.34 (0.10)
Baseline: R-CVAE	4.80 (0.10)	4.67 (0.10)
Mod-LN MLM	5.43 (0.10)	5.20 (0.10)
Ablation: Vanilla GPT-2	4.98 (0.10)	4.64 (0.10)
Mod-LN ARLM	5.40 (0.10)	5.32 (0.10)

Table 4: Humans manually evaluated the emotional control and readability of responses from the original data (human reference), Baseline and proposed models on a 7-point scale (1: low quality, 7: high quality). We also take the generative LM: vanilla GPT-2, as the ablation reference.

As shown in the table, the standard error of the mean among all annotators is .10, which is very low for a 7-point scale, indicating large agreement between annotators. Responses generated by Mod-LN MLM (BERT), Mod-LN ARLM (GPT-2), and the human-generated references had no statistically significant differences in emotion control and readability. All were rated significantly higher than plain GPT-2 and R-CVAE in both emotion control and readability ($p < .001$ for one-way repeated measures ANOVA). We also conducted pairwise multiple comparisons in our analysis as post-hoc analysis. In terms of emotion control, both of our two proposed models and original reference data were rated significantly better than vanilla GPT-2 ($p < .007$). For readability, both our models, vanilla GPT-2, and original reference data were rated significantly more readable than R-CVAE ($p < .001$).

5 Related Work

Emotional Text Generation. VAE-based models (Park et al., 2018; Shen et al., 2017; Zhao et al., 2017; Serban et al., 2017), adversarial networks (Kong et al., 2019; Li et al., 2017; Yu et al., 2017) and reinforcement learning systems (Li et al., 2019, 2016b) have dominated sentiment-aware dialogue models. Other methods have been developed using LSTM (Song et al., 2019) and GRU (Wei et al., 2019; Zhou et al., 2018). All these methods, however, are built on relatively coarse emotion types, partially due to the limited modeling ability of RNNs. Our model outperforms current state-of-the-art R-CVAE (Zhou and Wang, 2018) in the same 64-emoji settings.

Modulated Normalization. Though not common in NLP, modulated normalization has been previously used in computer vision. In addition to work mentioned in the introduction (De Vries et al., 2017), adversarial networks such as CGAN (Miyato and Koyama, 2018), self-attention GAN (Zhang et al., 2019a) and Style GAN (Karras et al., 2019) have used modulated normalization to inject external signal into their models. In NLP, previous studies have tried to modulate normalization for classification tasks (Houlsby et al., 2019) and multilingual machine translation (Bapna and Firat, 2019), however, both these methods require architecture-level modifications. Our method, on the other hand, is plug-and-play, requiring minimal modifications to the architecture and thus easier to deploy for a diverse set of applications.

6 Conclusions

We have proposed a modulated layer normalization approach to generating responses of varying specified emotions. Our approach allows us to leverage large pre-trained models, while remaining simple and easily-extendable. In empirical experiments, our approach substantially outperforms prior work and achieves comparable results using only 10% of the available training data, all while maintaining diversity, fluency, and coherence.

Abstract

As a language model that integrates traditional symbolic operations and flexible neural representations, recurrent neural network grammars (RNNGs) have attracted great attention from both scientific and engineering perspectives. However, RNNGs are known to be harder to scale due to the difficulty of batched training. In this paper, we propose effective batching for RNNGs, where every operation is computed in parallel with tensors across multiple sentences. Our PyTorch implementation effectively employs a GPU and achieves x6 speedup compared to the existing C++ DyNet implementation with model-independent auto-batching. Moreover, our batched RNNG also accelerates inference and achieves x20-150 speedup for beam search depending on beam sizes. Finally, we evaluate syntactic generalization performance of the scaled RNNG against the LSTM baseline, based on the large training data of 100M tokens from English Wikipedia and the broad-coverage targeted syntactic evaluation benchmark.[1]

1 Introduction

Neural language models have an excellent word prediction ability, which motivates researchers to develop several analysis methods for fine-grained evaluation, aiming at understanding which linguistic abilities the models have acquired during training (Linzen et al., 2016; Wilcox et al., 2018; Marvin and Linzen, 2018; Warstadt et al., 2020). So far, many efforts have been made on the evaluation of *syntactic* performance of models, including the abilities to resolve distant subject-verb number agreement in English. Since neural language models are the foundation of contemporary NLP systems, building a language model having robust sentence processing abilities like humans is an important goal, especially toward a system with human-like syntactic generalization abilities, not relying on the data-specific superficial cues found in the training data (McCoy et al., 2019; Linzen, 2020).

Past work has revealed that while sequential and unstructured models, such as LSTM and Transformer language models (Hochreiter and Schmidhuber, 1997; Vaswani et al., 2017), can induce several interesting syntactic behaviors, there is also a notable advantage in explicitly modeling syntax with specific architectures (Kuncoro et al., 2018; Wilcox et al., 2019; Hu et al., 2020). The representative of such models is the recurrent neural network grammars (RNNGs; Dyer et al., 2016), the top-down, left-to-right generative models of a parse tree and sentence.

While these results may suggest that RNNGs are a better modeling choice for language, unfortunately, they have a practical drawback in terms of scalability, due to their structure-sensitive computation mechanism (Kuncoro et al., 2019). Since the computational graphs of RNNGs depend on the tree structures of the sentences, training cannot be mini-batched easily. This is in contrast to LSTMs and Transformers, for which token-wise operations can be batched across sentences, allowing efficient computation on GPUs, which is the key to the data scalability. Although RNNGs are claimed to be a fascinating language model, in practice, they still do not replace the unstructured, computationally favorable models like LSTMs.

In this paper, we directly address the data scalability issue of RNNGs by showing that most computations during training can be batched across sentences. At the computational core of RNNGs is stack LSTMs (Dyer et al., 2015). In past work, Ding and Koehn (2019) have already shown that stack LSTM update operations can be reduced to a tensor operation by implementing the stack as a sin-

---

gle tensor with predefined maximum stack depth. Our work is built on this idea but with a few additional techniques to bridge the gap between the simple stack LSTMs and RNNGs. Importantly, we devise the efficient batching method for *composition* operations on the arbitrary number of stack items, which is unsolved in previous work.

The existing RNNG implementation is based on DyNet that supports the mechanism called Autobatch (Neubig et al., 2017), which automatically finds mini-batch units from the independent computational graphs over multiple sentences with lazy computation. While this mechanism is model-independent and allows intuitive implementation, the utility of this method rapidly plateaus as we increase the batch size. On the other hand, our present method allows effective parallel computation, increasing the training speed almost linearly as we increase the batch size.

In addition to this new batching mechanism for improved scalability, we also provide a new analysis on the role of the strong syntactic inductive bias for models that can access the larger amount of data. For syntactic generalization abilities, while Hu et al. (2020) suggest that the model inductive bias plays a more important role than data scale, they also report that LSTMs or Transformers such as the off-the-shelf large-scale models (e.g., GPT-2 or JRNN) perform much better than their scale-controlled LSTMs. Does an RNNG, which already works relatively well on a modest amount of data, still benefit from the data scale to further strengthen its syntactic ability? We train a new RNNG on about 100M tokens in Wikipedia and evaluate its syntactic performance on SyntaxGym test circuits (Gauthier et al., 2020), finding that the data scale generally brings further performance gains, while the model tends to lose some heuristics on surface patterns that LSTMs seem to find. Our result suggests that RNNGs' reliance on structures will be strengthened with more data, motivating future research on developing better syntactic representation itself as supervision to structured language models.

A related approach to our work is adding the syntactic bias into *sequential* language models, such as LSTMs, with knowledge distillation from RNNGs (Kuncoro et al., 2019, 2020). While motivations are similar, we provide a rather direct solution to resolve the scalability issue of RNNGs, opening up a new possibility of directly using them as an alternative to LSTMs.

From another perspective, our work can be complementary to this work, because knowledge distillation requires a teacher RNNG model, which itself is costly to obtain. For example, Kuncoro et al. (2020) trained an RNNG on a relatively large dataset of 3.6M sentences, which is approximately similar to the training data we use. While the detail is missing, they report that training takes three weeks on a GPU. On the other hand, our models get almost converged in three days. This direct improvement in training time greatly expands the applicability of RNNGs including a teacher of sequential models, and more direct use in computational psycholinguistics (Hu et al., 2020) and NLP applications such as syntactic neural machine translation (Eriguchi et al., 2017).

2 Preliminaries

2.1 Recurrent neural network grammars

RNNGs are joint generative models of a sentence and constituency tree. While RNN language models assign a next token probability, RNNGs assign a probability to next *action*, by which the parse state (stack LSTM) changes dynamically. In this work, we focus on the stack-only RNNG (Kuncoro et al., 2017), which has some resemblance to RNNs in that a single state vector $\mathbf{h}_t$ defines next action probability a_t:

$$a_t \sim \text{softmax}(\mathbf{W}_a \text{MLP}(\mathbf{h}_t) + \mathbf{b}_a)$$

At each step, $\mathbf{h}_t$ is obtained from the top element of stack LSTM, which preserves intermediate LSTM states up to $\mathbf{h}_t$. As a preparation for our batched RNNGs (Section 3), we try to formalize how this stack LSTM states change with each action. An RNNG internally preserves two different stacks: S_h and S_e. S_h is a stack LSTM, keeping the LSTM hidden states $\mathbf{h}_0 \cdots \mathbf{h}_t$.[2] S_e keeps stack elements, each of which is a word embedding $\mathbf{e}_w$, an open nonterminal embedding $\mathbf{e}_x$, or a closed constituent embedding $\mathbf{e}_c$ obtained by REDUCE action.

At each step, the number of candidate actions is $|\mathcal{N}| + 2$ given the set of nonterminal symbols $\mathcal{N}$. Each action changes S_h and S_e as follows:

- NT(x): Push open nonterminal embedding $\mathbf{e}_x$ onto S_e, getting a new LSTM state by $\mathbf{h}_{\text{new}} = \text{LSTM}(\text{top}(S_h), \mathbf{e}_x)$, and then push $\mathbf{h}_{\text{new}}$ onto

---

[2] Precisely, we also have to keep LSTM cell states. We omit this part for brevity.

S_h. This action corresponds to generating an open nonterminal, e.g, "(VP" (when x=VP), which will be closed later.

- GEN: First, generate a next token by sampling from $w \sim \text{softmax}(\mathbf{W}_w\text{MLP}(\mathbf{h}_t) + \mathbf{b}_w)$. Then, as in NT, push $\mathbf{e}_w$ onto S_e, getting a new LSTM state $\mathbf{h}_{\text{new}} = \text{LSTM}(\text{top}(S_h), \mathbf{e}_w)$, and push $\mathbf{h}_{\text{new}}$ onto S_h.

- REDUCE: First, repeatedly pop from S_e k-times until we find $\mathbf{e}_x$, an open nonterminal embedding. Letting $\mathbf{e}^{t-k} = \mathbf{e}_x$, then, apply a composition function, which is BiLSTM (Dyer et al., 2016) by default, to obtain a composed phrase representation $\mathbf{e}_c$:

  $$\mathbf{e}_c = \text{BiLSTM}([\mathbf{e}^{t-k}, \cdots, \mathbf{e}^t]).$$

  $\mathbf{e}_c$ is then pushed onto S_e. To synchronize two stacks, we also pop k-times from S_h and update the LSTM state by $\mathbf{h}_{\text{new}} = \text{LSTM}(\text{top}(S_h), \mathbf{e}_c)$, pushing it onto S_h.

By declaring the operations as above, we notice that the main reasons to prevent mini-batching are twofold: (1) the stacks have variable length, which varies at each step for each sentence; and more crucially, (2) internal operations in an action, especially in REDUCE and others, are largely different.

As we describe next, the issue regarding (1) has been largely solved in previous work. For (2), our strategy is essentially not joining different action types, but trying to improve the efficiency of each action as much as possible after grouping by action types. We find that in practice this strategy works quite well (Section 5.2), allowing models to benefit from a large batch size effectively.

2.2 Batched stack LSTMs

Ding and Koehn (2019) propose a sentence-level batched training algorithm for a restricted class of stack LSTMs designed for unlabeled dependency parsing without composition operations (Dyer et al., 2015). More specifically, Ding and Koehn (2019) deal with the parsing models defined by the following two operations only:[3]

- PUSH: Push $\text{LSTM}(\text{top}(S_h), \mathbf{e}_w)$ to S_h. $\mathbf{e}_w$ is the embedding of the next token.
- POP: Pop the top element from S_h.

At each step, the next action is either PUSH or POP for each sentence. This model still suffers from the problem (1) above. However, they show that by changing the data structure of stack, next PUSH and POP across sentences can be performed in batch. Given B sentences in a batch, let S_h^i be a stack for i-th sentence. What we need to do is to access all top elements of $S_h^i (i \in [0, \cdots, B-1])$ jointly, and this is possible by summarizing all stacks into a single stack *tensor*, denoted by $\mathbf{S}_h$, for which $\mathbf{S}_h[i, p]$ denotes p-th element (LSTM state) on the stack for i-th sentence.

The core idea behind achieving PUSH and POP jointly is that we perform LSTM updates for *all* stack top elements in a batch, but *only* proceed top stack pointers for PUSH batches. Given next actions $\mathbf{a}$ =[PUSH, PUSH, POP, $\cdots$] of length B, we get a vector $\mathbf{op} = [+1, +1, -1, \cdots]$, denoting whether next stack pointer is +1 (PUSH) or -1 (POP). By keeping stack top pointer vector $\mathbf{p}_h$, each step can be batched as the following two operations:

$$\mathbf{S}_h[(0, \mathbf{p}_h[0]+1)\cdots(B-1, \mathbf{p}_h[B-1]+1)] \leftarrow$$
$$\text{LSTM}(\mathbf{S}_h[(0, \mathbf{p}_h[0])\cdots(B-1, \mathbf{p}_h[B-1])], \mathbf{E}_w),$$
$$\mathbf{p}_h \leftarrow \mathbf{p}_h + \mathbf{op},$$

in which $\mathbf{E}_w$ is the next token embeddings.

Unfortunately, this batching relies on a strong assumption about models that one action (PUSH) involves all operations (LSTM update and pointer move by $\mathbf{op}$). This is not the case for RNNGs, for which any action cannot be reduced to a subset of other actions, necessitating a different strategy.

3 Batched RNNGs

Our batching algorithm for RNNGs is built on the following two observations:

(a) For all $a_t \in \{\text{NT}, \text{GEN}, \text{REDUCE}\}$, the last step is common and corresponds to PUSH operation for stack LSTM above with newly created embeddings $\{\mathbf{e}_x, \mathbf{e}_w, \mathbf{e}_c\}$. This final step can be batched if we get all new embeddings as a single tensor $\mathbf{E}_{\text{next}}$ (with size of $(B, |\mathbf{e}|)$).

(b) Then, the main problem is reduced to getting $\mathbf{E}_{\text{next}}$ efficiently. This is possible by separately filling $\mathbf{E}_{\text{next}}$ for each action, using a few additional pointer vectors to keep track of a stack state for each sentence.

---

[3] A restricted model of an arc-eager system (Nivre, 2004), which just POPs when LEFT-ARC occurs, can be achieved with these operations. RIGHT-ARC is modeled by PUSH. Essentially, this stack LSTM can only models the right spine of a tree at each step.

Algorithm 1 One training step for batched RNNG

```
Input Next action vector at $\mathbf{a}$;
      index vector for each action: $\mathbf{i}_{\text{gen}}, \mathbf{i}_{\text{nt}}, \mathbf{i}_{\text{red}}$
 1: $\mathbf{E}_{\text{next}} \leftarrow$ new tensor of size $(B, |\mathbf{e}_x|)$
 2: $\mathbf{E}_{\text{next}}[\mathbf{i}_{\text{gen}}] \leftarrow$ word_emb($\mathbf{x}[(\mathbf{i}_{\text{gen}}, \mathbf{b}[\mathbf{i}_{\text{gen}}])]$)
 3: $\mathbf{b}[\mathbf{i}_{\text{gen}}] = \mathbf{b}[\mathbf{i}_{\text{gen}}] + 1$          ▷ Move to next word.
 4: $\mathbf{E}_{\text{next}}[\mathbf{i}_{\text{nt}}] \leftarrow$ nt_emb($\mathbf{a}[\mathbf{i}_{\text{nt}}]$)
 5: $\mathbf{p}_q[\mathbf{i}_{\text{nt}}] \leftarrow \mathbf{p}_q[\mathbf{i}_{\text{nt}}] + 1$
 6: $\mathbf{q}[(\mathbf{i}_{\text{nt}}, \mathbf{p}_q[\mathbf{i}_{\text{nt}}])] \leftarrow \mathbf{p}_h[\mathbf{i}_{\text{nt}}] + 1$   ▷ Keep new NT depth.
 7: $\mathbf{p}_{\text{prev\_nt}} \leftarrow \mathbf{q}[(\mathbf{i}_{\text{red}}, \mathbf{p}_q[\mathbf{i}_{\text{red}}])]$
 8: $\mathbf{E}_{\text{red}} \leftarrow$ gather_children($\mathbf{p}_{\text{prev\_nt}}, \mathbf{p}_h[\mathbf{i}_{\text{red}}], \mathbf{S}_e$)
 9: $\mathbf{E}_{\text{next}}[\mathbf{i}_{\text{red}}] \leftarrow$ BiLSTM($\mathbf{E}_{\text{red}}$)          ▷ Composition.
10: $\mathbf{p}_q[\mathbf{i}_{\text{red}}] \leftarrow \mathbf{p}_q[\mathbf{i}_{\text{red}}] - 1$     ▷ Forget about reduced nts.
11: $\mathbf{p}_h[\mathbf{i}_{\text{red}}] \leftarrow \mathbf{p}_{\text{prev\_nt}} - 1$
12: $\mathbf{p}_h \leftarrow \mathbf{p}_h + 1$
13: $\mathbf{S}_h[\mathbf{p}_h] \leftarrow$ LSTM($\mathbf{S}_h[\mathbf{p}_h - 1], \mathbf{E}_{\text{next}}$)
14: $\mathbf{S}_e[\mathbf{p}_h] \leftarrow \mathbf{E}_{\text{next}}$
```

To obtain $\mathbf{E}_{\text{next}}$, for NT and GEN, we just need to lookup embeddings for next words and nonterminal symbols. We need an additional effort to obtain multiple $\mathbf{e}_c$s at once. Assuming a stack *tensor* as in Ding and Koehn (2019), we wish to pop k elements, up to $\mathbf{e}_c$, for multiple stacks by a single operation. Now the stack top positions can be accessed by $\mathbf{p}_h$ (Section 2.2), which will be the end indices. To obtain the last open nonterminal positions across a batch, just keeping the last nonterminal positions is insufficient because there are multiple open nonterminals in general. The following matrix and vector allow this operation:

- $\mathbf{q}$: A matrix of size (B, D) given a predefined stack depth bound D. $\mathbf{q}[b, d]$ denotes the position of d-th nonterminal on the b-th stack.
- $\mathbf{p}_q$: A B-dimensional vector, pointing to the last index of $\mathbf{q}$ (similar to $\mathbf{p}_h$ for $\mathbf{S}_h$).

For example, by $\mathbf{q}[(0, \mathbf{p}_q[0]) \cdots (B-1, \mathbf{p}_q[B-1])]$, we can retrieve all the top open nonterminal positions in a batch. Note that for each $\mathbf{q}[b]$, the index beyond $\mathbf{p}_q[b]$ will not be accessed, so we can signify the remove of top nonterminals just by a decrement of $\mathbf{p}_q$ without updating $\mathbf{q}$.

We need a few additional tensors to achieve fully batched stack tensor operations. Figure 1 shows an example.

- $\mathbf{S}_h$: A tensor of size (B, D, L, H) when the stack LSTM has L layers with H hidden dimensions. The core of batched stack LSTMs.
- $\mathbf{S}_e$: A tensor of size $(B, D, |\mathbf{e}|)$, corresponding to S_e in non-batched models (Section 2.1).
- $\mathbf{b}$: A B-dimensional vector, keeping the next token index in the sentence.

Stack						Next action
$\vert_0$	(S $\vert_1$	So $\vert_2$	(NP	it	) $\vert_3$	(VP

$$\mathbf{b} = [1,1,2] \qquad \mathbf{p}_h = [3,3,5] \qquad \mathbf{p}_q = [0,1,2] \qquad \mathbf{q} = \begin{bmatrix} \underline{1} & 3 & 0 & \cdots \\ 1 & \underline{3} & 0 & \cdots \\ 1 & 2 & \underline{3} & \cdots \end{bmatrix}$$

Figure 1: Example batched stack configuration. $x|_d$ means that x is at depth d. For example, "(NP it)" in the first sentence is closed so constitutes a single item on the stack. $\mathbf{p}_q$ points to the top positions of $\mathbf{q}$, which are underlined.

- $\mathbf{p}_h$: A B-dimensional vector, pointing to the top elements of $\mathbf{S}_h$.

Full algorithm Algorithm 1 describes operations in each step given next actions $\mathbf{a}$. Action index vector $\mathbf{i}_a$, keeps the indices of action a in $\mathbf{a}$; in Figure 1, $\mathbf{i}_{\text{gen}} = [1]$ and $\mathbf{i}_{\text{nt}} = [0]$. The operations are mainly categorized into filling $\mathbf{E}_{\text{next}}$ for each action (in red), pointer updates according to action definitions (3, 5, 6, 10, 12), and finally stack updates (13, 14), corresponding to the observed common operations (a).[4] *gather_children* is a function that returns a tensor summarizing reduced children node embeddings. Since the number of reduced children differs across batch, we implement this to return a padded tensor, using *gather* function in PyTorch.

Deviated from Ding and Koehn (2019), we *separately* perform each action, as indicated by the use of $\mathbf{i}_a$. This can be seen as a deficiency of our algorithm; however, this separation is necessary beyond very simple models, which are practically less attractive. Rather, our strategy can be applied to broader classes of structured neural models, including dependency parsing with composition, and we believe that our empirical success (Section 5) encourages further exploration of the presented strategy to various models.

How to set D? As in Ding and Koehn (2019), we need to specify the stack depth bound D for each batch. Increasing this value incurs more GPU memory. For training, we can precompute the minimum value of each sentence by simulating oracle transitions beforehand and use it. For inference, we fix $D = 100$, since we find that even for very long

---

[4] By $A[(\mathbf{x}, \mathbf{y})]$ for vectors $\mathbf{x}$ and $\mathbf{y}$, both with length l, we mean $A[(x[0], y[0]) \cdots (x[l-1], y[l-1])]$, corresponding to advanced indexing in PyTorch. We regard that $\mathbf{S}_h[0]$ is fixed by initial hidden vectors while $\mathbf{S}_e[0]$ is kept empty. $\mathbf{p}_h[b] = 0$ means that b-th stack is empty.

sentences (more than 150 words), the stack depth will never exceed 80 for English sentences.

A note on extra memory with stack tensors At first sight, our approach seems to suffer from the limitation in scalability due to fixed stack tensors ($\mathbf{S}_h$ and $\mathbf{S}_e$). The sizes of these tensors grow by model size, implying that we may not be able to employ a large batch size for a large model. In practice, however, this extra memory will not be a bottleneck in the total memory for training. This is because the main cause of required memory during training is rather a computational graph itself, which keeps all intermediate hidden states at each step. Our stack tensors can be seen as a "storage" to allow computing these intermediate values effectively with tensor operations. The extra memory for this storage is smaller than the total memory in a computational graph because the former depends on D while the latter depends on the total action length A, and $D \ll A$ in general.[5]

4 Other Improvements

Batched beam search For inference as a language model or as an incremental parser, RNNGs typically employ word-synchronous beam search (Stern et al., 2017; Hale et al., 2018), which is although known to be very slow (Crabbé et al., 2019) because it often requires large beam sizes, such as 100 or 1000, and operations are not batched. As a by-product of our batched training, we succeed at implementing fully batched beam search for RNNGs, excluding any *for* loops, by which we drastically improve the search speed (Section 5.3). This is possible by adding the "beam" dimension to all state tensors ($\mathbf{S}_h$, $\mathbf{q}$, etc.).

Subwords Given an increased amount of training data, the vocabulary size naturally increases. To suppress this effect, using subwords (Sennrich et al., 2016) now becomes a standard technique. We thus incorporate subword modeling into our RNNGs and employ it for our largest experiment in Section 6. Kuncoro et al. (2020) recently incorporate subwords in RNNGs, in which, each word is regarded as a new constituent with WORD label, e.g., (WORD cu| r| ry). This means that models always need to perform additional NT(WORD) and REDUCE for each *token*, even for unsegmented ones, e.g., (WORD I), greatly increasing the average action sequence length, which in turn affect the training time. In this work, we model subwords by a simpler method of just segmenting each token. For example, an NP looks like (NP Th| ai cu| r| ry). While Kuncoro et al. (2020) note that this simple modeling is less effective, our experiments suggest that this is a good enough strategy, considering the added computational costs with NT(WORD) actions.[6]

5 Evaluating Efficiency of Batching

The main focus of this section is a comparative evaluation of our PyTorch RNNG implementation with the existing DyNet implementation.[7] We show that: (1) with a large batch size training speed drastically improves, and models will tend to find better parameters (Section 5.2); and (2) our batched beam search hugely speeds up inference (Section 5.3).

5.1 Setting

While Penn Treebank (PTB; Marcus et al., 1993) has often been used to train RNNGs (Wilcox et al., 2019, 2020), it is too small and here we use a larger dataset of BLLIP corpus (Charniak et al., 2000), expecting that the effects of large batch size become clearer by this modestly sized dataset.

Preprocessing For preprocessing, we largely follow Hu et al. (2020), which also train an RNNG on this dataset. We partition the data according to their LG size, the largest training setting, amounting to 42 million tokens for training and 1,500 sentences for development. One difference we make is the handling of unknown tokens. We limit the vocabulary by the top frequent 50,000 word types in the training data. Hu et al. (2020) use all word types

---

[5] Our preliminary experiment suggests that our RNNG implementation can be scaled at least comparable model and data sizes to ELMo (Peters et al., 2018), a large-scale LSTM-based model, given a similar amount of computing resources. We examine the maximum allowable batch size for a model with 1,256 hidden dimensions, amounting to 94M parameters, which are comparable to ELMo (93M), and find that the batch size can be increased to 256, with the maximum action size in a batch of 16,000 (see Section 5.1) on a single V100 GPU (16GB). Transformer-level scalability (Devlin et al., 2019) would still be infeasible because of the RNNG's limited parallelism that is only on sentence-level, not token-level as in Transformers.

[6] We provide a pilot study about this method in Appendix B. Using BLLIP corpus and Penn Treebank, we explore the relationship between a suitable number of subword units and model sizes. The main result is that large subword units are effective for larger models, and also subword modeling almost always improves parsing accuracy.

[7] https://github.com/cpllab/rnng-incremental. This implementation supports word-synchronous beam search. For the training part, this is not implemented to use DyNet Autobatch so we modified it to enable that.

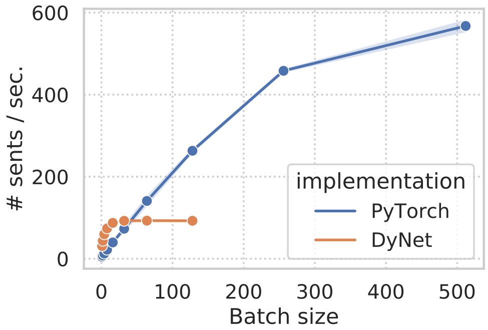

Figure 2: Training speed comparison (number of processed sentences / sec.) when increasing batch sizes to $[1, 2, 4, \cdots, 512]$. Shade denotes standard deviation.

that appear at least twice; however, this method vastly increases the vocabulary size and hence the model size. Unknown tokens are created in the same way with the Berkeley parser's surface feature rule (Petrov et al., 2006). The way to annotate parse trees is the same as well; we run Berkeley neural parser (Kitaev et al., 2019), a state-of-the-art constituency parser to assign accurate parses.

Model size and parameters We experiment with the most common model size of RNNG in the literature: 256 dimensions for input and LSTM hidden dimensions, with 2 layer LSTMs (Dyer et al., 2016; Hu et al., 2020). The total number of parameters is about 15M. The hyperparameters are summarized in Appendix A.

Other settings We employ some additional techniques to improve the efficiency of our batching mechanism. First, before training, we group sentences by their number of gold actions so that examples in each mini-batch have similar numbers of actions. Specifically, we first sort the sentences by action lengths, divide by every 4096 sentences, and then sample each batch from a single group.

Second, we predefine the maximum value for the total number of actions across sentences in a batch, which we set to 26,000. This is inspired by a similar mechanism in fairseq (Ott et al., 2019) for the maximum number of tokens. Using this means that the number of sentences in a batch will be adjusted to be smaller than the batch size when the action sequences (or sentences) are long, allowing us to interpret given batch size as the maximum that is fully exploited only for shorter sentences, which are in practice dominant in the data.[8]

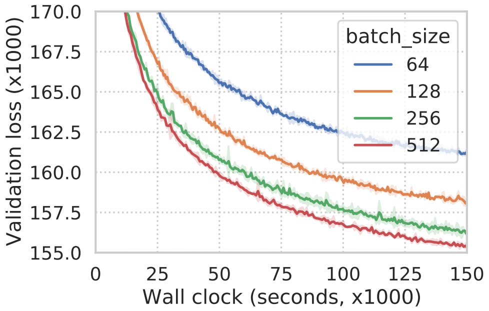

Figure 3: Training wall clock time vs. total validation loss for different batch sizes. X-value of i-th point is an averaged duration time to i-th validation step across three random seeds. Shade denotes standard deviation.

Every experiment is run on a single V100 GPU with 16GB memory. Unless otherwise noted, we perform every experiment three times with different random seeds, reporting an average score with standard deviation.

5.2 Effects of batch sizes

Although our batched training involves action-specific operations (Section 3), to our surprise, the efficiency improvement for our RNNG with large batch sizes is almost linear up to 256 (Figure 2). The improvement is narrow at 512, though this is mainly due to the restriction of the maximum number of actions in a batch (Section 5.1), which reduces the actual batch size for longer inputs. DyNet's Autobatch is quite effective up to 16, running much faster than ours due to the speed of C++, but further improvement is not obtained probably because of the increased overhead of finding mini-batch units themselves from a large computational graph.

Though this result clearly demonstrates the efficiency of our batching mechanism, it is *only* meaningful when the large batch size in fact leads to a faster model *convergence*. This is the case, as shown in Figure 3, where we compare the total validation losses as a function of actual wall clock time during training. The loss is calculated every 1000 batches. The model with batch size 512 converges fastest, and importantly, to better parameters. This result suggests that we can safely benefit from large batch size as long as memory permits. In the following experiments, we fix the batch size to 512.

---

[8] To reduce the memory further, we also employ mixed-precision training in PyTorch. Inference is performed with half-precision (fp16). We find that this does not change the results of beam search at all.

5.3 Beam search speed improvement

As we discuss in Section 4, we have also improved the efficiency of word-synchronous beam search, a standard technique to calculate incremental prefix probabilities (Hale, 2001) and a parse tree for RNNGs. Now, we evaluate the impact of this improvement. For PyTorch, we run it on V100 GPU; for DyNet, we find that it runs faster on CPUs so we instead use CPUs (Intel Xeon 6148, 20 cores x2), with Intel MKL. DyNet beam search is still too slow with this environment so we limit the number of tested sentences to 300 from the BLLIP development set. For PyTorch, we try two different batch sizes $\{1, 10\}$, with a restriction on the number of tokens in a batch, similarly to the total action size in training (Section 5.1). We fix this value to 250, with which the model can safely parse with the largest beam size of 1000.

Word-synchronous beam search employs two types of beam widths, action beam size (k) and word beam size (k_w), along with fast-tracked candidate size, denoted as k_s (see Stern et al. 2017). k is most akin to the standard beam size. Table 1 summarizes the results when increasing k (others are in the caption). The beam search of DyNet becomes prohibitively slow when $k \geq 50$. Strikingly, the increase in average runtime is more than linear against the beam size, especially for 10→50 and 50→100. The time increases, 0.5→11.3 (x22.6) and 11.3→48.6 (x4.3) are roughly quadratic to the increase of k (x5 and x2). This result is reasonable because in addition to the complexity of each step, which depends on k, the length of searched action sequence could also linearly grow by k.[9] The naïve DyNet implementation directly suffers from this computational cost.

Our batched beam search largely resolves this issue and now the average runtime only gradually increases by k. We note that as a parser or a language model, this speed is still not very fast, considering that this is on a GPU.[10] For the research purpose, including psycholinguistic assessments as done in Section 6, however, this improvement is significant, making experiments much easier even with large beam sizes. We still need to work on improving efficiency further, possibly by modifying learning methods to replace word-synchronous search (Stanojević and Steedman, 2020).

Action beam size k	10	50	100	200	400	1000
DyNet	0.5	11.3	48.6	100.6	201.3	NA
PyTorch (B=1)	1.7	2.1	2.3	2.5	2.9	4.1
PyTorch (B=10)	0.4	0.5	0.7	0.9	1.3	2.8

Table 1: Word-synchronous beam search speed (average seconds per sentence) comparison on the first 300 sentences in BLLIP development set. B denotes the batch size. Word beam sizes (k_w) / fast track sizes (k_s) are 10/1, 10/1, 10/1, 20/2, 40/4, and 100/10, respectively.

6 Syntactic Generalization Ability of Scaled RNNG

Finally, we evaluate the syntactic generalization abilities of the scaled RNNG. For this purpose, we adopt the test circuits used in Hu et al. (2020) via SyntaxGym (Gauthier et al., 2020). Here, a test *circuit* is a collection of test *suites*; e.g., "Long-Distance Dependencies" circuit contains a suite on a specific type of "filler-gap dependencies" as well as a suite on (pseudo) "cleft". For each example in a suite, a model succeeds if it can assign a higher likelihood on a grammatically critical position in the correct sentence. For example, given "*The farmer near the clerks knows/*know many people.*" in the "Agreement" circuit, a model is correct if it assigns $p(\textit{knows}|h) > p(\textit{know}|h)$. Note that for subword models the total likelihoods on subwords (not averaged) are compared.

In the previous literature, Hu et al. (2020) trained an RNNG on BLLIP (42M tokens). Here, we train subword RNNGs on 100M tokens from English Wikipedia, to which we assign parse trees with Berkeley neural parser. The model size is 35M with 30k subword units, following the experiment in Appendix B, which assesses the suitable number of subword units for different model sizes. We train this RNNG for three days (with three different seeds), and at inference fix the beam size k to 100 ($k_w = 10, k_s = 1$). We also train an RNNG with the subset of this data (42M tokens) to separate the effects of data size. Our LSTM baseline is the one used in Noji and Takamura (2020), which is basically an AWD-LSTM-LM (Merity et al., 2018)

---

[9] For a sentence of length N, the runtime of beam search is $O(k \times N \times M_w)$, where M_w denotes the maximum number of actions between two tokens (until choosing next SHIFT). The expected number of actions between two tokens (bound by M_w) grows by k because at each step, with a large k the chance that non-shift beam items remain in the next beam increases; hence, the runtime becomes quadratic to k in the worst case. We conjecture that this inefficiency is bounded at some k (see $k = 200$), though is severe for smaller ks.

[10] For smaller k, we can increase the batch size and the maximum number of tokens in a batch to further speedup.

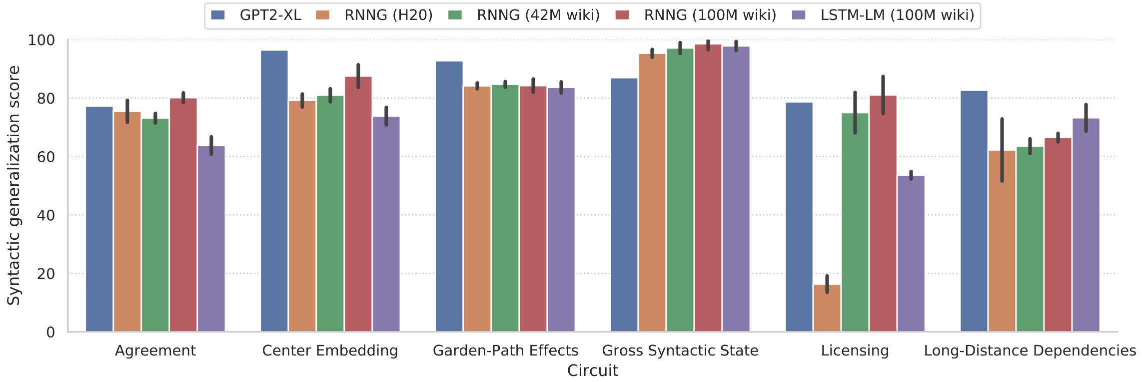

Figure 4: Circuit-level accuracies on SyntaxGym. For each circuit, suite-level accuracies are averaged across different test suites and random seeds to compute “Syntactic generalization score” of each model. Note that RNNG (H20) is a model trained on BLLIP (about 40M tokens) in Hu et al. (2020) but diverged from their results, because their suite-level accuracies are averaged across different models trained on various data sizes.

extended to be sentence-level and, on the Marvin and Linzen (2018) benchmark, shown to work better than GRNN (Gulordava et al., 2018), one of the models used in Hu et al. (2020).[11]

The main result on circuit-level accuracies is summarized in Figure 4. On the effects of the data scale, we observe a consistent improvement from “RNNG (42M wiki)“ to “RNNG (100M wiki)”. This result suggests that this amount of increase in training data is still beneficial for structural language models to strengthen their syntactic generalization ability. For some circuits, only RNNG (100M) outperforms GPT-2 (Radford et al., 2019) on average (“Agreement” and “Licensing”).

Comparing LSTM (100M) and RNNG (100M), RNNG generally outperforms LSTM, but with an exception on “Long-Distance Dependencies”. In order to inspect this, we break down this circuit into suites, (Figure 5), finding that this deficiency of RNNG is due to its poor performance on (pseudo) “cleft”, including the following example:

(1) a. What he did was prepare the meal .
b. *What he ate was prepare the meal .

On underlined tokens, models should assign a higher likelihood for (1a). Our LSTM performs nearly perfectly on these cases while our RNNGs perform badly. We conjecture that given more data and/or parameters, RNNGs will tend to strengthen their commitment to provided syntactic supervision, and hence may lose some lexical heuristics which LSTMs can exploit from surface patterns (e.g., an association of *did* → *prepare*). In fact, the ability of LSTM on cleft is rather brittle, as shown in a huge drop on “cleft_modifier”, which include cleft constructions with intervening modifiers.

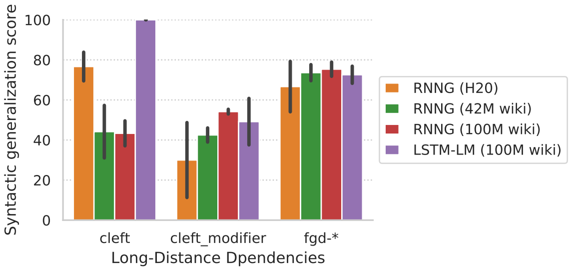

Figure 5: Suite-level accuracies on the “Long-Distance Dependencies” circuit. fgd-* is averaged across different test suites of filler-gap dependencies.

To rigorously handle these cases, models should notice that (1b) is a free relative clause and do not have an antecedent. However, the currently employed PTB annotation, which is limited to local structures, does not provide a distinction between these clause types, analyzing both as “(SBAR (WHNP What) (S (NP he) (VP did/ate)))”, which our RNNGs predict correctly. We also notice that Hu et al. (2020)’s RNNG (H20) performs rather similarly to our LSTM, while our RNNG (42M), trained on the comparable size of data to H20, is more similar to our RNNG (100M), suggesting that RNNG’s poor performance on cleft is not just due to the data scale. One possible explanation of the discrepancy between H20 and our 42M RNNG is

---

[11] Our LSTM implementation is available at https://github.com/aistairc/lm_syntax_negative. We train this LSTM on our subword-segmented Wikipedia (30k units). The model size is adjusted so that the total number of parameters becomes 35M, the same size as our RNNGs (3 layer LSTMs with 1150 hidden and 450 input dimensions).

that our RNNG might be better optimized thanks to improved training, or due to the sizes of hidden layers (256 for H20 and 656 for ours).

This problem poses a new interesting challenge. While RNNGs have been compared to LSTMs several times, the provided syntactic structures are fixed and effects of different annotations (formalism, quantity, etc.) are not explored. For such investigation, the training cost of RNNGs has been a practical burden, but that problem largely goes away with the current study. We expect that our new implementation and batching strategy provide fruitful future research opportunities on structured neural language models.

7 Conclusion

A large computational cost of training structured neural language models was a main practical burden for employing these models in applications and analyses. With special focus on RNNGs, we have provided a direct solution to this problem by showing that batched effective training is in fact possible. On the large scale experiments with SyntaxGym test circuits, we found that the data quantity further strengthens the syntactic generalization abilities of RNNGs, while the annotation quality or quantity will also be of practical importance towards a language model with human-like strong syntactic performance.

A Hyperparameters

We use the defualt parameter setting for the DyNet implementation. For our implementation, we use Adam optimizer (Kingma and Ba, 2015), which is found to be superior, while SGD has been used for DyNet implementation (Dyer et al., 2016; Wilcox et al., 2019). We set the learning rate and dropout rate to 0.001 and 0.1, respectively, which we find achieve lower validation loss robustly across different batch sizes.

B Effect of Number of Subword Units

We perform an experiment to understand the behaviors of our simple subword modeling (Section 4). We use the BLLIP corpus as preprocessed in Section 5.1 except the setting about vocabulary. We compare the fixed vocabulary models, which we train in the experiment of Section 5.2 (batch size 512), and several subword vocabulary models. The hyperparameters are the same as the fixed vocabulary models.

Subword units The number of subwords can be seen as a hyperparameter. To understand the effects of this size for RNNGs, we prepare three different subword vocabularies: 10k (10,240), 20k (20,480), and 30k (30,720). We use byte-pair encoding (Sennrich et al., 2016) implemented in sentencepiece (Kudo and Richardson, 2018).

Model sizes We prepare two different model sizes, 15M and 35M, to see the interaction between the suitable size of subword units and model size, by adjusting the number of two dimensions so that the total number of parameters becomes comparable to these numbers. For 15M parameter models, the dimensions are 528 for 10k units; 432 for 20k; and 336 for 30k. For 35M parameter models, these are 864, 752, and 656, respectively. The number of LSTM layers is fixed to 2.

Results We investigate (1) the effectiveness of our simple subword modeling itself, and (2) whether the optimal number of subword units depends on model sizes. For (1), one way of evaluation is to compare the perplexities of subword models and fixed vocabulary models (see Section 5.1). However, they are not directly comparable because the fixed vocabulary models replace many tokens with unknown tokens, which are easy to predict and make the comparison unfair (Mielke et al., 2019).

V (# params.) / beam k	100	200	400	1000
$V_{fix} = 50k$ (15M)	92.34	93.70	94.26	94.59
$V_{sb} = 10k$ (15M)	92.74	93.85	94.37	94.64
$V_{sb} = 20k$ (15M)	**92.77**	**93.95**	**94.48**	**94.80**
$V_{sb} = 30k$ (15M)	92.33	93.76	94.38	94.72
$V_{sb} = 10k$ (35M)	92.67	93.87	94.37	94.59
$V_{sb} = 20k$ (35M)	92.84	**93.93**	**94.50**	**94.79**
$V_{sb} = 30k$ (35M)	**92.92**	93.84	94.44	94.72
Hale et al. (2018)	87.1	88.96	90.48	90.96

Table 2: PTB development set parsing accuracy (F1) when changing beam size, averaged on three models with different random seeds. V_{fix} is the vocabulary size for fixed vocabulary models while V_{sb} is that for subword models. Hale et al. (2018) is trained only on PTB training set and is not directly comparable. Word beam $k_w = k/10$ and $k_s = k/100$.

V (# params.) / beam k	100	200	400	1000
$V_{fix} = 50k$ (15M)	52.34	49.53	48.26	47.53
$V_{sb} = 10k$ (15M)	69.09	65.34	63.74	62.81
$V_{sb} = 20k$ (15M)	**67.52**	**64.15**	**62.41**	**61.36**
$V_{sb} = 30k$ (15M)	70.43	66.41	64.50	63.41
$V_{sb} = 10k$ (35M)	67.66	64.13	62.41	61.47
$V_{sb} = 20k$ (35M)	63.60	60.33	58.78	57.90
$V_{sb} = 30k$ (35M)	**60.80**	**57.91**	**56.28**	**55.45**

Table 3: Perplexity on BLLIP validation set for each setting described in Table 2, averaged on three models with different seeds. For V_{sb}, perplexity is not subword-level but token-level, by summing subword likelihoods for each token.

We instead validate the effectiveness of our subword modeling by not language modeling, but parsing performance. Note that the text in the BLLIP corpus is Wall Street Journal, the same as Penn Treebank (PTB). Thus, we expect that the quality of auto parses provided to our training data is high, allowing us to assume that a good model should parse the gold PTB data more accurately. We run beam search on the PTB development (section 22) for each model and the results are summarized in Table 2. We can see that F1 scores consistently improve by subword modeling compared to the fixed vocabulary setting. The effects of model size (15M vs. 35M) are negligible, suggesting that the upper bound parsing performance using the current silver quality data can be reached with smaller models.

For (2) above, while comparing perplexities across subword and fixed-vocabulary models is impossible, comparing different subword units is possible by casting the subword-level likelihoods to token-level likelihoods (Mielke, 2019). Table 3 summarizes those values along with the results by fixed vocabulary models as reference. The effects of the number of subword units (V_{sb}) are clearer. For 15M models, the optimal V_{sb} is $20k$, while for larger 35M models, the optimal size is $30k$. This suggests that more parameters are needed to obtain better results for large models.

Verb Sense Clustering using Contextualized Word Representations for Semantic Frame Induction

Abstract

Contextualized word representations have proven useful for various natural language processing tasks. However, it remains unclear to what extent these representations can cover hand-coded semantic information such as semantic frames, which specify the semantic role of the arguments associated with a predicate. In this paper, we focus on verbs that evoke different frames depending on the context, and we investigate how well contextualized word representations can recognize the difference of frames that the same verb evokes. We also explore which types of representation are suitable for semantic frame induction. In our experiments, we compare seven different contextualized word representations for two English frame-semantic resources, FrameNet and PropBank. We demonstrate that several contextualized word representations, especially BERT and its variants, are considerably informative for semantic frame induction. Furthermore, we examine the extent to which the contextualized representation of a verb can estimate the number of frames that the verb can evoke.

1 Introduction

Contextualized word representations such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019) are known to be effective in many natural language processing tasks such as question answering, natural language inference, and semantic textual similarity. Contextualized word representations can generate different representations of the same word in different contexts and distinguish the polysemy of a word. It has been reported that this property is effective in word sense disambiguation (WSD) (Hadiwinoto et al., 2019) and word sense induction (WSI) (Amrami and Goldberg, 2018). Therefore, it appears that contextualized word representations can also be leveraged to induce semantic frames from a large corpus automatically.

A semantic frame is defined on the basis of the semantic roles that a predicate can take as its arguments. FrameNet[1] (Baker et al., 1998) and PropBank[2] (Palmer et al., 2005) are the two most well-known resources of semantic frames, both of which are manually compiled. These resources are used not only for semantic parsing (Yang and Mitchell, 2017) but also for information extraction (Gangemi et al., 2016), question answering (Shen and Lapata, 2007), and document summarization (Cheung and Penn, 2013).

These frame-semantic resources define the frame and semantic roles, and they provide example sentences in which they are annotated. For example, the verb "support" in FrameNet is defined to evoke two frames: the SUPPORTING frame and the EVIDENCE frame. Sentences (1) and (2) below are examples where these frames are annotated. In Sentence (1), "support" means 'supporting a person or a thing' and evokes the SUPPORTING frame. Its arguments are annotated with the semantic roles of Supporter and Supported. In Sentence (2), "support" means 'corroborating' and evokes the EVIDENCE frame. Its arguments are annotated with the semantic roles of Proposition and Support. In both examples, the frame-evoking word is "support," but its evoking frames are different.

(1) [$_{\text{Supported}}$ This study] is supported by [$_{\text{Supporter}}$ the fund]. (SUPPORTING)

(2) [$_{\text{Support}}$ Our results] support [$_{\text{Proposition}}$ the hypothesis]. (EVIDENCE)

Since the manual development of such broad-coverage frame-semantic resources is labor-intensive and time-consuming, many researchers have attempted to induce semantic frames from

Figure 1: 2D t-SNE projection of BERT representations of verb “support” in FrameNet. ● and × correspond to example sentences from SUPPORTING and EVIDENCE frames, respectively.

large corpora automatically. For example, Kawahara et al. (2014) extracted predicate-argument structures of each verb from large corpora and induced the frames that each verb evokes by clustering the extracted predicate-argument structures. Several researchers have recently proposed frame induction methods that leverage word vector representations. For example, Ustalov et al. (2018) collected subject-verb-object triples from a Web-scale corpus and induced the frames by clustering based on the concatenation of word vector representations of the triples. However, since these approaches first collect the tuples of a verb and its arguments and then perform the clustering based on their word representations without taking their contexts into account, they may fail to disambiguate the word senses that require contextual clues.

Therefore, we seek a frame induction method that makes better use of contextual information by leveraging contextualized word representations. Figure 1 shows a 2D projection of contextualized representations of the verb “support” in different sentences. We extracted example sentences of “support” from the frame-annotated sentences in FrameNet, acquired contextualized representations of the verbs by applying a pre-trained BERT, and then projected them into two dimensions by using t-distributed stochastic neighbor embedding (t-SNE) (Maaten and Hinton, 2008). As shown in the figure, these BERT representations are distributed separately depending on the frame that “support” evokes in each example.

Our objective is to exploit this property of contextualized word representations for semantic frame induction. As a first step, we investigate how well contextualized word representations can distinguish the frames that the same verb evokes and which type of representations are suitable for semantic frame induction. We also need to estimate the number of frames that a verb evokes to build a frame-semantic resource automatically. We clarify to what extent contextualized word representations of verbs can estimate the number of frames that verbs evoke, which are defined manually. Our investigation of contextualized word representations will help construct high-quality frame-semantic resources not only for high-resource languages and general domains but also for low-resource languages and specific domains.

2 Related Work

2.1 Contextualized Word Representations

Contextualized word representations encode semantic and syntactic information by learning linguistic patterns and constraints from a large amount of text and provide significant improvements to the state of the art for a wide range of natural language processing tasks. They are also widely applied as context-sensitive word representation extractors for summarization (Liu, 2019), neural machine translation (Zhu et al., 2019), and so on.

Recently, several contextualized word representations have been proposed. For example, ELMo (Peters et al., 2018) produces contextualized word representations by pre-training on a bidirectional language model task in 2-layer BiLSTMs. More recently, many Transformer-based (Vaswani et al., 2017) models have been proposed. BERT (Devlin et al., 2019) utilizes multilayer bidirectional Transformers and is pre-trained on two tasks: masked language modeling and next sentence prediction. RoBERTa (Liu et al., 2019) redesigns the pre-training conditions for BERT, and ALBERT (Lan et al., 2020) shares each layer's parameters in BERT to reduce the number of parameters. There are other models such as GPT-2 (Radford et al., 2019), which is a unidirectional model that is trained to predict the next word in a sentence, and XLNet (Yang et al., 2019), which is based on a permutation language model that learns a bidirectional context in an autoregressive manner.

2.2 Semantic Frame Induction

For semantic frame induction of a word in a context, it is a standard approach to extract predicate-argument structures and then perform the clustering of those structures. LDA-frames (Materna, 2012) is an approach that represents frames as tuples of subject and object and uses latent Dirichlet allocation (LDA) (Blei et al., 2003) to induce semantic frames. Kawahara et al. (2014) extracted predicate-arguments structures from a large Web corpus and then applied the Chinese restaurant process clustering-algorithm (Aldous, 1985) to group predicates with similar arguments. Ustalov et al. (2018) proposed the Triclustering, which produces subject-verb-object triples and then performs a graph-based clustering using the concatenations of their static word embeddings. These methods take only the predicates and their arguments into account, and they do not sufficiently consider the context.

In some works, contextualized word representations are already used for semantic frame induction. In a shared task at SemEval 2019 (QasemiZadeh et al., 2019), some researchers worked on an unsupervised semantic frame induction task, and they reported that ELMo and BERT were useful for the task. Arefyev et al. (2019) first performed group average clustering by using contextualized word embeddings of target verbs from BERT. Then, they performed clustering to split each cluster into two by using TF-IDF features with paraphrased words by using BERT. Anwar et al. (2019) used a concatenated representation of a target verb and the average word embedding of all words in a sentence obtained by skip-gram (Mikolov et al., 2013) or ELMo. They performed group average clustering based on Manhattan distance by using the embedding. Ribeiro et al. (2019) performed graph clustering based on Chinese whispers (Biemann, 2006) by using contextualized representations of frame-evoking verbs from ELMo or BERT.

The shared task dataset contains many example sentences in which different verbs evoke the same frame, and thus the dataset is suitable for evaluating semantic frame induction over verbs. However, there are few example sentences of verbs that evoke different frames in the dataset, and it is not ideal for analyzing the difference of frames that each verb evokes. Some researchers assumed that many verbs evoke only one frame, and they did not analyze the difference of frames that each verb evokes.

Also, there is a study that works on semantic frame induction by using contextualized word representations in semi-supervised learning. Yong and Timponi Torrent (2020) used ELMo or BERT and mapped high-dimensional representations of verbs to a low-dimensional latent space for better frame prediction. Their study aims to extend FrameNet. On the other hand, our goal is to build frame-semantic resources automatically in an unsupervised fashion.

2.3 Word Sense Disambiguation with Contextualized Word Representation

The task in this paper is to distinguish the difference of frames that the same verb evokes, and as such, can be regarded as a type of word sense disambiguation (WSD) task. For the WSD task, contextualized word representations have been reported to be useful. For example, Peters et al. (2018) performed the task by nearest neighbor matching with ELMo representations, and Hadiwinoto et al. (2019) used pre-trained BERT contextualized representations as features for WSD. While WSD aims to distinguish between the meanings of words on the same surface, the semantic frame induction we focus on aims to distinguish between intuitive concepts such as situations, objects, and events that words evoke.

3 Methodology

We investigate to what extent contextualized word representations recognize the difference of frames that the same verb evokes. Specifically, we focus on verbs that evoke more than one frame in frame-semantic resources and acquire contextualized word representations of them. We then apply clustering and evaluate how well the generated clusters and human-annotated frames match.

3.1 Frame-semantic Resources

We use FrameNet and PropBank in English as frame-semantic resources. Since our goal is to establish a semantic frame induction method that is not in a particular style, we use two well-known frame knowledge resources for our investigation: Berkeley FrameNet data release 1.7[3] and PropBank-annotated data from OntoNotes v5.0.[4]

FrameNet is developed within the framework of the theory of frame semantics proposed by Fillmore (2006). Each frame is shared by multiple frame-evoking words (lexical units), and hierarchical relations such as “Inheritance” or “Using” are defined between closely related frames. FrameNet has 1,222 frames, 13,572 lexical units, and 200,751 annotated sentences. The corpus consists of the British National Corpus and U.S. newswire texts.

---

[3] `https://framenet.icsi.berkeley.edu/fndrupal/framenet_data`

[4] `https://catalog.ldc.upenn.edu/LDC2013T19`

PropBank is developed as a corpus with semantic roles that can be used as training data in supervised learning. PropBank frames are defined for each verb as a frameset containing semantic role labels. There are two types of labels; one is ARG0-5. It indicates a necessary role and has a different meaning in each frameset. The other is an argument modifier (AM) label, which indicates an additional role common to all framesets (e.g., AM-TMP for time). For example, the frameset SUPPORT.01 (lend aid, credence to) of "support" is defined with ARG0 as 'helper' and ARG1 as 'person, thing or project being supported.' Sentence (3) is an example in which this frameset is annotated.

(3) $[_{\text{ARG1}}$ Students$]$ were $\underline{\text{supported}}_{.01}$ by $[_{\text{ARG0}}$ the scholarship$]$ $[_{\text{AM-TMP}}$ for four years$]$.

Unlike FrameNet, hierarchical relations are not defined between framesets; that is, each frameset is independent. PropBank has 5,607 framesets, 4,221 verbs, and 111,178 annotated sentences. The corpus consists of newswires, magazine articles, broadcast news, broadcast conversations, web data, conversational speech data, and pivot text.

3.2 Procedure

In our investigation, we follow the procedures below for each target verb that evokes more than one frame in the frame-semantic resources.

1. Acquire contextualized word representations of the target verbs in the set of frame-annotated example sentences in the frame-semantic resources.[5]
2. Apply clustering to their contextualized word representations by using a Gaussian mixture model. At this time, the number of clusters given to the model is equal to the number of frames in our dataset.
3. Find a mapping between the generated clusters and the human-annotated frames that maximize the overall number of matches. We use the match rate as the evaluation metrics.

4 Experiment on Frame Distinction

4.1 Dataset

We first determined the target verbs, and we then extracted example sentences of the target verbs from both FrameNet and PropBank. As target verbs, we used verbs that evoke two or more frames with at least 20 annotated sentences. For example, in FrameNet, the verb "support" is a target verb because there are 30 sentences in the SUPPORTING frame and 20 sentences in the EVIDENCE frame. In contrast, the verb "attend" is not a target verb. This is because although the verb "attend" evokes three frames, (ATTENTION, PERCEPTION_ACTIVE, and ATTENDING), there are 7 sentences in the ATTENTION frame, 4 sentences in the PERCEPTION_ACTIVE frame, and 24 sentences in the ATTENDING frame and only the ATTENDING frame includes 20 or more sentences.

For each verb, we considered frames that include at least 20 annotated sentences. In addition, if the target verb evokes more than 10 frames with 20 or more annotated sentences, we used the top 10 frames on the basis of the number of annotated sentences. We used a maximum of 100 annotated sentences for each frame. As a result, we have obtained 178 target verbs for FrameNet and 164 for PropBank. The average counts of frames per verb were 2.21 for FrameNet and 2.73 for PropBank, and the average counts of annotated sentences per frame were 41.68 for FrameNet and 70.34 for PropBank. In this paper, we used 120 verbs as the test set for the final evaluation and the remaining verbs as the development set for tuning the parameters for both FrameNet and PropBank.

4.2 Settings

We compared ELMo, $\text{BERT}_{\text{BASE}}$, $\text{BERT}_{\text{LARGE}}$, RoBERTa, ALBERT, GPT-2, and XLNet as contextualized word representations in order to explore the representation most suitable for semantic frame induction. We used publicly available pre-trained models. ELMo is the 'Original' model in AllenNLP,[6] and the other transformer-based models are pre-trained models[7] in Hugging Face.[8] For each model, we obtained contextualized word representations from the hidden layer that achieved the highest scores in the development sets for FrameNet and PropBank, respectively. Table 1 lists the size of the corpus used to pre-train models and the number of parameters, dimensions, layers, and hidden layers of models used to obtain the representations

---

[5] Tokenization is performed in the same way as used in the pre-training. If tokenization splits the target verb token into more than one sub-token, we use the contextualized word representations of the first sub-token.

[6] `https://allennlp.org/elmo`

[7] These models are specified by 'bert-base-uncased,' 'bert-large-uncased,' 'roberta-base,' 'albert-base-v2,' 'gpt2,' and 'xlnet-base-cased' in Hugging Face.

[8] `https://huggingface.co/transformers/`

Model	Corpus size	No. of parameters	No. of dimensions	No. of layers	Used layer
ELMo	11GB	94M	512	2	1|1
BERT$_{\text{BASE}}$	16GB	110M	768	12	9|7
BERT$_{\text{LARGE}}$	16GB	340M	1024	24	21|15
RoBERTa	160GB	125M	768	12	10|6
ALBERT	16GB	11M	768	12	9|8
GPT-2	40GB	117M	768	12	8|9
XLNet	158GB	110M	768	12	5|5

Table 1: Details of contextualized word representations. “Used layer” means hidden layer of model used to obtain the representations in FrameNet (left) and PropBank (right).

Model	FrameNet	PropBank
All-in-one-cluster	0.578	0.548
ELMo	0.631	0.607
BERT$_{\text{BASE}}$	0.750	0.765
BERT$_{\text{LARGE}}$	**0.769**	0.790
RoBERTa	0.767	**0.796**
ALBERT	0.705	0.712
GPT-2	0.666	0.650
XLNet	0.729	0.758

Table 2: Macro-average match rate of each verb for each of models and datasets.

for FrameNet and PropBank, respectively.

We used the Gaussian mixture model implementation provided by scikit-learn.[9] We adopted “spherical” as the covariance type, that is, the covariance matrix was a diagonal covariance with equal elements along the diagonal. We used five trials of clustering with different random seeds and adopted the result of the highest likelihood trial.

4.3 Results

Table 2 lists the macro-average match rate of each verb for each of the models and datasets. All-in-one-cluster means the average score when all the example sentences were in one cluster for each verb. That is, the score is the average of the percentages of examples that were annotated with the most frequently used frame for a verb. For example, the score of the verb “support” in FrameNet was 0.6 (30/50) since the numbers of example sentences from the Supporting frame and the Evidence frame were 30 and 20, respectively.

As shown in Table 2, BERT$_{\text{LARGE}}$ and RoBERTa achieved the highest scores for FrameNet and PropBank, respectively. We confirmed that they recognized the differences of frames that the same verbs evoke. BERT$_{\text{BASE}}$, XLNet, and ALBERT also achieved high scores. These results indicate that BERT, RoBERTa, XLNet, and ALBERT are useful for semantic frame induction. In contrast, the scores obtained for ELMo and GPT-2 were relatively low and almost the same as for the All-in-one-cluster. It indicates that the degree of the difference of frames captured by the contextualized word representations varied greatly.

The reasons for these results are described below. The high scoring BERT, RoBERTa, XLNet, and ALBERT are deep bidirectional language models based on Transformer. In contrast, GPT-2 is a unidirectional language model based on Transformer. Also, ELMo is a relatively sparse bidirectional language model that consists of only two unidirectional contexts concatenated together. Therefore, the scores of GPT-2 and ELMo were lower than those of the deep bidirectional language models.

We show several examples below. In these figures, the number given to each point represents the clustering result; that is, the points with the same number belong to the same cluster. Note that the value of the number has no meaning. Figure 2 shows a 2D t-SNE projection of BERT$_{\text{LARGE}}$ vectors for “support” in FrameNet. We can see that the example sentences from the Supporting frame and the Evidence frame form a cluster, respectively.

Figure 3 shows a 2D t-SNE projection of BERT$_{\text{LARGE}}$ vectors for “fire” in FrameNet. We can see that example sentences from the Firing frame form a single cluster, whereas the difference between the Shoot_projectiles frame and the Use_firearm frame is not captured. The Firing frame means ‘ending an employment relationship’ while the Shoot_projectiles and the Use_firearm frames mean ‘shooting a bullet’ and ‘shooting a gun’, respectively. The Firing frame is very different from the other two. On the other hand, the “Using” relation is annotated between the Shoot_projectiles frame and Use_firearm frame, which indicates that there is a strong connection between the two frames. We conduct an additional analysis on frames that have hierarchical

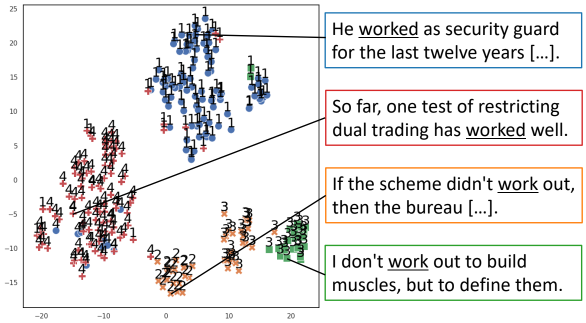
relations in Section 4.4.

Figure 4 shows a 2D t-SNE projection of $\text{BERT}_{\text{LARGE}}$ vectors for "work" in PropBank. The verb "work" has four types of framesets: WORK.01 (work), WORK.02 (arrange), WORK.03 (exercise), and WORK.09 (function, operate). We confirmed that $\text{BERT}_{\text{LARGE}}$ roughly captured the difference of frames, even for verbs that can have many framesets. In the examples where WORK.02 and WORK.03 were annotated, the verb "work" appears in the form of "work out," and it may have been a bit challenging to capture the difference of these framesets. This is because verbs that appear as part of phrasal verbs have relatively similar contextualized word embeddings since the same word appears near the verb.

Figure 5 shows a 2D t-SNE projection of $\text{BERT}_{\text{LARGE}}$ vectors for "cry" in PropBank. The verb "cry" has two types of framesets: CRY.01 (speak loudly, yell, demand, possibly while weeping) and CRY.02 (cry, weep). Like the verb "fire" in FrameNet, the resulting clusters could not be appropriately formed because the framesets of the verb "cry" are both related to 'weep' and are thus very similar.



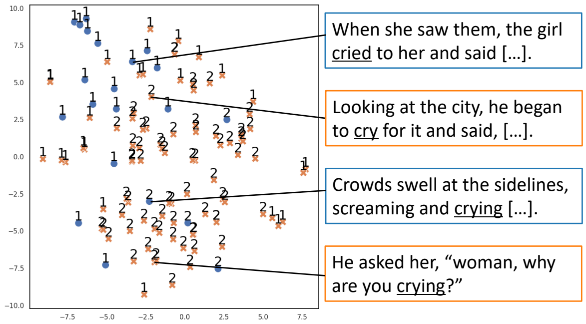
He worked as security guard for the last twelve years […].

So far, one test of restricting dual trading has worked well.

If the scheme didn't work out, then the bureau […].

I don't work out to build muscles, but to define them.

Figure 4: 2D t-SNE projection of $\text{BERT}_{\text{LARGE}}$ vectors for verb "work" in PropBank. ●, ×, ■, and + correspond to example sentences from WORK.01 (work), WORK.02 (arrange), WORK.03 (exercise), and WORK.09 (function, operate) framesets, respectively.



When she saw them, the girl cried to her and said […].

Looking at the city, he began to cry for it and said, […].

Crowds swell at the sidelines, screaming and crying […].

He asked her, "woman, why are you crying?"

Figure 5: 2D t-SNE projection of $\text{BERT}_{\text{LARGE}}$ vectors for verb "cry" in PropBank. ● and × correspond to example sentences from CRY.01 (speak loudly, yell, demand, possibly while weeping) and CRY.02 (cry, weep) framesets, respectively.

4.4 Effect of Hierarchical Relations on Evaluation

The frames with hierarchical relations defined in FrameNet appear in similar contexts. As is clear from the examples of "fire," it is not easy to distinguish these frames, even using contextual word representations. Moreover, it is unclear whether these frames should be defined as separate frames if semantic frame resources are to be automatically constructed in the future. Specifically, the importance of distinguishing between the Shoot_projectiles frame and the Use_firearm frame could be less important than distinguishing between the Shoot_projectiles frame and the Firing frame.

To investigate the practical usefulness, we attempted to evaluate the accuracy of the distinc-

Model	Gr w/o rel	Gr w/ rel	Diff
All-in-one-cluster	0.613	0.604	0.009
ELMo	0.680	0.644	0.036
BERT$_{\mathrm{BASE}}$	0.805	0.719	0.086
BERT$_{\mathrm{LARGE}}$	0.826	0.713	0.113
RoBERTa	0.836	0.707	0.129
ALBERT	0.758	0.670	0.088
GPT-2	0.724	0.655	0.069
XLNet	0.783	0.700	0.083

Table 3: Average match rate by groups without hierarchical relations (Gr w/o rel) and groups with hierarchical relations (Gr w/ rel). "Diff" represents difference between score of Gr w/o rel and score of Gr w/ rel.

tion between frames with hierarchical relations and frames without relations, separately. We first extracted verbs that had exactly two types of frames from FrameNet as a result of the procedure described in Section 4.1. We then divided the extracted verbs into two groups according to whether there is a hierarchical relation between the two frames or not and calculated the average match rate for each group.[10] By limiting our focus to verbs with two types of frames, we can ignore the tendency of the match rate to decrease as the number of frames increases. We assume that if a certain contextualized word representation appropriately captures the difference of frames, it should be able to distinguish the difference of frames with a high match rate.

Table 3 lists the results of the average match rate. In the models of BERT$_{\mathrm{LARGE}}$, RoBERTa, BERT$_{\mathrm{BASE}}$, XLNet, and ALBERT, which obtained relatively high scores in the results shown in Table 2, we can see that the group without relations got higher scores than the group with relations. It is arguably concluded this result indicates that these models accurately captured the essential difference of frames.

5 Estimation of Number of Frames

In the experiments in Section 4, we gave the number of frames in our dataset to the Gaussian mixture model. However, it is necessary to estimate the number of frames that each verb evokes for semantic frame induction. Therefore, we investigated how well we can estimate the number of frames on the basis of information criteria by using contextualized word representations. Specifically, we adopted a Bayesian information criterion (BIC) (Schwarz, 1978), which is used for determining the number of clusters, and an adjusted-BIC, in which the BIC is adjusted so that the estimated number of clusters is close to the number of human-annotated frames.

5.1 Information Criterion

The Bayesian information criterion (BIC) is one of the most widely used criterion for model selection. The BIC is defined as

$$\mathrm{BIC} = -2\ln(L) + k \cdot \ln(n_s), \qquad (1)$$

where L is the likelihood of the model, n_s is the number of samples, and k is the number of model parameters. The parameters of the Gaussian mixture model consist of the mean, covariance, and mixture weights. When the numbers of clusters and dimensions are represented by n_c and d, respectively, the number of parameters required to represent the mean is $d \times n_c$. Since we adopted spherical as the covariance type, where each component has its own single variance, the number of parameters required to represent the covariance is n_c. Since the mixture weights for each component are probabilities that sum to 1, the number of parameters required to represent the mixture weight is $n_c - 1$. Thus, the total number of model parameters is $k = (d + 2) \times n_c - 1$. When the BIC is used to determine the number of clusters, the number that minimizes the BIC is selected.

The first term on the right-hand side in Equation 1 decreases as the number of clusters increases because the likelihood of an optimized model generally increases as the number of parameters increases. The second term on the right-hand side is regarded as a penalty term that inhibits the increase in the number of clusters. The granularity of frames decided by human intuition may not be optimal in terms of the information criterion. Therefore, we introduce an adjusted-BIC in which the penalty term of the BIC is adjusted so that the granularity of the frames is close to human intuition. The equation of the adjusted-BIC (a-BIC) is defined as

$$\text{a-BIC} = -2\ln(L) + c \cdot k \cdot \ln(n_s), \qquad (2)$$

where c is a constant that adjusts the penalty, which is decided by using the development set.[11]

---

[10] Among the 120 verbs that were used as the test set in the experiment, the number of verbs that evoked only two frames was 96. The number of verbs in the group without the relations was 62, while the number of verbs in the group with the relations was 34.

[11] The constant c is increased from 1 in increments of 0.1, and we decide the value when the total number of frames and the total estimated number of clusters are as close as possible in the development set.

		ρ	Accuracy	RMSE
FrameNet	BIC	0.165	0.058	3.131
	a-BIC	0.177	0.517	1.195
PropBank	BIC	0.066	0.004	7.429
	a-BIC	0.631	0.608	1.008

Table 4: Evaluation on estimating the number of frames using BIC and a-BIC for FrameNet and PropBank.

5.2 Results

In the experiments in Section 4, we used only the verbs that evoke more than one type of frame. However, it is also essential for verbs that evoke only one type of frame to recognize that. Therefore, we added verbs that evoke only one frame. The number of verbs added was the same as the number of verbs used in the experiment in Section 4. We also used a maximum of 100 annotated sentences from each frame. As a result, we used 116 verbs for parameter tuning as the development set and 240 verbs for evaluation as the test set for FrameNet, and we used 88 verbs for parameter tuning as the development set and 240 verbs for evaluation as the test set for PropBank.

We used $\text{BERT}_{\text{LARGE}}$ as contextualization word representations. We evaluated the automatic estimation of the number of frames by using Spearman's rank correlation coefficient (ρ), accuracy, and root mean square error (RMSE) for the estimated number of clusters and the number of frames in our dataset. Table 4 lists the estimation results of the number of frames. For both FrameNet and PropBank, using the adjusted-BIC as the information criterion resulted in better scores than using the BIC. When using the adjusted-BIC, Spearman's rank correlation coefficients were 0.177 and 0.631 for FrameNet and PropBank, respectively. The accuracy scores were over 0.5, which means that we could correctly predict the number of frames for more than half of the verbs. The accuracy for FrameNet is lower than the accuracy for PropBank. Accurate prediction of the number of frames for FrameNet will need to consider semantic coherence across different verbs, since frames in FrameNet are not defined independently for each verb.

Table 5 shows the confusion matrices between the number of human-annotated frames and the estimated number of frames using the BIC and the adjusted-BIC for FrameNet and PropBank. We can see that the BIC tended to overestimate the number of frames. The constant c was tuned at 3.1 for FrameNet and 3.4 for PropBank.

6 Conclusion and Future Work

We investigated to what extent contextualized word representations can recognize the difference of frames that the same verb evokes. Specifically, we focused on verbs that evoke multiple frames and performed clustering based on contextualized word representations of target verbs. We calculated the match rate between the generated clusters and the human-annotated frames and compared seven contextualized word representations: ELMo, $\text{BERT}_{\text{BASE}}$, $\text{BERT}_{\text{LARGE}}$, RoBERTa, ALBERT, GPT-2, and XLNet. We found that BERT, RoBERTa, XLNet, and ALBERT achieved high performance in distinguishing the difference of frames that the same verb evokes. We also found that we can estimate the number of frames with an accuracy of more than 50% by using the adjusted-BIC, which adjusts the penalty term of the BIC.

In this paper, we focused on the difference of frames that each verb evokes. That is, we analyzed each verb separately. However, in FrameNet, frames are shared by several verbs. For example, the verbs "support," "prove," and "demonstrate" can evoke the same EVIDENCE frame. To induce FrameNet-style frames, we need to investigate to what extent contextualized word representations capture frames over verbs.

Semantic frame induction requires not only distinguishing the difference of frames that the same verb evokes but also grouping its arguments by the semantic role. For example, if a sentence contains a verb that evokes the EVIDENCE frame, the sentence contains what is claimed and what supports the claim as its argument. Contextualized word representations of the arguments will also be useful for grouping arguments by the same roles.

Furthermore, we only considered verbs as frame-evoking words, but we need to examine whether we can obtain similar results for words with other parts of speech that evoke frames such as nouns. These investigations are expected to bring us closer to our goal of automatically constructing high-quality semantic-frame resources. They can also induce semantic frames for under-resourced languages or specific domains since contextualized word representations do not require human-annotated texts.

Abstract

Neural topic modeling approach has been attracting much attention recently as it is able to leverage the advantages of both neural networks and probabilistic topic models. Previous works have proposed several models that are based on this framework and obtained impressive experimental results compared to traditional probabilistic models. However, the reported result is not consistent across the works, making them hard for gaining a rigorous assessment of these approaches. This work aims to address this issue by offering an extensive empirical evaluation of typical neural topic models in different aspects using large, diverse datasets as well as a thorough set of metrics. Precisely, we examine the performance of these models in three tasks, namely *uncovering cohesive topics*, *modeling the input documents*, and *representing them for downstream classification*. Our results show that while the neural topic models are better in the first and the third tasks, the traditional probabilistic models are still a strong baseline and are better in the second task in many cases. These findings give us more insights for choosing off-the-shelf topic modeling toolboxes in different contexts, as well as for designing more comprehensive evaluation for neural topic models.

1 Introduction

Classical topic modeling approach consists of statistical learning methods for uncovering the latent topics from a corpus and the semantic meaning of each document in the corpus. Notable works include the pioneering ones by (Hofmann, 1999; Blei et al., 2003). During its more than 20 years of research, topic modeling has also been applied to other fields beyond its original scope such as image analysis (Fei-Fei and Perona, 2005), and recommender systems (McAuley and Leskovec, 2013).
