Abstract

Hypernym discovery aims to identify all possible hypernyms of a given term. The most recent hypernym discovery models exploit multiple mapping functions to project a term to different semantic spaces and then aggregate these embeddings to a general representation for further classification. We refer to this model as a *parallel style* model. In this work, we observe that there are hierarchical relations between a target terms' hypernyms. However, these hierarchical relations were not sufficiently considered in the previous *parallel style* model. To leverage the hierarchical relations, we propose a *sequential style* model that recurrently maps the query words to their hypernyms, starting from the most specific ones to the less specific ones. Empirical studies on SemEval-2018 Task 9 confirm the effectiveness of the presented model.

1 Introduction

Hypernymy, namely "is-a" relation, is a vital lexical-semantic relation in natural languages, which relates general terms to their instances or subtypes. In a hypernymy relation, we name a specific instance or subtype *hyponym* and its related general term *hypernym*. For instance, (*apple*, *fruit*) is in hypernymy relation, where *apple* is a hyponym and *fruit* is one of its hypernyms. Due to its general representation ability of semantic relations, hypernymy becomes an essential concept in modern natural-language research, and hypernymy detection becomes a fundamental component in many natural language processing (NLP) tasks, such as taxonomy construction (Snow et al., 2006; Navigli et al., 2011), semantic search (Hoffart et al., 2014; Roller et al., 2014; Roller and Erk, 2016), textual entailment (Dagan et al., 2013; Bowman et al., 2015; Yu et al., 2020) and question answering (Yahya et al., 2013; Gupta et al., 2018).

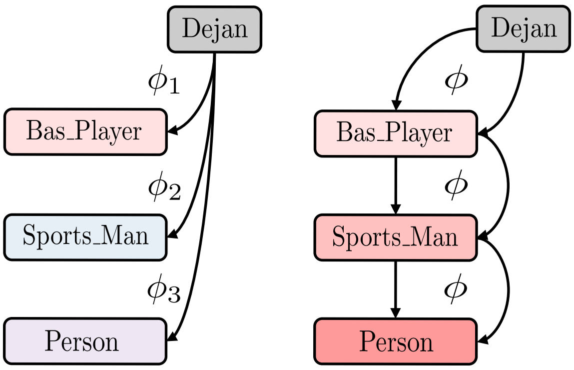

Figure 1: The parallel modeling (left) and sequential modeling (right). The Dejan is the name of a basketball player. The Bas_Player denotes the `Basketball Player` hypernym.

One branch of existing works builds the hypernymy-relation-identification problem as a "detection" task, which is only interested in whether a given term pair "is" or "is not" in hypernymy relation. These works formulate hypernym detection as a binary classification task. This hypernym detection task has been studied for years and plenty of models have been successfully applied in this task (Held and Habash, 2019a; Le et al., 2019).

This paper focuses on another problem named hypernym "discovery", which is different from the detection task. Given an input term, the hypernym discovery task retrieves a ranked list of its suitable hypernyms from a large corpus. For training, some hyponyms with their gold hypernym lists are provided. SemEval-2018 Task 9 (Camacho-Collados et al., 2018) is the only benchmark for this task. Existing studies working on this task mainly build a parallel mapping model (Bernier-Colborne and Barriere, 2018; Fu et al., 2014; Ustalov et al., 2017; Yamane et al., 2016). It introduces mul-

tiple parallel projections, each with independent parameters, to extract features and score the given hyponym/hypernym pair, as shown in the left picture of Figure 1. This model structure is motivated by the assumption that each fine-grained "is-a" relation should be modeled by a specific projection. However, the parallel mapping model may be ineffective due to uncountable "is-a" relation types in real-world applications. It may also suffer from overfitting due to its large model capacity. It also ignores the relations between different projections because they are independently learned.

To overcome the limitations of the parallel mapping model, we propose a recurrent mapping model. Our model is motivated by the observation that a hypernymy term may be produced by the "hypernymy transformation", which transforms a term to its closely related hypernym via a projection, as shown in Figure 1 (right). In the figure, we want to identify hypernyms of the term `Dejan`. The higher-level hypernym `Person` may be transformed from a `Dejan–Bas_Player–Sports_Man–Person` path. The parallel modeling in Figure 1 (left) may not have the ability to capture these sequential relations. Thus we devise a recurrent mapping model for these sequential relations. Note that the projection in our recurrent mapping model is shared among all hops. We assume that a higher-level hypernym term can be generated by operating multiple hypernymy transformations recurrently from the given term. In this way, we build the sequential relations between the transformed terms and largely reduce the parameters used in projection.

We also consider the types of hyponyms when building our recurrent mapping model. As pointed out in previous work (Bernier-Colborne and Barriere, 2018; Camacho-Collados et al., 2018), hyponyms are divided into two types, namely, the concept type and the entity type. This type information is available in the dataset. According to the type of a hyponym, the hypernymy relation can be divided into "subclass-of" (e.g. A guitar is an instrument) and "instance-of"(e.g. Rome is a city). The former represents the hypernymy relation between two concepts, and the latter connects an entity-hyponym with a concept-hypernymy. We first exploit two projections to obtain type-enhanced representation for different types of hyponyms, then feed the type-enhanced representation to a unified recurrent mapping model. In this way, we provide appropriate additional model capacity to handle different types of hyponyms and simultaneously we can utilize all data with hyponyms that belong to both types to train our model.

Our recurrent model outputs a representation vector at each hop. These vectors indicate hypernym representations from different hierarchy levels corresponding to the original hyponym. While scoring a candidate hypernym, we exploit an attention mechanism to aggregate hypernym representations from each hierarchy level. The attention weight of a level is viewed as the probability of the candidate hypernym lying in that level.

In summary, the contributions of this work are as follows:

- We propose a recurrent mapping model that utilizes a shared mapping unit to model the inherent hierarchical dependencies between hypernyms.
- To exploit the hyponym-type information, we use an independent projection matrix for each type to map hyponyms of different types to hypernym space.
- We utilize the attention mechanism into the aggregation module to obtain learnable weight.

2 Related Work

Earlier research on hypernym detection mainly focuses on unsupervised methods, which can be categorized into pattern-based methods and distributional methods. Pioneered by Hearst (1992), the pattern-based methods pre-define some common patterns that indicate hypernym relation, for example, word phrase "such as", "especially". Words occurring together in these pre-defined patterns will be extracted as hyponym/hypernym pairs. This method is quite intuitive. However, one serious problem is sparsity, since many hyponym/hypernym pairs never co-occur explicitly in the corpus, let alone in specific patterns. As a result, this method can provide high accuracy, at the cost of low recall. Seitner et al. (2016) try to improve this method by proposing an extended set of patterns, while (Snow et al., 2004; Shwartz et al., 2016) put forward methods to learn such lexical-syntactic patterns automatically. To further alleviate the sparsity problem, distributional models are proposed. Based on distributional inclusion hypothesis (DIH, Geffet and Dagan (2005)), these models represent every word as a distributional vector. Hyponym/hypernym pairs that never co-occur in the corpus can be captured based on the relation on their distributional vectors.

Most recent studies on hypernym discovery are supervised methods. Fu et al. (2014) was inspired by the well-known example "$V(king) - V(queen) \approx V(man) - V(woman)$", where V(w) is the embedding of the word w. The authors observed that the same linguistic regularities are preserved between hyponym and hypernyms. Thus they supposed that a hyponym can be projected to its hypernym. Besides the uniform linear projection, they also proposed piece-wise linear projections to model fine-grained hypernymy relations. Ustalov et al. (2017) makes use of negative examples to regularize the model, which further improves the performance of the model. Yamane et al. (2016) jointly learns the clusters and projections, the number of clusters can be determined depending on the learned projections and vice versa.

Some other work (Bernier-Colborne and Barriere, 2018; Held and Habash, 2019b) utilize a mix of both unsupervised and supervised methods. Dash et al. (2020) argued that hypernym relation can be represented as strict partial order relation (transitive, irreflexive and asymmetric) and they introduced a model which takes strict partial order relation as soft constraint.

3 Problem Formulation

Hypernym discovery task aims to identify all hypernym terms of a given hyponym term. Formally, let $\mathcal{V}$ be the set of all terms, and $\mathcal{X}$ and $\mathcal{Y}$ denote the set of all hyponym terms and candidate hypernym terms, respectively. Both $\mathcal{X}$ and $\mathcal{Y}$ are subsets of $\mathcal{V}$. For a given hyponym $x \in \mathcal{X}$, a hypernymy detector is expected to find all hypernym terms $y \in \mathcal{Y}$ that make (x, y) a hypernymy relation.

4 Methodology

In this section, we introduce the proposed Recurrent Mapping Model (RMM). It consists of three components: a type enhanced representation module that maps the hyponym embedding via different projections, a recurrent mapping module that transforms the term features into multiple concept-level semantics and an aggregation module that aggregates hypernym representations from each hierarchy level and compute a final score via the aggregated vector. We next describe each component in detail.

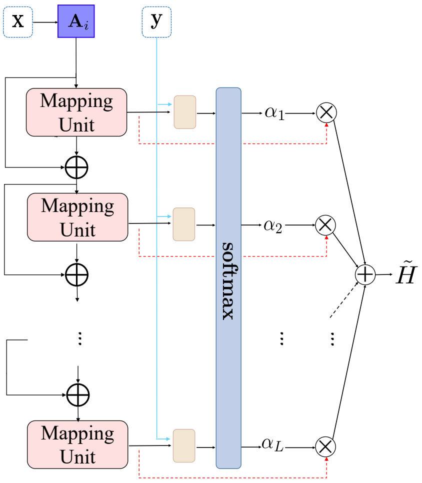

Figure 2: Overview of RMM model.

4.1 Type Enhanced Representation

Type information is essential for hypernym discovery. It implies different hypernym types that provide the hyponyms' attributes. Utilizing type information may increase the hypernym-discovery performance. Specifically, let $\mathbf{x} \in \mathbb{R}^{d\times 1}$ be the embedding of hyponym term x, for its type indexed by i, we introduce a projection $\mathbf{A}_i \in \mathbb{R}^{d\times d}$ to map the hyponym embedding as a type enhanced representation $\mathbf{t} \in \mathbb{R}^{d\times 1}$ as follows:

$$\mathbf{t} = \mathbf{A}_i \mathbf{x} \tag{1}$$

In this way, we provide appropriate additional model capacity to handle different types of hyponyms and simultaneously we can utilize all data with hyponyms that belong to both types to train our model.

4.2 Recurrent Mapping Module

One motivation of this paper is that we assume the candidate hypernym terms may come from different concept levels. The hypernym term at a higher concept-level can be obtained by transforming from a lower-level hypernym term. To model this transformation process, we build a recurrent mapping module with a shared projection function. Specifically, let $\mathbf{h}_l \in \mathbb{R}^{d\times 1}$ denote the transformed concept semantics at the l^{th} level (or the term representation after l-hop transformations). The transformation from a l^{th}-level concept semantics to a

$(l+1)^{\text{th}}$-level is then formulated as

$$\hat{\mathbf{h}}_{l+1} = \mathbf{W}_\phi \mathbf{h}_l \tag{2}$$

In Equation 2, the semantic representation of the primary concept level is exactly the type-enhanced representation, that is $\mathbf{h}_0 = \mathbf{t}$. $\mathbf{W}_\phi \in \mathbb{R}^{d \times d}$ is the learnable projection matrix which is shared during each transformation. We recurrently make L transformations from the original hyponym embedding. We hope this recurrent mapping process captures the relationships of different concept-levels and associates the given hyponym term with its hypernym terms at different concept levels.

Theoretically, when the number of layers increases in a neural network, its model capabilities become large and it should produce lower training error. However, the gradients may vanish after they are propagated through many layers, thus degrade the model performance (He et al., 2016). Consequently, optimizing the projection matrix in Equation 2 is difficult when the maximum number of transformations L becomes large. Following the previous work (He et al., 2016), we introduce residual network (ResNet) to overcome the gradient vanishing problem as follows:

$$\mathbf{h}_{l+1} = \hat{\mathbf{h}}_{l+1} + \mathbf{h}_l \tag{3}$$

ResNet improves the training efficiency by reformulating the $(l+1)^{\text{th}}$-level representation with reference to the l^{th}-level representation. In addition, the ResNet also forces the model to *remember* the past information during multi-hop transformation.

4.3 Aggregation Module

After obtaining the multi-hop representations of the given hyponym term, we obtain a final representation via letting multi-hop representations attend to the candidate embedding.

Concretely, by calculating dot product between representations from each hop and candidate hypernym, we can get a weight vector. The attention weight of a level is viewed as the probability of the candidate hypernym lying in that level. The weight vector and the final score of the candidate term embedding $\mathbf{y}$ being the input's hypernym are calculated as follows:

$$\begin{aligned} \alpha_l &= \frac{\exp(\mathbf{h}_l \cdot \mathbf{y})}{\sum\limits_{k=1}^{L} \exp(\mathbf{h}_k \cdot \mathbf{y})} \\ \widetilde{H} &= \sum_{l=1}^{L} \alpha_l \cdot \mathbf{h}_l \\ s_y &= \widetilde{H} \cdot \mathbf{y} \end{aligned} \tag{4}$$

This mechanism allows the model to adaptively assign weights for representations from each hop based on the candidate terms. We expect this aggregation strategy to provide appropriate scores that correctly rank the true hypernym terms ahead of other candidate terms.

4.4 Loss Function

Hypernymy discovery is viewed as a ranking problem. Existing models optimize this ranking problem using a pair-wise loss function. They first score the candidate hypernym terms by training a binary classifier that identifies whether a given (x, y) pair supports a hypernymy relation, then rank the candidates by descending order of their matching scores. Although pair-wise loss function is efficient, it learns to score each candidate independently (Shi and Weninger, 2017). Instead of optimizing the model via pairwise loss, we introduce the list-wise loss function that learns to score the candidates collectively.

Let $\mathcal{X}_{train}$ be the set of hyponym terms in the training set. For each hyponym term x in the training set, let $\mathcal{Q}_x$ denote a set of candidate hypernyms, which consists of only gold hypernym terms of x, and $\mathcal{C}_x$ denotes a controllable number of negative candidates. Then we compute the cross-entropy loss with the sampled positive and negative candidates as follows:

$$\mathcal{L} = -\sum_{x \in \mathcal{X}_{train}} \frac{1}{|\mathcal{Q}_x|} \sum_{y \in \mathcal{Q}_x} \log \frac{\exp(s_y)}{\sum_{y' \in \mathcal{Q}_x \cup \mathcal{C}_x} \exp(s_{y'})} \tag{5}$$

where $\frac{1}{|\mathcal{Q}_x|}$ is a normalizing term that balances the learning of all gold candidate scores. The number of negative candidates $|\mathcal{C}_x|$ is optional in practice, we leave it as a hyperparameter. We may set $\mathcal{C}_x = \mathcal{Y} - \mathcal{Q}_x$ with enough computation source available. In this way, we simultaneously optimize the scores for a collection of candidates, improving the training efficiency.

5 Experiments

5.1 Data Sets

We evaluate the performance of our model on SemEval-2018 Task 9 [1]benchmark for hypernym discovery. This shared task consists of five different subtasks covering both general-purpose (multiple languages-English, Italian, and Spanish) and domain-specific (Music and Medicine domains) tasks. For each subtask, a large textual corpus, a vocabulary including all valid hypernyms and a training and testing set of hyponyms and its gold hypernyms are provided. In this paper, we consider the three English subtasks: 1A (general), 2A (medical) and 2B (music). The summarized statistics of the datasets are shown in Table 1. For more details, we refer the reader to the original SemEval-2018 Task 9 (Camacho-Collados et al., 2018) paper.

subtask	corpus size	#train	#test
1A	16G	1500	1500
2A	800M	500	500
2B	500M	500	500

Table 1: Data set statistics

Three metrics were used for the performance evaluation.

Mean Average Precision (MAP) For a given query word, average precision(AP) is the average of the correctness of each obtained hypernym from the search space. MAP is the mean of this value among all queries in the data set.

Mean Reciprocal Rank (MRR) Since MAP ignores the exact rank of the true hypernyms, we introduce the Mean Reciprocal Rank (MRR) metric which focuses on the top results performance. Mean Reciprocal Rank (MRR) is the average of the reciprocal ranks over all queries. The reciprocal rank of an individual query is the reciprocal of the rank in which the first true hypernym is returned.

Precision at K (P@K) Precision at K is the proportion of the top-K results that are true hypernyms of a given query.

Following the same evaluation procedures as previous studies (Bernier-Colborne and Barriere, 2018; Held and Habash, 2019b; Dash et al., 2020), the scorer script provided by SemEval-2018 Task 9 is exploited for evaluating our proposed model and comparing fairly with other recent models.

5.1.1 Compared Models

We compare our model with baseline models: MFH (Camacho-Collados et al., 2018), vTE (Camacho-Collados et al., 2018), 300-sparsans(Berend et al., 2018), and NLP-HZ (Qiu et al., 2018). 8 SPON (Dash et al., 2020), Hybrid of SVD & NN (Held and Habash, 2019b).

Besides, we also compare our model with recent models. Brief descriptions of these models are given as follows.

CRIM (Bernier-Colborne and Barriere, 2018) In the CRIM model, multiple parallel projections are introduced to map the queries to different spaces. A logistic regression function is then applied to compute the final score. In addition, this module is combined with an unsupervised system that identifies hypernym based on specific Hearst-style patterns. The final output of CRIM is the combination of both supervised and unsupervised models.

SPON (Dash et al., 2020) In the SPON model, non-negative activations and residual connections are exploited to enforce asymmetry and transitive as soft constraints.

Hybrid of SVD & NN (Held and Habash, 2019b) This model is a hybrid system which exploits both unsupervised and supervised approaches at the same time.

In their proposed supervised module, the nearest neighbor approach is used. Given a hyponym, candidate hypernyms which are its nearest neighbors are returned. A similarity cut-off point is trained on tuning data, such that if there is no neighbor with a similarity greater than the cutoff point, the model simply returns the most frequent set of hypernyms from the entire training set.

5.2 Implementation

We trained 200-dimensional word embeddings via the standard skip-gram word2vec algorithm (Mikolov et al., 2013) on the provided textual corpus. The representations of the hyponyms and hypernyms are directly initialized by the pre-trained word2vec embeddings. In the training process of our model, hyponym embeddings are fixed and hypernym embeddings are learnable. To avoid overfitting, dropout is applied after each mapping function. Besides, an early stop strategy is also used. Thus, if MAP on the validation set does not

Table 2: Performance comparison on different models on the benchmark datasets. In the first column, Hybrid denotes the Hybrid of SVD/NN model and Sparsans represents the 300-sparsans model. The results of RMM are average from 3 runs of experiments. Other reported results are from their corresponding original paper.

increase after 200 continuous epochs, training will be terminated. The max epoch is set to 1000. In addition, gradient clipping is used in the weight updating process, with a clip of $1e^{-4}$. We use the Adam optimizer with beta1=beta2=0.9 and with a learning rate of $2e^{-4}$ for all datasets. We choose two separate embedding transformation matrices for two different query types. When initializing these projection matrices in the mapping function, we add random noises of Gaussian distribution (zero mean and $\frac{1}{200}$ variance) to an identity matrix. Finally, we implement our model using PyTorch on a Linux machine with a GPU device Tesla V100 SXM2 32GB.

5.3 Results

5.3.1 Overall Results

Table 2 shows the MAP, MRR and P@5 performance of our model and the other baseline models across multiple hypernym discovery sub-tasks. The value of L is tuned over the validation set, we used L=2 for subtask 1A and L=3 for 2A and 2B. Note that, to avoid the performance randomness, the performance of our model is the average of three random runs. For the other compared models, the reported performance is taken from their original paper. The values printed in **bold** font are the top-performing models in the comparison.

In the table, it is clear that our recurrent mapping model (RMM) outperforms almost all existing baseline models on all the general English hypernym discovery tasks. More specifically, on all sub-tasks, RMM outperforms any supervised hypernym discovery models on all metrics. The only model that RMM does not fully beat is the Hybrid of SVD/NN model, which uses both unsupervised and supervised approaches. We note however that RMM scores best 6 out of the 9 metrics across the compared methods.

In addition, RMM outperforms the most recent supervised models, i.e. CRIM and SPOM by a significant margin. This performance suggests that the true hypernym rank is generally higher than other candidate words using RMM.

Figure 3: The comparison of RMM with different mapping units. In each sub-figure, x axis represents the number of mapping units and the y axis represents the performance of the corresponding model. The results reported is an average of three experiments.

5.3.2 The Impact of the Number of Mapping Units

We now examine the impact of the chosen number of mappings on RMM. In our recurrent mapping process, we use mapping functions from a specific term to a more general term it belongs to. The number of mappings can be understood as the number of projections from the original query. Thus, this value is a hyper-parameter in RMM. We let L denote the number of mapping units.

As discussed above, we speculate that the correct hypernym might be chosen by different mapping units (MU). Here we present experimental results to support this claim and show how this value affects the performance of RMM. We vary L from 1 to 4 to observe the performance. The experimental results are shown in Figure 3. Note that all values in the figure are the average over three runs.

The results indicate that RMM is sensitive to L. RMM shows a general increasing performance when increasing L. This might be due to that the hypernym semantics transformation is captured by our model. We find that RMM performs best at $L = 3$ for 2A, 2B and $L = 2$ for 1A. This phenomenon is consistent with the typical hypernymy transformation situation in the data set. We observe that, in general, the true hypernym list is often in the form of a two or three layers hierarchical structure. Here we list two examples of the hierarchical structure: `guitar` → `stringed instrument`→ `musical instrument`; `alternative rock`→ `rock music`→ `music` → `music style`. So that RMM will be effective when choosing L as 2 or 3.

It also can be noted that when choosing $L = 4$, RMM achieves a lower performance on all data sets. This result confirms our claim and shows the effectiveness of the sequential structure exploited in RMM.

5.3.3 Ablation Study

To more precisely evaluate RMM and to comprehensively analyze the contribution of each component of our model, we conduct an additional experiment of ablation studies.

Specifically, this experiment involves three components, ResNet connection between mapping units, separate transformation function for query type and the attention mechanism to identify the importance of mapping units. By removing or modifying each of them individually, we are able to observe their effects on our model.

The experiment was performed on the same datasets along with the same experimental setup and hyperparameters as in the main experiment.

Without Residual Mechanism RMM uses a residual mechanism to overcome the gradient vanishing problem and to improve the model performance. In this ablation setup, we directly remove this ResNet connection and refer to this setup as $\text{RMM}_{\text{w/o ResNet}}$.

Without Separating Query Types Before multi-hop mapping, RMM model exploits two different learnable projection matrices for query types of `entity` and `concept` to transform original embedding to "is-a" embedding. In this ablation experiment, we unify these two projection matrices and refer to this setup as $\text{RMM}_{\text{w/o QType}}$. It's worth noting that hyponyms in 2A(music) are all of concept type, thus unifying these two projection matrices can get a close performance as before.

Without Attention Mechanism RMM model makes use of an attention mechanism to aggregate hypernym representations from all mapping units according to candidate hypernyms. In this ablation experiment, to verify its contribution, we remove this weighting mechanism and instead use a mean approach, which simply averages the representations of the output of each unit to aggregate semantics from all mapping units. We refer to this setup as $\text{RMM}_{\text{w/o Att}}$.

Table 3 shows the result of our ablation study. It shows that all components are critical for RMM. Specifically, we can see that removing ResNet degrades the model performance, which proves ResNet can avoid the information loss between units. Without using the query type, model performance degrades as well. It's notable that CRIM (Bernier-Colborne and Barriere, 2018) also utilized the type information of hypernyms by training separate logistic regression classifiers for different types of hyponyms. However, their ablation study suggests that their type modeling actually degrades the model performance which is contrary to the results shown in our ablation study. It indicates that the type information is better modeled in our model. From the last raw of Table 3, we can conclude that taking the average of each mapping unit's output decreases the model performance.

Model	1A			2A			2B		
	MAP	MRR	P@5	MAP	MRR	P@5	MAP	MRR	P@5
RMM	27.12	39.07	23.41	38.56	54.89	37.17	63.86	74.75	61.61
$\text{RMM}_{\text{w/o ResNet}}$	25.78	37.08	22.41	35.80	55.65	34.52	62.39	74.38	60.21

(c) Case 3 from 2B (d) Case 4 from 2B

Figure 4: Case Studies. The values in the bracket represent the weights on the first, the second and the third mapping units filtered by hypernym.

5.3.4 Case Study

In this subsection, we present a detailed result analysis on 4 randomly chosen cases from our testing sets, with the aim to validate our motivation of the recursive structure of RMM being capable of capturing the near hypernym first and far hypernym later. We observe the weights on different units and wish to examine if RMM indeed assigns higher weights to relative-lower units when the true hypernym is near the query word and vice versa. The results are shown in Figure 4.

From the figure we can observe that RMM is able to assign a higher weight to the first mapping units for its first hop hypernym. This is seen in all 4 cases by assigning a weight more than 0.9 to the first unit for their immediate hypernym. For example, in Figure 4(a) the hypernym `Politician` for query `Bill Clinton`. On the contrary, for a far hypernym of a query, a higher weight is on the last mapping units. For example, in Figure 4(c), the hypernym `Music Genre` for query `Latin Pop`, a higher weight is on the third units.

This result confirms the capability of RMM in capturing the latent hypernymy transformation and hierarchical dependencies between hypernyms.

6 Conclusion

Hypernym discovery is a basic task in natural language processing. Existing studies focus on designing better models for discovering better mapping functions from hyponyms to hypernyms. However, the latent semantic transformation between the hypernyms of one hyponym is not considered. In this study, both the mapping and the semantic transformation between hypernyms are considered by a recursive mapping model. In addition, with the attention mechanism, different levels of transformations are softly mixed in the final representation for the final classification task. Empirical studies on a public hypernym discovery task verify the superiority of the presented recursive model.

This study is a first attempt on modeling the transformation between hypernyms and we only achieve preliminary progress. The better usage of this will definitely promote the effectiveness of hypernym discovery. In practice, this transformation can be extracted and graph convolutional network (GCN) or other neural networks can be exploited for explicitly this information. Also, the combination of unsupervised and supervised models has shown advantages. However, most of these hybrid models are two separate processes and the supervised part highly depends on the pre-defined "is A" patterns. To build a uniform hybrid model still remains an open problem. We will study these open problems in our future work.

Abstract

Prior studies on event knowledge in sentence comprehension have shown that the aspect of the main verb plays an important role in the processing of non-core semantic roles, such as locations: when the aspect of the main verb is imperfective, locations become more salient in the mental representation of the event and are easier for human comprehenders to process.

In our study, we tested the popular language model BERT on two datasets derived from experimental studies to determine whether BERT's predictions of prototypical event locations were also influenced by aspect. We found that, although BERT efficiently modelled the typicality of locations, it did so independently of the verb aspect. Even when the transformer was forced to focus on the verb phrase by masking the context words in the sentence, the typicality predictions were still accurate; in addition, we found aspect to have a stronger influence on the scores, with locations in the imperfective setting being associated with lower surprisal values.

1 Introduction

It has been generally acknowledged in sentence processing research that humans activate generalized event knowledge in the process of understanding natural language sentences (McRae and Matsuki, 2009). Reading/listening verbs (e.g., *open*) activate expectations about their typical arguments (e.g., *door*) (McRae et al., 1998; Ferretti et al., 2001) and vice versa (McRae et al., 2005); the same effect has been found for nouns and their typical co-arguments (Hare et al., 2009). These expectations concerning typical arguments are encoded in the mental lexicon, and are exploited by humans to evaluate the plausibility of verb-argument combinations. Such knowledge is used during sentence processing to generate predictions about upcoming arguments: using different experimental paradigms (e.g. EEG, eye-tracking etc.), previous studies provided evidence that sentences including typical argument combinations are easier for humans to process (Bicknell et al., 2010; Matsuki et al., 2011).

Other studies have investigated the role played by *verb aspect* in event knowledge activation, particularly for non-core roles such as *locations* and *instruments*. Aspect is a grammatical device that denotes the duration, onset, and completion status of an event. According to linguistic theory, a fundamental opposition exists between the *imperfective* aspect (e.g., *The customer was eating in the restaurant*), which describes the event as on-going, and the *perfective* aspect (e.g., *The customer had eaten in the restaurant*), which describes the event as a closed unit and focuses on the resulting state (Madden and Zwaan, 2003).

Based on the above-mentioned literature, Ferretti et al. (2007) used stimulus-onset asynchrony priming and the EEG paradigms to show that, in English, specific expectations were activated for event locations by the verbs describing those events, but only when the verbs were in the imperfective form. Similar findings have been reported for instruments by Truitt and Zwaan (1997) and, more recently, by Madden-Lombardi et al. (2017) in a self-paced reading experiment in French. In line with these findings, Coll-Florit and Gennari (2011) found that imperfective verbs were related to a wider range of semantic associations than perfective ones, because the mental representation of an event as on-going allows one to focus more easily on all the entities that are relevant to the described action (instruments, places, objects, etc.).

In this study, we modelled two datasets on locations using BERT, a state-of-the-art language model (Devlin et al., 2019), and we tested whether verb aspect influenced the model's predictions for upcoming event's locations, by comparing them

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2922–2929
August 1–6, 2021.

in terms of perfective and imperfective sentences. We found that i) BERT was able to accurately identify typical locations for an event, and that it did so independently of the aspect of the main verb, since the activation levels of locations did not differ significantly across conditions; ii) even when the transformer was forced to focus on the main verb and the other words in the sentence were masked, BERT's typicality predictions were still accurate, and an additional effect of aspect appeared, with locations having significantly lower surprisal values in the imperfective condition.

2 Related Work

Transformer models have become increasingly popular in NLP in recent years (Vaswani et al., 2017; Devlin et al., 2019). The most successful model is probably BERT, which is trained on a *masked language modeling* objective: given the left and the right context of a masked word in a natural language sentence, the model has to predict the word. This conceptually simple yet powerful mechanism has made BERT a very appealing option for NLP researchers working on supervised tasks, and its contextualized representations have taken state-of-the-art performances to new heights.

A number of psycholinguistic-inspired studies designed tests to investigate the actual linguistic abilities of neural network models, including Transformer models. Most of these studies have focused on syntactic phenomena, such as verb-subject agreement and filler-gap dependencies (Linzen et al., 2016; Wilcox et al., 2018; Gulordava et al., 2018; Futrell et al., 2019; Prasad et al., 2019). By contrast, Ettinger (2020) focused on the semantic and pragmatic abilities of the BERT language model by using stimuli from the N400 experiments conducted by Kutas and Hillyard (1984), and showed that the model was strong in associating nouns with their hypernyms, but struggled to handle negations. Close to the spirit of our contribution, Misra et al. (2020) investigated BERT's predictions in a setting aimed at reproducing human semantic priming; they reported that BERT was indeed sensitive to "priming" and predicted a word with higher probability when the context included a related word as opposed to an unrelated one, but this effect decreased in the presence of strongly informative and constraining contexts.

Recent work by Metheniti et al. (2020) has explored the capacity of BERT to reproduce the selectional preferences for verbs - which, from our perspective, was equivalent to modeling the thematic fit of typical event participants (Sayeed et al., 2016; Santus et al., 2017; Chersoni et al., 2020; Marton and Sayeed, 2021). Metheniti and colleagues reported that the correlation of the predictions with human judgements increased when they applied attention masks to the context words in the sentence and forced the model to focus only on the verbs. Finally, Transformers have been used to model typicality effects in language by Misra et al. (2021), although in a different context; i.e. the influence of typicality on category membership judgements.

To the best of our knowledge, the current study is the first to attempt to model argument typicality predictions with BERT for a non-core role (location), and the first to investigate whether and how such predictions are influenced by verb aspect, as in the case in human language processing.

3 Experiments

3.1 Datasets

In our work, we used two datasets that we obtained from the previous studies. The first dataset, which we refer to as **Ferretti07**, consists of the experimental items used by Ferretti et al. (2007) in their EEG experiment. The authors made available a subset of 38 items in which the verb phrase was specifically biased to be followed by a locative prepositional phrase in sentence completion tasks. We excluded 6 of them, in which the location noun was extremely rare and was not included in BERT's basic vocabulary[1]. Each item consisted of an intransitive sentence, with the verb phrase in either the past perfect tense (perfective condition, $PERF$) or the progressive past tense (imperfective condition, $IMPERF$), and a location argument, either typical (TYP) or less typical but still plausible (NON_TYP) (see Example 1).

(1) a. The boy had fished at the lake. $(PERF, TYP)$
b. The boy was fishing at the lake. $(IMPERF, TYP)$
c. The boy had fished at the swamp. $(PERF, NON\_TYP)$
d. The boy was fishing at the swamp. $(IMPERF, NON\_TYP)$

---

[1] In such cases, the location nouns would be split by the BERT tokenizer.

Interestingly, Ferretti et al. (2007) found that atypical locations elicited significantly larger N400 amplitudes in the imperfective condition, but there were no significant differences in the perfective one, suggesting that the differences in location typicality become salient only when the event is being described as on-going. Typical locations elicited smaller N400 amplitudes, while aspect was found to have no main effect *per se*, being significant only in the interaction with typicality.

We generated another dataset, which we refer to as **Ferretti01**, by using the typicality judgements dataset created by Ferretti et al. (2001). From their data, we extracted all the verb-argument pairs for which the mean typicality rating was $>= 4$ on a Likert scale, for a total of 135 pairs, and asked two PhD students in Linguistics who were proficient English speakers, to use the same pairs to generate complete English sentences with a structure similar to the items in **Ferretti07**. A third PhD student, a native speaker of British English, made the final check of the correctness of the sentences. [2] Each item in **Ferretti01** came in the $PERF$ vs. $IMPERF$ condition (see Example 2).

(2) a. He had danced in the ballroom. ($PERF$)
b. He was dancing in the ballroom ($IMPERF$)

3.2 Model and Settings

Similarly to Misra et al. (2020), we considered the surprisal score for an argument word (in our case, the location) as a measure of the model's expectations in the given context; we replaced the location token at the end of each sentence with a *[MASK]* and we asked BERT to predict its probability.

Surprisal was shown to be an efficient predictor of self-paced reading times (Hale, 2001; Levy, 2008; Smith and Levy, 2013) and of the N400 amplitude (Frank et al., 2013), and we expected it to be inversely correlated with typicality: the more typical a location in a given context is, the less surprising it will be.

To approximate the results of the original study by Ferretti et al. (2007), BERT's surprisal scores for the locations would have to show an interaction between aspect and typicality, with the scores being significantly higher for atypical fillers only in the imperfective condition. Moreover, typical fillers should be assigned lower surprisal scores.

We experimented with the *bert-base-uncased* model, as implemented in the HuggingFace's Transformers library (Wolf et al., 2019). [3] For each sentence, we masked the location loc, corresponding to the last token in the sentence (e.g., *The girl was skating in the [MASK]*), and computed its Surprisal score $Surp$ in the context C as:

$$Surp(loc|C) = -logP(loc|C) \tag{1}$$

where $P(loc|C)$ is the probability computed by the softmax layer of BERT for the loc word as the masked token in the sentence context C.

Finally, we experimented with two different settings: a *standard* setting, in which BERT was able to see the entire context of the sentence, and a *context mask* setting, in which we used an **attention mask** on all the sentence tokens except for the verb phrase ones (see Example 3).

(3) a. The boy was fishing at the *[MASK]* (*standard*)
b. ~~The boy~~ was fishing ~~at the~~ *[MASK]* (*context mask*)

In this setting, we blocked BERT's self-attention mechanism, forcing it to use only the verb phrase to predict the masked token. In this way, we were able to analyze the effect of the tense without the interference of the other context words. [4]

4 Results and Analysis

We ran all the comparisons between scores using linear mixed effects models with the LMER function in the R statistical software (see also Appendix B for the full results). We first compared the surprisal scores that we obtained in the standard setting, in which BERT had access to all the tokens in the sentence. No main effect of aspect was found ($p > 0.1$), neither in the **Ferretti01** nor in the **Ferretti07** dataset. In other words, verb aspect did not seem to have an influence on the activation degree of typical location fillers, as the scores in the two conditions were essentially equivalent.

On the other hand, BERT's predictions for the typicality of the location fillers seemed to be extremely accurate. In the **Ferretti07** dataset, a

---

[2] More details on the dataset creation are in Appendix A.

[3] `github.com/huggingface/transformers`

[4] A similar setting was proposed by Metheniti et al. (2020) for modeling human judgements on selectional preferences: with the context mask, the authors found increased correlation between model predictions and human ratings.

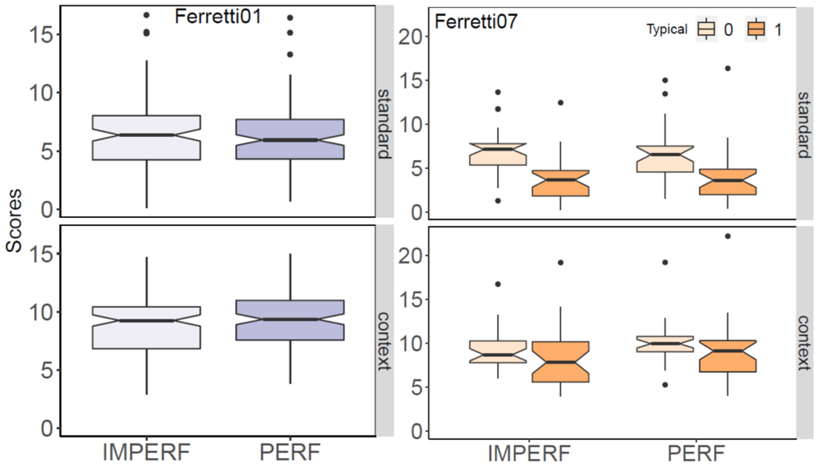

Figure 1: Boxplots with the surprisal scores calculated on the **Ferretti01** dataset (left) and on the **Ferretti07** dataset (right), in the standard setting (above) and in the context mask setting (below).

main effect of typicality was found ($p < 0.001$), with TYP sentences showing significantly lower Surprisal scores in the TYP condition than the NON_TYP ones (see also the boxplots in Figure 1, on the right). The interaction of aspect and typicality, however, was not significant ($p > 0.1$). Note that the NON_TYP locations were selected by Ferretti et al. (2007) in order to be plausible, and thus it is interesting that BERT correctly identified the ones of the TYP sentences as being more typical. However, the verb aspect did not play a role in this, since this ability was not influenced by the aspect condition. As a possible explanation, Klafka and Ettinger (2020) recently showed how the semantic information about the animacy of an argument noun in BERT was spread over the tokens of a sentence, and the same might be true also for the semantic information about the typicality of a location in a given event context. Pairwise comparisons confirmed that TYP sentences obtained significantly lower scores for both the $PERF$ and $IMPERF$ conditions ($p < 0.001$), while no significant difference between $PERF$ and $IMPERF$ in typicality condition was found. We then repeated the experiments using the context mask to block BERT's attention mechanism for all the words in the sentence except for the verb phrase tokens (recall Example 3b.) and we observed some interesting changes in our results. On the one hand, in the **Ferretti01** dataset, we observed a marginally significant effect of aspect ($p < 0.1$), with lower surprisal scores for the $IMPERF$ condition. On the other hand, in the **Ferretti07** dataset, we found main effects for *both* typicality ($p < 0.01$) and aspect ($p < 0.05$), while the interaction was again not significant ($p > 0.1$). Pairwise comparisons, similarly to the standard setting, revealed that TYP sentences had significantly lower scores for both the $PERF$ ($p < 0.05$) and the $IMPERF$ conditions ($p < 0.01$). Moreover, TYP sentences differed between $PERF$ and $IMPERF$ conditions, with the latter having significantly lower scores ($p < 0.05$). Finally, even NON_TYP sentences had lower surprisal scores in the $IMPERF$ condition, but the difference was only marginally significant ($p < 0.1$).

It should be noted that, in both settings, our results differed from those of Ferretti et al. (2007), as their study found no main effect of aspect and an interaction between aspect and typicality: atypical locations elicited significantly larger N400 components only in the imperfective condition, suggesting that imperfective verbs lead to very specific expectations on upcoming locations in human sentence processing, while expectations are way less defined with perfective verbs. By contrast, our results in the standard setting showed that BERT accurately modelled the typicality of locations without relying on the aspect of the verb, while in the context mask setting aspect influenced the predictions independently of typicality.

Finally, we checked the degree to which the typicality predictions of the model were influenced by the lexical frequencies of the target location words, which we extracted from a 2019 Wikipedia dump. [5] We found that the Surprisal scores in the **Ferretti07** dataset were not correlated at all in the standard setting, with a Spearman correlation of $\rho = -0.04$,

---

[5] `https://github.com/IlyaSemenov/wikipedia-word-frequency`.

while a weak but significant inverse correlation existed for the context mask setting at $\rho = -0.28$. This suggests that BERT's predictions are not influenced by word frequency when the entire context is available. However, when the number of contextual cues was reduced in the context mask setting, frequency might have played a more prominent role. From this point of view, it is interesting to observe the "errors" of the model: Example 4 shows the only four sentence pairs in which, in both the standard and the context mask settings, a lower score was assigned to a NON_TYP filler. Interestingly, in cases *a-c*, BERT assigns a lower Surprisal score to a more generic and frequent filler than the TYP one, which is more specific for the described event scenario. As for *d*, it can be observed that the two candidate locations (*desert-hole*) had very similar plausibility levels.

(4) a. The girl was skating/had skated in the rink (TYP) / ring (NON_TYP).
    b. The boy was tobogganing/had tobogganed down the hill (TYP) / street (NON_TYP).
    c. The tourist was browsing/had browsed in the shop (TYP) / park (NON_TYP).
    d. The snake was slithering/had slithered in the desert (TYP) / hole (NON_TYP).

The tendency of masked language models to select a generic and frequent word when faced with the alternative of a more specific and typical filler for the event scenario was also reported by Rambelli et al. (2020) in a logical metonymy interpretation task, e.g., when asked to predict a verb for the masked position in a sentence like *The auditor begins [MASK] the taxes*, they chose generic verbs like *doing* instead of more specific ones like *auditing*, which should be preferred in the given context.

5 Conclusions

In this study, we tested whether BERT exhibited aspect-related activation effects for event locations, and whether different degrees of location typicality were identified more easily in sentences in the imperfective aspect. Verb aspect, as shown in previous studies (Ferretti et al., 2007; Madden-Lombardi et al., 2017), plays an important role in the mental representation of an event; in particular, the imperfective aspect is related to the simulation of an on-going event, giving more saliency to all the entities involved, such as the event location.

Our results showed that BERT was able to identify typical locations for events, even when it had to differentiate them from plausible but less typical ones. However, the semantic information exploited by the Transformer for the task was not linked to the verb tense, as there were no differences found between the $PERF$ and the $IMPERF$ sets. In general, no aspect-related effects on the activation of event locations were observed.

Verb aspect played a role only when the Transformer was forced to focus on the verb phrase in the context mask setting. On the one hand, BERT was still able to distinguish between typical and non-typical locations. On the other hand, the imperfective aspect was associated with significantly lower Surprisal scores for both typicality conditions. Aspect did not interact with typicality: in particular, BERT did not predict the pattern observed in Ferretti et al. (2007)'s experimental study, for which specific expectations for event locations emerge only in processing imperfective sentences.

We take these results as preliminary evidence that BERT's predictions were somewhat sensitive to aspect-related differences, and could reflect some subtle nuances of argument typicality. Our implementation is available at a public repository.[6]

Acknowledgments

We thank Lei Siyu, Chen Jing and James Britton for their help in preparing the experimental materials, and the anonymous reviewers for their feedback.

Impact Statement

Our paper is the first to study the role of verb aspect in BERT predictions on upcoming arguments. Using locations as a case study, and through a comparison with the results of the experimental studies, we showed that BERT was able to discriminate between different degrees of typicality in context. Additionally, when less cues were available from the context, aspect had an important effect on the predictions, with imperfective verbs being associated with lower surprisal values for locations. We hope that our study has shed light on new research directions to investigate the interface of grammar and event knowledge using modern Transformer-based masked language models.

A Appendix A

The dataset by Ferretti et al. (2001) includes mean typicality ratings for 277 verb-location pairs on a Likert scale from 1 to 7, where 7 is the highest possible score (see examples in Table 1). The judgements were collected by asking to human subjects the following: *On a scale from 1 to 7, how common it is to* ***verb*** *in a* ***location****?*

Verb	**Location**	**Mean Rating**
gamble	casino	7.0
study	bedroom	5.8
marry	island	3.7
fish	pool	1.0

Table 1: Examples of the typicality judgements from the dataset by Ferretti et al. (2001). Scores range from 1 = not typical at all to 7 = very typical.

Two PhD students in Linguistics, both advanced speakers of English, voluntarily helped us in using these ratings to build the sentences of the **Ferretti01** dataset. First, we selected as typical only the verb-location pairs with a mean score $>= 4$.

Then, for each pair, we added a preposition that could be used to introduce the location in a prepositional complement. Each student took care of half of the pairs in the dataset, and then they revised each other's work. Since for this dataset we wanted BERT to compute the Surprisal scores for several candidate location fillers, the students tried to use prepositions that, given a verb, could go well with all its potential fillers in the dataset. Fillers that would have been much more likely than others given a verb-preposition pair were discarded from the dataset.

If the verb was strictly transitive, the students added a typical object, the first that came into their mind. In the end, we generated the final sentences of the dataset by randomly appending a personal pronoun subject (*He* or *She*), and we generated the sentence pairs for the two condition by varying the form of the verb: progressive past tense for the $IMPERF$ condition, past perfect tense for the $PERF$ condition.

Finally, another PhD student in Linguistics, native speaker of British English, checked that all the sentences were correct and plausible in English.

Abstract

A myriad of explainability methods have been proposed in recent years, but there is little consensus on how to evaluate them. While automatic metrics allow for quick benchmarking, it isn't clear how such metrics reflect human interaction with explanations. Human evaluation is of paramount importance, but previous protocols fail to account for *belief biases* affecting human performance, which may lead to misleading conclusions. We provide an overview of belief bias, its role in human evaluation, and ideas for NLP practitioners on how to account for it. For two experimental paradigms, we present a case study of gradient-based explainability introducing simple ways to account for humans' prior beliefs: models of varying quality and adversarial examples. We show that *conclusions about the highest performing methods change when introducing such controls*, pointing to the importance of accounting for belief bias in evaluation.

1 Introduction

Machine learning has become an integral part of our lives; from everyday use (e.g., search, translation, recommendations) to high-stake applications in healthcare, law, or transportation. However, its impact is controversial: neural models have been shown to make confident predictions relying on artifacts (McCoy et al., 2019; Wallace et al., 2019) and have shown to encode and amplify negative social biases (Manzini et al., 2019; Caliskan et al., 2017; May et al., 2019; Tan and Celis, 2019; González et al., 2020; Rudinger et al., 2018).

Explainability aims to make model decisions transparent and predictable to humans; it serves as a tool for model diagnosis, detecting failure modes and biases, and more generally, to increase trust by providing transparency (Amershi et al., 2019). While automatic metrics have been proposed to evaluate various properties of explanations such as faithfulness, consistency and agreement with human explanations (Atanasova et al., 2020; Robnik-Šikonja and Bohanec, 2018; DeYoung et al., 2020), these metrics do not inform us about human interaction with explanations.

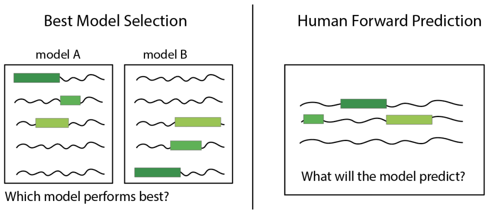

Figure 1: Evaluation protocols considered in this work

Doshi-Velez and Kim (2017) suggested *human forward prediction*, a simulation task in which humans are given an input and an explanation, and their task is to predict the expected model output, regardless of the gold answer. Recent studies include Nguyen (2018); Lage et al. (2019); **?**); Poursabzi-Sangdeh et al. (2021). Such protocols are widely used and can provide valuable insight into human understanding of explanations. However, prior work has not accounted for how humans' prior beliefs (*belief biases*) interact with the evaluation; simulating model decisions becomes an easier task when the model being evaluated makes predictions which align with human expectations. We argue that not considering belief bias in such protocols *may lead to misleading conclusions about which explainability methods perform best.*

Other protocols have evaluated participant's ability to select the best model based on explanations offered by different interpretability methods (e.g. decide which model would generalize 'in the wild') (Ribeiro et al., 2016a). However, comparisons have been made between a model which is clearly in line with human beliefs, and another which exploits spurious correlations diverging from human expec-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2930–2942

tations. When differences are less obvious, humans may not be able to leverage their belief biases, and conclusions may change.

This paper, which includes evaluations for both of the previously mentioned tasks, closes an important gap: to the best of our knowledge, no prior work in NLP addresses the interaction of belief bias with current human evaluations of explainability.

Contributions. We provide an overview of belief bias meant to highlight its role in human evaluation and provide some preliminary ideas for NLP practitioners on how to handle such cases. Using *human forward prediction* and *best model selection* (Figure 1), we present a case-study where we compare two gradient-based explainability methods in the context of reading comprehension (RC), introducing conditions to take into account belief bias. We find that both explainability methods are helpful to participants in the standard settings (in line with most previous work), but the *conclusions about the best performing models change when incorporating additional control conditions*, reinforcing the importance of accounting for such biases.

2 Belief Bias

Belief bias is a type of cognitive bias, defined in psychology as *the systematic (non-logical) tendency to evaluate a statement on the basis of prior belief rather than its logical strength* (Evans et al., 1983; Klauer et al., 2000; Barston, 1986). Cognitive biases are not necessarily bad; they help us filter and process a great deal of information (Bierema et al., 2020), and have been widely studied in real human-decision making (Tversky and Kahneman, 1974; Kahneman, 2003; Furnham and Boo, 2011). However, in evaluations involving human participants, such biases may alter results and affect conclusions (Anderson and Hartzler, 2014; Wall et al., 2017).

Classic psychology studies of belief bias have assessed how prior beliefs affect syllogistic reasoning (Newstead et al., 1992; Klauer et al., 2000; Evans et al., 1983; Markovits and Nantel, 1989; Evans and BT). Consider the following example by Anderson and Hartzler (2014):

(a) *If all birds are animals, and if no animals can fly, then no birds can fly.*
(b) *If all cats are animals, and if no animals can fly, then no cats can fly.*

In syllogistic reasoning, the task for humans is to assess the *logical* validity of such arguments while ignoring believability. While both arguments are logically valid, most work converges on the finding that humans will rate argument (a) as invalid more often than (b), biased by the fact that the premise in (a) is less believable.

In psychology, belief bias has been tied to the *dual-processing* theory, which assumes that reasoning is performed by two competing cognitive systems: (1) *system 1* which takes care of fast, heuristic processes and (2) *system 2* which handles slower, more analytical processes (Evans, 2003; Trippas and Handley, 2018; Evans and Curtis-Holmes, 2005; Croskerry, 2009). Generally, humans tend to have a cognitive preference for relying on fast, intuitive *system 1* processes, rather than engaging in the slow and more analytical *system 2* processes. Belief bias is attributed to system 1 (Evans and Curtis-Holmes, 2005; Evans, 2008; Evans and Frankish, 2009; Stanovich and West, 2008) due to several factors, reviewed in detail by Evans (2003); Caravona et al. (2019).

For the purposes of NLP studies relying on crowd workers, one relevant finding is that **time pressures exacerbate reliance on previous beliefs** (Evans and Curtis-Holmes, 2005). Since crowd workers generally are incentivized to work as quickly as possible to maximize their hourly pay, reliance on belief bias is to be expected.

Another relevant finding for NLP is that threatening or negatively charged arguments (e.g. content violating political correctness and social norms) leads to greater engagement of system 2, whereas **neutral content leads to increased reliance on belief bias** (Goel and Vartanian, 2011; Klaczynski et al., 1997). Since NLP studies tend to be performed on neutral content such as passages from Wikipedia – content which may not sufficiently engage participants' system 2 processes – belief bias is more likely to play a role in human performance.

This study aims to highlight the phenomenon of belief bias to encourage NLP practitioners to assess the role it plays in their evaluations, and introduce mechanisms to account for belief bias effects. We illustrate how belief bias effects can significantly affect the results of human evaluation of explainability for two paradigms: *human forward prediction* and *best model selection*.

3 Related Work

Human forward prediction. Human forward prediction experiments have been recently presented in the context of synthetic data (Poursabzi-Sangdeh et al., 2021; Lage et al., 2019; Slack et al., 2019) to evaluate explainability methods for *their ability to make model decisions predictable to humans*. In this paradigm, humans are presented with explanations and tasked with predicting the model's decision regardless of the ground truth (Doshi-Velez and Kim, 2017).[1]

In NLP, Nguyen (2018) introduced human forward prediction for LIME explanations (Ribeiro et al., 2016b) of sentiment analysis of product reviews and correlated the results with automatic evaluations. Unlike with synthetic data, participants have prior beliefs on what the *true* outcome is. Since participants in Nguyen (2018) had no training phase to learn how explanations correlate with predictions and the model being evaluated sufficiently matched human behavior, humans likely relied *exclusively* on their prior knowledge and beliefs to complete the task at hand.

? improved on this protocol by adding a training phase. This is something we also do in our experiments (section 5), but it is unlikely to solve the belief bias problem because even after training, humans will naturally opt for fast, heuristic mechanisms (e.g. belief bias) in order to simplify tasks (Wang et al., 2019); this is particularly true if the model is high performing (i.e. likely aligns with human beliefs).

The protocol by **?** had another key feature: they leave out the explanations for the test data points. This would seem like an advantage for evaluating explainability methods in the context of reading comprehension where explanations can, in theory, simply highlight the answer span, making it easy to guess the model output from the explanations. However, it is easy to control for the amount of explanation provided by the explanation methods we compare; in our experiments below, we highlight the top 10 tokens with highest attribution scores. This key feature in their protocol is problematic for two reasons:

- It makes the human learning problem much harder, and we argue it is infeasible to expose participants to enough examples to make human forward prediction learnable (unless the task is made very easy on purpose; again by only evaluating high performing models). If it is not learnable, participants fall back on belief bias.
- It introduces a systematic bias between the training and test scenarios.

The protocol in **?** also does not randomize the order in which participants are exposed to problems with or without explanations.

We improve on the above protocol by introducing a condition which can help account for belief bias effects: evaluating explainability methods on low-quality models, the predictions of which substantially differ from human beliefs. This means that in order to succeed in the task, humans cannot simply rely on their previous beliefs, therefore, helping us assess the ability of explanations in helping humans to *realign* their expectations of model behavior. The predictions of reading comprehension models can also be made different from human answers by introducing distractor sentences that fool machine reading models, but not humans (Jia and Liang, 2017). If in human forward prediction, participants predict the true answer rather than spans in the distractor sentences, this suggests participants may be relying on their belief biases.

Best model selection. Ribeiro et al. (2016b) presented an evaluation of explainability methods for text classification, where explanations for decisions of two different models on the same instance are presented side by side, and humans decide which model is likely to generalize better. With some exceptions (Lertvittayakumjorn and Toni, 2019), there has not been much follow up work on this task, but this scenario is important: it mimicks the decisions about what model is *safer for deployment*. Ribeiro et al. (2016b) and Lertvittayakumjorn and Toni (2019) both make a single comparison between a model which clearly diverges from human intuition, and a model that generalizes and *aligns with humans' beliefs*. Accounting for the extent to which belief biases are leveraged (e.g. by introducing additional model comparisons where differences are not so obvious or where models are of low quality) is important in such paradigms, and can allow us to better evaluate where explanation methods may fail.

In the following sections, we show that introducing conditions which take into account belief biases can have an effect on the conclusions for both *human forward prediction* and *best model se-*

---

[1] Using synthetic data from fictitious domains effectively controls for belief bias (Lage et al., 2019; Slack et al., 2019). Slack et al. (2019), for example, evaluate explanations in the domain of recommending recipes and medicines to aliens.

lection. We emphasize that many other potential strategies can be introduced and this is largely dependent on the goals of the evaluation protocol; we merely provide one example case with the following strategies:

(1) Introducing low quality models which considerably diverge from humans' prior beliefs (*human forward prediction*)

(2) Introducing evaluation problems with distractor sentences (*human forward prediction*)

(3) Introducing model comparisons where relying on belief bias is not enough to obtain high performance (*best model selection*)

4 Experimental Setup

This section introduces the general setup of the experiments, with details specific to each experimental paradigm described in section 5 and section 6.

4.1 Models

We evaluate explanations produced by three BERT-based (Devlin et al., 2019) models:

(a) a high performing model (**HIGH**): BERT-base, fine-tuned on SQuAD 2.0. *This model is more aligned with human beliefs.*

(b) a medium performing model (**MEDIUM**): tinyBERT, a 6-layer distilled version of BERT (Jiao et al., 2020), fine-tuned on SQuAD 2.0. It performs about 20 F_1 points below HIGH. *This model somewhat aligns with human intuition, but performs significantly lower.*

(c) a low performing model (**LOW**): BERT-base, fine-tuned to always choose the first occurrence of the last word of the question. This system mimicks a rule-based system[2]; however, we evaluate gradient-based methods requiring a neural model. *This model diverges significantly from human beliefs.*

4.2 Data

We use SQuAD 2.0 (Rajpurkar et al., 2018), a RC dataset consisting of 150k factoid question-answer pairs, with texts coming from Wikipedia articles. We opt for this data as it contains short passages that can be read by humans in a short time. In the human forward prediction experiments, we refer to experiments using this data as ORIG. As described in section 2, Wikipedia texts could by themselves induce people to rely on their belief bias, but this particular dataset allows us to also introduce controls for the bias: the adversarial version of the data (Jia and Liang, 2017), has been shown to distract models but not humans. This means that in order to perform the task with success, humans need disregard their belief biases, and in some cases align with distractor sentences. We refer to this data in our simulation experiments as ADV.

4.3 Explainability Methods

We focus on gradient-based approaches, as they require no modifications to the original network, and are considerably faster than perturbation-based methods. We compare two explainability methods:

Gradients. Computing the gradient of the prediction output with regard to the features of the input is a common way to interpret deep neural networks (Simonyan et al., 2013) and capture relevant information regarding the underlying model.

Integrated gradients. Integrated gradients approach (IG) (Sundararajan et al., 2017) attributes an importance score to each input feature by approximating the integral of gradients of the model's output with respect to the inputs along the path, from the references to the inputs. IG was introduced to address the sensitivity issues which are present in vanilla gradients and implementation invariance.

5 Experiment 1: Human Forward Prediction

Human forward prediction for evaluating explainability was proposed by Doshi-Velez and Kim (2017). They argue that if a human is able to simulate the model's behavior, they understand *why* the model predicts in that manner. For the reasons previously outlined, we suspect that belief biases may be affecting performance and the conclusions once can draw from this task. We investigate this by asking the following: *Can humans predict model decisions, if model behavior considerably diverges from their own beliefs?*

Stimuli presentation. We include: (i) HIGH, which is finetuned to solve SQuAD 2.0 and (ii) LOW, which is finetuned to select the first appearance in the context of the last word in the question. We evaluate each of the two models twice: with or without adversarial data. We contrast using

---

[2] This model achieves about 0.90 F1 for this task, but in the results we show its performance on the actual RC task

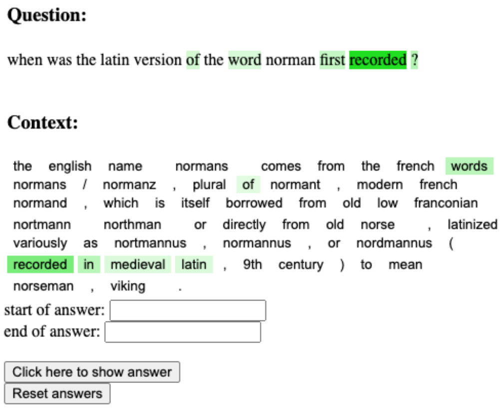
vanilla gradients and IG with a baseline condition, in which no explanations are shown (BASELINE).

We highlight the top-10 tokens[3] with the highest attribution scores wrt. the start and end positions of the predicted span, and zero out the rest.[4] The two sets of tokens often overlap.

Participants were provided with a question and a passage (with or without explanations) and were told to pick the *shortest* span of text which matched the model prediction. They saw the actual model answers before the next example (done for both baseline and explanation conditions), which was an important part of training to infer model behavior. Before the model prediction was shown, their answers were locked to prevent any further changes. An example of our interface can be found in Figure 2 and the instructions are shown in Appendix A.

We ran these experiments on Amazon Mechanical Turk, recruiting participants with approval ratings greater than 95%[5] and ensuring different groups of participants per condition by specifying that participation is only allowed once, otherwise risking rejection[6]. We paid participants $5.25 for about 20 minutes of work (to ensure at least a $15 hourly pay) and obtained at least three annotations per example. The data included 120 unique questions divided into small fixed batches (the same questions across conditions). About 75% of questions are accurate in the HIGH model, and around 15% are accurate for the LOW model. In total, we obtained 4,300 data points across 123 participants (35 data points per participant).

Results. As humans often did not select the exact span that was provided as ground truth, we *manually* labeled the spans as correct or incorrect. We also inspected the impact of training in human forward prediction, e.g., the learning effect of multiple exposures on annotator accuracy. Both with vanilla gradients and integrated gradients, we observe an increase in the participants' accuracy at around 15 examples. In contrast, in our baseline condition, performance either stays constant or drops slightly. To reduce the noise introduced due to the training period, we remove the first 15 examples of each participant. The results without this preprocessing (Appendix A) suggest that **the effect of training differed across explainability methods**, as will be discussed later in the section.



Question:

when was the latin version of the word norman first recorded ?

Context:

the english name normans comes from the french words normans / normanz , plural of normant , modern french normand , which is itself borrowed from old low franconian nortmann northman or directly from old norse , latinized variously as nortmannus , normannus , or nordmannus (recorded in medieval latin , 9th century) to mean norseman , viking .

start of answer:
end of answer:

Figure 2: Interface for Experiment 1 for LOW condition. To select model predictions, participants clicked on tokens to select the start and end of the span. Then they would see the actual model prediction.

Using the average human accuracies per example, we run a one-way ANOVA to test for significant differences across the groups. As we obtained statistically significant results, we then ran the Tukey honest significant difference (HSD) test (Tukey, 1949), comparing the means of every condition to the means of every other condition. The results are presented in Table 1.

As expected, in the absence of explanations (BASELINE), **humans rely on belief bias and predict the gold standard answer more often than the model prediction** (y in Table 1). Even with training (seeing the true model prediction), humans fail to catch onto the simple rule used by the LOW model, when no explanations are presented.

Overall, explanations derived from both of the gradient-based approaches lead to statistically significant improvements over the baseline. This indicates that the **explanations allow humans to realign their expectations of the model behavior**, better than with no explanations.

For HIGH-ORIG, the standard setting explored in previous evaluations, both IG gradients and vanilla gradients perform well, with IG gradients performing better. Given these results and the theoretical advantages of IG over vanilla gradients, one could arrive at the conclusion that IG are better for simulatability. However, **the differences between the two gradient-based methods are reversed in the conditions where humans cannot rely on their previous beliefs** (LOW). The gap be-

---

[3] Explanations should be *selective* (Mittelstadt et al., 2019)

[4] Ribeiro et al. (2016a) use the top 6 attributes; we opt for 10 given that our texts are slightly longer.

[5] Previous research has shown that proper filtering and selection of participants on Mechanical Turk, can be enough to ensure high quality data (Peer et al., 2014).

[6] We also remove such (few) repetitions at analysis

Table 1: Human forward prediction results (Human($\hat{y}$)) for Low and High models, compared to no explanations (Baseline). Each experiment is run on vanilla SQuAD 2.0 data (Orig) and adversarial SQuAD 2.0 data (Adv). Human(y) is the dataset ground truth and an indicator of belief bias. Statistically significant results are indicated with an asterisk. Time is the average time per question. The best $\hat{y}$ results in each condition are bolded.

tween gradients and IG as large as 0.11, and being statistically significant. This finding is *surprising* and points again to the importance of not drawing incorrect conclusions about the best performing method using the standard paradigm.

Finally, in the HIGH conditions, model behavior decreases about 13% F1 score with the presence of **adversarial examples**, meaning that the model we used does get affected by adversarial inputs. We observe that human performance is considerably lower in HIGH-ADV as opposed to HIGH-ORIG. **With vanilla gradients, performance is more aligned with the ground truth labels than with model behavior,** showing that in this condition humans are also relying on their prior beliefs. **With IG, where performance is less aligned with prior beliefs (ground truth), the end performance increases**, but it seems that this condition is considerably more difficult for humans.

Effect of training. In BASELINE, training does not affect either the LOW or HIGH conditions (see Table 3 in Appendix A for the raw results). For the LOW model, multiple factors can be taking place (possibly at the same time): (1) the task is too far from the humans' beliefs and there is no mechanism to help participants realign their expectations, (2) participants may not be incentivized to seriously engage and look for patterns, (3) participants opt for a mixed strategy, where for some questions they go with their prior beliefs and for others, choice is random (as seen in their performance in y).

For HIGH conditions in BASELINE, performance remains higher than LOW but this is likely due to belief bias and not training, given that performance remains constant after removing the training data points. We hypothesize that for HIGH, instances where the model does not align to human intuition might be more detrimental than in explanation conditions. More specifically, if humans are aware that the model aligns with their beliefs after some examples but encounter instances where it doesn't (model is not 100% accurate), they will likely develop an expectation that the model is bound to make some errors, without any indication of when.

In addition, our raw results suggest IG required longer training. While this does not mean IG is a worse method than vanilla gradients, explanations derived from IG may have confused participants due to containing information which was irrelevant to them. It may be that experts (e.g. system engineers knowledgeable about neural networks) can take better advantage of such explanations; however, we leave this exploration of the interaction of human expertise with explanations as a direction for future work.

6 Experiment 2: Best Model Selection

This section presents the setup and results of our model selection experiments; a task where humans select the model that is more likely to succeed in the wild. We present the participants with the explanations from two models (High vs Low and High vs Medium), and ask them to decide which model is likely to perform better. As a follow-up, we also experimented with *soliciting explanations about what leads the worse model to fail*. Intuitively, comparative evaluation difficulty depends on how clear the difference is between the compared objects. Explanations should at least show the difference between a high-performing model and a low-performing one, enabling human participants to predict which is better (standard setting).

Stimuli presentation. We presented participants with saliency information from both models (a high performing model + one of the lower performing models), and their task was to determine which model performs best in the wild. We shuffled the order at random so that the best model would not remain in a fixed position. We obtain 120 samples (question-context pairs), and show the explanations next to each other as seen in Figure 1. The participants are told that the highlighted attributes are the words the model found important in making its decision. A screenshot of the UI is shown in Figure 4 in section B and the instructions provided to the participants are also shown in section B. These experiments were also ran on Amazon Mechanical Turk with the same general procedures and pay. The same subset of 120 examples is used in all conditions. We obtained at least three annotations per example and ended with a total of 1440 data points across 48 participants (30 examples each).

Results. For each example shown to annotators, we obtained the average accuracy scores and performed a standard T-test to compare the performance of the two methods. The results are shown in Table 2. Using explanations from both methods, when shown the High and Low model, humans are clearly able to correctly select the better one. With IG, humans achieve **0.95** accuracy on average, while with vanilla gradients they achieve **0.89**. The difference is *not* statistically significant. The fact that users are consistently able to discriminate between High and Low models is expected, and serves as a *sanity check* that these explanations are meaningful for humans.

Condition	Gradients	IG
High vs low	0.89	0.95
High vs medium*	0.85	0.52

Table 2: Both methods do well in (High vs Low). In high vs Medium, performance drops dramatically for IG. * = statistical significant difference ($\rho < 0.001$)

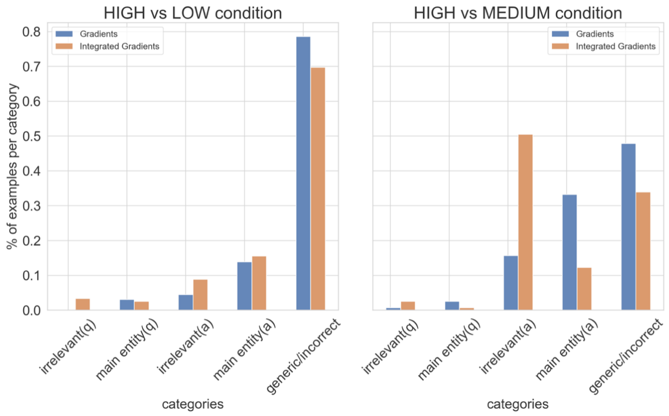
When the same experiment was repeated in the High vs Medium condition, we found clear and statistically significant differences between the two explainability methods. Using IG, participants reach only **0.52** accuracy, while with vanilla gradients their performance is **0.85**. This is *surprising*, given that the difference in performance between the two models is still quite large (about 20% F1); the expectation is that both methods would capture this difference relatively well. It appears that when both models *more or less* align with human beliefs, the task is much more difficult. To solve the task, humans now need to engage in more analytical thinking and cannot simply rely on belief biases to solve the task. We further investigate these differences through qualitative coding.

Qualitative analysis. After each instance, we asked participants to describe how the worse model will fail. We do not provide detailed guidelines in order to not further bias the participants by introducing specific criteria. The instructions given to the participants are shown in Appendix B.

We collected 1440 responses, which were all inspected manually to uncover categories (codes). After multiple iterations, we tagged each response with one code (categories are mutually exclusive, no response can be placed in two). A description of the categories and their distribution are shown in Figure 3, and examples of feedback per category are provided in the Appendix B.

In the High vs Low condition, feedback for both methods was generic (about 70-80% of the time), e.g., *model B is likely incorrect so it is worse*. This was expected: this task should be easy when model differences are large and humans can rely on their *system 1* processes to get through the task without thinking deeply about the explanations.

In the High vs Medium condition, the distribution of the feedback categories is very different. For IG, 50% of the time participants *felt* the highlighted tokens where irrelevant. This is not the case for gradients, where only about 15% of responses fell in that category. Additionally, for vanilla gradients, 50% of feedback is generic, signaling that in this condition, it may have been an easy task as well; explanations are making model behavior clear enough. It remains an open question whether IG explanations may in fact be more faithful to the model reasoning. In that case, *expert users* (e.g. a system engineer debugging a system) may not find IG attributions irrelevant and would be able take better advantage of the information provided. For this reason, other kinds of human participants may show different results. Nevertheless, as evaluating on non-experts (crowdsourced workers for example) is common, this preliminary result is important: it shows that **conclusions can shift dramatically when introducing additional model comparisons** which reduce the participants' ability to rely on prior knowledge.



Category	Description
irrelevant(q)	The model puts emphasis on irrelevant entities in the **question**.
Main entity (q)	The model does not put emphasis on the main entity in the **question**
irrelevant(a)	The model puts emphasis on irrelevant entities in the **answer**.
Main entity (a)	The model does not put emphasis on the main entity in the **answer**
generic/ incorrect	"Model is worse, because it is incorrect."

Figure 3: Feedback categories and their distribution. We observed that the HIGH vs MEDIUM condition results are considerably different from the HIGH vs LOW condition, with more participants giving generic answers for vanilla gradients, and emphasizing the irrelevant terms highlighted in the IG condition.

7 Discussion: Mitigating Belief Bias

This study introduced *additional conditions* in which the human participants could not rely on their belief biases to facilitate the task at hand. We presented a case study on evaluating reading comprehension models in model selection and human forward prediction paradigms, and we showed that this simple addition led to different conclusions in the evaluation and a better understanding of how humans interacted with explanations. Other tasks and paradigms might call for different setups, but generally including conditions with models of varying quality would be helpful both for the purposes of bias control, and for simulation of real-life use of explainability techniques to support decisions about which model is safer to deploy.

To conclude, we will briefly mention other directions for mitigating belief biases that can also be explored in future work and which should be kept in mind when developing evaluation protocols for explainability.

Reducing ambiguity. Ambiguity of task instructions leads humans to align interpretations to their own prior beliefs (Heath and Tversky, 1991); this may lead to misinterpretation and results which do not reflect the intended interaction with explanations. Ambiguity may also be present in other parts of the evaluation setup. For example, Lamm et al. (2020) evaluate the effectiveness of explanations in helping humans detect model errors for open-domain QA, but the data they use contains questions where multiple answers can be true. Users may deem an answer to be correct or incorrect based on their understanding of the question, which makes the effect of explanations blurry. Removing ambiguous instances from the data can be a way of reducing such confounds.

Removing time constraints. Time constraints exacerbate reliance of system 1 processes, which leads to humans relying on belief biases. In crowd-sourced evaluations, it is common practice to to provide workers with enough time to perform tasks, but workers may have intrinsic motivations for performing tasks quickly. A major challenge for evaluation research with crowd workers is creating better incentives for engaging in system 2 processes, e.g. pay schemes which encourage workers to be more analytical and accurate (Bansal et al., 2019).

Include fictitious domains. Using data from domains from which subjects have no prior beliefs e.g. fictitious domains, may be an efficient way of controlling for belief bias in some tasks[7]. This strategy has been used outside of NLP (Poursabzi-Sangdeh et al., 2021; Lage et al., 2019; Slack et al., 2019), where subjects are asked to imagine alternative worlds such as scenarios involving aliens. In QA for example, one could introduce context-question pairs that describe facts about fictitious scenarios that sufficiently differ from human reality.

8 Conclusion

The main contribution of this paper is bringing the discussion of belief bias from psychology into the context of evaluating explainability methods in

---

[7] Again, we emphasize that some strategies are task dependent; fictitious domains may not be relevant in some tasks.

NLP. Belief bias is a phenomenon which plays a role in human decision making and which interacts with previous evaluations in a way which may affect the conclusions we draw from these paradigms. We provide an overview of belief bias, making a connection between findings in psychology and the field of NLP, and present a case study of evaluating explanations for BERT-based reading comprehension models. We show that introducing models of various quality and adversarial examples can help to account for belief bias, and that introducing such conditions affects the conclusions about which explainability method works better. Finally, we provide additional insights and ideas for how to account for belief bias effects in human evaluation.

9 Broader Impact Statement

The work presented here makes strides towards a better understanding about the interaction of humans with explanations of model decisions. We have highlighted a phenomenon studied in psychology with hope that this opens the door to more NLP research involving a wider and more interdisciplinary understanding of humans, and the effect of explainability.

This study involved human participants recruited on Mechanical Turk platform. No personally identifiable data was collected from the participants, they were made aware that the data would only be used for research, and they were not exposed to any emotionally traumatizing or offensive stimuli. We ensured a minimum $15 hourly wage.

A Experiment 1: Human Forward Prediction

Below we show the instructions provided to the participants, as well as an example of the saliency maps presented to participants for adversarial examples.

Instructions. Question-answering systems are a particular form of artificial intelligence. The task here is for you to learn to predict how the system answers questions. In other words, when in a bit, you are presented with questions, the task is not to provide the right answer, but to guess the answer the system provided. For each question, you will also see a context paragraph. The answer is a span of text in this paragraph. Instead of writing out the answer, you can simply mark the relevant span.

If you want to select a new answer, please click *reset answer*, if you are ready to see the model answer, please click *show answer*. Note that your answer will lock at that time.

Raw Results. In our evaluation, we use the first 15 points as training, therefore, we discard them from the main evaluation but show them in this section. Overall, we see that training, for the most part has a positive effect, or not so much of an effect. These scores can be seen in Table 3.

	MODEL	HUMAN		
		BASELINE		
LOW-ORIG	0.17	0.14	0.52	52.27
LOW-ADV	0.15	0.10	0.36	54.36
HIGH-ORIG	0.79	0.53	0.58	37.12
HIGH-ADV	0.66	0.35	0.48	47.64
		INTEGRATED (IG)		
LOW-ORIG	▨	*0.34	0.35	41.68
LOW-ADV		*0.36	0.28	44.38
HIGH-ORIG	▨	*0.71	0.76	46.87
HIGH-ADV		0.46	0.47	42.99
		GRADIENTS		
LOW-ORIG	▨	***0.64**	*0.09	*32.16
LOW-ADV		***0.63**	0.23	*30.05
HIGH-ORIG	▨	***0.82**	*0.84	44.65
HIGH-ADV		***0.57**	*0.62	*52.30

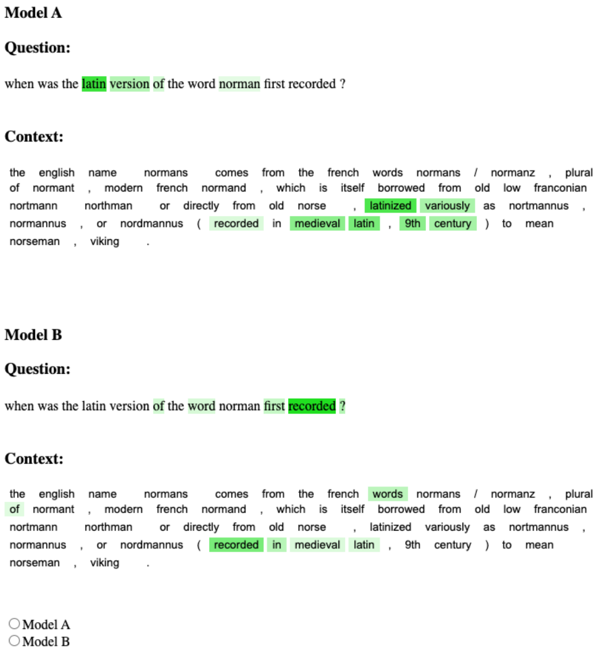
Table 3: Raw scores, before removing data points on training session

B Experiment 2: Best Model Selection

Below we show the instructions given to the participants, and more details about the qualitative analysis of the feedback we obtained.

Instructions. Question-answering (QA) systems are a particular form of artificial intelligence. We have trained two QA systems and have extracted the most important words the model uses to make its final decision. Based on these highlighted words, your task is to select the model that you think is more likely to perform best. Additionally, please write how the low-performing model fails and/or how it could be better (try to be detailed)

User Interface. An example instance, as shown to the participants, can be seen in Figure 4.



Model A

Question:

when was the latin version of the word norman first recorded ?

Context:

the english name normans comes from the french words normans / normanz , plural of normant , modern french normand , which is itself borrowed from old low franconian nortmann northman or directly from old norse , latinized variously as nortmannus , normannus , or nordmannus (recorded in medieval latin , 9th century) to mean norseman , viking .

Model B

Question:

when was the latin version of the word norman first recorded ?

Context:

the english name normans comes from the french words normans / normanz , plural of normant , modern french normand , which is itself borrowed from old low franconian nortmann northman or directly from old norse , latinized variously as nortmannus , normannus , or nordmannus (recorded in medieval latin , 9th century) to mean norseman , viking .

○ Model A
○ Model B

Figure 4: Experiment 1 UI: LOW(bottom) vs HIGH(top) condition.

Qualitative analysis of feedback. In Table 4, we include a few examples of the sentence that were categorized using the qualitative codes. Unsurprisingly, once participants found a strategy for giving feedback , they mostly stuck to it.

After categorizing all the feedback into each category, we visualize the distribution per condition. This can be found in Figure 3. We find that for the HIGH vs LOW conditions, the distribution is very similar between gradients and integrated gradients. Many participants gave very generic feedback , for example by simply saying that ”model A is better because it is correct, and model B is wrong”. This was not surprising, as here the differences were supposed to be clear and it is likely most participants did not have to think too hard before making

QUALITATIVE CODES	EXAMPLES
Irrelevant (q)	**1.** Model A only extracted some important words but also some punctuations in the question which is insufficient to derive to a good answer. Model B extracted a number of key important words that would lead to the correct answer. **2.** Option b chose quantitative statements, while option A seems confused about what it's looking for since it highlights all sorts of things in the question.
main entity (q)	**1.** The words "year" and "norman" in the question were not extracted by Model A. The Model will not be able get the correct answer without knowing what to look for. **2.** The question was asking about the year lavoisier's work was published but neither of the key words in this question were highlighted. Model A had no idea where to locate the answer without considering those key words.
main entity (a)	**1.** The answer requires a year; it hasn't highlighted any years as part of the answer. **2.** Answer needed to be a name and option A chose nothing that could be a name.
Irrelevant (a)	**1.** Model B has highlighted many extra words in the answer **2.** Both models selected the correct terms, but model A selected more irrelevant terms in the answer too, so it's less likely to choose the correct one from those numerous options. **3.** B highlighted the answer but also too much unneeded info.
Generic/correctness	**1.** Model A does not highlight the right answer **2.** Model B is wrong and model A is correct

Table 4: Examples of some of the feedback categorized into these classes

a decision. However, the distribution is very different for the HIGH vs MEDIUM conditions. Here, for standard gradients, the feedback followed a similar pattern as in the previous condition, but about 30% less examples received generic feedback than before. For integrated gradients, most examples received feedback regarding the irrelevant terms being highlighted, showing that even when the difference in performance between models is large (20 F1 points), this method makes the distinction difficult for the best model selection task.

Combining Static Word Embeddings and Contextual Representations for Bilingual Lexicon Induction

Abstract

Bilingual Lexicon Induction (BLI) aims to map words in one language to their translations in another, and are typically through learning linear projections to align monolingual word representation spaces. Two classes of word representations have been explored for BLI: static word embeddings and contextual representations, but there is no studies to combine both. In this paper, we propose a simple yet effective mechanism to combine the static word embeddings and the contextual representations to utilize the advantages of both paradigms. We test the combination mechanism on various language pairs under the supervised and unsupervised BLI benchmark settings. Experiments show that our mechanism consistently improves performances over robust BLI baselines on all language pairs by averagely improving 3.2 points in the supervised setting, and 3.1 points in the unsupervised setting[1].

1 Introduction

Bilingual Lexicon Induction (BLI) aims to find bilingual translation lexicons from monolingual corpora in two languages (Haghighi et al., 2008; Xing et al., 2015; Zhang et al., 2017a; Artetxe et al., 2017; Conneau et al., 2017), and is applied on numerous NLP tasks such as POS tagging (Zhang et al., 2016), parsing (Xiao and Guo, 2014), and machine translation (Irvine and Callison-Burch, 2013; Qi et al., 2018).

Most work on BLI learns a mapping between two static word embedding spaces, which are pretrained on large monolingual corpora (Ruder et al., 2019). Both linear mapping (Mikolov et al., 2013; Xing et al., 2015; Artetxe et al., 2016; Smith et al., 2017) and non-linear mapping (Mohiuddin et al., 2020) methods have been studied to align the two spaces. Recently, other than the static word embeddings, contextual representations are used for BLI due to the significant progresses on cross-lingual applications (Aldarmaki and Diab, 2019; Schuster et al., 2019). Although the static word embeddings and the contextual representations exhibit properties suited for alignment, there is no works to combine the two paradigms.

On one hand, the static word embeddings have been widely used for BLI, but one specific embedding mapping function does not ensure that in all conditions, words in a translation pair are nearest neighbors in the mapped common space. On the other hand, the contextual representations contain rich semantic information beneficial for alignment, but the dynamic contexts of word tokens pose a challenge for aligning word types.

In this paper, we propose a combination mechanism to utilize the static word embeddings and the contextual representations simultaneously. The combination mechanism consists of two parts. The first part is the unified word representations, in which a spring network is proposed to use the contextual representations to pull the static word embeddings to better positions in the unified space for easy alignment. The spring network and the unified word representations are trained via a contrastive loss that encourages words of a translation pair to become closer in the unified space, and penalizes words of a non-translation pair to be farther. The second part is the weighted interpolation between the words similarity in the unified word representation space and the words similarity in the contextual representation space.

We test the proposed combination mechanism in both the supervised BLI setting which can utilize a bilingual dictionary as the training set, and the unsupervised BLI setting which does not allow using any parallel resources as supervision signal.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2943–2955
August 1–6, 2021.

On BLI benchmark sets of multiple language pairs, our combination mechanism performs significantly better than systems using only the static word embeddings and systems using only the contextual representations. Our mechanism improves over robust BLI baselines on all language pairs, achieving average 3.2 points improvement in the supervised setting, and average 3.1 points improvement in the unsupervised setting.

2 Background

The early works on Bilingual Lexicon Induction (BLI) date back to several decades ago, including feature-based retrieval (Fung and Yee, 1998), distributional hypothesis (Rapp, 1999; Vulić and Moens, 2013), and decipherment (Ravi and Knight, 2011). Following Mikolov et al. (2013), which pioneered the embedding based BLI method, word representation based method becomes the dominant approach, and can be categorized into two classes: static word embedding based method, and contextual representation based method.

- **Static Word Embedding Based Method**

  Word embeddings of different languages are pre-trained in large monolingual corpora independently. Then a mapping function is applied to align the embedding spaces of the two languages (Mikolov et al., 2013; Xing et al., 2015; Artetxe et al., 2016; Smith et al., 2017).

  We follow one robust BLI system VecMap (Artetxe et al., 2018a,b), which maps both source space and target space into a third common space. Let E_x and E_y be the word embedding matrices in two languages for a given bilingual dictionary such that their ith rows are the embeddings of words of the ith translation pair in the dictionary. The training objective is to find mapping functions W_x and W_y such that

$$W_x^\star, W_y^\star = \underset{W_x, W_y \in M_d(\mathbb{R})}{\arg\max} \; cos(E_x W_x, E_y W_y) \tag{1}$$

  where d is the dimension of the embeddings, $M_d(\mathbb{R})$ is the space of $d \times d$ matrices of real numbers. The optimal W_x and W_y maximizes the cosine similarity between words of each translation pair in the mapped common space. In the unsupervised version where no bilingual dictionary is given, an artificial dictionary is initialized and iteratively updated through training W_x and W_y according to equation (1) (Artetxe et al., 2018b).

  Both mapping functions are constrained to be orthogonal during training by setting $W_x = U$ and $W_y = V$, where $U\Sigma V^T = X^T Y$ is the singular value decomposition of $X^T Y$. Such orthogonal constraint is based on the assumption that the source embedding space and the target embedding space are isometric, which is a particularly strong assumption that does not hold in all conditions (Zhang et al., 2017b; Søgaard et al., 2018). To depart from the isometry assumption, Patra et al. (2019) uses a semi-supervised technique that leverages both seed dictionary and a larger set of unaligned word embeddings, Mohiuddin et al. (2020) uses a non-linear mapping function that is not constrained to be orthogonal.

  We propose another method to relax the isometry assumption by combining the contextual representations with the word embeddings to compensate the shortage of the overly strong assumption.

- **Contextual Representation Based Method**

  Contextual representations can be obtained through multilingual pre-training, which encodes whole sentence and outputs contextual representation for each word (Devlin et al., 2019; Lample and Conneau, 2019). Due to the rich context information contained in the contextual representations, there are endeavors to align them in different languages (Schuster et al., 2019; Aldarmaki and Diab, 2019; Wang et al., 2020; Kulshreshtha et al., 2020; Cao et al., 2020).

  Since a word may appear in different sentences with different contexts, Schuster et al. (2019) use an average anchor to summarize multiple contexts for a word type and align the anchors of different languages, while other works aim to align each individual context representation based on parallel corpora, including learning alignment on sentence level representations and applying the learned mapping on word level contextual representations (Aldarmaki and Diab, 2019), using word alignments in a parallel corpora to learn the mapping for word contextual representations (Wang et al., 2020), and directly minimizing

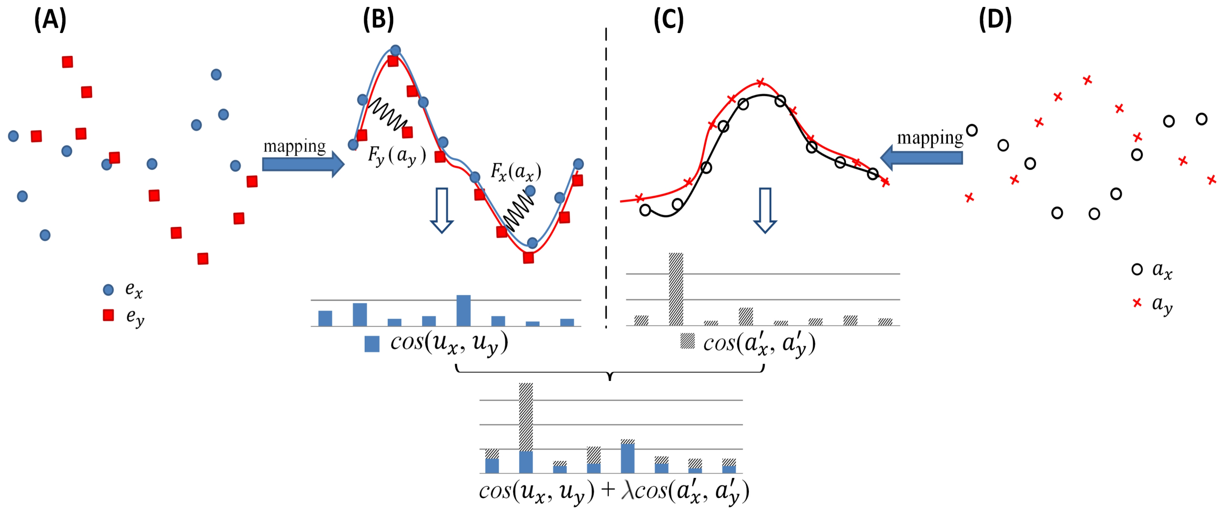

Figure 1: The illustration of the proposed combination mechanism. (A) is the static word embedding space, where e_x and e_y are the source and target embeddings, respectively. (B) is the unified word representation space which consists of the mapped word embeddings pulled by a spring network F_x/F_y with the contextual representations as input. We just depict two springs for illustration. (C) is the mapped contextual representation space. (D) is the original contextual representation space. a_x and a_y are the source and target contextual representations, i.e., the average anchors, respectively. In the similarity interpolation shown in the bottom, u_x and u_y are the unified word representations in the two languages, $a_x^{'}$ and $a_y^{'}$ are the mapped contextual representations in the two languages, cos denotes the cosine similarity function, λ denotes the weight.

the distance between two contextual representations of an aligned word pair in parallel corpora without mapping (Cao et al., 2020).

We adopt the average anchor method for the contextual representations (Schuster et al., 2019), which does not depend on parallel corpora. Let the contextual representation of a source word x in context c_i be denoted as r_{x,c_i}. If x appears a total of p times in the source corpus, the average anchor for x across all contexts is:

$$a_x = \frac{\sum_{i=1}^{p} r_{x,c_i}}{p} \tag{2}$$

Similar to the mapping for the static word embeddings, we conduct mapping for the average anchors. Let A_x and A_y be the matrices of average anchors in two languages with correspondence to word pairs from a given bilingual dictionary. The mapping functions V_x and V_y are optimized by maximizing $cos(A_x V_x, A_y V_y)$, where A_x and A_y are fixed, V_x and $V_y \in M_{d'}(\mathbb{R})$, and d' is the dimension of the contextual representations.

Besides the above methods, there is another direction that extracts word alignments in pseudo parallel corpora for BLI. The pseudo parallel corpora are built by either the unsupervised machine translation (Artetxe et al., 2019) or the unsupervised bitext mining (Shi et al., 2021). Both methods need significant computation overload or use monolingual corpora that are magnitudes larger than ours, and are beyond the scope of this paper that focuses on representation based methods.

3 Proposed Combination Mechanism for BLI

Since there is no work to combine both the static word embeddings and the contextual representations, we propose a combination mechanism illustrated in Figure 1. The mechanism first builds a unified word representation space that unifies the static word embeddings and the contextual representations, then performs similarity interpolation between the unified space and the contextual space.

3.1 The Unified Word Representations

As shown in Figure 1, the original word embedding space (A) is mapped to (B) through the mapping functions. Since the mapping functions are orthogonal, (A) is just rotated to (B). Notice that the spaces of the two languages are not necessarily isometric everywhere, some words in certain translation pairs are still far away from each other after rotation. To pull words in a translation pair getting closer, we propose a spring network that can pull the mapped embedding points to better positions such that words in a translation pair are nearest neighbors of each other. Since the contextual representations contain rich context information that can be used as the flexible adjustment, the spring network takes the contextual representations as input, and outputs offsets for the word embeddings.

Specifically, in the unified word representations, the mapped word embeddings are pulled to new positions by offsets, which are produced by the spring network with the the contextual representations as input:

$$\begin{aligned} U_x &= E_x^{'} + \gamma_1 \odot F_x(A_x) \\ U_y &= E_y^{'} + \gamma_2 \odot F_y(A_y) \end{aligned} \quad (3)$$

where U_x and U_y are the unified word representations, $E_x^{'}$ and $E_y^{'}$ are the mapped word embeddings, F_x and F_y are the spring networks, and $\gamma_{1\mathrm{or}2}$ is the weight vector, which is used to element-wisely multiply each row of the output of the spring network. Take the source side for example, the mapped word embedding matrix $E_x^{'}$ is added with a weighted offset produced by the spring network F_x on the contextual representation (i.e., the average anchor) matrix A_x.

The Spring Network stacks two feedforward layers with Tanh activations on top of the contextual representation matrices. The first layer transforms the dimension of the contextual representation d' to the dimension of the word embedding d. Equations (4-5) list the network structure of both sides.

$$A_x^1 = \phi(\theta_x^0(A_x)), \quad A_y^1 = \phi(\theta_y^0(A_y)) \quad (4)$$

$$A_x^2 = \phi(\theta_x^1(A_x^1)), \quad A_y^2 = \phi(\theta_y^1(A_y^1)) \quad (5)$$

where ϕ denotes the Tanh activation, and θ denotes the feedforward layer. $A_{x/y}^2$ is the output of the spring network, and fulfills as the offset distance to compensate the deviation of words in each translation pair in the mapped word embedding space.

Since we use cross-lingual pre-training (Lample and Conneau, 2019) to generate the contextual representations, which are actually BPE's (Sennrich et al., 2016) contextual representations, we have to form the contextual representations in the word level. Suppose a word x has q BPEs, and x appears p times in the monolingual corpus, then the word level contextual representation $a_x = \sum_{i=1}^{p} (\sum_{j=1}^{q} r_{b_j,c_{i,j}}/q)/p$, where $r_{b_j,c_{i,j}}$ denotes the representation of the jth BPE with the ith context $c_{i,j}$. a_x actually averages q BPEs' representation at first, then averages p contexts. After this cascaded averaging, it constitutes one row of A_x.

Contrastive Training is used to train the spring networks F_x and F_y with the pre-trained mapped word embeddings and the contextual representations fixed in the unified space. Basically, through the spring adjustment, the training encourages parallel words to get closer, and drives non-parallel words to be farther. It is divided into two scenarios: supervised contrastive training and unsupervised contrastive training.

- In the supervised contrastive training, given a bilingual dictionary with I translation pairs, the contrastive loss is:

  $$\begin{aligned} \mathcal{L}_{sup} = -\sum_{i=1}^{I}(J \times cos(u_x^i, u_y^i) \\ -\sum_{j=1}^{J} cos(u_x^i, u_{\bar{y}}^j)) \end{aligned} \quad (6)$$

  where u_x^i and u_y^i are the unified representations corresponding to the ith entry of the given bilingual dictionary.

  In equation (6), (u_x^i, u_y^i) is the positive translation pair according to the given dictionary, and the cosine similarity of this pair is maximized during training, while $(u_x^i, u_{\bar{y}}^j)$ is the negative pair where $\bar{y}$ is not aligned to x. The cosine similarity of $(u_x^i, u_{\bar{y}}^j)$ is minimized during training.

  We select J negative pairs for a source word x. In the implementation, we use Jbest outputs of the current model excluding the correct translation as the negative pairs. To keep balance between positive and negative pairs, the positive pair is copied J times to pair with negative pairs.

  During inference, we select $y = \arg\max_y cos(u_x, u_y)$ as the translation of x.

- In the unsupervised contrastive training, no bilingual dictionary is given. The contrastive loss is the same to that of the supervised contrastive training, except that the bilingual dictionary is not given. We initialize the bilingual dictionary using the output of the static word embedding based unsupervised method, and iteratively update it by using the trained model of last iteration to find new translations for given source words and compose a new dictionary, which is used to train the new model. Such process iterates until the dictionary does not change any more.

3.2 Similarity Interpolation

The similarity interpolation is for inference. As shown in Figure 1, both the unified word representation space and the mapped contextual representation space can output the cosine similarities between words. Given a source word x, we interpolate both similarities as below:

$$\mathcal{S} = cos(u_x, u_y) + \lambda cos(a_x^{'}, a_y^{'}) \qquad (7)$$

where λ is the weight, $a_{x/y}^{'}$ is the mapped contextual representation, which is pre-trained as introduced in the section of the background of the contextual representation based method. We aim to find y that has the maximal $\mathcal{S}$ as the translation of x.

In the supervised setting, λ is tuned on the validation set consisting of translation pairs. In the unsupervised setting, λ is tuned by an unsupervised procedure: when source-to-target model and target-to-source model have been trained, the word x in the validation set is aligned to y' based on equation (7), then y' is back aligned to x based on the inverse version of equation (7). We select λ that has the highest accuracy of this back alignment to x.

4 Experiments

We test our combination mechanism in supervised and unsupervised BLI tasks on English-Espanish (EN-ES), English-Arabic (EN-AR), English-Chinese (EN-ZH), English-German (EN-DE), and English-French (EN-FR).

4.1 Data

We need monolingual corpora to compute the contextual representations. Unfortunately, most existing BLI datasets distribute pre-trained word embeddings alone, but not the monolingual corpora used to train them. For that reason, we use WikiExtractor[2] to extract plain text from Wikipedia dumps, and preprocess the resulting corpora using standard Moses (Koehn et al., 2007) tools by applying sentence splitting, punctuation normalization, tokenization, and lowercasing. On these corpora, we use the cross-lingual pre-training system XLM (Lample and Conneau, 2019)[3] to compute the contextual representations.

Meanwhile, we also use these corpora to train the static word embeddings by using fastText[4] to ensure that both the contextual representations and the static word embeddings come from the same data. We use the bilingual dictionaries released by Muse project[5] in our experiments. Note that some words in these dictionaries do not necessarily appear in our monolingual corpora, we have to recompose the training, validation, and test sets such that all words in these sets are included in our monolingual corpora. In the end, we have 5000 entries with unique source words in the training set, and 1500 entries with unique source words in both the validation set and the test set for all language pairs.

4.2 Baseline Systems

Baseline systems are divided into two tasks as below. We run the released code of each baseline system in our experiments.

Supervised BLI task, which is allowed to use bilingual dictionaries for training and validation. The baseline systems are:

- **Muse**: Supervised Muse is set as the baseline in Conneau et al. (2017). It uses iterative Procrustes alignment for supervised BLI.
- **VecMap**[6]: Artetxe et al. (2018a) use a multi-step framework consisting of several steps: whitening, orthogonal mapping, re-weighting, de-whitening, and dimensionality reduction.
- **RCSLS**[7]: In addition to use CSLS during inference, Joulin et al. (2018) minimize a convex relaxation of CSLS loss during training, and improve the supervised BLI performance.

Table 1: P@1 on all language pairs. "Unified" denotes our unified word representation based method, which computes $cos(u_x, u_y)$, "Contextual" denotes the contextual representation based method, which computes $cos(a_x^{'}, a_y^{'})$, "Interpolation" denotes our similarity interpolation, which computes $cos(u_x, u_y) + \lambda cos(a_x^{'}, a_y^{'})$. The subscript "VecMap" denotes that our method is based on the work of Artetxe et al. (2018a), the subscript "RCSLS" denotes that our method is based on the RCSLS criterion in training (Joulin et al., 2018). In unsupervised BLI, there is no subscript in our method, which means using the default "VecMap" (Artetxe et al., 2018b).

- **BLISS**[8]: Patra et al. (2019) use a semi-supervised method that leverages both the bilingual dictionary and a larger set of unaligned word embeddings.

Unsupervised BLI task, which is not allowed to use any parallel resources for training and validation. The baseline systems are:

- **Muse**: Unsupervised Muse (Conneau et al., 2017) uses adversarial training and iterative Procrustes refinement.
- **VecMap**: Artetxe et al. (2018b) use careful initialization, robust self-learning procedure, and symmetric re-weighting to improve the unsupervised mapping result.
- **Ad.**[9]: Mohiuddin and Joty (2019) include regularization terms for adversarial auto-encoder for the unsupervised BLI.

4.3 Experimental Settings

We use fastText to train the word embeddings for BLI. The dimension of the word embeddings is 300. The contextual representations are extracted from XLM, and the dimension of the contextual representations is 1024. For each word type, we randomly select ten sentences containing the word from the monolingual corpora to do the averaging to get the contextual representation. The influence of the number of selected sentences for each word type is reported in section 4.5.2. Regarding the spring network, we use ten negative pairs for each source word in the supervised contrastive training, and use one negative pair for each source word in the unsupervised contrastive training.

All inferences in our experiments, including all baseline systems, use CSLS which is introduced in Conneau et al. (2017). The results are evaluated by Precision@1 (P@1).

4.4 Main Results

Table 1 summarizes the main results of the supervised and the unsupervised BLI tasks on all test sets. In both tasks, our proposed methods achieve significant improvements, with average 3.2 points higher than the strongest baseline RCSLS in the supervised task, and with average 3.1 points higher than the strong baselines VecMap and Ad. in the unsupervised task.

In the supervised task, we have two independent bases to build our proposed methods. One is VecMap (Artetxe et al., 2018a), the other is RCSLS (Joulin et al., 2018). They are the preprocessing steps to align the static word embeddings, and align the contextual representations in the two languages. Our methods build upon these alignments, and further train the spring networks and the unified word representations for the combination. The performances of our methods with these two bases are

Table 2: Result comparison between using XLM and using mBART for the contextual representations.

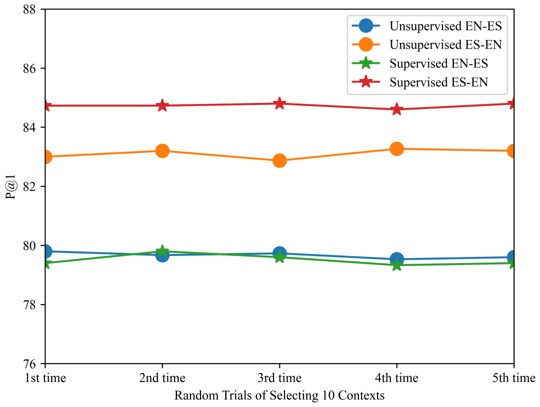

Figure 2: Performances of 5 random trials of selecting 10 sentences to gather contexts for each word type.

reported in Table 1 with the corresponding subscripts.

Table 1 shows that if we use VecMap as the basis of our method, we can improve 3.6 points over the corresponding VecMap baseline. If we use RCSLS as the basis, we can improve 3.2 points over the corresponding RCSLS baseline. In our methods, "Unified" can achieve around 2 points improvement over the corresponding baselines. Although "Contextual" obtains inferior performances, it is complementary to "Unified". When "Contextual" is combined with "Unified" through the interpolation, the performance is further improved, achieving the best performance among all systems. It shows that our combination mechanism is effective to utilize the merits of both the static word embeddings and the contextual representations.

In the unsupervised task, we achieve the significant improvements over the baselines. "Unified" is 1.5 points better than VecMap baseline. "Contextual" is inferior to other methods, but it can provide useful complements to "Unified", resulting in the final 3.1 points improvement through interpolation.

In summary, our combination mechanism consistently improves the performances for both distant language pairs, such as EN-AR and EN-ZH, and closely-related European language pairs.

4.5 Analyses

4.5.1 XLM v.s. mBART

Our results in Table 1 are based on using XLM for obtaining the contextual representations. In this section, we also use mBART (Liu et al., 2020) to compare with XLM. Table 2 shows the comparison result. XLM pre-trains the Transformer encoder through the masking mechanism, while mBART pre-trains the full Transformer encoder-decoder through multilingual denoising. Regarding BLI task, we obtain the contextual representations from the encoder. Table 2 shows that XLM and mBART get similar BLI performances since only encoder is used. In some directions, mBART performs slightly better than XLM, while in other directions, XLM is slightly better. According to the average performance, XLM ties with mBART in the supervised task, and is slightly better in the unsupervised task.

4.5.2 The Randomness of Contexts

The contextual representations are derived randomly from sentences of the monolingual corpora. We study if this random derivation affects the performances. Firstly, we run 5 times of randomly selecting 10 sentences to gather contexts for each word type in the "Unified" setting. Figure 2 shows

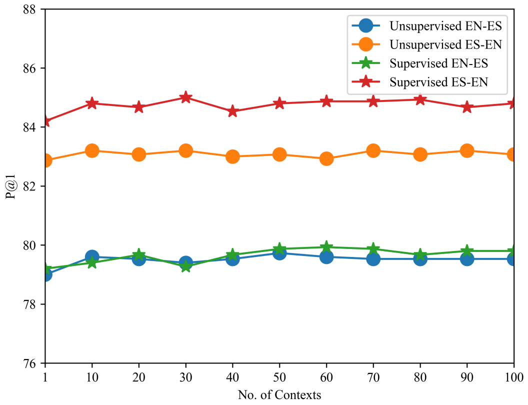

Figure 3: Performances of randomly selecting 1-100 sentences to gather contexts for each word type.

Table 3: P@1 of using WaCKy corpora.

that the performance is stable in the 5 trials. Secondly, we try randomly selecting 1-100 sentences to gather contexts for each word type. Figure 3 shows that selecting 1 sentence will drag the performance down to baseline, which indicates that 1 sentence is too random to gather enough information for BLI.

We only list the studies on EN-ES due to space limit. Studies on other language pairs can be found in the appendix.

4.5.3 The Influence of Selecting Encoder Layer

In the above experiments, we derive the contextual representations from the first layer of the encoder of XML/mBART. In this section, we show how different will be when we change the layer in the "Unified" setting. Figure 4 shows that as layer go higher, the performance drops. Please refer to the appendix for performances of other language pairs.

4.5.4 Results of using WaCKy Corpora

WaCKy corpora is introduced in Dinu et al. (2014) for BLI, but only word embeddings trained on WaCKy corpora are provided in their work. To obtain the contextual representations, we find WaCKy corpora from BUCC[10], and use the corresponding dictionaries with the same training, validation, and test split. We use mBART instead of XLM for computing the contextual representations in this task.

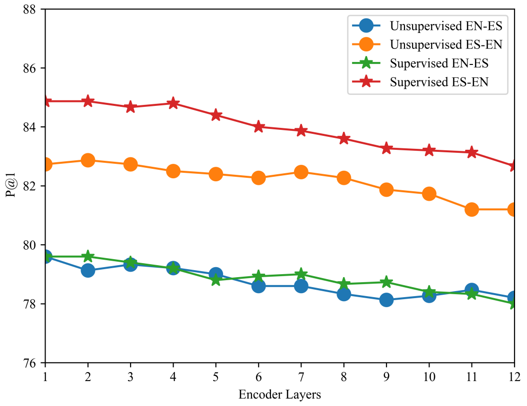

Figure 4: Performances of selecting different layer of XLM encoder to derive the contextual representations.

Table 3 shows that our combination mechanism is robust on this dataset. Both "Unified" and "Interpolation" perform better than the baselines. "Interpolation" achieves significant improvements in the supervised setting.

5 Discussion

The static word embeddings in our paper are trained by skip-gram or CBOW, while the word embeddings from XLM/mBART are trained by the pretraining objectives. Different training objectives result in quite different word embeddings. Actually, they show remarkably different behavior for BLI. By using VecMap, the word embeddings from XLM/mBART perform averagely around 30 points lower than the static word embeddings used in our paper. We also test fastText with 1024 dimension and word2vec with 300 dimension for fair comparison. They all perform remarkably better than the word embeddings from XLM/mBART. We plug in the word embeddings from XLM/mBART in place of the fastText static embeddings in our combination approach, and obtain much worse performance. This indicates that the static word embeddings trained by skip-gram or CBOW are more suitable for BLI and our combination approach.

---

[10] https://comparable.limsi.fr/bucc2020/bucc2020-task.html

In addition, regarding the asymmetry in Figure 1, we used to try the spring function that takes the static word embeddings as input, but got much worse results. This indicates that the spring function conditioned on the static space may be not helpful for BLI. Such observation may also explain that symmetrizing Figure 1 by yielding two unified spaces to combine performs slightly worse than the asymmetry version of Figure 1 of this paper. This is because that the spring function conditioned on the static space is introduced to maintain the symmetry, while this introduced spring function is not helpful for the combination.

6 Conclusion

Most BLI systems use either the static word embeddings or the contextual representations, but there is no works to combine both. In this paper, we propose a combination mechanism, which consists of the unified word representations and the similarity interpolation. The unified word representations use a spring network to pull the static word embeddings with offsets produced by the contextual representations, and compose a unified space such that parallel words are nearest neighbors to each other. The similarity interpolation is applied afterward to interpolate the similarities in the unified space and the contextual representation space. BLI experiments on multiple language pairs show that our combination mechanism can utilize the merits of both the static word embeddings and the contextual representations, achieving significant improvements over robust baseline systems in both the supervised and the unsupervised BLI tasks.

Appendix

A Experiment Environment and Settings

Our experiment is running on a Linux machine with GTX 1080Ti. The version of cuDNN is 7.6.0 and the version of CUDA is 10.1. We also use the PyTorch deep learning framework. The version of PyTorch is 1.6. The average runtime in our experiment is 5 to 10 minutes for one language pair, excluding the time for training word embeddings by fastText.

Regarding Wikipedia corpora used in our experiments, their download links are: `https://dumps.wikimedia.org/${lg}wiki/latest/${lg}wiki-latest-pages-articles.xml.bz2`, where ${lg} should be replaced with the corresponding languages. ${lg} can be set as "en", "es", "ar", "zh", "de", and "fr". We download them on Jan. 2, 2021. Regarding WaCKy corpora, we use WaCKy corpora[11] provided by BUCC2020 for obtaining the contextual representations, and use the provided word embeddings trained on this corpora. The BUCC2020 dictionaries are downloaded from the same page. We concat the three training sets with high, mid, low frequency as one training set, and concat the three test sets with high, mid, low frequency as one test set. Because no translations are provided in the test set of BUCC2020, we look up the Muse dictionaries to get the translations. All source words in the test set can find translations in the Muse dictionaries.

The evaluation script for computing precision@1 (P@1) is: `https://github.com/artetxem/vecmap.git/eval_translation.py`.

B Parameter Settings

The parameter size of the spring network is 796202. We use default parameter settings of VecMap and RCSLS.

language	λ
EN→ES	0.11
ES→EN	0.05
EN→AR	0.10
AR→EN	0.30
EN→ZH	0.12
ZH→EN	0.10
EN→DE	0.11
DE→EN	0.25
EN→FR	0.13
FR→EN	0.11

Table 4: The optimal hyperparameter λ in the unsupervised settings

Regarding the hyperparameter λ in the similarity interpolation, we search the optimal value in [0.05-0.3] with step size of 0.01. We found $\lambda = 0.1$ is superior on validation sets in all supervised settings. The optimal value of λ found by the unsupervised tuning procedure in the unsupervised settings, which is introduced in section 3.2, is shown in Table 4. In the search range, the performances has low variance, and are better than the baselines.

C The Influence of Selecting Encoder Layer in Other Language Pairs

We report the influences on EN-AR, EN-ZH, EN-DE, EN-FR in Figure 5. It shows that as we select higher layers for deriving the contextual representations, the performances become lower. This trend exists in most language pairs, except that the trend in EN-ZH is not significant.

---

[11] `https://corpus.leeds.ac.uk/serge/bucc`

D The Randomness of Contexts in Other Language Pairs

We report the randomness analyses on EN-AR, EN-ZH, EN-DE, EN-FR in Figure 6. It shows that trying 5 times of selecting 10 random sentences for gathering contexts gets stable performances in all language pairs. In most cases, using 1 sentence for computing the contextual representation drags the performance down, which indicates the inadequacy of 1 sentence for gathering contexts.

E Performances on Words with Different Frequencies

We use WaCKy corpora and the dictionaries provided by BUCC2020[12] to study the performances on words with different frequencies. The provided dictionaries are divided into groups of high frequency words, mid frequency words, and low frequency words. We test our combination mechanism on these three groups respectively. The results are presented in Table 5 and Table 6. We can see that our combination mechanism is effective on all three groups.

Exploring Unsupervised Pretraining Objectives for Machine Translation

Abstract

Unsupervised cross-lingual pretraining has achieved strong results in neural machine translation (NMT), by drastically reducing the need for large parallel data. Most approaches adapt masked-language modeling (MLM) to sequence-to-sequence architectures, by masking parts of the input and reconstructing them in the decoder. In this work, we systematically compare masking with alternative objectives that produce inputs resembling real (full) sentences, by reordering and replacing words based on their context. We pretrain models with different methods on English↔German, English↔Nepali and English↔Sinhala monolingual data, and evaluate them on NMT. In (semi-) supervised NMT, varying the pretraining objective leads to surprisingly small differences in the finetuned performance, whereas unsupervised NMT is much more sensitive to it. To understand these results, we thoroughly study the pretrained models and verify that they encode and use information in different ways. We conclude that finetuning on *parallel* data is mostly sensitive to few properties that are shared by most models, such as a strong decoder, in contrast to unsupervised NMT that also requires models with strong cross-lingual abilities.

1 Introduction

Neural machine translation (NMT) is notoriously data-hungry (Koehn and Knowles, 2017). To learn a strong model it requires large, high-quality and in-domain parallel data, which exist only for a few language-pairs. The most successful approach for improving low-resource NMT is backtranslation (Sennrich et al., 2016), that exploits abundant monolingual corpora to augment the parallel with synthetic data. However, in low-resource settings, it may fail to improve or even degrade translation quality if the initial model is not strong enough (Imankulova et al., 2017; Burlot and Yvon, 2018).

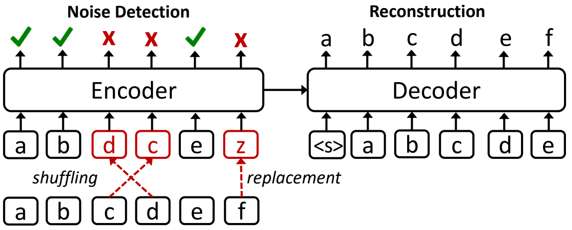

Figure 1: We consider noising methods that produce inputs which resemble real sentences, unlike masking.

Unsupervised pretraining is a complementary technique, that has revolutionized many natural language understanding (NLU) tasks (Wang et al., 2019). The dominant approach is to train a (large) model on a lot of unlabeled data using the masked language modeling (MLM; Devlin et al. (2019)) objective and then finetune it on a downstream task. Besides improving generalization, good initialization drastically reduces the need for labelled data. This paradigm has been applied recently to NMT yielding impressive results in low-resource settings, with models such as XLM (Conneau and Lample, 2019), MASS (Song et al., 2019) and BART/mBART (Lewis et al., 2020b; Liu et al., 2020), that adapt MLM to sequence-to-sequence architectures. Although pretraining alone is not enough to outperform backtranslation, it helps the initial model to produce synthetic data of sufficient quality, and combining them yields further improvements.

Most prior work in pretraining has focused on optimizing the masking strategy (Rogers et al., 2021). Similarly, MASS and mBART consider slightly different masking strategies. However, due to differences in their experimental setup (i.e., capacity or training data) and lack of analysis that goes beyond evaluation on downstream tasks, it is unclear if there is a meaningful difference between them, as far as NMT is concerned. They also suffer from a pretraining-finetuning discrepancy (Yang et al., 2019), in which a model is pretrained on masked inputs, but finetuned on full sentences.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2956–2971
August 1–6, 2021.

In this work[1], we explore different objectives to masking for unsupervised cross-lingual pretraining. We inject noise that creates examples (Fig. 1), similar to those encountered in finetuning, unlike masking. This includes, randomly replacing input words based on their context using a cross-lingual generator, inspired by Clark et al. (2020), and locally reordering input words, which prevents the cross-attention from naively (monotonically) attending over the source. We also explore auxiliary losses over the encoder to improve its representations.

First, we pretrain models with different configurations, on English-German, English-Nepali and English-Sinhala monolingual data. Then, we *systematically* compare them on the downstream tasks of supervised, semi-supervised and unsupervised NMT. In (semi-) supervised NMT, we observe that models yield surprisingly similar results, although some methods are better than others. We find that even pretraining with shuffled inputs leads to significant improvements over random initialization, similar to the concurrent work of Sinha et al. (2021) on pretrained encoders for NLU. Unsupervised NMT, however, reveals large (up to 9 BLEU points) differences, and against our expectations, masking achieves the best performance. To understand these results, unlike prior work, we thoroughly analyze the pretrained models using a series of probes, and discover that each objective drives the models to encode and use information in unique ways.

Based on our findings, we conclude that each finetuning process is sensitive to specific properties of pretrained models, similar to Artetxe et al. (2020). We hypothesize that (semi-) supervised NMT is mostly sensitive to the LM abilities of pretrained models, as the source→target mappings can be learnt from the parallel data. Unsupervised NMT requires models to also rely on their own word-translation abilities. Our contributions are:

1. We *systematically* compare many pretraining methods, including alternatives to masking, in three NMT tasks and for three language-pairs.
2. We discover that (semi-) supervised NMT is not sensitive to the pretraining strategies. Our ablation (§4.4) suggests that a strong decoder is the most important factor, while differences in the encoder (§4.5) don't affect the results.
3. Unsupervised setting is much more sensitive to the pretraining objective, and masking methods are the most effective. We hypothesise that learning to copy is important here (§5.2) as is cross-lingual encoding (§4.5).
4. We analyze the pretrained models with a series of probes (§5.1, §5.2, §5.3), and show noticeable differences in how they encode and use information, offering valuable insights.

2 Related Work

Pretraining for NMT Ramachandran et al. (2017) first explored unsupervised pretraining for NMT using LMs trained on monolingual data of the source and target languages to initialize the encoder and decoder of an RNN-based TM (Bahdanau et al., 2015). Conneau and Lample (2019) adopt the same approach, by extending BERT/MLM (Devlin et al., 2019) to the cross-lingual setting (XLM). They randomly mask tokens from input sentences in many languages, and the model is trained to predict them. However, the same pretrained XLM is used to (separately) initialize both the encoder and decoder of a downstream translation model (TM), which neglects the interaction between them. MASS (Song et al., 2019) addresses this limitation, by extending MLM to sequence-to-sequence pretraining, which includes the cross-attention mechanism, and achieved further improvements in low-resource and unsupervised NMT. Liu et al. (2020), concurrently demonstrated comparable results with a similar approach (mBART), but on a larger scale. Both mBART and MASS, consider different strategies for reconstructing masked input spans.

Objectives Yang et al. (2019) point out that BERT (Devlin et al., 2019) is pretrained with masked inputs, but then finetuned on full sentences, which creates a discrepancy. To address this, they change the self-attention in Transformers (Vaswani et al., 2017) to predict tokens conditioned on all permutations of other tokens in a sentence and Song et al. (2020) extend this to sequence-level pretraining for NLU. MARGE (Lewis et al., 2020a) explores multi-lingual pretraining for document-level NMT, by reconstructing texts from a set of retrieved relevant documents. Clark et al. (2020) propose the replaced token detection (RTD) objective for pretraining text encoders. They replace tokens with samples from a MLM and train the encoder as a discriminator to predict whether each word is real or fake. Similar ideas have been previously explored in NMT with contextual data augmentation (Fadaee et al., 2017; Kobayashi, 2018; Gao et al., 2019).

3 Pretraining

Our pretraining model is a multilingual denoising sequence autoencoder, based on the Transformer (Vaswani et al., 2017).

We assume access to a corpus of unpaired data, containing text in two languages A, B. Given a text sequence of N tokens $\boldsymbol{x} = \langle x_1, x_2, ..., x_N \rangle$ we first add noise to it and obtain its corrupted version $\boldsymbol{x'}$. An encoder transforms $\boldsymbol{x'}$ into a sequence of contextualized representations $h(\boldsymbol{x'}) = \langle h_1, h_2, ..., h_N \rangle$, which are given as input to the decoder, that produces a reconstruction of $\boldsymbol{x}$. The reconstruction loss is the negative log-likelihood (NLL) of $\boldsymbol{x}$:

$$\mathcal{L}_{\mathrm{R}} = \frac{1}{N} \sum_{t=1}^{N} - \log p(\boldsymbol{x}_t | \boldsymbol{x}_{<t}, h(\boldsymbol{x'})) \quad (1)$$

Each batch contains sentences in either A, or B and to distinguish between them, we add language id tokens at the end of the source sentences, and the beginning of the target sentences.

3.1 Pretraining Methods

In this section, we describe the methods that we use to inject noise into the model. We also explore auxiliary losses over the encoder, aiming to improve the input representations.

Masking Similar to prior work, we replace a random subsequence M of the input tokens with a special `[MASK]` token and train the model to reconstruct the original input. We consider masking words as well as spans following mBART.

Masking + eMLM When using masking noise we also explore the addition of an auxiliary MLM loss over the *encoder* to which we will refer as eMLM. This explicitly trains the encoder to reconstruct the representations of masked tokens:

$$\mathcal{L}_{\mathrm{eMLM}} = \frac{1}{|M|} \sum_{t \in M} - \log p(\boldsymbol{x}_t | \boldsymbol{x}_{\notin M})) \quad (2)$$

Replacing We inject word replacement noise, by extending Clark et al. (2020) to the cross-lingual setting. Specifically, we jointly train a *separate* cross-lingual (mBERT-like) MLM generator. First, we mask a random subset M of the input tokens[2] and the generator is trained to predict them:

$$\mathcal{L}_{\mathrm{G}} = \frac{1}{|M|} \sum_{t \in M} - \log p(\boldsymbol{x}_t | \boldsymbol{x}_{\notin M})) \quad (3)$$

For each masked token $\boldsymbol{x}_t$, the generator produces a distribution $p_{\mathrm{G}}(\boldsymbol{x}_t | \boldsymbol{x}_{\neq t})$. We replace the masked tokens with samples from p_{G} to obtain $\boldsymbol{x'}$, and feed the updated (corrupted) input to the encoder. We consider two configurations for the generator:

- *Untied*: The default setting, we use a small generator, which is half the size (x0.5 parameters) of the encoder, following Clark et al. (2020).
- *Tied*: We tie the weights of the encoder and the generator. This setting implicitly adds an auxiliary MLM loss over the encoder, and can be thought as a counterpart of "replace+eMLM".

Replacement + RTD Motivated by the results of Clark et al. (2020) in monolingual NLU, we add a replacement token detection (RTD) head over the encoder that gives direct supervision to the model regarding the location of noise. The RTD head $D(\cdot)$ is a token-level discriminator over the encoder outputs $h(\boldsymbol{x'})$, that predicts if an input token $\boldsymbol{x'_t}$ is original or replaced. We parameterize D with a non-linear projection followed by a sigmoid function: $D(\boldsymbol{x'_t}) = \mathrm{sigmoid}(\boldsymbol{u}^\top \mathrm{RELU}(\boldsymbol{W_D}\, h(\boldsymbol{x'_t})))$. The RTD loss is defined as the average token-level binary cross-entropy:

$$\begin{aligned}\mathcal{L}_{\mathrm{RTD}} = \frac{1}{N} \sum_{t=1}^{N} & - (\boldsymbol{x}'_t = \text{original}) \log D(\boldsymbol{x}'_t) \quad (4) \\ & - (\boldsymbol{x}'_t \neq \text{original})(1 - D(\boldsymbol{x}'_t))\end{aligned}$$

Shuffling Although pretrained models, such as MASS or mBART, do pretrain the cross-attention mechanism, the input words remain in their original positions and this biases the models into learning only naive monotonic alignments. To *actively* pretrain the cross-attention, we locally shuffle a random subset of *whole-words* in the input, using the method of (Lample et al., 2018). The length of reordering is bounded by k (positions). Small k introduce local shuffling, while large k allow words to be moved farther from their original position, making the input more like a bag-of-words (BoW).

3.2 Optimization

During pretraining, we minimize a weighted sum of the reconstruction L_{R}, and depending on the method, some of the auxiliary L_{eMLM}, L_{G}, L_{RTD} losses. We assign equal weight ($\lambda = 1$) to all losses, except for L_{RTD} for which we set its weight $\lambda = 25$ following Clark et al. (2020), to account for the fact that is in a different scale.

---

[2] We use whole-word masking, that masks all the (subword) tokens of a word, instead of independent token masking.

4 Experiments

Datasets We focus on low-resource translation and consider three diverse language-pairs: English-German, English-Nepali and English-Sinhala. For English-German, we use the low-resource WMT News Commentary v13 (Bojar et al., 2018) [3] parallel dataset, which contains approximately 275K sentences. For pretraining, we use as monolingual data the WMT News Crawl articles (Bojar et al., 2018) from the year 2007 to 2017, which comprise 190M and 270M sentences for English and German, respectively. For English-Nepali and English-Sinhala, we use the same data as in Guzmán et al. (2019). The (pretraining) monolingual data contain 5M sentences from Common Crawl and Wikipedia per language, while the parallel data are approximately 600K sentences from the Bible, Open Subtitles, GNOME/KDE/Ubuntu, and Paracrawl.

Pre-processing For Nepali and Sinhala, we use the preprocessing scripts[4] provided by Guzmán et al. (2019), whereas for English and German, we use directly the raw data without any preprocessing. We use sentencepiece (SPM; Kudo and Richardson (2018)) with the "unigram" model, to train a subword-unit tokenization model on the concatenation of the monolingual data of each language-pair. We learn a joint vocabulary of 60K symbols for the English-German models, and 20K symbols for the English-Nepali and English-Sinhala models.

Evaluation For English-German, we use the WMT *newstest2017* as dev-set and the *newstest2018* and *newstest2019* as test-sets. For English-Nepali and English-Sinhala, we use the evaluation datasets provided by Guzmán et al. (2019), which are drawn from Wikipedia articles. We evaluate models using BLEU (Papineni et al., 2002) computed with SacreBLEU (Post, 2018). We report detokenized BLEU when translating into German and English, and tokenized BLEU when translating into Nepali and Sinhala, following Guzmán et al. (2019). At test time, we decode with beam search, using beams of size 5.

Model and Training Our models are based on the Transformer architecture (Vaswani et al., 2017). We use the Transformer-base configuration to reduce the computational cost and be able to explore more methods. We describe in detail the model architecture and hyperparameters, as well as the pretraining and finetuning processes, in Appendix §A. Our code is based on the official mBART implementation in Fairseq (Ott et al., 2019).

4.1 Supervised Translation

In our first experiment (Table 1), we evaluate each pretrained model on supervised NMT by finetuning it on the parallel data. As a baseline we use a randomly initialized TM with identical configuration and vocabulary to that of the pretrained models, denoted as "random". We also pretrain a model equivalent to mBART denoted as "mask (span)".

Results All pretraining methods yield large improvements over random initialization, in all directions and language pairs. The differences between each method are more pronounced in en↔de, whereas in en↔ne and en↔si, all models reach much lower scores, especially in en→X, probably because of low-quality training data, and a domain mismatch between the parallel and test data.

When we compare each type of input noise in isolation, we observe that masking and replacement achieve similar results, and both are better than shuffling. However, pretraining with shuffling noise alone still yields surprisingly strong results. It improves over random initialization in all experiments, and it even reaches similar BLEU scores to masking and replacements in en↔ne and en↔si. Note that, the common denominator in all pretrain-

---

[3] http://www.statmt.org/wmt18/translation-task.html

[4] https://github.com/facebookresearch/flores

ing methods is the decoder, which is trained as a conditional LM with teacher forcing and the only difference is the input conditioning context. This implies that *one* key factor in pretraining for NMT is improving the LM capabilities of the decoder.

Auxiliary Losses The best results are obtained by "mask+eMLM" and "replace+tied", both of which benefit from an encoder MLM loss. We observe, that eMLM and tying are more effective in the X→en than en→X direction, especially for en↔ne and en↔si. This makes intuitive sense because eMLM improves the representations of the encoder, which is more important for languages with limited or low-quality data. Specifically, we observe that adding eMLM improves BLEU by +0.7 for ne→en, +0.4 for si→en and tying the generator with the encoder yields +0.7 BLEU for ne→en, +0.7 BLEU for si→en. Wang et al. (2020) make a similar observation in experiments in multilingual NMT.

Incorporating RTD, however, has a negative effect in most experiments. This is unexpected, given that Clark et al. (2020) showed that pretraining text encoders with RTD outperformed MLM in NLU tasks. This warns us that methods which produce strong encoders for NLU might not necessarily improve encoders for NMT. Note that, Siddhant et al. (2020); Wang et al. (2020) have discovered similar surprising results in cross-lingual NLU tasks.

Noise Combination We also consider a combination of the best replacement-based variant "replace+tied" with shuffling. Shuffling is applied after the replacements are sampled and we limit the length of reordering to $k = 3$ to prevent extreme corruption of the input. We observe that this combination yields small gains in most experiments. We also explored more pretraining methods and configurations, including the injection of noise into the decoder, but they didn't produce significant differences in terms of BLEU (see Appendix D).

4.1.1 Parameter Sensitivity Analysis

We also explore how changing key parameters of each pretraining method affects performance in supervised NMT. We report the results in Table 2. We observe there is a "sweet-spot" for the amount of noise used in each method. Shuffling shows larger variability and we find that by making the token swaps less local (i.e., increasing k that makes the input more BoW), yields better results.

Generator Size Next, we focus on why tying the encoder and generator yields better results. Either the encoder benefits from the implicit MLM loss, or tying improves the generator and consequently its samples. We train an *untied* model with equal capacity to the encoder "replace=35% (x1.0)", and a similar model, but we sample replacements with nucleus sampling[5] (Holtzman et al., 2020) with top-p=0.9, to avoid low-probability tokens. Neither of those variants yields any measurable difference with "replace=35%", which suggests that MLM is responsible for the improvements.

Table 2: Supervised NMT results (mean and SEM of 3 runs), for different configurations of pretrained models.

RTD Position We also explore if the position of the RTD head is responsible for its negative effects in NMT, as it might force the encoder to preserve information irrelevant for NMT to its outputs. To test this, we train a model with RTD over its fourth (RTD=4) instead of last/top (RTD=6) layer. We find that this change has a marginal effect on BLEU.

4.2 Semi-supervised Translation

In Table 3 we report results for semi-supervised NMT, using backtranslation. Both the forward and backward TM are initialized from the same model. We generate the backtranslations from the same monolingual data that we used for pretraining with greedy-sampling, which is preferable for weak TMs (Edunov et al., 2018), and upsample the real data to maintain a 1:1 ratio with the synthetic data.

Results Backtranslation yields significant gains in all experiments, and the initialization from pretrained models boosts performance even more. The relevant performance between methods is consistent with the supervised NMT, but their differences shrink further. We suspect that adding more data narrows the room for improvement of pretraining.

One exception is the initialization from "shuffle=5", which yields marginal gains in en↔de and even fails to reach the randomly initialized model

Table 4: Finetuning results to **unsupervised** NMT.

in si↔en and ne↔en. Note that, one of the advantages of backtranslation is improving the LM capabilities of the decoder with the addition of more clean target data. We hypothesize that shuffling noise mainly pretrains the decoder as a LM, and its benefits are largely neutralized by backtranslation.

4.3 Unsupervised Translation

In Table 4 we evaluate the pretrained models on unsupervised NMT (Artetxe et al., 2018; Lample et al., 2018), using *only* the monolingual data. In this experiment we focus on en↔de, because unsupervised NMT in en↔ne and en↔si yields very low BLEU scores (Guzmán et al., 2019; Liu et al., 2020). In each batch, we generate backtranslations on-the-fly in the target language and the model is optimized to reconstruct the original sentences (i.e., $\text{en}\rightarrow\text{de}'\rightarrow\widehat{\text{en}}$), following the same finetuning process as mBART (see Appendix B for details).

Results Unlike the experiments on parallel data (§4.1, §4.2), unsupervised NMT reveals large differences between pretrained models. Strikingly, "shuffle=5" yields the lowest BLEU scores by a large margin. This further supports the hypothesis that its primary strength is its decoder. We hypothesize that all pretraining methods produce strong decoders, but not encoders. Since in supervised NMT the models can learn source-to-target mappings from the parallel data, models with better cross-lingual abilities have a small edge. However, in the unsupervised setting having a fluent decoder alone is not enough as the models have to rely on their own word-translation capabilities (§4.5) to be able to produce sufficient backtranslations.

Another unexpected result is that pretraining with masked inputs outperforms replacements. Replacement-based models should intuitively be favoured, because the mistakes injected by the generator during pretraining resemble those produced by backtranslation. Masking-based models, however, are exposed to very different inputs without any signal from parallel data to help them transition to the new training regime, unlike supervised NMT.

In our analysis (§5.2), we find that masking biases models towards copying from the input, whereas replacements make models more "cautious" because some input words are fake. We hypothesize that the ability of mask-based models to copy words, such as dates or named entities, is critical to kickstart the backtranslation process.

4.4 Supervised Translation Ablations

To estimate how important of each part of the pretrained model is for NMT, we conduct an ablation experiment. First, we transfer all the weights of a pretrained model to a downstream model, except the weights of the ablated component. Next, we freeze the pretrained weights for all components except for the ablated one, which we reinitialise randomly. Finally we finetune only the ablated component, to isolate the effects on the final score to the component and prevent the other components from compensating (details in Appendix B.1).

We divide the model into four parts: (1) the *embedding* matrix, which is used for both the encoder and decoder embeddings and the vocabulary (output) projection, (2) the *encoder* layers, (3) the *decoder* layers and (4) the *cross-attention* layers, which link the decoder with the encoder. We re-

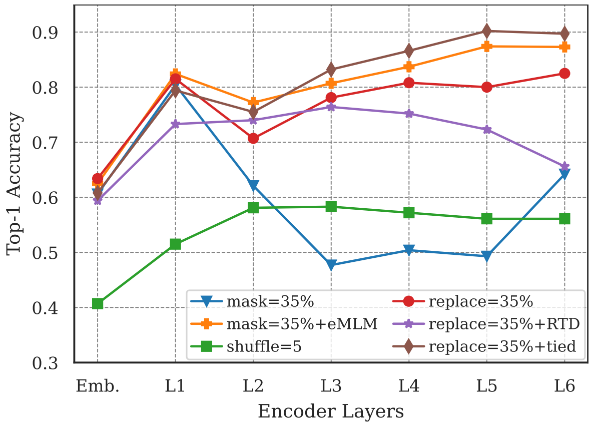

Figure 3: Parallel sentence retrieval accuracy (de→en).

port the de→en supervised NMT ablation results in Figure 2. Higher BLEU scores show that a model can better recover after an ablation, which we interpret as an indication that the ablated parameters are less important. We ablate each component both individually and combined with cross-attention, to allow the model to better learn to connect source and target representations. We find in both settings, that all models recover better after resetting their encoders than their decoders, implying that the pretrained decoder parameters are more important.

4.5 Cross-lingual Sentence Retrieval

To study the cross-lingual abilities of the encoder of each pretrained model, we evaluate them on parallel sentence retrieval. In Figure 3, we report the (per layer) accuracy of each encoder, on the de→en Tatoeba test set (Tiedemann, 2020)[6].

The results indicate that different objectives do affect the encoder's cross-lingual abilities. The fact that this is not reflected in the BLEU scores of the finetuned models further supports that even a small parallel data-set is enough to align them to similar degrees. As hypothesized, shuffling induces the least effective cross-lingual representations. The RTD loss inhibits cross-linguality, as accuracy decreases for each layer closer to the RTD loss (L6). The "mask" model exhibits an unexpected behaviour, where its accuracy drops in its middle layers before rising up again in its output layer. We do not have a satisfying explanation for this and we leave it for future work. However, adding an MLM loss over the encoder completely changes this behaviour, and both "mask+eMLM" and "replace+tied" yield the best results.

We also notice an interesting result in the accuracy of the embeddings. Shuffling noise induces poor alignment, unlike the other methods that have much better aligned embeddings. We believe that this result is connected to the unsupervised NMT results. Note that, the quality of embeddings affect the decoder as well, as their embeddings are tied.

5 Analysis

Finetuning on parallel data drives models towards similar destinations (BLEU), but the results in unsupervised NMT hinted that their starting points are different, which implies that the finetuning process itself is critical. We shift our focus to the pretrained models themselves and using a series of probes we study how pretraining methods affect their behaviour and the knowledge that they encode. For clarity, here we discuss only the en↔de results. The en↔ne and en↔si results are included in Appendix C and are consistent with this analysis.

5.1 Encoder Denoising Capabilities

In this section, we study how well the encoders of the pretrained models are able to denoise the input. For each model, first, we corrupt its inputs using the corresponding noising method and then train a linear classifier over its encoder outputs, using the identity of the original input token as the label, similar to Brunner et al. (2019). In Figure 4 we report the perplexity (PPL ↓) of each classifier evaluated on the wmt18 en↔de devset. We report separately the scores for real and corrupted tokens. We observe that, as expected, in all models the PPL over non-corrupted tokens is almost perfect (PPL ≈ 1), indicating that the encoders perfectly preserve the input in their outputs. However, the results vary significantly for corrupted tokens.

---

[6] We follow Libovický et al. (2020) and obtain the encoder sentence representations for each layer with mean pooling, followed by zero-centering per language (separately). Then, for each source sentence we retrieve its nearest neighbor from the target sentences based on cosine distance.

Method	PPL (original)	PPL (corrupted)
mask=35%	1.2	256.5
mask=35% +eMLM	1.3	91.8
shuffle=5	4.0	1274.9
replace=35%	1.4	1816.4
replace=35% +RTD	1.9	1236.2
replace=35% +tied	1.4	1233.4

Figure 4: Perplexity (PPL ↓) of the token prediction probe for the en↔de pretrained models.

Method	Entropy (original)	Entropy (corrupted)
mask=35%	0.00	2.99
mask=35% +eMLM	0.00	3.00
shuffle=5	0.09	0.16
replace=35%	0.63	2.85
replace=35% +RTD	0.68	2.93
replace=35% +tied	0.65	2.76

Figure 5: Entropy of decoder's distributions during the reconstruction of original and corrupted tokens.

Masking The representations of masked tokens yield the lowest PPL, which implies that token reconstruction happens partially in the encoder. However, the eMLM loss over the encoder makes the outputs much more predictive of the original tokens. This shows that the reconstruction loss does not push the encoder to denoise the input well enough, unlike the similar[7] but explicit signal from eMLM.

Shuffling The PPL for original tokens is very low, whereas for shuffled tokens extremely high. This shows that the encoder does *not* fix the word order but simply relays the input to the output. This is in line with Xu et al. (2021) who showed that in Transformer-based NMT word-reordering happens in the decoder, instead of the encoder.

Replacement We observe a huge gap in how predictive the representations of real and replaced tokens are. We suspect that the encoder is "misled" by the replacements and relays their information to its outputs. Both tying and RTD help the encoder to generate representations that are more predictive of the true input. RTD, however, interferes slightly with the representations of real tokens.

5.2 Decoder Uncertainty

Next, we focus on the decoder and study how its token-level uncertainty varies while it reconstructs original and corrupted tokens. For each model, first, we corrupt its inputs using the corresponding noising method and then measure the entropy of the decoder's distributions for each target token. Low entropy values indicate that the decoder predicts the target tokens with certainty, by exploiting the encoder representations. Figure 5 shows the average entropy for original and corrupted tokens.

Masking When the decoder is presented with masked inputs, it directly copies the unmasked tokens (exactly *zero* entropy). By contrast, predicting masked tokens is naturally harder, and the decoder becomes very uncertain. Adding eMLM over the encoder does not change this behaviour.

Shuffling The decoder of "shuffle=5" predicts all tokens with extreme certainty. Note that, in every step, the decoder has to choose the correct token out of N input tokens, instead of the full vocabulary, and combined with the constraints imposed by the ground-truth prefix, it is very easy for the model to find which input word to copy next. Therefore, we hypothesize that during pretraining the model mainly relies on the LM capabilities of the decoder.

Replacement We observe that the decoder is uncertain not only for fake but to a small extent, for real words as well. If a replacement is coherent and complies with the grammar of a given language, the decoder can be misled, which makes it "question" the identity of all words. RTD or tying with the generator show no clear effects.

5.3 Decoder Sensitivity to Encoder Outputs

This analysis aims to estimate the reliance of the decoder on the outputs (i.e., representations) of the encoder. First, we feed to the encoder a corrupted sentence $\boldsymbol{x} = \langle x_1, x'_2, x'_3, \ldots, x_N \rangle$, where x'_i denotes a corrupted token, and obtain its outputs $\boldsymbol{h} = \langle h_1, h'_2, h'_3, \ldots, h_N \rangle$. Then, we block the information of h'_i and measure how much it affects the reconstruction loss. We consider two blocking methods: (1) *zeroing*, in which we replace h'_i with a zero vector, and (2) *mixing*, in which we replace h'_i with random representations from other sentences in a batch. The amount by which the reconstruction loss increases implies how useful is the information in h'_i, and how sensitive the decoder is to them.

In Figure 6 we report the differences with and without blocking, in terms of the reconstruction loss (NLL). The models trained with shuffling originally yield the best reconstruction, which shows that it is comparatively the easiest noise for the decoder. Replacement is slightly harder than masking noise, because with masked inputs the decoder can easily tell when to copy and when to predict, while

---

[7] The eMLM and reconstruction losses are similar, but are applied in different places (encoder vs. decoder). The signal from reconstruction reaches the encoder through the decoder.

Method	NLL (original)	NLL (zeroed)	NLL (mixed)
mask=35%	1.46	2.69	3.35
mask=35% +eMLM	1.42	3.37	4.13
shuffle=5	0.68	8.40	10.36
replace=35%	1.55	1.49	1.50
replace=35% +RTD	1.62	1.51	1.59
replace=35% +tied	1.53	1.53	1.50

Figure 6: Change in reconstruction loss (NLL ↓) after blocking the representations of corrupting tokens.

replacements can be misleading (recall §5.2).

Masking "mask" and "mask+eMLM" reconstruct the input equally well, but when the representations of masked tokens are zeroed, "mask+eMLM" is affected more. eMLM forces the reconstruction to partially happen in the encoder (recall §5.1), so the decoder relies more on it. Mixing increases NLL even more, as we inject misleading information.

Replacement RTD leads to worse reconstruction error, which suggests that it is interfering even in the pretraining phase. Surprisingly, blocking the representations of replaced words not only does not increase the reconstruction loss but even slightly decreases it. This implies that during pretraining, the models learn to *ignore* the replaced words.

Shuffling Zeroing the representations of misplaced tokens is destructive and replacing them with random representations, increases the loss even further. The decoder focuses so heavily on putting words in the right order and has no "doubts" about their identity. Therefore, when presented with missing or misleading information, instead of "falling back" into an unconditional LM, that uses only on the target prefix, it completely fails[8].

5.4 Visualization of Encoder Representations

In Figure 7, we visualize the encoder token representations using t-SNE (van der Maaten and Hinton, 2008) and color code them based on whether the belong to original or corrupted tokens (see Appendix C.1 for details and more visualizations). Masking induces separated representation between masked and unmasked tokens, which enables the decoder to copy with certainty (see §5.2), while eMLM, that pushes the encoder to reconstruct the corrupted tokens, makes them more similar to the original ones (see §5.1). Although the representations of original and reordered tokens have a large overlap, we observe some separated clusters of original and misplaced tokens, implying that the encoder is partially aware of shuffling noise. As expected, adding RTD over the "replace" models enables allows it to identify more corrupted tokens, as shown by the size of the corresponding clusters.

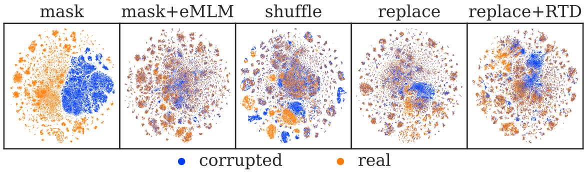

Figure 7: Visualization of encoder representations

6 Conclusions

In this work, we explore new unsupervised pretraining methods for NMT. We consider alternative objectives to masking, such as reordering or replacing input words, that produce training examples similar to real sentences.

We discover that (semi-)supervised NMT is not very sensitive to the pretraining objective. While some methods are better than others, most models converge to similar BLEU scores (§4.1, §4.2). Surprisingly, even pretraining with shuffled inputs yields competitive results with the other methods. Our ablation experiments (§4.4) imply that pretraining benefits more the decoder than the encoder.

In unsupervised NMT, however, the results vary significantly (§4.3). Shuffling noise leads to significantly worse performance, whereas masking noise, unexpectedly, yields the highest BLEU. Experiments on parallel sentence retrieval (§4.5) show that different objectives do affect the encoder cross-lingual abilities, and are reflected on the unsupervised NMT results. Through further and extensive analysis of pretrained models (§5), we find that they encode and use information in different ways.

We conclude that finetuning to each downstream NMT task is sensitive to different properties of pretrained models. (Semi-) Supervised NMT benefits from strong and fluent decoders, because the signal from the parallel data compensates for encoders with poor cross-lingual representations. Unsupervised NMT finetuning, however, requires models with good source-target mappings, and is also sensitive to certain model biases, such as the tendency to copy (§5.2) induced by mask-based pretraining.

Acknowledgments This work was conducted within the EU project Gourmet, under grant agreement No 825299. It was also supported by the UK EPSRC grant EP/S001271/1 (MTStretch). It was performed using computing resources in CSD3 using funding from the UK EPSRC (capital grant EP/P020259/1), and DiRAC funding from the Science and Technology Facilities Council.

---

[8] NLL after zeroing is 8.4. It equals to PPL of $\exp(8.4) = 4447$, which is very high even for a weak unconditional LM.

A Model Configuration & Training

We use 6 Transformer layers in both the encoder and the decoder, with embedding/hidden size of 512, feed-forward filter size of 2048, 8 attention heads and we apply 0.1 dropout to all layers. We optimize our models using Adam (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_1 = 0.999$, and $\epsilon = 10^{-6}$. All models use sinusoidal positional embeddings.

We tie the weights of the embedding and output (projection) layers of all sub-networks (Press and Wolf, 2017; Inan et al., 2017), which involves the encoder, decoder and MLM generator. For pretraining, we use a learning rate of $5e^{-4}$ with a linear warm-up of 16K steps, followed by inverted squared decay. We train each model for 300K steps with mini-batches of 24K tokens on 8 Nvidia V100 GPUs, which requires approximately 4-5 days. The maximum sentence length is set to 256 tokens. For the finetuning experiments, we use a learning rate of $3e^{-5}$ with a linear warm-up of 2.5K steps and mini-batches of 12K tokens. We finetune each model for 60K in the supervised setting and 120K steps in the semi-supervised setting. We also use increased the dropout to 0.3 and set label smoothing (Szegedy et al., 2016) to 0.1, to avoid over-fitting on the limited parallel data.

B Unsupervised NMT

Instead of adding input noise, like Artetxe et al. (2018); Lample et al. (2018), we follow the finetuning process of mBART (Liu et al., 2020). To prevent models from copying the source during backtranslation and force the transition to the translation task, we allow only the most frequent tokens in the target languageto be generated for the first 2K steps. Specifically, we mask tokens with frequency less than 10^{-3}, as measure in the monolingual data. For model selection, we use a small subset of 200 sentences from the wmt18 devset.

B.1 Supervised Translation Ablations

In Figure 8, we visualize the experimental protocol for our ablation experiment. To test (i.e., ablate) a component, the process is the following:

1. We transfer all the weights of a pretrained model to a downstream model, except the weights of the ablated component.

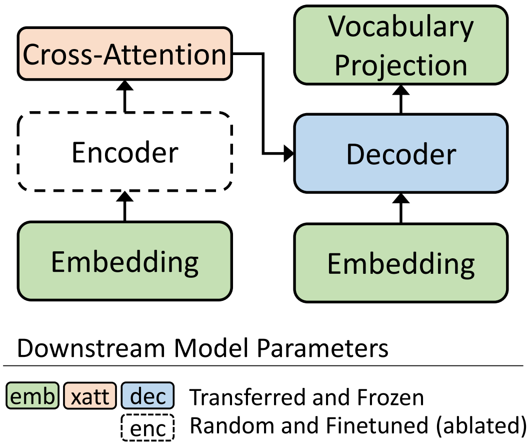

Figure 8: Visualization of the ablation experiment, using the ablation of the encoder as example. The figure shows the high-level architecture of a model and the colors correspond to the parameter set. The input embeddings of the encoder, the decoder and the vocabulary projection have the same color as they share the same parameters. During finetuning, we update only the weights of the ablated component, and all the other (pretrained) weights are frozen.

	- emb	- dec	- enc	- emb - xatt	- dec - xatt	- enc - xatt
mask	11.8	20.4	26.2	26.5	26.2	29.1

replace +tied	13.6	24.3	27.0	27.2	29.0	29.5

Figure 9: Ablation results for supervised NMT on en→de (wmt19). We reset each main component individually (left) and with the cross-attention (right).

2. We freeze the pretrained weights and finetune only the ablated (i.e., randomly initialized) component.

We decided to follow this protocol, in order to isolate the effects on the final BLEU score on the ablated component, and to also prevent the other components from compensating. In concurrent work, Gheini et al. (2021) have considered a similar experimental protocol, but to study a different but related phenomenon. In Figure 8, we show the ablation results for the en→de direction.

C Analysis Results in Other Languages

In Figures 10, 11, 12, 13, 14, 15, we report the analysis results 5 on the en↔ne and ↔ne pretrained models, evaluated on their NMT dev sets.

---

we assume a shared multi-lingual vocabulary

We observe that the results are very consistent with those for en↔de.

Training Details of Probing Classifier For the analysis in Sec. 5.1, each classifier is trained on the monolingual data for 50K steps, and optimized with Adam using a learning rate of 0.0001. Only the parameters of the classifier are updated and the rest of the model remains *fixed*.

C.1 Visualization of Encoder Representations

In this section, we visually inspect the input token representations. We compare each method based on how the representations evolve through the layers of the encoder, by focusing on two aspects of each token, (1) its *language* and (2) whether it has been *corrupted* or not. The goal is to inspect how each model encodes these two types of information about the input tokens.

Methodology We sample 5K sentences from the English-German monolingual data and pass them through the encoder of each model using corresponding noising method. For each token, we keep its representations from every layer and label them by language and noise. We keep only the representations of the 2K most frequent tokens and exclude the representations of special tokens, such as the `[BOS]`, `[EOS]`, and language IDs, which significantly skew the results. The final dataset contains approximately 100K token representations per layer (600K in total). For the visualization, we project to 2D with t-SNE (van der Maaten and Hinton, 2008). For each model, we visualize the representations of its encoder per layer (L1 to L6), which we colour-code by language (top-row) and the identity (bottom-row) of each token. L1 refers to the outputs of the first Transformer layer, therefore the tokens have been contextualized once.

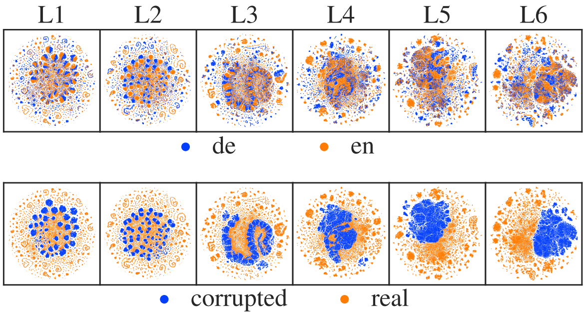

Figure 16: Visualization of encoder representations from the “mask=35%” model.

Masking In Fig. 16 we visualize the encoder of the “mask=35%” pretrained model. Real and masked tokens occupy different regions, whereas the tokens from each language are much closer to each other. All models trained with masking noise exhibit similar behaviour. In the first layer, the masked tokens are organized into multiple small clusters, but the encoder progressively groups them into larger structures. We visually verify that the encoder keeps the masked tokens separated even in the last layer. This aligns with our findings in Sec. 5.1, which suggest that the reconstruction loss does not incentivize the encoder to denoise the representations of masked tokens. Also, it enables the model to easily identify the real tokens and can copy them, as discussed in Sec. 5.2.

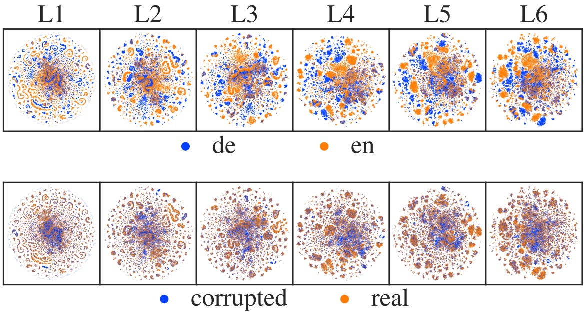

Figure 17: Visualization of encoder representations from the “mask=35%+eMLM” model.

Masking+eMLM In Fig. 17 we visualize the “mask=35%+MLM” model. Adding eMLM makes the masked and real tokens are indistinguishable from each other. Intuitively, to minimize the MLM loss the encoder must generate representations that are predictive of the true identity of the masked tokens, therefore similar to real tokens. We observe a small overlap between English and German tokens, as there are more language-specific clusters. We believe that is because the eMLM loss pushes the representation to better encode the grammar and semantics of each token.

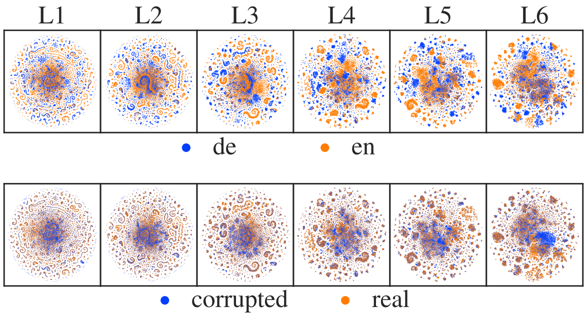

Figure 18: Layer-wise visualization of encoder representations from the “replace=35%” model.

Replacement In Fig. 18 we visualize the “replace=35%” model. There is a moderate separation between languages, slightly less than the “mask=35%+MLM” model. However, we observe that the representations of real and fake tokens generally overlap with each other, unlike the “mask=35%” model, especially in the lower layers. This is because the model is always given as input embeddings of actual words and not `[MASK]`, which unless contextualized all of them are treated the same. Only in the last layer, we can see the formation of a fake-only cluster. This suggests that the pretraining objective (i.e., reconstruction) creates a bias towards discriminating between real and fake token. However, the separation is not as extreme as in the masked-based models but is not obvious if the encoder can’t or is not biased to more clearly separate them.

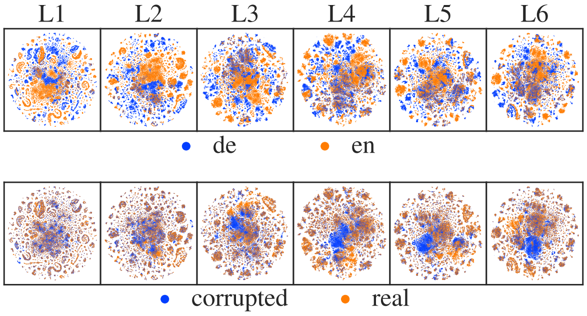

Figure 19: Visualization of representations from the “replace=35%+RTD=4” model, that is trained with an RTD head over the 4th layer of the encoder.

Replacement Token Detection In Fig. 19 we visualize the “replace=35%+RTD=4” model, that is trained with an RTD head over the 4th layer of the encoder. The only difference with the “replace=35%+RTD=6” is that the effects of RTD start to show earlier. Compared to the “replace=35” the

Table 5: Finetuning results to supervised NMT. "dec:X" denotes method that add noise to the the decoder. We report the average of 3 runs and the standard error of the mean.

representations are more clustered and less spread-out, even in the lower layers. The real and fake tokens are much better separated, and the separation peaks at layer 4, which visually verifies the bias introduced by RTD, but the separation is not as extreme as for masking noise. Although this suggests that separating masked/original words is harder than real/fake, it also depends on the weight used for the RTD loss during pretraining, which is not something we have explored. Also, the visualization suggests that the separation remains approximately constant in the remaining layers. There is no perceptible difference with "replace=35" in terms of language.

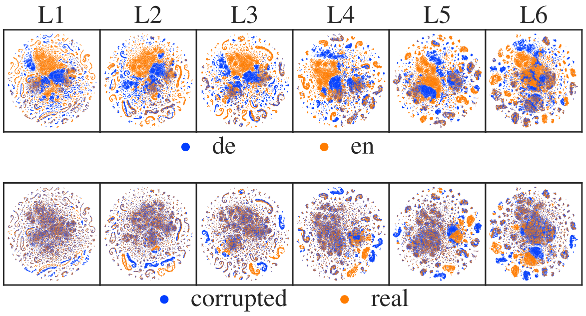

Figure 20: Visualization of representations from the "shuffle=5" model.

Shuffling In Fig. 20 we visualize the "shuffle=5" model. We observe a strong separation between languages, that slightly decreases in the upper layers. The language clusters are relatively large, unlike the much smaller and local language-specific clusters seen in the other models. As for noise, initially all tokens are represented similarly, but as the encoder re-contextualizes the input, it puts more misplaced tokens in separate clusters. This shows that the model becomes progressively more "aware" about the misplaced tokens in the input. After manual inspection of the clusters with corrupted tokens, we found that the majority of them contain punctuation marks. This makes intuitive sense, as it should be easy for the model to identify punctuation marks that has been misplaced.

D Additional NMT Experiments

In Table 5 we report some additional results for supervised NMT 4.1 omitted from the main paper. Besides combining shuffling and word replacements in the input, we also introduce noise in the decoder side, by randomly replacing 15% words of the decoder's input with the `[MASK]` token ("dec:mask=15%") or with samples from the generator ("dec:replace=15%"). Note that, we reduce the amount of noise in this case to avoid disrupting training. Overall, we observe that both methods increase performance in some language pairs, but the improvements are marginal.

We also experimented with RTD over shuffled inputs, by training the model to explicitly detect if words were misplaced or not, but this configuration lead to poor results.

Bowman et al. (2016) reported that masking more than 20% of words in the decoder hurts its LM capabilities.

Knowledge-Grounded Dialogue Generation with Term-level De-noising

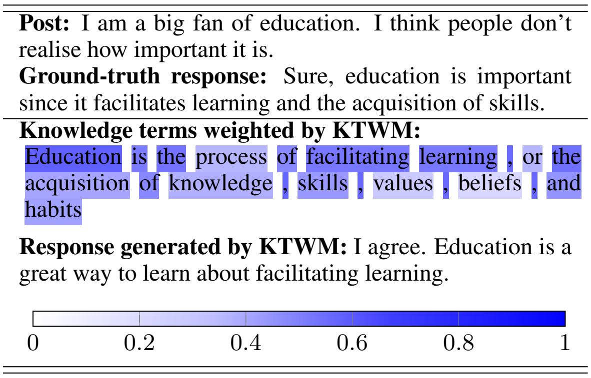
Abstract

Dialogue generation has been improved through injecting knowledge into generative models. However, addition of knowledge through simple selection of sentences or paragraphs is likely to introduce noise and diminish the effectiveness of the generative models. In this paper, we present a novel **K**nowledge **T**erm **W**eighting **M**odel (KTWM) that incorporates term-level de-noising of the selected knowledge. KTWM includes a module for generating Simulated Response Vectors (SRVs) and uses SRVs attention distributions with the knowledge embeddings to determine knowledge term weights. Our experiments demonstrate that KTWM, combined with various knowledge selection algorithms, consistently achieves statistically significant improvements over methods without term weighting when applied to two publicly available datasets Wizard of Wikipedia (Wiz) and Holl-E. The results are particularly improved for the Wiz test data with unseen topics, demonstrating the robustness of the KTWM noise-reduction approach.

1 Introduction

Research in dialogue generation has rapidly evolved from sequence-to-sequence (Sutskever et al., 2014) and Transformer models (Vaswani et al., 2017) to approaches with pre-trained models such as BERT (Devlin et al., 2019), XLNet (Yang et al., 2019) and T5 (Raffel et al., 2020). More recently, it included techniques that use knowledge, in addition to the original posts, to improve the quality of the generated responses (Ghazvininejad et al. (2018), Moghe et al. (2018), Dinan et al. (2019), Galley et al. (2019), Lian et al. (2019), Zheng and Zhou (2019), Zhao et al. (2020a), Zhao et al. (2020b)).[1] This approach is referred to as *knowledge-grounded dialogue generation* and is the primary concern of this paper.



Post: I am a big fan of education. I think people don't realise how important it is.
Ground-truth response: Sure, education is important since it facilitates learning and the acquisition of skills.

Knowledge terms weighted by KTWM:
Education is the process of facilitating learning , or the acquisition of knowledge , skills , values , beliefs , and habits

Response generated by KTWM: I agree. Education is a great way to learn about facilitating learning.

Table 1: Example of a post, ground truth response, injected knowledge and generated response by the Knowledge Term Weighting Model (KTWM). The term highlights indicate the predicted probability of a term being useful.

In particular, we consider the key issue of effectively incorporating the selected knowledge into the generation process. For example, Weston et al. (2018) apply a *retrieve and refine* method to expand the post with the retrieved knowledge and then use it in the generation process. Lian et al. (2019) consider the post and response *posterior distributions* and the post *prior distribution* to train jointly the model for knowledge selection and response generation. Kim et al. (2020) view the knowledge selection as a sequential decision problem, first selecting the best ranked knowledge using a sequential latent variable model, and then generating a response based on selected knowledge.

To the best of our knowledge, all prior approaches focus on the selection and injection of knowledge at the sentence or paragraph level. However, that makes it hard to control for potential

---

[1] Previous works used a variety of terms to refer to a post such as 'question', 'utterance','source' and 'query'. Similarly for response they used 'answer', 'response', and 'target'. In this paper we call the first role the 'post' and the second role the 'response' and we aim to generate the response for the given post.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2972–2983
August 1–6, 2021.

noise, i.e., for inclusion of non-relevant words, and previous studies (Galley et al. (2019), Zheng et al. (2020)) have shown that adding noise can decrease the response generation quality. Therefore, it is important to investigate whether and how we can adjust the contributions of terms in the selected knowledge. Prior research has not considered that issue systematically.

Our paper fills this gap by introducing a novel *Knowledge Term Weighting Model* (KTWM) for dialogue generation, which effectively estimates term weights of the injected knowledge and incorporates such weights into the response generation. The response generation thus benefits from such nuanced term-level knowledge weighting, promoting important knowledge terms rather than treating equally all the terms in the selected sentences. In Table 1 we show an example of the KTWM term weighting and its generated response: the terms 'education', 'is', 'facilitating' and 'learning' are given higher weights correctly as they do appear in the ground-truth response, while the words 'values' and 'beliefs' are correctly assigned lower scores.

We conducted an extensive range of experiments with KTWM on two publicly available datasets: Wiz (with seen and unseen test topics) (Dinan et al., 2019) and Holl-E (Moghe et al., 2018). KTWM performs consistently well with different selections of knowledge, specifically with Post-KS (Lian et al., 2019), SKT (Sequential Latent-Knowledge Selection) (Kim et al., 2020) and TED (Transformer with Expanded Decoder) (Zheng and Zhou, 2019). Our work achieves both a superior performance in knowledge-grounded dialogue generation and new insights into the impact of the knowledge term weighting on that performance. The code of our method is publicly available at *https://github.com/tonywenuon/acl2021_ktwm* and enables reproducibility of our results.

2 Related Work

The knowledge-grounded dialogue generation can be tackled by decomposing it into two subproblems: (1) selecting knowledge from a large pool of candidates (*knowledge selection*), and (2) generating a response from the selected knowledge and context (*knowledge-grounded response generation*).

Knowledge-grounded Response Generation Ever since the knowledge-based dialogue generation task was released by DSTC-7 (Galley et al., 2019), research interest in the topic has been steadily growing. Ghazvininejad et al. (2018) proposed a multi-task learning approach to produce responses. The posts and knowledge are used in the encoders and share the same decoder parameters. Luan et al. (2017) expanded the scope and introduced personality information into the model. They assumed that the trainable parameters can potentially capture persona from the non-conversational data (Tweets). Yavuz et al. (2019) adopted pointer-generator networks within a hierarchical framework that enabled them to include external knowledge in addition to the context. Ye et al. (2020) proposed a latent variable based generative model, which contains a joint attention mechanism conditioned on both context and external knowledge. Li et al. (2019) applied a deliberation network to create a two-stage generative model that combines both context and knowledge and, in the second generation stage, makes use of the outputs from the first stage. Zheng and Zhou (2019) proposed Transformer with Expanded Decoder (TED) architecture that assigns different weights to different knowledge sources and incorporates them into the generation process.

While the above approaches and models focus on incorporating knowledge and context to generate responses, they do that at the sentence or paragraph level. Our work deals with the quality of the incorporated knowledge at the term level, weighing all the individual knowledge terms when generating the responses.

Knowledge Selection Considering the mechanisms for response generation, Weston et al. (2018) proposed to retrieve candidate content from a knowledge set and use it to expand the post. The result is a truncated sequence that represents a refined post. (Lian et al., 2019) select the knowledge by approximating the prior distribution (i.e., $p(knowledge|post)$) with the posterior-distribution (i.e., $p(knowledge|post, response)$) and then inject it into the decoder. Kim et al. (2020) trained a knowledge selection module and a response generation module jointly, but treated the knowledge selection as a sequential decision problem, using input and knowledge from the previous turns to select the knowledge in the subsequent turns. Zheng et al. (2020) separated the knowledge selection process from the generation process so that all the downstream generation tasks can use the selected knowledge. They mapped posts to the best knowledge representations in both the training and the testing phase, and used the learned models to rank new post-knowledge pairs.

In this context, KTWM can be viewed as an optimization step following the knowledge selection. It is focused on learning knowledge term weights to distinguish between relevant and non-relevant terms and weighing higher those that are useful for the response generation.

3 Method

In this section we introduce the basic concepts and describe in detail our method KTWM for term-weighting of the injected knowledge. We assume that for a collection of posts P and responses R, we have a collection $\{K_{pr}\}$ of knowledge sets with sentences relevant to the specific post-response pair (p, r). For a given pair (p, r) we consider a knowledge injection process that involves three stages: (1) knowledge selection, (2) knowledge term-weighting, and (3) decoding with the weighted knowledge terms. Our primary focus is on (2), i.e., the effectiveness of the term-weighting for the knowledge incorporated in the KTWM. Thus we provide a detailed description of the term-weighting model (Figure 1) and the use of the KTWM decoder (Figure 2).

3.1 Knowledge Selection and Representation

We represent each post p, response r, and a knowledge sentence k as a vector of terms. The set K_{pr} typically contains multiple knowledge sentences and we use BM25 retrieval method to rank the sentences by their relevance to the post (in the test phase) or response (in the training phase). For knowledge injection we take the top ranked sentence. When the knowledge injection requires a specific number of terms to be used, we include additional sentences from the ranked list to meet that requirement (used in §4.4.3).

When a knowledge sentence k is retrieved based on a response r as a query, we define a ground truth vector GT_{know} for the knowledge k with the weight of 1 assigned to the knowledge terms that are present in r and the weight of 0 assigned to those that are not, i.e., $GT_{know} = (e_1, e_2, \ldots, e_l)$, where $e_i \in \{0, 1\}, i = 1, \ldots, l$.

Encoders. We adopt Transformer (Vaswani et al., 2017) as the backbone framework for the training and testing of KTWM. Transformer encoder consists of a self-attention layer and a transition layer involving the layer normalisation and residual network. Formally, the attention is defined as

$$Attention(Q, K, V) = softmax\left(\frac{QK^T}{\sqrt{d_m}}\right)V, \tag{1}$$

where Q, K, and V are embedding matrices and d_m is the embedding dimension of the model. First we compute the dot similarity of the Q and K and then apply the weighted summation with V. The representation of Q is updated with the information from K and V. If Q, K, V originate from the same source, e.g., an input post, the attention is referred to as self-attention. Otherwise, if they originate from different sources, e.g., Q relates to the decoding token and K and V are from a post, the attention turns to be a mutual-attention operation.

Figure 1 shows transformer encoders (*encoders* for short) used for the post, knowledge, and response representations and processing. We use w to designate an original term and $\widehat{w}$ to designate the term's representation. In Figure 1, n, m, and l are three pre-defined hyper-parameters which refer to the length of the post (p), response (r), and knowledge (k), respectively (e.g. w_{pi} means the i-th term of the post). Any sequence that is longer or shorter than the given length will be truncated or padded to the given length. By applying the encoder

$$V_{post} = Encoder(w_i)(i \in [1, n]) \tag{2}$$

we obtain the post terms representations V_{post}, comprising $\widehat{w}_{p1}, \widehat{w}_{p2}, \ldots, \widehat{w}_{pn}$ (in Figure 1), from the original terms $w_{p1}, w_{p2}, \ldots, w_{pn}$. Similarly to V_{post} in Eq. (2), we obtain V_{know} and V_{resp} as term representations of the corresponding knowledge and the response, respectively.

3.2 Knowledge Term Weighting

The fundamental premise of our approach is that knowledge terms related to or present in the response should be more effective in improving dialogue generation. Thus, it can be beneficial to use methods such as attention distribution of response and knowledge embeddings to determine the weights of individual knowledge terms. However, in the real setting and during the test phase, we can only use terms and knowledge related to the post. Furthermore, the post embeddings can significantly differ from the response ones. Thus, assigning weights to the knowledge terms based on

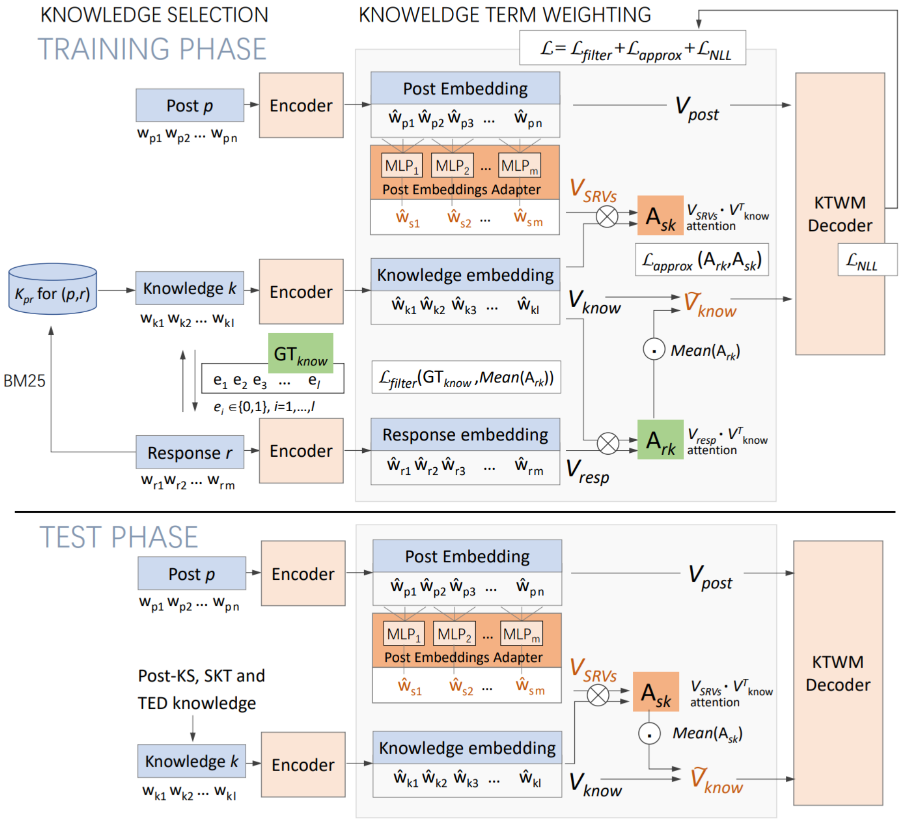


Figure 1: Architecture of the Knowledge Term Weighting Model (KTWM) showing the operations in the training and test phase. ⊗ designates matrix multiplication; ⊙ designates element-wise multiplication.

their similarity to post embeddings is unlikely to be sufficient (Xing et al., 2018).

For that reason, we aim to learn how to transform the post embeddings to be effective in knowledge term weighting. We achieve that by training a *Post Embeddings Adapter* that can, for a new post, generate *Simulated Response Vectors* (SRVs) and use them in place of the response vectors to score post related knowledge terms.

To that effect, we introduce a set of Multi-Layer Perceptrons (MLPs):

$$MLP = \sum_{i=1}^{n} \widehat{w}_{pi} W_i + b \tag{3}$$

$$\widehat{w}_{sj} = MLP_j(\widehat{w}_{p1}, \widehat{w}_{p2}, \ldots, \widehat{w}_{pn})(j \in [1, m]) \tag{4}$$

where W_i and b are trainable parameters for each term p_i of the post p; $\widehat{w}_{sj}$ is the representation of the j-th term of the simulated response vector (SRV). The number of MLPs is the same as the number of terms in a given response.

During the training phase, MLPs learn the transformation of the post embeddings into SRVs that captures the ground truth response representation for a given post p. SRVs are then used to assign appropriate weights to the knowledge terms when response information is not available.

SRVs Approximation and Training. The training phase begins with V_{post}, V_{know}, V_{resp} and randomly initiated parameters of MLPs to produce the initial set of V_{SRVs} for a given post. Each iteration then involves comparison of (a) the response embeddings V_{resp} and knowledge embeddings V_{know}, and (b) SRVs with the knowledge embeddings V_{know}. More precisely, we compute the term-wise attention distributions A_{rk} and A_{sk}:

$$A_{rk} = sigmoid(V_{resp} V_{know}^T) \tag{5}$$

$$A_{sk} = sigmoid(V_{SRVs} V_{know}^T) \tag{6}$$

where $A_{rk} \in \mathbb{R}^{m \times l}$ and $A_{sk} \in \mathbb{R}^{m \times l}$; m and l are hyper-parameters that are the maximum length of the response and knowledge sentence.

A_{rk} reflects the relationship between the response terms and the knowledge terms: for each response term, A_{rk} includes attention scores with all knowledge terms. Similarly, A_{sk} includes attention scores between SRVs and the knowledge representations. The knowledge terms with larger response-knowledge attention scores are expected to produce output closer to the true response. In the training phase, that is guided by the *filtering loss* for A_{rk}:

$$\mathcal{L}_{filter} = BCE(GT_{know}, Mean(A_{rk})) \quad (7)$$

where GT_{know} is the *knowledge ground truth* vector which indicates whether the knowledge terms appear in the corresponding response or not and BCE is the Binary Cross Entropy loss function. $Mean(\cdot)$ computes the mean values for knowledge terms (in the matrix columns) across response terms ($Mean(\cdot) \in \mathbb{R}^l$).

At the same time we aim to train MLPs to create SRVs similar to the response representations V_{resp}. In each iteration we compute and compare A_{sk} to A_{rk} and apply the *approximation loss* function:

$$\mathcal{L}_{approx} = MSE(Mean(A_{rk}), Mean(A_{sk})) \quad (8)$$

where $MSE(\cdot)$ is the Mean Squared Error function. $Mean(\cdot)$ of A_{rk} and A_{sk} produces l-length knowledge term vectors whose values are used to characterise the importance of each knowledge term. We use these weights to update the knowledge vector:

$$\widetilde{V}_{know} = Mean(A_k) \odot V_{know} \quad (9)$$

where $\odot$ denotes element-wise multiplication and A_k corresponds to A_{rk} in the training phase and to A_{sk} in the test phase. V_{post} and the weighted knowledge vector $\widetilde{V}_{know}$ become input for the KTWM decoder.

3.3 KTWM Decoder

In order to incorporate multiple sources of input, we adopt a decoder design that is similar to the TED model by Zheng and Zhou (2019). Figure 2 shows the architecture of our KTWM decoder. The blue frames are the standard Transformer decoder set-up with a self-attention layer and a mutual-attention layer (for the post), followed by a feed-forward layer.

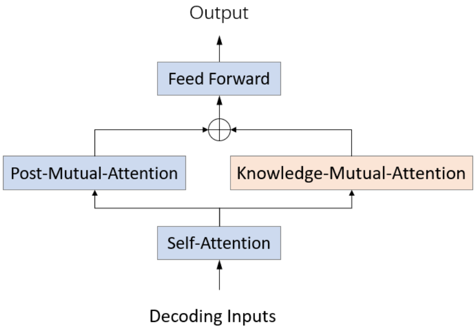

Figure 2: Knowledge Term Weighting Model Decoder.

KTWM includes an additional knowledge-mutual-attention layer which applies the same process to the knowledge, i.e., replicates the post-mutual-attention layer for the knowledge. However, while TED focuses on assigning different weights to different sources, KTWM is already provided with scored knowledge terms. We use V_{PMA} to denote the post-mutual attention, V_{KMA} for knowledge-mutual attention and V_{dec} for the decoding tokens representation matrix. With the attention defined by Eq. (1), we can express:

$$V_{PMA} = Attention(V_{dec}, V_{post}, V_{post}) \quad (10)$$

$$V_{KMA} = Attention(V_{dec}, \widetilde{V}_{know}, \widetilde{V}_{know}). \quad (11)$$

The *final mutual attention* V_{MA} in the decoder is then calculated from V_{PMA} and V_{KMA}:

$$V_{MA} = V_{PMA} \oplus V_{KMA} \quad (12)$$

where $\oplus$ means element-wise summation. The feed forward layer is a standard Transformer transition layer (Vaswani et al. (2017)).

Finally, we adopt Negative Log Likelihood (NLL) to train the model:

$$\mathcal{L}_{NLL} = -\sum_{t=1}^{m} logP(y_t|y_{<t}, p, k). \quad (13)$$

Given a post (p), knowledge (k), and the previously predicted terms ($y_{<t}$), $\mathcal{L}_{NLL}$ maximises the probability of the currently predicted term. During the training phase, $P(y_t|y_{<t}, p, k)$ is replaced with $P(r_t|r_{<t}, p, k)$, i.e., we use the ground truth response as the input instead of the model output from the previous steps (Goyal et al., 2016).

We assume that all three loss functions are equally important and create the final loss function as a sum:

$$\mathcal{L} = \mathcal{L}_{filter} + \mathcal{L}_{approx} + \mathcal{L}_{NLL} \quad (14)$$

KTWM thus provides a flexible learning framework, enabling injection of knowledge based on different selection criteria. We compare KTWM effectiveness when used with Post-KS, SKT and TED model by incorporating the knowledge that each of these methods selects.

4 Experiments

We conduct empirical evaluation of KTWM compared to state-of-the-art baselines.

4.1 Datasets

In our experiments we use two publicly available datasets: Wizard of Wikipedia (Dinan et al., 2019) and Holl-E (Moghe et al., 2018). Both are purposefully created by humans editors to support dialogue generation research.

Wizard of Wikipedia (Wiz). Dinan et al. (2019) employed Amazon Mechanical Turk (MTurk) workers to generate the datasets. The workers can assume two different roles: a wizard (a teacher) and an apprentice (a student). An apprentice asks a question according to a given topic and a wizard answers the question based on the provided question-related information (retrieved from Wikipedia). The response can quote the retrieved knowledge or can be generated entirely by the wizard without considering the knowledge. Thus, for each question-response pair there is related knowledge that can be used for knowledge-grounded dialogue generation research.

The Wiz dataset consists of 22,311 dialogues with 201,999 dialogue turns divided into a training dataset and two test datasets referred to as *seen test set* and *unseen test set*. The seen test set includes topics that have already been seen in the training set. In the unseen dataset, there are topics that may not have been included in the training dataset.

Holl-E Moghe et al. (2018) also made use of MTurk workers to create an annotated dataset that focuses on movies as two workers talk with each other about a chosen movie. When answering another worker's question, one is provided with four sources: movie plots, reviews, comments, and fact tables related to the movies. These sources can be considered as background knowledge. The final response is produced by copying from the sources or by modifying the sources. The Holl-E dataset provides training set and test test and contains 9,071 conversations, covering 921 movies.

4.2 Metrics, Setup and Baselines

Metrics. For performance evaluation, we adopted standard lexical-based metrics: BLEU (Papineni et al., 2002), METEOR (Lavie and Agarwal, 2007) and embedding-based metric: BOW Embedding (Liu et al., 2016). BLEU 1-4 metrics measure co-occurrence of n-gram terms in two given sequences, e.g., the generated responses and the ground truth responses. METEOR is an adaptation of BLEU that considers the presence of synonyms and common word stems. BOW Embedding measures the similarity of two sentences from the semantic perspective. Specifically, it computes the *average metric*, *greedy metric* and *extrema metric* based on word embeddings of compared sentences. The average metric considers cosine distance between pairs of sentence-level representations (e.g., the predicted response and ground truth response) by averaging the representations of their constituent words and calculates the average across all pairs. The greedy metric considers the maximum cosine scores along rows and columns in the similarity matrix. The extrema metric of two sentences first creates a sentence vector with the highest word-embedding values (along the dimension) and then computes the similarity score. BLEU, METEOR[2] and BOW Embedding[3] are calculated using NLG evaluation sources.

Experiment Setup. For the sake of comparison, we fixed a set of parameters across all the experiments. The number of dimensions in embeddings is set to 100. The vocabulary size is 30,000. The vocabulary is obtained by ranking terms by word frequency in the training set. The minimum sequence length is set to 8 and the maximum length is 30. We train using mini-batches of size 64. We use Adam optimiser (Kingma and Ba, 2015) for optimisation. The initial learning rate is set to 0.001 and halved when the loss score does not decrease for two epochs. In the training phase we use response-retrieved knowledge, i.e., the sentences retrieved by BM25 algorithm using responses as queries (see Figure 1). The top 1 ranked knowledge sentence is injected into KTWM. In the test phase, we retrieve knowledge using BM25 algorithm and posts as queries. All the experiments are conducted on a single TITAN V GPU. For Wiz dataset, an experiment requires about 6 hours to complete, while for Holl-E about 2.5 hours.

Baselines. We compare KTWM with three strong baselines:

Post-KS (Lian et al., 2019) uses an elaborate knowledge selection module and injects the selected knowledge into a generative model by approximating prior-distribution (i.e., $p(k|p)$) with posterior-distribution (i.e., $p(k|p, r)$).

---

[2] https://github.com/Maluuba/nlg-eval

[3] https://github.com/neural-dialogue-metrics/EmbeddingBased.

SKT (Kim et al., 2020) considers knowledge selection as a sequential problem. It jointly trains a knowledge selection and a generative model by taking into account inputs and knowledge from previous turns.

TED (Zheng and Zhou, 2019) uses a knowledge-grounded generative model that assigns different weights to different sources when generating responses. It applies knowledge ranking using BM25, which is the same as in our setting.

4.3 Experiment Design

Our experiments focus on term weighting of the selected knowledge rather than the knowledge selection itself. Since the baseline models (Post-KS[4], SKT[5] and TED[6]) incorporate knowledge selections, we conduct a comparative evaluation of KTWM by incorporating knowledge specific to each baseline method. Furthermore, since all three baselines inject knowledge at the sentence level, by selecting the top ranked sentence, we do the same with KTWM.

4.4 Experiment Results

4.4.1 Performance of Generating Response

We summarize KTWM experiments with the Wiz and the Holl-E datasets in Table 2. Results for the Wiz seen and unseen test sets are in Table 2, sections (a) and (b), respectively. Results for the Holl-E dataset are in Table 2, section (c). Since METEOR extends BLEU metrics by considering word stems and synonyms, we take it as the main metric for discussing the experiment results. We observe that:

(1) For all of three datasets, KTWM outperforms each baseline method across all lexical and embeddings based metrics with a statistically significant difference.

(2) KTWM with Post-KS knowledge achieves the largest relative improvement considering the METEOR score: increase of 45.3%, 54.5% and 40.0% for the three test sets, respectively.

(3) For the Holl-E dataset, KTWM with TED knowledge outperforms other two baseline models. TED knowledge comprises top sentences retrieved using BM25 algorithm.

(4) On the Wiz datasets, KTWM achieves a remarkable performance in terms of BLEU-1 and METEOR scores. A consistent and strong performance in the Wiz unseen test data indicates the robustness and generalization of KTWM.

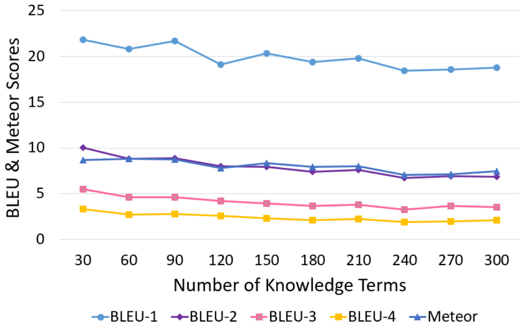

Figure 3: Effects of the increased number of knowledge terms on the KTWM performance (Wiz seen test set).

4.4.2 Results of Knowledge Term Weighting

The loss function (Eq. (7)) controls KTWM ability to distinguish between relevant and non-relevant knowledge terms, similar to a binary classifier. We set a threshold of 0.5 for a knowledge term's predicted score and consider the overlap between the predicted and the truth useful knowledge terms. This leads to precision/recall evaluation of the positive and the negative class prediction. Table 3 shows results from the Wiz seen test set. They are representative of the results for the other two datasets.

We observe that the precision of predicting useful terms is 50% and noisy terms is over 91% (with a high F-1 score, 94%). Thus KTWM term weighting is effective in detecting noisy terms while only half of the predicted useful terms overlap with the ground truth terms. Since noisy terms are assigned lower term weights, KTWM is effective improving the dialogue generation performance. Appendix A shows illustrations of the KTWM noise reduction.

4.4.3 Analysis of Input Sequence Length

We analyze the effects of knowledge de-noising by considering the *useful terms proportion* (UTP) as we increase the number of injected knowledge terms: $UTP = \frac{Num\ of\ distinct\ useful\ terms}{Num\ of all\ injected\ terms}$. We use UTP_K for UTP when the number of injected knowledge terms is K (e.g., UTP_{30} for 30 knowledge terms). Our analysis shows that UTP_{30} is 12.23% and UTP gradually decreases with additionally injected knowledge leading to UTP_{300} of only 3.35%. Figure 3 shows a gradual decline of the KTWM performance with the increased length of injected knowledge, as the proportion of noisy

terms increases.

We also investigate the effects of the loss functions $\mathcal{L}_{filter}$ and $\mathcal{L}_{approx}$ on the KTWM performance by running experiments with and without them. In Table 4 we show the results on the Wiz seen test set using BM25 to select knowledge. We note that, after removing $\mathcal{L}_{filter}$ loss function, BLEU-1 and Average scores decrease, while BLEU-4 and METEOR scores increase. Since $\mathcal{L}_{filter}$ aims to ensure that relevant response terms are promoted, it is not surprising that the metrics focused on unigrams are most affected. However, this impact on KTWM is less notable than the removal of the $\mathcal{L}_{approx}$. Without $\mathcal{L}_{approx}$, the KTWM loses the ability to align simulated response vectors SRVs with the response embeddings to capture the attention distribution between the knowledge and the response embeddings that is needed to score knowledge terms. This increases the noise ratio and reduces the KTWM performance scores across all metrics.

5 Conclusions

Current knowledge-grounded dialogue models select and inject knowledge either through traditional (unsupervised) retrieval technique, such as BM25, or by incorporating knowledge selection within the dialogue generation model. Most of them incorporate knowledge as sentences or paragraphs. Past research provided evidence (Galley et al. (2019), Zheng et al. (2020)) that inserting useful terms can increase the response generation performance but it is necessary to control for negative effects of noisy terms.

In our work, we introduce a novel Knowledge Term Weighting Model (KTWM) that performs knowledge term-level weighting and de-noising of injected knowledge. We demonstrate that KTWM effectively estimates weights of knowledge terms and yields better response generation performance than state-of-the-art baseline models when evaluated on two broadly used datasets. Besides the superior response generation outcomes, our research provides important insights into the importance of the knowledge term weighting. As part of our future work we intend to (1) extend the KTWM models to incorporate multiple sources of evidence, such as balancing between selected knowledge and dialogue contexts (i.e., previous dialogue turns) and (2) take into account inter-dependencies among terms when weighting the selected knowledge.

A Examples of Knowledge Term Weights and KTWM Generated Responses

In Table 5 and 6 we present examples of post/response pairs and selected knowledge with terms weighted by KTWM.

As explained in §4.4.2, we use a threshold of 0.5 on term scores to classify terms into useful and noisy ones and study the effect of this selection on the overall performance of KTWM. In the examples, we visually show the weights of each terms. Terms are highlighted in different shades of blue colour according to the weight (note the colour legend at the bottom of the tables). All the examples are extracted from the Wiz seen test set. They are sorted by the number of words that exceed the threshold.

In Table 5 we see that the key words are tagged with dark blue, indicating that KTWM has assigned high weights to them. From the KTWM generated responses, we can see that if the words appear in the post and ground-truth response simultaneously, the KTWM works effectively, i.e., can correctly incorporate injected knowledge into the generated response.

On the other hand, the negative examples in Table 6 show that the term scoring can be ineffective if there is no good overlap with the ground truth response. We observe in these examples that most of the words with relatively high scores do not exist in both post and response. At the same time, if the injected knowledge does not contain useful terms, the produced responses might be irrelevant. In Table 6, most of terms have light blue colour, indicating that KTWM detected a relatively low importance of these terms correctly.

The examples in these two tables also confirm statistical results shown and discussed in §4.4.3. KTWM term weights still induce noise, especially when the injected knowledge does not contain useful terms (i.e. terms that present in the ground truth response), resulting in a worse response generation performance.

We note that the both sets of examples include highlighted punctuation (e.g., ‘,’) and language structural terms (e.g., ‘the’, ‘is’) which obtain high KTWM weights. We assume that such terms are widely distributed in post and response sets and therefore detected as important.

Post: I love avengers!! Have you watched the Infinity War movie? I think it was really good and I can’t wait till the next movie to find out what happens. **Response:** The Avengers Infinity War was so good. What a cliff hanger. Blows my mind that the Avengers made their comic debut way back in 1963. **Knowledge Terms Weighted by KTWM:** In ” Avengers : Infinity War ” , the Avengers join forces with the guardians of the galaxy to confront Thanos , who is trying to collect the infinity stones **Response generated by KTWM:** I love the Avengers. the Avengers was the Avengers, Infinity War. He is such a great show.
Post: I have never actually been to a horse race in Kentucky, where is the Derby held at anyways? **Response:** Louisville Kentucky, it ends the Kentucky Derby festival usually. **Knowledge Terms Weighted by KTWM:** The Kentucky Derby presented by Woodford reserve is a horse race that is held annually in Louisville , Kentucky , United States , on the first Saturday in may . **Response generated by KTWM:** I’m not sure but I know that it is located in Kentucky race in the United States and Canada.
Post: New York city is quite impressive. **Response:** Yeah they say that New York and LA are the two largest markets in our country. **Knowledge Terms Weighted by KTWM:** The city of New York , often called New York City or simply New York , is the most populous city in the United States **Response generated by KTWM:** Yes, it is. The city of New York is the most populous city in the United States.
Post: Hi there! I drive a Honda Civic. Do you have a car? **Response:** I have a VW golf, but was looking to change to a Honda Civic. I heard that the Civic has got larger throughout the years. **Knowledge Terms Weighted by KTWM:** The Honda Civic type R is the highest performance version of the Honda Civic made by Honda Motor company of Japan **Response generated by KTWM:** I have a Honda Civic. They are the second most commonly used in the US in Japan.
Post: Well that’s interesting, but seems like it could get confusing! I bet humans have been hiking ever since we could walk though! **Response:** Yeah hiking has been around for ever, the term bush walking is endemic to Australia. **Knowledge Terms Weighted by KTWM:** Hiking is the preferred term , in canada and the united states , for a long , vigorous walk , usually on trails (footpaths) , in the countryside **Response generated by KTWM:** Well, hiking is a long term hiking is used in the United States, and the countryside on trails.

Table 5: Positive cases that the injected knowledge is properly weighted by the proposed KTWM model. The background colour stands for the probability of being a useful term.

Post: Yes, indeed. What cultural meanings come to mind when you think of dance? **Response:** Some of its many functions that come to mind are social, ceremonial, and competitive in meaning. **Knowledge Terms Weighted by KTWM:** One open question regarding the nature of the mind is the mind body problem , which investigates the relation of the mind to the physical brain and nervous system **Response generated by KTWM:** I'm not sure but I do know that the spiritual core is associated with mind and mind.
Post: I have written a few historical fiction novels that i am currently trying to get published. **Response:** That's really cool, historical fiction is such a fun genre to read. **Knowledge Terms Weighted by KTWM:** Historical romance (also historical novel) is a broad category of fiction in which the plot takes place in a setting located in the past **Response generated by KTWM:** That's great. I love romance novels. It's a broad category of historical fiction, and fantasy.
Post: I would have to say Snooki still, she is such a ball of fire. **Response:** Since you like Snooki so much, did you happen to see the Spinoff of Jersey shore called ”Snooki and Jwoww”? **Knowledge Terms Weighted by KTWM:** She attended Columbia high school , in east greenbush , New York , and New York Institute of Technology **Response generated by KTWM:** I don't know much about Vietnamese style, but i know it has been around since 1700
Post: Are they popular in other areas of the world like Europe or Asia ? **Response:** Similarly! In the European Union vehicles in this size are known as large good vehicles. **Knowledge Terms Weighted by KTWM:** Western civilisation traces its roots back to western Europe and the western Mediterranean **Response generated by KTWM:** I'm not sure, but I do know that they are native to the Mediterranean Mediterranean cuisine.
Post: Wow that's interesting. The food world has really diversified. **Response:** Yeah or you can cook without heat. Like in south America they make Ceviche, which is fish that is cooked in lemon or lime juice and the acid cooks the fish. **Knowledge Terms Weighted by KTWM:** Bow Wow Wow are an English 1980s new wave band , created by Malcolm Mclaren **Response generated by KTWM:** Yes, it is! It's the world's most popular foods in the world.

Table 6: Negative cases that the injected knowledge is not properly weighted by the proposed KTWM model. The background colour stands for the probability of being a useful term.

Inspecting the concept knowledge graph encoded by modern language models

Abstract

The field of natural language understanding has experienced exponential progress in the last few years, with impressive results in several tasks. This success has motivated researchers to study the underlying knowledge encoded by these models. Despite this, attempts to understand their semantic capabilities have not been successful, often leading to non-conclusive, or contradictory conclusions among different works. Via a probing classifier, we extract the underlying knowledge graph of nine of the most influential language models of the last years, including word embeddings, text generators, and context encoders. This probe is based on concept relatedness, grounded on WordNet. Our results reveal that all the models encode this knowledge, but suffer from several inaccuracies. Furthermore, we show that the different architectures and training strategies lead to different model biases. We conduct a systematic evaluation to discover specific factors that explain why some concepts are challenging. We hope our insights will motivate the development of models that capture concepts more precisely.

1 Introduction

Natural language processing (NLP) encompasses a wide variety of applications such as summarization (Kovaleva et al., 2019), information retrieval (Zhan et al., 2020), and machine translation (Tang et al., 2018), among others. Currently, the use of pre-trained language models has become the *de facto* starting point to tackle most of these tasks. The usual pipeline consists of finetuning a pre-trained language model by using a discriminative learning objective to adapt the model to the requirements of each task. As key ingredients, these models are pre-trained using massive amounts of unlabeled data that can include millions of documents and billions of parameters. Massive data and parameters are supplemented with a suitable learning architecture, resulting in a highly powerful but also complex model whose internal operation is hard to analyze.

The success of pre-trained language models has driven the interest to understand the mechanisms they use to solve NLP tasks. As an example, in the case of BERT (Devlin et al., 2019), one of the most popular pre-trained models based on the Transformer (Vaswani et al., 2017), several studies have attempted to access the knowledge encoded in its layers and attention heads (Tenney et al., 2019b; Devlin et al., 2019; Hewitt and Manning, 2019). In particular, Jawahar et al. (2019) shows that BERT can solve tasks at a syntactic level by using Transformer blocks to encode a soft hierarchy of features at different levels of abstraction. Similarly, Hewitt and Manning (2019) show that BERT is capable of encoding structural information from text. In particular, using a structural probe, they show that syntax trees are embedded in a linear transformation of the encodings of BERT.

In general, previous efforts have provided strong evidence indicating that current pre-trained language models encode complex syntactic rules. However, relevant evidence about their abilities to capture semantic information remains still elusive. As an example, Si et al. (2019) attempts to locate the encoding of semantic information as part of the top layers of Transformer architectures finding contradictory evidence. Similarly, Kovaleva et al. (2019) focuses on studying knowledge encoded by self-attention weights. Their results provide evidence for over-parameterization but not about language understanding capabilities.

In this work, we study to what extent pre-trained language models encode semantic information. As a key source of semantic knowledge, we analyze their ability to encode the concept relations embedded in the conceptual taxonomy of Word-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2984–3000
August 1–6, 2021.

Net[1] (Miller, 1995). Understanding, organizing, and correctly using concepts is one of the most remarkable capabilities of human intelligence (Lake et al., 2017). Therefore, quantifying the ability that a pre-trained language model can exhibit to encode the conceptual organization behind WordNet is highly valuable. This knowledge may provide useful insights into the inner mechanisms that these models use to encode semantic information. Furthermore, identifying what they find difficult can provide relevant insights into how to improve them.

Unlike most previous works, we do not focus on a particular model but target a large list of the most popular pre-trained language models. In this sense, one of our goals is to provide a comparative analysis of the benefits of different approaches. Following Hewitt and Manning (2019), we study semantic performance by defining a probing classifier based on concept relatedness according to WordNet. Using this tool, we analyze the different models, enlightening how and where semantic knowledge is encoded. Furthermore, we explore how these models encode suitable information to recreate the structure of WordNet. Among our main results, we show that the different pre-training strategies and architectures lead to different model biases. In particular, we show that contextualized word embeddings, such as BERT, encode high-level concepts and hierarchical relationships among them, creating a taxonomy. This finding corroborates previous work results (Reif et al., 2019) that claim that BERT vectors store sub-spaces that correspond with semantic knowledge. Our study also shows evidence about the limitations of current pre-trained language models, demonstrating that they have difficulties to encode specific concepts. For example, all the models struggle with concepts related to "taxonomical groups". Our results also reveal that models have distinctive patterns regarding where in the architecture they encode the semantic information. These patterns are dependant on architecture and not on model sizes.

2 Study methodology

Probing methods consist of using the representation of a frozen pre-trained model to address a particular task. If the probing classifier succeeds in this setting but fails using an alternative model, it means that the source model encodes the knowledge needed to solve the task. Furthermore, the classifier's performance can be used to measure how well the model captures this knowledge (Conneau et al., 2018). We use a probing method at the semantic level applying it to the nine models presented in Section 2.2. Our study sheds light on whether the models encode relevant knowledge to predict concept relatedness in Wordnet.

To study how accurately the models encode semantic information, we measure correctness in predicted relations among concepts at two levels: (a) pair-wise-level by studying performance across sampled pairs of related or unrelated concepts, and (b) graph-level by using pair-wise predictions to reconstruct the actual graph. We describe both approaches in Sections 2.3 and 2.4, respectively.

2.1 WordNet splits and sampling

We partitioned the available WordNet synsets at 70/15/15 for training, validation and test sets respectively. Our experimental setup ensures no overlap in concepts among these sets. As an example, if the concept related to "house" fell in the training set, then all its lemmas are considered in this partition (e.g. "home", "residence", etc.), and neither this concept nor those lemmas will be present in the validation or test sets. Our sampling setup also balances the number of times each concept acts as hypernym or as a hyponym in the relation, whenever possible. Thus the benefit of learning whether a word is a "prototypical hypernym", as pointed out by Levy et al. (2015), is close to zero. Further details are available in Appendix A.1.

2.2 Word embedding models

This study considers the most influential language models from recent years. We consider the essential approaches of three model families: non contextualized word embeddings (NCE), contextualized word embeddings (CE), and generative language models (GLM). We consider Word2Vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014) for the first family of approaches. For the CE family, we consider ELMo (Peters et al., 2018b), which is implemented on a bidirectional LSTM architecture, XLNet (Yang et al., 2019), and BERT (Devlin et al., 2019) and its extensions ALBERT (Lan et al., 2020) and RoBERTa (Liu et al., 2019), all of them based on the Transformer architecture. GPT-2 (Radford et al., 2018) and T5 (Raffel et al.,

---

[1] WordNet is a human-generated graph, where each one of its 117000 nodes (also called synsets) represent a concept. In this work, we use hyponymy relations, representing if a concept is a subclass of another.

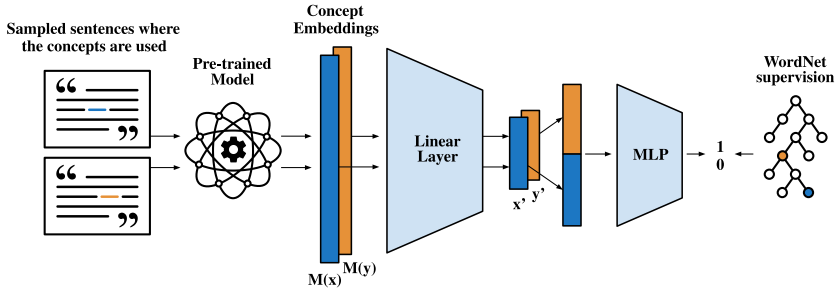

Figure 1: Inputs to the edge probing classifier correspond to the model embeddings $M(x)$ and $M(y)$ of concepts x and y, respectively. $M(x)$ and $M(y)$ are projected into a common lower dimensionality space using a linear layer. The resulting embeddings x' and y' are concatenated and fed into a Multi-Layer Perceptron that is in charge of predicting if the concept pair is related or not.

2019) are included in the study to incorporate approaches based on generative language models.

For models in the CE and GLM families, the embedding is extracted after running the model on a sentence where the concept is used in context. Then we discard the context and keep only the first token that correspond to the specific mention of the concept. Finally we concatenate the hidden states of every layer of the model, for the selected token.

2.3 Semantic probing classifier

We define an edge probing classifier that learns to identify if two concepts are semantically related. To create the probing classifier, we retrieve all the glosses from the Princeton WordNet Gloss Corpus[2]. This dataset provides WordNet's synsets gloss sentences with annotations identifying occurrences of concepts within different sentence contexts. The annotations provide a mapping of the used words to their corresponding WordNet node. We sample hypernym pairs A, B. Then, from an unrelated section of the taxonomy, we randomly sample a third synset C, taking care that C is not related to either A or B. Then, $\langle A, B, C \rangle$ forms a triplet that allows us to create six testing edges for our classifier. To train the probing classifier, we define a labeled edge $\{x, y, L\}$, with x and y synsets in $\{A, B, C\}$, $x \neq y$. $L \in \{0, 1\}$ is the target of the edge. If y is direct or indirect parent of x, $L = 1$, while $L = 0$ in other case. For each synset x, y, we sample one of its sentences $S(x)$, $S(y)$ from the dataset. Let M be a model. If M belongs to the NCE family, x and y are encoded by $M(x)$ and $M(y)$, respectively. If M belongs to the CE or GLM families, then x and y are encoded by the corresponding token of $M(S(x))$ and $M(S(y))$, respectively.

To facilitate the evaluation of embeddings of different sizes, we first project each concept's encodings x and y into a low dimensionality space using a linear layer (see Figure 1). These vectors, denoted as x' and y', are concatenated and fed into a Multi-Layer Perceptron (MLP) classifier. The linear layer and the MLP are the only trainable parameters of our setting, as we use the source model weights without any finetuning. Throughout all the experiments we used an MLP classifier with a single hidden layer of 384 hidden units.

We use this MLP to learn the structural relation between concept pairs, providing the test with a mechanism that allows the embeddings to be combined in a non-linear way. Tests based on linear transformations such as the one proposed by Hewitt and Manning (2019) did not allow us to recover the WordNet structure. This indicates that the sub-spaces where the language models encode semantics are not linear. The fact that syntactic information is linearly available suggests that syntax trees might be a critical intermediate result for the language modeling task. In contrast, semantic information emerges as an indirect consequence of accurate language modeling. Still, it might not constitute information that the model relies on for NLP tasks, as postulated by Ravichander et al. (2020).

To discard the possibility of the MLP being memorizing properties of words and thus giving an undeserved credit to the analyzed models, we generated alternative training and validation sets with random word embeddings of the same size as the real ones. During training and inference, these vectors were kept frozen. These tests showed around 50% accuracy in the binary classification task, indicating that the MLP cannot do better than chance in that scenario. Thus, if in a later experiment the same MLP

	BERT	49	48	**49**
	RoBERTa	56	54	**55**
	XLNet	52	48	**50**
	ALBERT	53	50	**51**

Table 1: Tree Edit Distance against the ground truth graph (large models used). We display both strategies for estimating d_e along with their average score.

succeeds at the task, the merit can be attributed to the input embedding itself. This result is consistent with the fact that our experimental setup ensures no overlap in concepts among training, development, and testing sets.

2.4 Reconstructing the structure of a knowledge graph

The probe classifier predicts if a pair of concepts $\langle u, v\rangle$ form a valid $\langle$parent, child$\rangle$ relation according to WordNet, where $h_{\langle u,v\rangle} \in [0, 1]$ denotes the corresponding classifier output. It is important to note that valid $\langle$parent, child$\rangle$ relations include direct relations (e.g. $\langle$dog, poodle$\rangle$), and transitive relations (e.g. $\langle$animal, poodle$\rangle$), and that the order of the items matters.

To reconstruct the underlying knowledge graph, for each valid $\langle$parent, child$\rangle$ relation given by $h_{\langle u,v\rangle} >$ threshold, we need an estimation of how close are the nodes in the graph. We do this by introducing the concept of "parent closeness" between a parent node u and a child node v, denoted by $d_e(u, v)$. We propose two alternative scores to estimate d_e:

i) Model Confidence Metric (MCM): All the models considered in this study capture close relations more precisely than distant relations (supporting evidence can be found in Appendix D). This means that a concept like *poodle* will be matched with its direct parent node *dog* with higher confidence than with a more distant parent node (e.g. *animal*). Thus, we can define $d_e(u, v) = 1 - h_{\langle u,v\rangle}$.

ii) Transitive Intersections Metric (TIM): We explore a metric grounded directly in the tree structure of a knowledge graph. Note that nodes *u* and *v* that form a parent-child relation have some transitive connections in common. Specifically, all descendants of *v* are also descendants of *u*, and all the ancestors of *u* are also ancestors of *v*. Then, the closer the link between *u* and *v* in the graph, the bigger the intersection. Accordingly, for each edge $e = \langle u, v\rangle$, we define $d_e(u, v)$ as:

$$-\left(\sum_{j \in N \setminus \{u,v\}} h_{\langle u,j\rangle} h_{\langle v,j\rangle} + h_{\langle j,u\rangle} h_{\langle j,v\rangle}\right) * h_{\langle u,v\rangle}, \tag{1}$$

where the first term of the sum accounts for the similarity within the descendants of nodes u and v, and the second term accounts for the similarity within the ancestors of nodes u and v. The term $h_{\langle u,v\rangle}$ at the right-hand side accounts for the edge direction, and N denotes the set of nodes (concepts).

A strategy to find a tree that comprises each node's closest parents is the minimum-spanning-arborescence (MSA) of the graph defined using d_e. The MSA is analogous to the minimum-spanning-tree (MST) objective used by Hewitt and Manning (2019), but for directed graphs. The formulation of the MSA optimization problem applied to our proposal is provided in the Appendix A.3.

3 How accurate is this knowledge?

3.1 Semantic edge probing classifier results

Table 2 shows the results obtained using the edge probing classifier. Results show that regardless of model sizes, performance is homogeneous within each family of models. Additionally, results show that NCE and GLM methods obtain a worse performance when all the layers are used than those achieved by CE methods. When single layers are

Family	Model	Emb. Size All/Best Layer	Best Layer	F1-score All Layers	F1-score Best Layer
NCE	Word2Vec (Mikolov et al., 2013)	300 / -	-	.7683 ± .0135	-
	GloVe-42B (Pennington et al., 2014)	300 / -	-	.7877 ± .0084	-
GLM	GPT-2 (Radford et al., 2018)	9984 / 768	6	.7862 ± .0132	.7921 ± .0108
	T5-small (Raffel et al., 2019)	7168 / 512	4	.8156 ± .0098	.8199 ± .0081
	GPT2-xl (Radford et al., 2018)	78400 / 1600	13	.7946 ± .0151	.8029 ± .0118
	T5-large (Raffel et al., 2019)	51200 / 1024	17	.8148 ± .0119	.8331 ± .0102
CE	ELMo-small (Peters et al., 2018b)	768 / 256	2	.7986 ± .0126	.7880 ± .0119
	BERT-base (Devlin et al., 2019)	9984 / 768	10	.8240 ± .0123	.8185 ± .0104

Table 2: Results obtained using the edge probing classifier. We study the performance in many model variants, considering small and large versions of several models. Results are grouped by method families.

used, GLM shows improved performance, suggesting that these models capture semantics earlier in the architecture, keeping their last layers for generative-specific purposes. In contrast, CE models degrade or maintain their performance when single layers are used.

Note that Table 2 shows pair-wise metrics not graph metrics. As we are dealing with graphs, predicted edges are built upon related edges. Thus, drifts in small regions of the graph may cause large drifts in downstream connections. Furthermore, our setup balances positive and negative samples. However, the proportion of negative samples can be considerably larger in a real reconstruction scenario. As a consequence, we emphasize that these numbers must be considered together with the results reported in sections 3.2 and 4.

3.2 Extracting the Knowledge Graph

Predicting a knowledge graph has a complexity of at least $O(N^2)$ in the number of analyzed concepts. In our case, this imposes a highly demanding computational obstacle because WordNet has over 82000 noun synsets. To accelerate experimentation and facilitate our analysis and visualizations, we focus on extracting a WordNet sub-graph comprising 46 nodes not seen during training or validation. These nodes are picked to include easily recognizable relations. We use the tree-edit-distance to evaluate how close are the reconstructed graphs to the target graph extracted from WordNet. Table 1 shows our results.

Table 1 shows that graphs retrieved using CE models are closer to the target than graphs provided by NCE and GLM models. In particular, the best results are achieved by BERT, ALBERT, and XLNet, indicating that these models encode more accurate semantic information than the alternative models. These results are consistent with those obtained in Section 3.1. The graphs for all the models can be found in Appendix C.

4 What is easy or hard? What are these models learning?

Section 3 shows that different model families differ in their errors. Furthermore, it shows that within the same family, models have similar biases. In this section, we elucidate which semantic factors impact the performance of these models and which ones do not affect their F1-score.

Figure 3-a shows that most models decrease their F1-score as concepts get more specific. We hypothesize that higher-level concepts (e.g., *Animal*) appear more frequently and in more diverse contexts, as they are also seen as instances of their sub-classes (e.g., *Dog*, *Cat*, *Chihuahua*), allowing the models to learn more precise representations for them. In contrast, lower-level concepts will only appear in specific contexts (e.g., texts about *Apple-Head-Chihuahua*). Figure 3-b corroborates

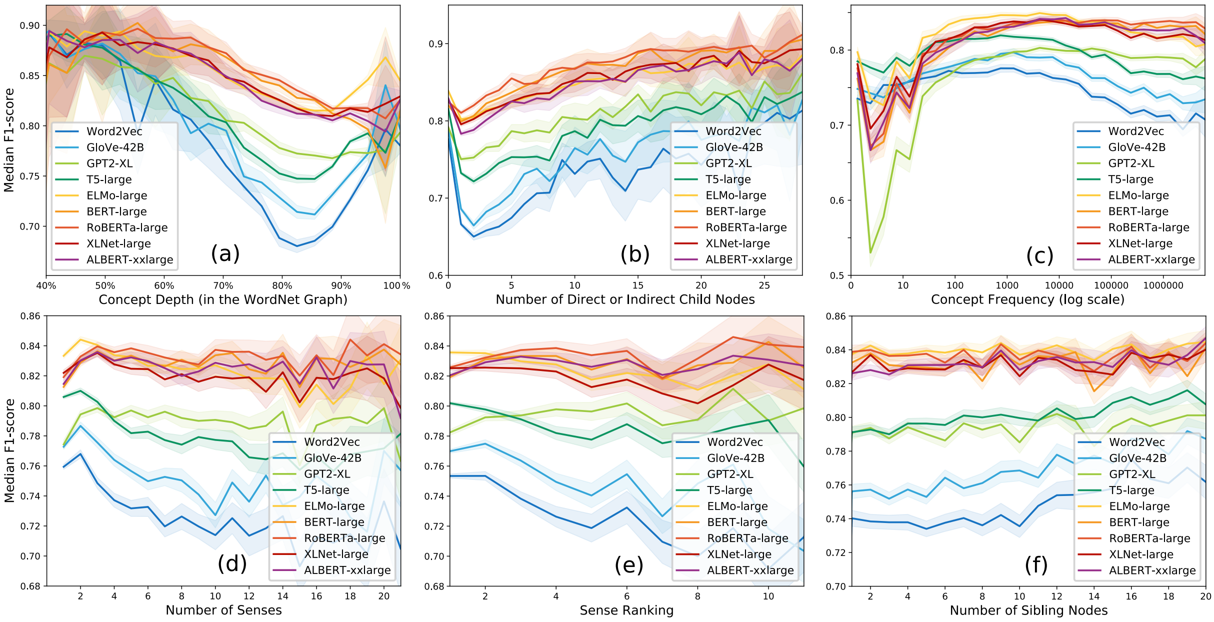

Figure 3: Semantic factors with a high (top charts) or low (bottom charts) impact on F1-score, along with their 90% confidence intervals. Charts only display ranges where at least 100 samples existed. Appendix D shows additional factors along with the specific implementation details.

this intuition, as concepts with a higher number of sub-classes have higher F1-scores. Figure 3-c shows that models degrade their F1-score when concepts are too frequent. In particular, NCE and GLM models are more sensitive to this factor.

Another finding is that CE and GLM models are almost unaffected by the number of senses that a certain word has, neither to their sense ranking or their number of sibling concepts, displaying almost flat charts (see Figures 3-d-e-f). This result suggests that these models pay more attention to the context than to the target word. This behavior is opposed to what NCE models exhibit according to Yaghoobzadeh et al. (2019), as NCE models tend to focus more on frequent senses.

In most cases, the same family models have similar behaviors, especially within the NCE or CE families. Also, different families show different patterns. Table 3 shows some salient examples. Surprisingly, all models struggle in the category “taxonomic groups”. Manual inspection of sentences makes us believe that the context confuses CE and GLM models in these cases. In many sentences, the corresponding concept could be nicely replaced by another, conveying a modified but still valid message. This phenomenon does not occur in other categories such as “social group” or “attribute”, even though these concepts are closely related to “taxonomic groups”.

5 Where is this knowledge located?

As mentioned in Section 7, prior work has not shown consensus about where is semantic information encoded inside these architectures. Our experiments shed light on this subject. Figure 4 shows how each layer contributes to the F1-score.

Figures 4-a and 4-b show the performance across layers for the CE-based models. They reveal that while BERT and RoBERTa use their top-layers to encode semantic information, XLNet and ALBERT use the first layers. Figure 4-c shows that while GPT-2 uses all its layers to encode semantics, T5 shows an M shape related to its encoder-decoder architecture. The chart shows that T5 uses its encoder to hold most of the semantic information. We also note that small models show similar patterns as their larger counterparts.

6 Further discussion and implications

Table 4 summarizes our main findings. Findings (1), (2), and (3) indicate that, to a different extent, all models encode relevant knowledge about the hierarchical semantic relations included in WordNet. However, as we mention in Section 4, we observe that the ability to learn about a concept depends on its frequency in the training corpus and the specificity of its meaning. Furthermore, some concept categories seem to be hard for every model family, while some are particularly difficult

Family	Model	artifact	attribute	living thing	matter	person	relation	part	social group	taxonomic group
NCE	Word2Vec	.7120	.7044	.7295	.7402	.7208	.7264	.7532	.7497	.6920
	GloVe-42B	.7389	.7213	.7421	.7633	.7351	.7567	.7759	.7579	.6648
GLM	GPT-2	.7903	.7730	.7300	.7582	.7207	.7612	.7540	.8155	.3030
	T5	.7868	.7649	.7862	.8002	.7735	.7963	.8051	.7868	.6944
CE	ELMo	.8308	.8093	.8187	.7756	.8022	.7679	.7580	.8312	.6011
	BERT	.8249	.8094	.7593	.7645	.7379	.7662	.7499	.8516	.4804
	RoBERTa	.8315	.8167	.7823	.7614	.7585	.7649	.7441	.8552	.4921
	XLNet	.8319	.8064	.7907	.7636	.7779	.7659	.7526	.8422	.5371
	ALBERT	.8231	.8050	.7758	.7685	.7826	.7727	.7610	.8556	.4277

Table 3: Average F1-score for some semantic categories revealing models strengths and weaknesses. Several other categories are reported in Appendix E along with their standard deviations.

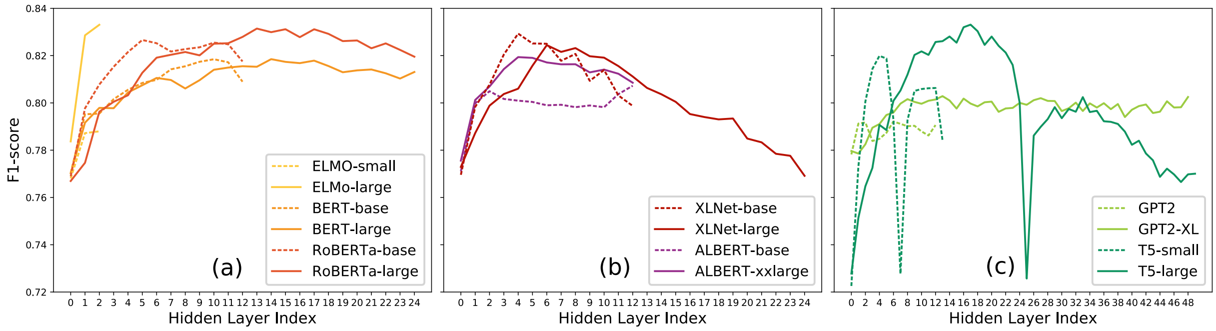

Figure 4: F1-score for hypernym prediction across each model layer.

for contextual models such as CE. We hypothesize that stronger inductive biases are required to capture low-frequency concepts. Furthermore, we believe that new learning approaches are needed to discriminate accurate meaning for high-frequency concepts. As expected, our findings indicate that model families have different biases leading to different behaviors. Thus, our results can illuminate further research to improve semantic capabilities by combining each family of models' strengths. For example, one could combine them as ensembles, each one equipped with a different loss function (i.e., one generative approach resembling GLM-based methods and another discriminative resembling CE-based methods).

Findings (4), (5), and (6) suggest that instead of a standard finetuning of all layers of BERT according to a given downstream task, to improve semantic capabilities, one could perform a task profiling to decide the best architecture for the task and also how to take advantage of it. Using only a limited number of layers or choosing a different learning rate for each layer, one could exploit the semantic knowledge that the pre-trained model carries, avoiding the degradation of this information present at the top layers, especially when using T5, XLNet, or ALBERT-large. Accordingly, recent work on adaptive strategies to output predictions using a limited number of layers (Xin et al., 2020; Liu et al., 2020; Hou et al., 2020; Schwartz et al., 2020; Fan et al., 2020; Bapna et al., 2020) would benefit from using architectures that encode knowledge in the first layers. To the best of our knowledge, these works have only used BERT and RoBERTa, achieving a good trade-off between accuracy and efficiency. Only Zhou et al. (2020) has explored ALBERT, reporting improved accuracy by stopping earlier. Our findings explain this behavior and suggest that T5 or XLNet may boot their results even further as these architectures have sharper and higher information peaks in their first layers.

Findings (7) and (8) suggest that recent success in semantic NLP tasks might be due more to the use of larger models than large corpora for pretraining. This also suggests that to improve model performance in semantic tasks, one could train larger models even without increasing the corpus size. A similar claim has been proposed by (Li et al., 2020) leading to empirical performance improvements.

Finally, finding (9) is important because it suggests that contextual models pay as much attention to the context as to the target word and are probably

	Finding	Supporting Evidence	Involved Models
(1)	All models encode a relevant amount of knowledge about semantic relations in WordNet, but this knowledge contains imprecisions.	All	All
(2)	The ability to learn concept relations depends on how frequent and specific the concepts are. Some model families are more affected.	Fig. 3a-c	NCE and GLM
(3)	Concept difficulty is usually homogeneous within each model family. Some semantic categories challenge all models.	Table 3	All
(4)	Some models encode stronger semantic knowledge than others, usually according to their family.	Tables 2, 1, 3	ELMo, BERT, RoBERTa, ALBERT, XLNet, T5
(5)	Some models focus their encoding of semantic knowledge in specific layers, and not distributed across all layers.	Table 2, Fig. 4	GLM
(6)	Models have distinctive patterns as to where they encode semantic knowledge. Patterns are model-specific and not size-specific.	Table 2, Fig. 4	All
(7)	Model size has an impact in the quality of the captured semantic knowledge, as seen in our layer-level probe tests.	Table 2, Fig. 4	ELMo, RoBERTa, ALBERT, GPT-2, T5
(8)	Semantic knowledge does not depend on pre-training corpus size.	Tables 2, B-5	-
(9)	Contextual models are unaffected by multi-sense words.	Fig. 3d-f	CE and GLM

Table 4: Summary of our main findings and their corresponding supporting evidence.

biased in favor of contextual information, even if they are not based on the Masked-Language-Model strategy. We believe that this inductive bias could be exploited even further in the design of the underlying architecture. Thus this finding might elucidate a design direction to encourage more effective learning of semantic knowledge.

7 Related work

The success of deep learning architectures in various NLP tasks has fueled a growing interest to improve understanding of what these models encode. Studies like Tenney et al. (2019b) claim that success in a specific task helps understand what type of information the model encodes.

Evidence of syntactic information: Using probing classifiers, Clark et al. (2019) claims that some specific BERT's attention heads show correspondence with syntactic tasks. Goldberg (2019) illustrates the capabilities that BERT has to solve syntactic tasks, such as subject-verb agreement. Hewitt and Manning (2019) proposes a structural probe that evaluates whether syntax trees are encoded in a linear transformation of BERT embeddings. The study provides evidence that syntax trees are implicitly embedded in BERT's vector geometry. Reif et al. (2019) has found evidence of syntactic representation in BERT's attention matrices, with specific directions in space representing particular dependency relations.

Evidence of semantic information: Reif et al. (2019) suggests that BERT's internal geometry may be broken into multiple linear subspaces, with separate spaces for different syntactic and semantic information. Despite this result, previous work has not yet reached a consensus about this topic. While some studies show satisfactory results in tasks such as entity types (Tenney et al., 2019a), semantic roles (Rogers et al., 2020), and sentence completion (Ettinger, 2020), other studies show less favorable results in coreference (Tenney et al., 2019b), Multiple-Choice Reading Comprehension (Si et al., 2019) and Lexical Relation Inference (Levy et al., 2015), claiming that BERT's performance may not reflect the model's true ability of language understanding and reasoning. Tenney et al. (2019b) proposes a set of edge probing tasks to test the encoded sentential structure of contextualized word embeddings. The study shows evidence that the improvements that BERT and GPT-2 offer over non contextualized embeddings as GloVe is only significant in syntactic-level tasks. Regarding static word embeddings, Yaghoobzadeh et al. (2019) shows that senses are well represented in single-vector embeddings if they are frequent and that this does not harm NLP tasks whose performance depends on frequent senses.

Layer-wise or head-wise information: Tenney et al. (2019a) shows that the first layers of BERT focus on encoding short dependency relationships at the syntactic level (e.g., subject-verb agreement). In contrast, top layers focus on encoding long-range dependencies (e.g., subject-object dependencies). Peters et al. (2018a) supports similar declarations for Convolutional, LSTM, and self-attention architectures. While these studies also support that the top layers appear to encode semantic information, the evidence to support this claim is not conclusive or contradictory with other works. For example, Jawahar et al. (2019) could only identify one SentEval semantic task that topped at the last layer. In terms of information flow, Voita et al. (2019a) reports that information about the past in left-to-right language models gets vanished as the information flows from bottom to top BERT's layers. Hao et al. (2019) shows that the lower layers of BERT change less during finetuning, suggesting that layers close to inputs learn more transferable language representations. Press et al. (2020) shows that increasing self-attention at the bottom layers improves language modeling performance based on BERT. Other studies focus on understanding how self-attention heads contribute to solving specific tasks (Vig, 2019). Kovaleva et al. (2019) shows a set of attention patterns repeated across different heads when trying to solve GLUE tasks (Wang et al., 2018). Furthermore, Michel et al. (2019) and Voita et al. (2019b) show that several heads can be removed without harming downstream tasks.

Automated extraction of concept relations: Although the main focus of our work is not to master the probing task of extracting knowledge from WordNet, but to use it as an instrument to verify and compare the abilities of current families of language models to encode this kind of knowledge, for completitude we include a brief mention of previous literature regarding this subject. Relation extraction is an active research topic. Early works are either feature-based, usually relying on SVMs, Maximum Entropy, or on a set of manually defined rules (Hearst, 1998; Kambhatla, 2004; Dashtipour et al., 2017; Minard et al., 2011; Weeds et al., 2014; Chen et al., 2015). Other methods rely on manually defined distance metrics to estimate the relatedness of two semantic instances (Dandan et al., 2012; Panyam et al., 2016). Following works have used different types of neural networks or LSTM modules for this task (Liu et al., 2013; Zeng et al., 2014, 2015; Zhang and Wang, 2015; Song et al., 2018), or attention-based and transformer-based mechanisms with outstanding results (Zhou et al., 2016; Baldini Soares et al., 2019; Huang et al., 2020; Qin et al., 2021; Zhong and Chen, 2021).

Alternative approaches: Several alternative approaches have been used in previous works. Some are dataset-focused (Miller et al., 1994; Levy et al., 2015; Wang et al., 2018; Wiedemann et al., 2019), usually relying on annotated corpora that challenge semantic abilities. These approaches have provided useful insights, but usually suffer from low availability of data as they usually cover a small fraction of the WordNet ontology. As an example, BLESS (Baroni and Lenci, 2011) includes gold-standard annotations for only 200 concepts. Other approaches have tested semantic ability by using prompt-engineering and inspecting the predictions of the models (Petroni et al., 2019; Ettinger, 2020; Talmor et al., 2020), but other works have also shown a high variability in the results depending on the prompt design (Balasubramanian et al., 2020; Reynolds and McDonell, 2021; Zhao et al., 2021).

8 Conclusions

In this work, we exploit the semantic conceptual taxonomy behind WordNet to test the ability of current families of pre-trained language models to learn semantic knowledge from massive sources of unlabeled data. Our main conclusion is that, indeed, to a significant extent, these models learn relevant knowledge about the organization of concepts in WordNet, but also contain several imprecisions. We also notice that different families of models present dissimilar behavior, suggesting the encoding of different biases.

We hope our study helps to inspire new ideas to improve the semantic learning abilities of current pre-trained language models.

Acknowledgments

We thank the anonymous reviewers, whose helpful comments led to increased clarity and improved analysis. We would also like to thank all the members of the IALab research group for their helpful feedback and suggestions. We acknowledge Alex Medina for his help in the early stages of this project. This work was partially funded by the Millennium Institute for Foundational Research on Data and the Fondecyt project number 1200211.

A Implementation details

A.1 Edge probing classifier details

To study the extent to which these Language Models deal with semantic knowledge, we extend the methodology introduced by Tenney et al. (2019b). In that study, the authors defined a probing classifier at the sentence level, training a supervised classifier with a task-specific label. The probing classifier's motivation consists of verifying when the sentence's encoding help to solve a specific task, quantifying these results for different word embeddings models. We cast this methodology to deal with semantic knowledge extracted from WordNet. Rather than working at the sentence level, we define an edge probing classifier that learns to identify if two concepts are semantically related.

To create the probing classifier, we retrieve all the glosses from the Princeton WordNet Gloss Corpus. The dataset provides WordNet's synsets gloss with manually matched words identifying the context-appropriate sense.

As a reference of size, the selected annotations in the corpus accounted for 41502 lemmas, corresponding to 34371 WordNet synsets. This resulted in 230215 valid WordNet relations.

In WordNet, each sense is coded as one of the synsets related to the concept (e.g., sense *tendency.n.03* for the word tendency). Using a synset A and its specific sense provided by the tagged gloss, we retrieve from WordNet one of its direct or indirect hypernyms, denoted as B (see Figure 5). If WordNet defines two or more hypernyms for A, we choose one of them at random. We sample a third synset C, at random from an unrelated section of the taxonomy, taking care that C is not related to either A or B (e.g., *animal.n.01*). Then, $\langle A, B, C\rangle$ form a triplet that allows us to create six testing edges for our classifier: $\langle A, B\rangle$, which is compounded by a pair of related words through the semantic relation *hypernym of*, and five pairs of unrelated words ($\langle A, C\rangle$, $\langle B, C\rangle$, $\langle B, A\rangle$, $\langle C, A\rangle$, $\langle C, B\rangle$). We associate a label to each of these pairs that show whether the pair is related or not (see Figure 5). Note that we define directed edges, meaning that the pair $\langle A, B\rangle$ is related, but $\langle B, A\rangle$ is unrelated to the relationship *hypernym of*. Accordingly, the edge probing classifier will need to identify the pair's components and the order in which the concepts were declared in the pair.

We create training and testing partitions ensuring that each partition has the same proportion of leaves versus internal nodes. The latter is essential to identify related pairs. During training, we guarantee that each training synset is seen at least once by the probing classifier. To guarantee the above, we sample each synset in the training set and sample some of its hypernyms at random. Then. we randomly sample some unrelated synset for each related pair that has no relation to any of the words in the related pair. We create three partitions from this data on 70/15/15 for training, development, and testing foldings, respectively.

We train the MLP classifier using a weighted binary cross-entropy loss function. Since we have one positive and five negative examples per triplet, we use a weighted loss function with weights 5 and 1 for the positive and negative class, respectively. Accordingly, positive and negative examples have the same relevance during training. We implemented the linear layer and the MLP classifier using a feed forward network with 384 hidden units. The MLP was trained using dropout at 0.425 and a L_2 regularizer to avoid overfitting.

To create the vector representations for each of the word embeddings models considered in this study, we concatenate the hidden state vectors of all the layers for each tagged synset. For both CE and GLM-based models, each gloss was used as a context to build specific contextual word embeddings. If the gloss has more than one tagged token, we take only the first of them for the analysis.

A.2 WordNet metrics: distance

Lets say that we name *"Case-1"* if y is ancestor of x, and *"Case-2"* otherwise. Let $d_W(x, y)$ be the Wordnet distance between two synsets x, y, defined by:

$$d_W(x,y) = \begin{cases} d_{\text{path}}(x,y) & \textit{Case-1}, \\ d_{\text{path}}(x,z) + d_{\text{path}}(y,z) & \textit{Case-2}, \end{cases} \tag{2}$$

where $d_{\text{path}}(x, y)$ is the length of the shortest path between x and y in WordNet, measured in number of hops, and z is the closest common ancestor of x and y in the case that y is not an ancestor of x.

A.3 Minimum-Spanning-Arborescence optimization problem

Given a graph G with nodes N and unknown edges E, we define an auxiliary graph G' with nodes N and edges E', comprised of all possible directed edges. For each edge $e \in E'$, we obtain a prediction h_e that estimates the probability of that

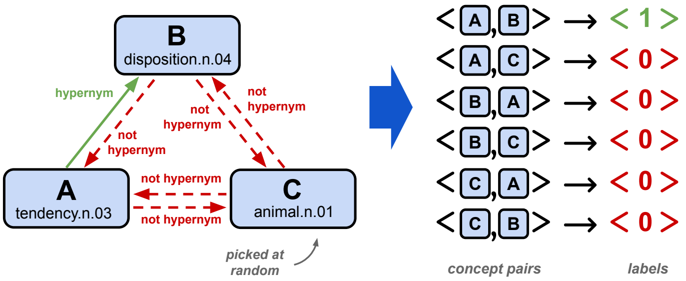

Figure 5: Each triplet is used to create related and unrelated pairs of words according to the relationship *hypernym of*. We create six edge probing pairs, and therefore, the edge probing classifier will need to identify the pair's components and the order in which the words were declared in the pair.

edge representing a valid hypernymy relation, and a distance d_e that estimates the "parent closeness"[3] between the nodes in G.

We define $\delta(v)$ to be the set of edges $\{\langle u,v\rangle : u \in N, u \neq v\}$ where edge $\langle u,v\rangle$ represents a $\langle$parent, child$\rangle$ relation. We also define $\gamma(S)$ to be the set of edges $\{\langle u,v\rangle \in E' : u \notin S, v \in S\}$. We estimate the graph topology of G defined by $E \subset E'$ by solving the following optimization problem:

$$\max_{r\in N} \sum_{e\in E'} x_e h_e \quad \text{s.t.} \quad x_e \in X^* \tag{3}$$

$$X^* = \arg\min \sum_{e\in E'} x_e d_e \tag{4}$$

$$\text{s.t.} \begin{cases} x_e \in \{0,1\} & e \in E' \\ \sum_{e\in\delta(v)} x_e = 1 & \forall v \in N \setminus \{r\} \\ \sum_{e\in\gamma(S)} x_e \geq 1 & \forall S \subset N \setminus \{r\} \end{cases} \tag{5}$$

Objective function (3) is used to find the best root node r; and the nested optimization problem (5) is the minimum spanning arborescence problem applied to the dense graph G'. The final binary values of x_e estimate E by indicating if every possible edge e exist in the graph or not. To solve this optimization problem, we need estimates of h_e and d_e for each edge e. We use the output of the probing classifier as an estimate of the probability of h_e, and use TIM and MCM scores as estimates for d_e (See Section 2.4).

B Pre-Training corpus comparison

Family	Model	Corpus Size	
		Tokens	Size
NCE	Word2Vec	33B	150GB*
	GloVe-42B	42B	175GB*
GLM	GPT-2	10B*	40GB
	T5	180B*	750GB
CE	ELMo	0.8B	4GB*
	BERT	3.9B	16GB
	RoBERTa	38.7B*	160GB
	XLNet	32.9B	140GB*
	ALBERT	3.9B	16GB

Table 5: Pre-Training corpus sizes used for each one of the studied models. The official sources report corpus sizes in terms of number of tokens or uncompressed size in GB. The symbol * denotes values estimated by us based on official available information. Sizes represents uncompressed corpus sizes.

C Additional Reconstructed Graphs[4]

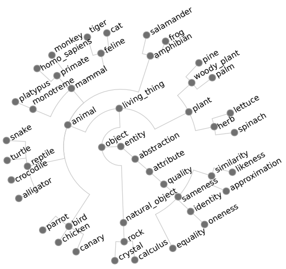

Figure 6: Ground Truth Knowledge Graph

---

[3] The value of this distance will be small if the hypernym relation is close, or large if it is distant or not valid.

[4] Due to space restrictions, the graphs corresponding to Word2Vec, ELMo, T5, BERT will only be included in an extended version of this paper, uploaded to ArXiv

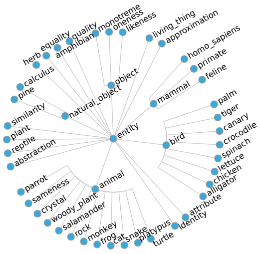

Figure 7: GloVe-42B reconstruction using TIM

Figure 9: RoBERTa-large reconstruction using TIM

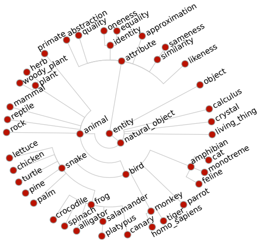

Figure 10: XLNet-large reconstruction using TIM

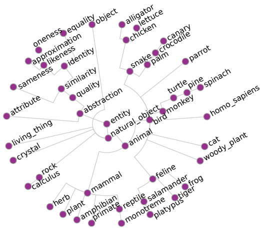

Figure 11: ALBERT-large reconstruction using TIM

D Further information about the impact of semantic factors.[5]

Relative depth in the WordNet graph: (Figure 3-a). For each synset, we compared F1 with depth score (0 % for the root and 100 % for leaves) measuring differences between higher/lower level concepts.

Concept frequency: In Figure 3-c we evaluate if frequent concepts are easier or harder to capture for these models. The frequency was computed by counting occurrences in the 38 GB of OpenWebText Corpus (`http://Skylion007.github.io/OpenWebTextCorpus`).

Number of Senses and Sense Ranking: (Figure 3-d-e) We studied if models are impacted by multi-sense concepts such as "period", and by their sense ranking (how frequent or rare those senses are). Surprisingly contextualized models, and specially CE models have no significant impact by this factor, suggesting that these models are very effective at deducing the correct sense based on their context. These charts also suggest that these models may be considering context even more than the words themselves. This is intuitive for Masked-Language-Models such as BERT, but not for others, such as GPT-2. Non-contextualized models are impacted by this factor, as expected.

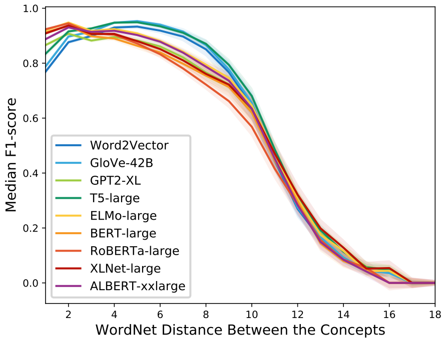

Figure 12: **Graph distance between concepts**: We measured the impact of the number of "hops" that separate two tested concepts on pair-wise F1 score. This chart reveals a strong correlation of all the models in this aspect. As an example of this phenomenon, closer relations such as ⟨chihuahua, dog⟩ are, in general, considerably easier to capture than distant relations such as ⟨chihuahua, entity⟩. For details on how we implement the distance in WordNet, check Appendix A.2.

---

[5] Due to space restrictions, other factors and graphs will only be included in an extended version of this paper, uploaded to ArXiv

Abstract

Multilingual Neural Machine Translation (MNMT) has aroused widespread interest due to its efficiency. An exciting advantage of MNMT models is that they could also translate between unsupervised (zero-shot) language directions. Language tag (LT) strategies are often adopted to indicate the translation directions in MNMT. In this paper, we demonstrate that the LTs are not only indicators for translation directions but also crucial to zero-shot translation qualities. Unfortunately, previous work tends to ignore the importance of LT strategies. We demonstrate that a proper LT strategy could enhance the consistency of semantic representations and alleviate the off-target issue in zero-shot directions. Experimental results show that by ignoring the source language tag (SLT) and adding the target language tag (TLT) to the encoder, the zero-shot translations could achieve a +8 BLEU score difference over other LT strategies in IWSLT17, Europarl, TED talks translation tasks.

1 Introduction

Neural Machine Translation (NMT) based on the *encoder-decoder framework with attention mechanism* (Sutskever et al., 2014; Bahdanau et al., 2015; Luong et al., 2015; Wu et al., 2016; Gehring et al., 2017; Vaswani et al., 2017) has achieved state-of-the-art (SotA) results in many language pairs (Deng et al., 2018; Barrault et al., 2019). Pioneered by (Dong et al., 2015; Firat et al., 2016; Zoph and Knight, 2016; Ha et al., 2016; Johnson et al., 2017), researchers start to investigate the possibility of using a single model to translate between multiple languages, which is the Multilingual Neural Machine Translation (MNMT). Benefiting from the transferring ability of multilingual modeling, MNMT could achieve better translation quality between low-resource language directions than bilingual models (Gu et al., 2018; Wang et al., 2019). More exciting, MNMT could even translate between zero-shot language directions (Johnson et al., 2017; Gu et al., 2019; Pham et al., 2019; Kudugunta et al., 2019).

Unlike bilingual NMT, language-specific signals should be accessible to the MNMT model so that the model can distinguish the translation directions. Ha et al., (2016) first introduced a universal encoder-decoder framework for MNMT models with language-specific coded vocabulary to indicate different languages. The *encoder-decoder* architecture is identical to bilingual models (Bahdanau et al., 2015; Vaswani et al., 2017). To further simplify the MNMT models, Johnson et al., (2017) propose to add language tags (LTs) to the beginning of input data to indicate the target language. Then a shared vocabulary could be learned for all languages. The training data of different languages could thus be mixed-up to train the MNMT model. Such a strategy greatly simplifies the training and decoding procedure. We call it the *LT strategy*. This paper focuses on investigating the impact of LT strategies for zero-shot translation directions in MNMT (zero-shot MNMT). We conduct translation experiments (Section 3) and visualization analysis (Section 4) on several multilingual benchmarks with different LT strategies. We observe that:

- The TLT is more important than the SLT. The SLT even causes negative effects on the zero-shot translation.
- The placements of LTs have a surprisingly large impact on the translation quality. Placing different LTs on different parts of the NMT model lead to a +8 BLEU score difference in our experiments.

Our contributions are mainly twofold: (i) We

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3001–3007
August 1–6, 2021.

Strategy	Source sentence	Target sentence
Original	`Hello World!`	`¡Hola Mundo!`
T-ENC	**`__es__`** `Hello World!`	`¡Hola Mundo!`
T-DEC	`Hello World!`	**`__es__`** `¡Hola Mundo!`
S-ENC-T-ENC	**`__en__`** **`__es__`** `Hello World!`	`¡Hola Mundo!`
S-ENC-T-DEC	**`__en__`** `Hello World!`	**`__es__`** `¡Hola Mundo!`

Table 1: Examples of modified input data by different LT strategies. The bold tokens are the SLT (`__en__`) or TLT (`__es__`). T-ENC is identical to (Johnson et al., 2017), which adds the TLT to the encoder (source) side. T-DEC means placing the TLT on the decoder (target) side of model. S-ENC-T-ENC and S-ENC-T-DEC place the SLT on the encoder side, but the former also places the TLT on encoder side, while the latter on the decoder side.

find that the LT strategies are crucial for the zero-shot MNMT translation quality. Ignoring SLTs and placing the TLTs on the encoder side could achieve the best performance during our experiments. (ii) We conduct extensive visualization analysis to demonstrate that the proper LT strategy could enhance the consistency of semantic representation and alleviate the off-target issue (Zhang et al., 2020), thus improving the translation quality. To the best of our knowledge, this is the first paper to systematically study the importance of LT strategies for zero-shot translation quality.

2 Background and Notations

Improving the consistency of semantic representations and alleviating the off-target issue (Zhang et al., 2020) are effective ways to improve the zero-shot translation quality (Al-Shedivat and Parikh, 2019; Arivazhagan et al., 2019; Zhu et al., 2020). The semantic representations of different languages should be close to each other to get better translation quality (Ding et al., 2017). The off-target issue indicates that the MNMT model tends to translate input sentences to the wrong languages, which leads to low translation quality.

Due to its simplicity and efficiency, LT strategy has become a fundamental strategy for MNMT (Dabre et al., 2020). Though previous work adopted different LT strategies (Wang et al., 2018; Blackwood et al., 2018; Conneau and Lample, 2019; Liu et al., 2020b), the usages of LT strategies are intuitive and lack systematic study. In this paper, we investigate 4 popular LT strategies, namely `T-ENC`, `T-DEC`, `S-ENC-T-ENC` and `S-ENC-T-DEC`. Each of them only requires simple modifications to the input data. Table 1 comprehensively illustrates the strategies with an English to Spanish translation pair (`Hello World!` → `¡Hola Mundo!`).

3 Experiments

3.1 Experiment Settings

Datasets We carry out our experiments on the publicly available IWSLT17 (Cettolo et al., 2017), TED talks (Qi et al., 2018) and Europarl v7 (Koehn, 2005) datasets. Table 2 shows an overview of the datasets. We choose four different languages (English included) for both IWSLT17 and Europarl, and 20 languages for TED talks. All the training data are English-centric parallel data, which means either the source-side or target-side of the sentence pair is English. We have 6, 6, and 342 zero-shot translation directions and an average of 145k, 1.96M (M = million), and 187k sentence pairs per direction for the three datasets respectively. We choose the official tst2017, WMT `newstest08`, and the TED talks testsets (Qi et al., 2018) as our test sets, respectively. We learned a joint SentencePiece model (Kudo and Richardson, 2018) for sub-word training on all languages with 40,000 merge operations for each dataset. We limit the size of joint vocabulary to 40,000 for all three datasets.

Settings We use the open-source implementation (Ott et al., 2019) of Transformer model (Vaswani et al., 2017). Following the settings of (Liu et al., 2020a), we use a 5-layer encoder and 5-layer decoder variation of Transformer-base model (Vaswani et al., 2017) for TED and IWSLT17. For Europarl v7, we use a standard Transformer-big model (Vaswani et al., 2017). Sentence pairs are batched together by approximate sentence length. Each batch has approximately 30,000 source tokens and 30,000 target tokens. We use the Adam (Kingma and Ba, 2015) optimizer to update the parameters and

Dataset	languages	#zero-shot directions	#training sents per direction	#sents per testset
IWSLT17	en, it, nl, ro	6	145k	1144
Europarl	en, fr, de, es	6	1.96m	2000
TED	en, ar, he, ru, ko, it, ja zh, es, fr, pt, nl, tr, ro pl, bg, vi, de, fa, hu	342	187k	4507

Table 2: An overview of the datasets. The second column is the languages the training data contains. The third column denotes the number of zero-shot translation directions. The fourth and fifth column denote the averaged number of training data and test data per language direction, respectively.

Dataset	LT Strategy	Supervised	Zero-Shot	Off-Target (%)
IWSLT17	T-ENC	32.30	**16.00** (+14.02)	**9.16**
	T-DEC	32.43	10.44	29.50
	S-ENC-T-ENC	32.56	1.98	94.14
	S-ENC-T-DEC	32.39	7.67	48.87
Europarl	T-ENC	35.55	**32.25** (+24.24)	1.18
	T-DEC	35.49	30.73	**1.13**
	S-ENC-T-ENC	35.53	8.01	79.53
	S-ENC-T-DEC	35.53	29.81	2.26
TED talks	T-ENC	25.63	**10.69** (+8.78)	**12.63**
	T-DEC	25.58	3.11	58.47
	S-ENC-T-ENC	25.84	4.07	65.03
	S-ENC-T-DEC	25.63	1.91	77.02

Table 3: Translation results on 3 datasets. The **supervised** and **zero-shot** column denote the averaged BLEU score of supervised or zero-shot directions. The **off-target (%)** denotes the averaged percentage of sentences being translated to wrong languages in zero-shot directions.

train each model for 100,000 steps to make sure it converges. We use beam search for heuristic decoding, and set the beam size to 4. We use SacreBLEU (Papineni et al., 2002; Post, 2018) to evaluate the translation results. To calculating the percentage of off-target translations, we use the langdetect[1] tool to detect the language of the translated sentences.

3.2 Experimental Results

We show the translation results on the IWSLT17, Europarl, and TED talks datasets in Table 3. For all three datasets, different strategies achieve comparable BLEU score on supervised directions. However, for the zero-shot directions, the BLEU score varies significantly using different LT strategies. One observation is that the `T-ENC` strategy consistently outperforms the other three strategies on all datasets in terms of BLEU score with large margin, regardless of the corpus size and number of languages. In terms of off-target issue, `T-ENC` achieves the best performance in most cases.

Besides, ignoring the SLT (`T-ENC` v.s. `S-ENC-T-ENC`) also helps the zero-shot BLEU score. The percentage of off-target translations reaches 94.14% in the **IWSLT17** dataset by `S-ENC-T-ENC` strategy, while only 9.16% by `T-ENC` strategy. It indicates that the model translates almost all the sentences to the wrong languages in `S-ENC-T-ENC`, while to the right languages in `T-ENC`. It proves again the SLT hurts the zero-shot translation.

Another interesting observation is that placing the TLT on the encoder side also helps the zero-shot performance. Compared with `T-ENC`, both the translation quality and off-target performance are significantly worse in `T-DEC`. We will study

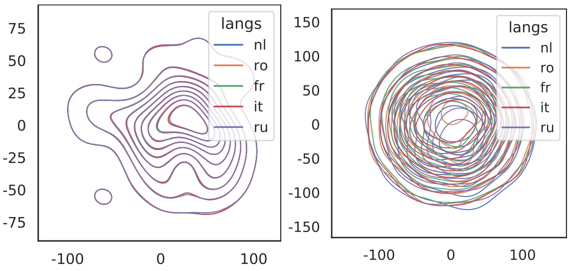
---

[1] https://github.com/Mimino666/langdetect

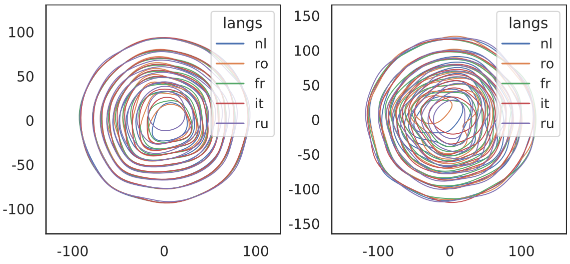
the reasons behind the above observations by visualization analysis in Section 4.

4 Visualization Analysis

We conduct the visualizations on the TED talks data to analyze the impact of different LT strategies on the semantic representation consistency and the off-target issue in MNMT.



(a) T-ENC (b) T-DEC



(c) S-ENC-T-ENC (d) S-ENC-T-DEC

Figure 1: KDE visualization of encoder output using different LT strategies. 5 languages (nl, ro, fr, it, ru → zh) are randomly chosen for better readability.

Enhancing the Semantic Representation Consistency Figure 1 shows the kernel density estimation (KDE) (Parzen, 1962) of t-SNE (Van der Maaten and Hinton, 2008) reduced average encoder output on different languages. We randomly chose 5 source languages (nl, ro, fr, it, ru → zh) instead of all languages for clearer visualization. We choose 100 sentences for each language, and each sentence has its corresponding translation in the other 4 languages. The contour lines drawn by Kernel Density Estimation tools [2] was used to estimate the semantic distribution of the encoder outputs. The contour lines visualize the semantic representation of different languages. The representations are more consistent if the contour lines of different languages overlap more with each other.

The contour lines are nearly perfectly overlap with each other in `T-ENC` (Figure 1a), while they do not for the other strategies. Comparing Figure 1a and Figure 1c, we can see that ignoring SLT greatly helps the model to learn more consistent representations. Comparing Figure 1a and Figure 1b, placing TLT to encoder side instead of the decoder side also helps the semantic consistency. Both comparisons validate that `T-ENC` could learn the most consistent and different semantic representations, thus achieves the best BLEU score. It might be why the shape of contour lines in `T-ENC` is significantly different from other strategies.

Alleviating the off-target Issue Figure 2 shows the attention visualization of a Russian to Italian translation example using different LT strategies. The x-axis is the Italian translation.

In Figure 2a1, `T-ENC` strategy pays attention to the TLT (in this case, the token `__it__` in the red background) during the whole translation procedure (left-to-right). Compared to `T-ENC`, both `T-DEC` and `S-ENC-T-DEC` pay less attention to the TLT after a few tokens are generated. It validates that placing the TLT on the encoder side would also help the model distinguish the target languages. The `S-ENC-T-ENC` pays nearly equal attention to both SLT and TLT, which might make the model confused about which one is the target language. Both comparisons prove that the `T-ENC` strategy has the best ability to distinguish the target languages, thus alleviates the off-target issue.

Combining Both Semantic Consistency and off-target Issue Figure 3 visualizes the cosine similarity of the layer-wise encoder and decoder output of different languages in zero-shot setting (English excluded). We sampled 100 muti-way data from the test set and averaged the cosine similarity between each language.

In the many-to-one setting, we randomly select Russian as the target language and translate the other 18 languages to Russian to obtain the model outputs. The similarity improves from encoder layer 0 to 3 and decoder layer 0 to layer 4, which indicates that the semantic consistency improves as the layer goes up. Interestingly, the similarity drops from encoder layer 3 to layer 4. It might be because the decoder interacts with the encoder directly between encoder layer 4 and decoder layer 0, thus interferes with the top-layer encoder output. But the dropping trend is less rapid in `T-ENC` than in other strategies. The `T-ENC` achieves the highest similarity on the last layer, which shows that the `T-ENC` learns more consistent semantics representations.

---

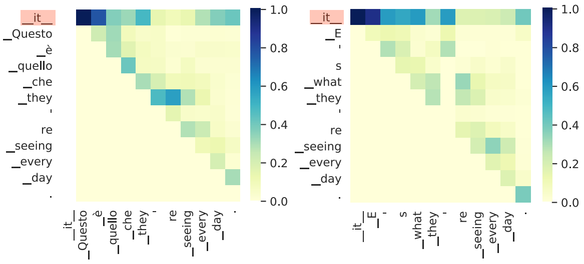
(a1) T-ENC (a2) S-ENC-T-ENC

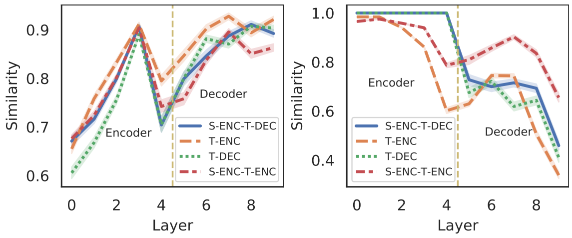
(a) The Decoder Cross Attention



(b1) T-DEC (b2) S-ENC-T-DEC

(b) The Decoder Self Attention

Figure 2: Attention visualization on a Russian to Italian translation example using different LT strategies. Note that we present the cross-attention for `T-ENC` and `S-ENC-T-ENC`, the decoder self-attention for `T-DEC` and `S-ENC-T-DEC` to visualize the TLT token.



(a) many-to-one (b) one-to-many

Figure 3: The cosine similarity of layer-wise output using different LT strategies. Note that layer 0 to 4 are the encoder layers, layer 5 to 9 are the decoder layers.

In the one-to-many setting, we treat Russian as the source language and translate Russian to the other 18 languages to get the model output. The semantic similarity drops as the layer goes up in all four strategies. It indicates that the model can distinguish different target languages as the layer goes up. `T-ENC` achieves the lowest similarity at the last layer output among all strategies. It shows again that the `T-ENC` has the best ability to alleviate the off-target issue.

5 Conclusion

We show that the language tags in MNMT are not just indicators for translation directions but also significantly impact the zero-shot translation quality. By extensive experiments and visualization analysis, we found that (i) ignoring the SLTs could help the models learn consistent semantic representations. (ii) Placing the TLTs on the encoder side could help the decoder pay more attention to the target language, thus alleviating the off-target issue. Zero-shot translation quality could be improved by investigating how to enhance the semantic representation consistency further and alleviate the off-target issue by optimizing LT strategies. We will conduct methods to optimize the LT strategy in our future work.

Abstract

Multi-hop question generation requires complex reasoning and coherent language realization. Learning a generation model for the problem requires extensive multi-hop question answering (QA) data, which are limited due to the manual collection effort. A two-phase strategy addresses the insufficiency of multi-hop QA data by first generating and then composing single-hop sub-questions. Learning this generating and then composing two-phase model, however, requires manually labeled question decomposition data, which is labor intensive. To overcome this limitation, we propose a novel generative approach that optimizes the two-phase model without question decomposition data. We treat the unobserved sub-questions as latent variables and propose an objective that estimates the true sub-questions via variational inference. We further generalize the generative modeling to single-hop QA data. We hypothesize that each single-hop question is a sub-question of an unobserved multi-hop question, and propose an objective that generates single-hop questions by decomposing latent multi-hop questions. We show that the two objectives can be unified and both optimize the two-phase generation model. Experiments show that the proposed approach outperforms competitive baselines on HOTPOTQA, a benchmark multi-hop question answering dataset.

Sub-Questions	Which team is headquartered in Affalterbach, Baden Württemberg, Germany? After contracted by AMG, Dario Franchitti competed in what series?
Answer	DTM

1 Introduction

Question generation aims to automatically generate valid and coherent questions based on given context, which is widely applied to enrich question answering (QA) datasets, facilitate text comprehension (Ko et al., 2020), seek clarification in conversation (Rao and Daumé III, 2019), etc. Recently, neural encoder-decoder based approaches have shown promising results for simple, single-hop question generation (Du and Cardie, 2018). Such approaches directly maps context (e.g., text passages) to questions without *reasoning*, and thus struggle when generating multi-hop questions (Pan et al., 2020). Here, reasoning refers to identifying and aggregating the relevant information taken from multiple documents to derive the question. Table 1 illustrates the reasoning process of a multi-hop question; in this example, the entity that links the two passages, i.e., "AMG", is firstly identified, and the relations around it in the context are transformed into a question. To model such reasoning processes in an end-to-end manner requires extensive training data, and is thus impractical due to the

extensive collection effort of multi-hop QA data.

To address this problem, recent studies propose to augment the generation model with an explicit reasoning progress. For example, a straightforward solution is to identify the anchoring entities via named entity recognition (NER), and find relations via relation extraction. The extracted structural reasoning path, in the form of subject-predicate-object triples as illustrated in Table 1, is then fed to the generation model as auxiliary features (Yu et al., 2020b). However, the reasoning capability is constrained by the off-the-shelf extraction tools which cannot be extended to arbitrary context (Yang et al., 2018; Dhingra et al., 2020).

Another line of recent studies on multi-hop question answering models the reasoning process by decomposing a multi-hop question into several sub-questions (Min et al., 2019; Wolfson et al., 2020). As illustrated in Table 1, the answer of the multi-hop question can be derived by answering a series of single-hop sub-questions. Ideally, question generation can also adopt this two-phase strategy which first generates sub-questions and then composes the sub-questions into a multi-hop question. However, this strategy requires a parallel corpus that annotates each multi-hop question to its corresponding sub-questions, and obtaining such annotations still requires extensive efforts and costs.

To address these issues, we propose to jointly optimize the two-phase model using *non-parallel* single-hop and multi-hop corpuses only, in which the questions are not paired. We propose a generative objective that models the multi-hop and single-hop question generation (QG) tasks in a unified way. The key idea is that each question, either multi-hop or single-hop, can be considered a partially observed ⟨multi-hop question, sub-question⟩ pair and treat the unobserved part as a latent variable. In the generative modeling of multi-hop QG, we use the two-phase model as a generation model and introduce a posterior model to estimate unobserved sub-questions. The generation and the posterior models are jointly optimized via variational inference (Kingma and Welling, 2014). For generative single-hop QG, we instead use the two-phase model as a posterior model to estimate unobserved multi-hop questions, and the posterior model is jointly optimized with a generation model that decomposes a multi-hop question into sub-questions. In this way, we integrate the optimization of the two-phase model in both generative multi-hop and single-hop QG tasks, serving as the generation and the posterior model, respectively.

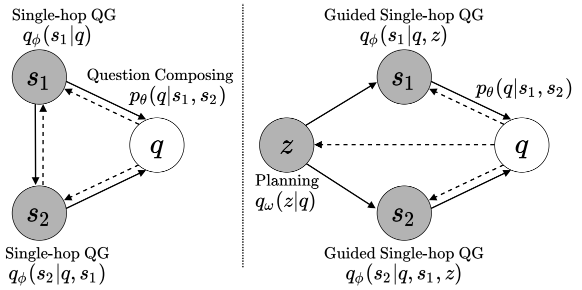
Optimizing the generative objective in the text space is, however, prone to compounding errors due to the diversities of potential reasoning paths. There are multiple ways to raise a single-hop question given the same piece of information, and it is challenging to find the valid one only given the text passages. We address this challenge by equipping the generative modeling with a planning mechanism that uses a latent variable to encode the desired reasoning path. In this way, the inference of sub-questions is guided by a pre-sampled plan (i.e., the latent variable) and thus maintains consistency with the target multi-hop question. We achieve latent variable learning by incorporating an end-to-end differentiable bottleneck into the sub-question generation model, which can be naturally integrated into the overall objective. Moreover, the proposed planning mechanism also promotes a more stable training. This is because the original generative modeling involves a sequential sampling of latent variables (i.e., sub-questions), which is known to cause high variance and result in an unstable training (He et al., 2020). The planning mechanism relieves the sequential sampling requirement, since it encodes the high-level planning and covers the dependency between sub-questions.

Our contributions are summarized as follows:

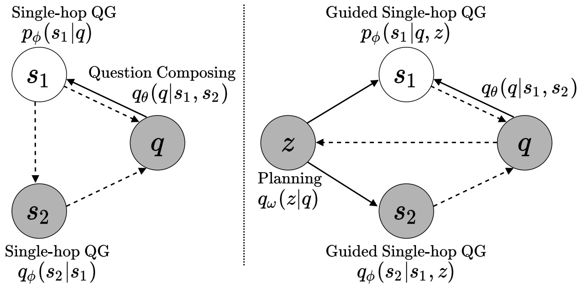
- We propose a novel generative objective that unifies non-parallel question corpuses and relieves the requirements of extensive annotations for learning a two-phase question generation model.
- We propose a planning mechanism to guide the generation towards sub-questions that are more probable to compose into a multi-hop question.
- We conduct experiments on a benchmark multi-hop question answering dataset. The results show that our approach outperforms the state-of-the-art under both language generation and question answering based evaluations.

2 Preliminaries

Let $D_{\mathcal{M}} = \{(q_i, a_i, c_i) | 1 \leq i \leq N\}$ be a set of N multi-hop question-answer-evidence triples, where the evidence is a set of potentially relevant sentences $c_i = \{d_1, d_2, ..., d_k\}$, and each multi-hop question q requires reasoning over multiple sentences to find the answer a. Multi-hop question generation (QG) aims to generate a question q that has the pre-selected answer a given the evidence set



(a) Generative multi-hop QG (left) with planning (right)



(b) Generative single-hop QG (left) with planning (right)

Figure 1: A graphical representation of the proposed generative model. White circles denote the observed variables and gray circles denote the latents. [1]

c. Existing studies adopt a strategy commonly used in single-hop question generation, which formulates multi-hop QG as a seq-to-seq problem. Since extensive annotation efforts are needed to produce multi-hop QG examples, few multi-hop QG examples are available. Thus, a naive adoption of seq-to-seq learning may not yield an effective multi-hop QG model, especially in the low-resource scenario.

To address data insufficiency, a two-phase strategy is considered based on the assumption that each multi-hop question q can be decomposed into two single-hop sub-questions s_1 and s_2.[2] The multi-hop question generation is then performed by a sub-question generation model $p_\mathcal{S}$ and a question composing model $p_\mathcal{C}$ as

$$p(q|a, c) = p_\mathcal{C}(q|s_1, s_2)p_\mathcal{S}(s_2, s_1|a, c). \qquad (1)$$

The training of these two models require question decomposition data, which are pairs of a multi-hop question and its corresponding sub-question annotations $\{(q, \langle s_1, s_2\rangle)\}$. However, it is non-trivial to obtain the question decomposition data, which requires extensive human annotation effort.

3 Proposed Model

We take a two-phase approach for multi-hop question generation while do not require a question decomposing dataset that contains pairs of multi-hop questions and sub-questions. We assume that a single-hop question answering dataset $D_\mathcal{S}$ and a multi-hop dataset $D_\mathcal{M}$ are available for training. Both datasets are non-parallel, i.e., contain question-answer pairs but not sub-questions, and the evidence passages of both datasets shall come from the same source (e.g., Wikipedia articles).

Under these problem settings, we aim to learn the single-hop QG model $p_\mathcal{S}$ and the question composing model $p_\mathcal{C}$ using both $D_\mathcal{S}$ and $D_\mathcal{M}$. To effectively train these two models in the absence of question decomposition data, we propose a unified generative formulation that naturally connects single-hop and multi-hop questions. Specifically, in modeling the generation process of multi-hop questions, we treat the corresponding sub-questions as latent variables and propose an objective that jointly optimizes $p_\mathcal{S}$ and $p_\mathcal{C}$ (Sec. 3.1). We further extend the generative formulation to model the generation of single-hop questions, and both generation processes together form the overall optimization objective (Sec. 3.2). Then, we propose a planning-aware generation strategy to better optimize the objective in Sec. 3.3. We summarize the overall learning and inference process in Sec. 3.4.

3.1 Generative Modeling of Multi-Hop QG

We now reconsider the two-phase question generation strategy in Eqn. 1. Since we do not have the parallel data, it is infeasible to directly model the conditional probability $p(q|s)$, where $s = \{s_1, s_2\}$ is the set of sub-questions of q. We thus propose to treat the unobserved sub-questions as latent variables, and describe $p(q|a, c)$ in a generative way as

$$p(q) = \sum_s p(q, s) = \sum_s p_\theta(q|s)p_\psi(s) \qquad (2)$$

where $p(q)$ and $p(q, s)$ are shorthands for $p(q|a, c)$ and $p(q, s|a, c)$, [3] p_ψ is a conditional prior model, and p_θ is a generation model for multi-hop questions. Since this likelihood is intractable, we instead derive and optimize its evidence lower bound

---

[1] Note that the generation of single-hop questions s, multi-hop question q, and planning variables z are conditioned on evidence set c and answer a, which is omitted in Fig. 1.

[2] The formulation can be easily extended to more sub-questions

[3] Same below for brevity when the context is clear.

(ELBO) (Kingma and Welling, 2014)

$$\log p(q) \geq \mathbb{E}_{q_\phi(s|q)}[\log \frac{p_\theta(q|s)p_\psi(s)}{q_\phi(s|q)}]$$
$$= \mathbb{E}_{q_\phi(s|q)}[\log p_\theta(q|s)] - \text{KL}(q_\phi(s|q)||p_\psi(s)) \tag{3}$$

where $q_\phi(s|q)$ is a posterior model for latent variable s, and KL denotes the Kullback-Leibler divergence. We now substitute the latent variable s with two sub-questions, s_1 and s_2, and define the factorized form of the posterior and the prior in a hierarchical manner

$$\begin{aligned} q_\phi(s|q) &= q_\phi(s_2|q, s_1)q_\phi(s_1|q) \\ p_\psi(s) &= p_\psi(s_2|s_1)p_\psi(s_1). \end{aligned} \tag{4}$$

We can now rewrite the ELBO in Eqn. 3 with the factorization and obtain

$$\begin{aligned} \log p(q) \geq\ & \mathbb{E}_{q_\phi(s_1|q)q_\phi(s_2|s_1,q)}[\log p_\theta(q|s_1, s_2)] \\ & - \text{KL}(q_\phi(s_1|q)||p_\psi(s_1)) \\ & - \text{KL}(q_\phi(s_2|q, s_1)||p_\psi(s_2|s_1)) \\ & := \mathcal{L}_{\text{ELBO}}(q) \end{aligned} \tag{5}$$

Fig. 1(a) shows the directed graphical model of the generative modeling of multi-hop question generation. Specifically, given an evidence set and a pre-selected answer, a single-hop question s_1 is first sampled. Given s_1 and relevant information in the context, a second sub-question s_2 that satisfies a valid reasoning process is further sampled. Since two sub-questions are both unobserved, we estimate s_1 and s_2 using the posterior model q_ϕ. The sub-questions then form the observed multi-hop question q via question composing as $p_\theta(q|s_1, s_2)$.

To perform effective optimization, we tie the parameters of the posterior model q_ϕ at different hierarchies, i.e., $q_\phi(s_1|\cdot)$ and $q_\phi(s_2|\cdot)$, as one single-hop QG model. Such parameter tying also applies to the prior model p_ψ. We implement the generation model p_θ, the prior p_ψ, and the posterior q_ϕ in Eqn. 5 using pre-trained encoder-decoder models which will be detailed in Sec. 3.4. We notice that the prior p_ψ and the generation model p_θ actually play the same role as the single-hop QG model $p_\mathcal{S}$ and question composing model $p_\mathcal{C}$ in Eqn. 1. Thus, the generative modeling enables a joint optimization of $p_\mathcal{S}$ and $p_\mathcal{C}$ using multi-hop QA data only and without question decomposing data.

3.2 Generative Modeling of Single-Hop QG

Considering that the multi-hop QA data is limited, we propose to integrate single-hop QA data into the joint optimization objective. We extend the proposed generative modeling by assuming that each single-hop question is obtained by decomposing an unobserved multi-hop question. With a slight abuse of notation, we use (s, a, c) to denote a single-hop question-answer-evidence triple, and describe $p(s|a, c)$ as

$$p(s) = \sum_q p(s, q) = \sum_q p_{\theta'}(s|q)p_{\psi'}(q) \tag{6}$$

where we omit the condition as in Eqn. 2, and q is a multi-hop question that has a sub-question s. The generation model $p_{\theta'}$ and the prior model $p_{\psi'}$ are parameterized with θ' and ψ', respectively. We treat the unobserved q as a latent variable and derive the evidence lower bound as

$$\begin{aligned} \log p(s) \geq \mathbb{E}_{q_{\phi'}(q|s)}[\log p_{\theta'}(s|q)] \\ -\text{KL}(q_{\phi'}(q|s)||p_{\psi'}(q))] := \mathcal{L}_{\text{ELBO}}(s) \end{aligned} \tag{7}$$

where $q_{\phi'}$ is a posterior model to estimate the unobserved question q.

Fig. 1(b) illustrates the generative modeling for single-hop QG. Specifically, a multi-hop question is first sampled by the prior $p_{\psi'}$, and we assume that its sub-question set includes the observed single-hop question s. The question s is then generated by decomposing the multi-hop question q via $p_{\theta'}(s|q)$. We estimate the unobserved multi-hop question q using the posterior model $p_{\phi'}$.

We observe that the posterior approximation in single-hop QG (dashed line in Fig. 1(b)-left) is the same as the generative process in multi-hop QG (solid line in Fig. 1(a)-left). Thus, we can realize the posterior model $q_{\phi'}(q|s)$ by reusing the prior p_ψ and the generative model p_θ in Eqn. 5 as

$$q_{\phi'}(q|s) = p_\theta(q|\hat{s}, s)p_\psi(\hat{s}|s) \tag{8}$$

where $\hat{s}$ is the unobserved second sub-question that forms the multi-hop question together with s. Note that we no longer need a hierarchical form since one sub-question is observed.

Further, we observe that the generative process in single-hop QG (solid line in Fig. 1(b)-left) is part of the posterior approximation of multi-hop QG (dashed line in Fig. 1(b)-left). This way, we realize the generation model $p_{\theta'}$ and the prior $p_{\psi'}$ using the models already present in multi-hop QG

$$\begin{aligned} p_{\theta'}(s|q) &= q_\phi(s|q) \\ p_{\psi'}(q) &= p_\theta(q|s_1, s_2)p_\psi(s_2|s_1)p_\psi(s_1) \end{aligned} \tag{9}$$

Table 2: Question Generation Diversification Example.

Supportive Evidence	
After Franchitti did not secure a single-seater drive in 1995, he was contracted by the AMG team to compete in touring cars in the DTM and its successor — the International Touring Car Championship.	
Potential Generated Sub-Questions	
Q: Did Dario Franchitti secure a single seater drive in 1995?	**A:** No
Q: Dario Franchitti was contracted by which team to compete in the DTM?	**A:** AMG
Q: The International Touring Car Championship is the successor of what series?	**A:** DTM
Q: After contracted by AMG, Dario Franchitti competed in what series?	**A:** DTM

where the prior $p_{\psi'}(q)$ is inferred by first estimating and then composing the latent sub-questions s_1 and s_2. Note that p_θ, p_ψ, and q_ϕ are all taken from the generative modeling of multi-hop QG. Thus, the single-hop QG objective (Eqn. 7) optimizes the same set of models as in multi-hop QG objective (Eqn. 3). This way, we seamlessly unify the multi-hop and single-hop QA data for joint optimization.

3.3 Planning Guided Question Generation

There is a challenge under the generative formulation: the diversification of feasible generated questions can impinge the model training. Given the same evidence set and pre-selected answer, there can be multiple ways to raise a questions (Lee et al., 2020). However, not every potential single-hop question is qualified as a sub-question to form the target multi-hop question, as illustrated in Table. 2. To address this challenge, we propose to learn a latent planning variable which serves as a generation planning to guide the generation process.

The latent planning variable aims to capture the high-level reasoning required to answer the multi-hop questions, which is abstracted as a reasoning path in existing studies. In order to model decision making of the reasoning path, we define the latent variable z as a discrete variable. We now incorporate the latent variable into the generative modeling of multi-hop QG

$$\begin{aligned}\log p(q) &= \log \sum_s \int_z p(q,z,s)dz \\ &\geq \mathbb{E}_{q_\omega(z|q)}[p(q|z)] - \mathrm{KL}(q_\omega(z|q)||p_\omega(z)) \\ &:= \mathcal{L}_{\mathrm{ELBO}}(q,z)\end{aligned} \tag{10}$$

where q_ω and p_ω are posterior and prior models, respectively, and the reason of having the same parameters ω will be detailed later. The conditional probability $p(q|z)$ is modeled by letting the terms of $\mathcal{L}_{\mathrm{ELBO}}(q)$ in Eqn. 5 be additionally conditioned on the sampled latent variable z (as illustrated in Fig. 1(a)-right). The generation of sub-questions, both prior p_ψ and posterior q_ϕ, is now aware of the planning as

$$\begin{aligned}q_\phi(s|q,z) &= q_\phi(s_1|q,z)q_\phi(s_2|q,z) \\ p_\psi(s|z) &= p_\psi(s_1|z)p_\psi(s_2|z).\end{aligned} \tag{11}$$

We now no longer need a hierarchical form like Eqn. 4, since the latent planning variable already encodes the information of the other sub-question. Thus, this formulation also alleviates the high variance issue commonly encountered in hierarchical variational training (Vahdat and Kautz, 2020).

We also consider the planning guided mechanism in the generative modeling of single-hop QG

$$\begin{aligned}\log p(s) &= \log \sum_q \int_z p(s,z,q)dz \\ &\geq \mathbb{E}_{q_\omega(z|q)}[p(s|z)] - \mathrm{KL}(q_\omega(z|s)||p_\omega(z)) \\ &:= \mathcal{L}_{\mathrm{ELBO}}(s,z)\end{aligned} \tag{12}$$

where $p(s|z)$ is modeled by letting the prior and the posterior in $\mathcal{L}_{\mathrm{ELBO}}(s)$ be additionally conditioned on z The realizations in Eqn. 8 and Eqn. 9 are now formulated as

$$\begin{aligned}q_{\phi'}(q|s,z) &= p_\theta(q|\hat{s},s)p_\psi(\hat{s}|z) \\ p_{\psi'}(q|z) &= p_\theta(q|s_1,s_2)p_\psi(s_1|z)p(s_2|z)\end{aligned} \tag{13}$$

We implement the latent variable as discretized VAE (van den Oord et al., 2017) by adding a learnable codebook between the encoder and the decoder. The codebook is a set of prototype vectors $e_k, k \in 1, 2...K$, each having the same dimensionality as that of the encoder output. The discrete variable is obtained by using a nearest-neighbor lookup to find the vector closest to the encoder output. The corresponding prototype vector is then fed into the decoder as an additional context embedding to which every decoding step could attend. With this discretization bottleneck design, the encoder-decoder model and the codebook can be jointly optimized.

3.4 Learning and Inference

We initialize the generative model p_θ, the prior p_ψ and the posterior q_ϕ using BART (Lewis et al., 2020), a pre-trained seq-to-seq model. BART uses the standard Transformer based encoder-decoder architecture (Vaswani et al., 2017), and is optimized by reconstructing the intentionally corrupted documents. We adopt an initial fine-tuning step for all three models using question answering data $D_{\mathcal{S}}$ and $D_{\mathcal{M}}$, which adjusts the initialization pretrained from general texts to better fit the question generation tasks. We then optimize p_θ, p_ψ, and q_ϕ together with the discretization bottleneck q_ω using the generative modeling of both multi-hop and single-hop question answering data

$$\mathcal{L} = \sum_{q \in D_{\mathcal{M}}} \mathcal{L}_{\text{ELBO}}(q, z) + \sum_{s \in D_{\mathcal{S}}} \mathcal{L}_{\text{ELBO}}(s, z) \quad (14)$$

After training the single-hop QG model (i.e., p_ψ), question composing model (i.e., p_θ), and the bottleneck q_ω, inference follows the two-stage strategy. We first infer a latent planning variable given the evidence set and the answer. The sub-questions are generated based on the inferred planning variable and are composed into a multi-hop question.

4 Experiments

To show the effectiveness of the proposed approach, *planning guided latent reasoning* (PLAR), we experiment on two multi-hop question generation settings (Sec. 4.1). We compare against state-of-the-art approaches in both settings (Sec. 4.2). We further consider a question answering based performance measure, and analyze the effectiveness of the proposed generative modeling (Sec. 4.3).

4.1 Settings

We use HOTPOTQA (Yang et al., 2018), a crowd-sourced multi-hop question answering (QA) dataset in our experiments. It contains over 90K question answering examples, and the evidence set of each question includes relevant paragraphs from Wikipedia. The question-relevant sentences within these paragraphs are further annotated as supporting facts. We follow the original data split of HOTPOTQA, which includes 90,440 / 6,072 examples for training and evaluation, respectively. We further hold out 6,072 examples from the training data as the validation set. We use SQuAD (Rajpurkar et al., 2016) as the single-hop QA dataset, which has over 100K questions also crowd-sourced based on Wikipedia articles. Following the conventional evaluation metrics, we use n-gram **BLEU** (Papineni et al., 2002), **METEOR** (Banerjee and Lavie, 2005), and **ROUGE-L** (Lin and Hovy, 2002) to evaluate the question generation quality.

We consider two input settings to thoroughly evaluate the multi-hop question generation (QG) performance: *sentence-level* and *paragraph-level*. In the first setting, following the existing multi-hop QG task formulation (Pan et al., 2020; Yu et al., 2020b), we take the question-relevant sentences (i.e., supporting facts) along with the answer as inputs to generate the question. However, human annotated supporting facts are not always available, while identifying two relevant paragraphs is relatively achievable. Thus, we further consider a paragraph-level setting where, besides the answer, we instead use the paragraphs containing supporting facts as part of the input. In both settings, in order to simulate a low-resource scenario, we train PLAR and other baselines using two different subsets of the question answering examples, HOTPOT-10K and HOTPOT-30K, containing 10K and 30K randomly sampled training examples, respectively.

Note that we do not utilize any annotated question decomposition dataset (e.g., QDMR (Wolfson et al., 2020)). This is because it is labour-intensive to obtain the extra question decomposition annotations, which are not present in HotpotQA. Thus, it is not practical to assume such decomposition annotations would be available in different QA tasks. We aim to tackle this challenge by utilizing non-parallel single-hop questions, which is relatively easy to acquire and do not require extra task-specific annotations.

We compare with three baselines that are based on seq-to-seq models and are competitive in single-hop question generation tasks: **ASs2s** (Kim et al., 2019), **Maxout-QG** (Zhao et al., 2018), **BART** (Lewis et al., 2020). We compare with two baselines that consume auxiliary reasoning path features for multi-hop QG: **RC-QG** (Yu et al., 2020b) uses reasoning chains built via named entity recognition and relation extraction; and **SG-DQG** (Pan et al., 2020) adopts semantic role labeling techniques to build semantic graphs. We also compare the full **PLAR** with its two variants: **Pipeline** individually trains a single-hop QG model and a question composing model using synthetic question decomposition data obtained as Perez et al. (2020); and **PLAR w/o plan** uses the generative objectives as PLAR without the planning mechanism.

Table 3: Question Generation Results (Sentence-Level)

Model		Hotpot-30K				Hotpot-10K			
		BLEU-1	BLEU-4	METEOR	ROUGE-L	BLEU-1	BLEU-4	METEOR	ROUGE-L

	SG-DQG	32.93	12.32	16.40	29.81	31.12	12.27	15.25	27.90
Proposed	Pipeline	30.11	11.65	15.20	27.28	28.23	10.02	13.21	25.21
	PLAR w/o plan	35.19	13.48	17.54	31.02	33.68	13.87	16.64	28.87
	PLAR	**37.32**	**14.94**	**18.87**	**32.63**	**35.96**	**15.32**	**17.37**	**29.85**

4.2 Overall Results

Table 3 shows that PLAR consistently outperforms baselines on both subsets in the sentence-level input setting. We can see that PLAR achieves a significant performance gain for all metrics. For example, PLAR (32.63) outperforms SG-DQG (29.81) under ROUGE-L on Hotpot-30K. Meanwhile, we also find that the generative modeling is essential to the performance gain of PLAR. For examples, PLAR w/o plan (16.64) achieves 25.9% improvements over Pipeline (13.21) under METEOR on Hotpot-10K. This validates that unifying single-hop and multi-hop QA data can effectively alleviate the data scarcity issue. We further find that Pipeline has a heavier performance decrease (comparing with the baselines) when having fewer data. For example, Pipeline outperforms RC-QG under BLEU-4 on Hotpot-30K, while it is outperformed by RC-QG on Hotpot-10K. This is largely because the training of each phase is individual performed which is prone to data insufficiency especially in a more extreme low-resource scenario.

For the paragraph-level input setting, Table 4 shows the results that PLAR consistently outperforms the baselines by a large margin. For example, PLAR (17.79) achieves a gain of more than 33% compared to SD-DQG (13.37) under METEOR on Hotpot-30K. By comparing PLAR (27.64) with PLAN w/o plan (24.81) and Pipeline (23.04) under ROUGE-L on Hotpot-10K, we find that the contribution of the planning mechanism is more significant than that of the generative modeling. This is largely because the diversification of potential sub-questions raises greater challenges in the paragraph-level setting. Using the planning variables, PLAR can effectively generate the feasible sub-questions. We also provide qualitative examples in Appendix to show the effectiveness of the planning variables. We also find that the reasoning path augmented baselines are not as competitive as in the sentence-level input setting. For example, RC-QG outperforms all the seq-to-seq based baselines under METEOR in the sentence-level setting, while it only outperforms ASs2s in the paragraph-level setting. The reason is that handcrafted reasoning features cannot generalize well to a larger evidence set. PLAR overcomes this limitation by optimizing reasoning capability taking advantage of both single-hop and multi-hop QA data.

4.3 Discussion

We first study whether the generated questions can boost the question answering performance. We compare the performances of a BERT QA model (Devlin et al., 2019) on both subsets, where the QA model is trained using QA data generated by different QG models. The results in Table 5 show that the learning of multi-hop QA models relies heavily on sufficient supervision, since a significant perform reduction is observed when training on a subset only. PLAR achieves more effective training than the baselines and its variants, especially in the more challenging subset. It achieves the most performance gain (17.3%) over the subset-only training result under F1 on Hotpot-30K. We also find that the QG results of BART do not improve QA performance while BART performs comparable to other baselines (e.g., SG-DQG) on automatic evaluation metrics. This is aligned with our intuition that the text fluency is insufficient for obtaining multi-hop questions that benefit the QA task. It is essential to incorporate reasoning into the generation process.

We now study the effect of unified generative question generation. To investigate how the generative multi-hop (Eqn. 5) and single-hop objective (Eqn. 7) contribute to the overall question generation training, we compare PLAR with PLAR using multi-hop objective only and PLAR using planning guided multi-hop objective under varying sizes of single-hop question answering data. The results on

Table 4: Question Generation Results (Paragraph-Level)

MODEL		HOTPOT-30K				HOTPOT-10K

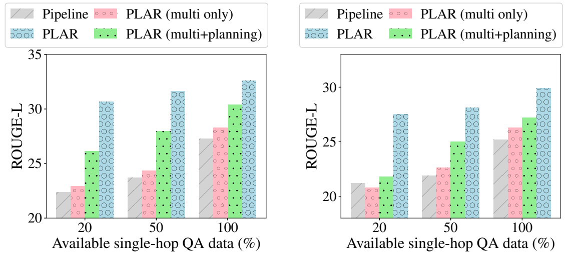
* Both question generation and question answering are performed in the paragraph-level setting.



(a) Results on HOTPOT-30K (b) Results on HOTPOT-10K

Figure 2: Effects of unified generative modeling

the two subsets under ROUGE-L in the sentence-level setting are shown in Fig. 2(a) and Fig. 2(b). We can see that both objectives are important. For example, when using complete single-hop QA data on HOTPOT-30K, multi-hop and single-hop generative objectives bring 7.3% and 11.5% improvement, respectively. We further find that the performance gain of PLAR is largely attributed to the single-hop generative objective when available single-hop questions are limited. The reason is that without the generative single-hop objective, training the sub-question generation model heavily relies on the initial fine-tuning step, and is thus prone to single-hop QA data insufficiency. The full PLAR model addresses this limitation by further training the sub-question generation model with supervision from generative single-hop and multi-hop QG.

5 Related Work

Question generation has a wide range of applications besides expanding question answering data, such as initiating a conversation of dialogue systems (Mostafazadeh et al., 2017), providing practice exercises for educational purposes (Jia et al., 2020), and accelerating real-time question answering (Seo et al., 2019). It also has great potential in enriching task-oriented dialogue datasets (Sun et al., 2016, 2017; Huang et al., 2020a; Kim et al., 2020b). Early studies build on encoder-decoder models and utilize different evidence information, e.g., Wikipedia passages (Du and Cardie, 2018), reviews (Yu et al., 2020c), and dialogue history (Gao et al., 2019). These studies often assume that the questions are single-hop which be answered by one piece of evidence. As more high-quality multi-hop question answering datasets become available (e.g., HOTPOTQA (Yang et al., 2018)), recent years have seen a growing interest in multi-hop question generation. Most recent approaches add heuristically extracted features to the encoder-decoder model, which relies on large-scale training data and can still suffer from error propagation (Yu et al., 2020b; Pan et al., 2020). A recent study (Yu et al., 2020a) which also studies low-resource question generation assumes that a large amount of unanswered multi-hop questions are available, which is also difficult to obtain. We aim to overcome these limitations in this study.

Our study is also related to generative modeling which treats unobserved variables (e.g., features or labels) as latent variables, and approximates the distribution through variational inference (Kingma and Welling, 2014). Generative modeling has been applied to dialogue response generation (Zhao et al., 2019; Huang et al., 2020b; Yang et al., 2020), policy learning (Huang et al., 2019, 2020c), sentiment analysis (Xu et al., 2017; Li et al., 2019), knowledge retrieval (Lee et al., 2019; Kim et al., 2020a; Su et al., 2021; Tan et al., 2021), and text style transfer (He et al., 2020). While these works focus on utilizing unlabeled data to boost model performance, we aim to unify non-parallel question corpuses to enable joint learning.

6 Conclusions

We proposed a jointly optimized two-phase model named PLAR for low-resource question generation. PLAR effectively utilizes non-parallel single-hop and multi-hop question answering data to perform optimization. We further designed a planning mechanism to guide the generation process of sub-questions so that the generation results are valid to compose a multi-hop question. Experimental results confirm that PLAR achieves better performance compared with the state-of-the-art under various metrics, especially in a question answering based evaluation. For future work, we will explore the heterogeneous multi-hop QG task that requires reasoning beyond plain texts, e.g., tables.

A Implementation Details

We use HotpotQA split as the original paper (Yang et al., 2018) [4], and use SQuAD v1.1 (Rajpurkar et al., 2016) [5] training set only since single-hop question answering data only involves in the training. We use the BART-base model implementation from huggingface library [6] as the single-hop question generation model and question composing model. We set the batch size to 32 in sentence-level setting and 16 in paragraph-level setting. The models are trained by Adam (Kingma and Ba, 2015) with a learning rate initially set to 3e-5 on NVIDIA GeForce RTX 2080 Ti. We use grid search to find the best hyperparameters for the models based on validation performance, which we use a combination of METEOOR, ROUGE-L and BLEU scores to measure. [7] We set dimensionality of codebook of the planning mechanism (i.e., K) to 100, which is chosen among $\{50, 75, 100, 150, 200\}$

B Sub-Question Generation Qualitative Analysis

Table 6 and 7 show question generation results from PLAR and Pipeline model.

C Planning Mechanism Case Study

Table 8 and 9 show the generation results by different sampled planning variables z in the paragraph-level setting. We can see that with different predicted z (denoted by different z_i), PLAR raises different sub-questions and presents different high-level reasoning type. We also find that some planning variable cannot lead to a reasonable multi-hop question, and the prediction of PLAR can well capture the correct plan (denoted by higher $p(z|a, c)$).

Table 6: Sub-Question Generation and Question Composing Examples.

Supportive Evidence	**Paragraph A. Dario Franchitti**
	[1] George Dario Marino Franchitti, MBE (born 19 May 1973), known professionally as Dario Franchitti, is a retired Scottish racing driver. [2] After Franchitti did not secure a single-seater drive in 1995, he was contracted by the AMG team to compete in touring cars in the DTM and its successor — International Touring Car Championship.
	Paragraph B. Mercedes-AMG
	[1] Mercedes-AMG GmbH, commonly known as AMG, is the high performance division of Mercedes-Benz. [2] AMG independently hires engineers, manufactures and customizes Mercedes-Benz AMG vehicles. [3] Mercedes-AMG is headquartered in Affalterbach, Baden Württemberg, Germany.
Groundtruth QA Pair	After he was contracted by the team that is headquartered in Affalterbach, Baden-Württemberg, Germany, Dario Franchitti competed in what series? (Answer: DTM)
PLAR QG results	**Sub-question 1:** Affalterbach Germany is the location of what team?
	Sub-question 2: After contracted by AMG, Dario Franchitti competed in what series?
	Multi-hop question: After he was contracted by the team that is headquartered in Affalterbach, Baden-Württemberg, Germany, Dario Franchitti competed in what series?
Pipeline QG results	**Sub-question 1:** What is headquartered in Affalterbach Baden Germany?
	Sub-question 2: Dario Franchitti competed in what series in 1995?
	Multi-hop question: Dario Franchitti competed in what series in 1995 in Affalterbach Baden Germany?

Supportive Evidence	**Paragraph A. Force India VJM10**
	[1] The Force India VJM10 is a Formula One racing car designed and constructed by Force India to compete during the 2017 Formula One season. [2] The car is driven by Sergio Pérez and Esteban Ocon, who joined the team after Nico Hülkenberg left the team at the end of the season.
	Paragraph B. Esteban Ocon
	[1] Esteban Ocon (born 17 September 1996) is a French racing driver who currently drives in Formula One for Force India. [2] He made his Formula One debut for Manor Racing in the 2016 Belgian Grand Prix, replacing Rio Haryanto. [3] Ocon is part of the Mercedes-Benz driver development programme.
Groundtruth QA Pair	Force India VJM10 is a Formula One racing car previous driven by Nico Hülkenberg, and is now driven by which driver born 17 September 1996? (Answer: Esteban Ocon)
PLAR w/ Planning z_1 $p(z_1 \mid c,a)=0.71$	**Sub-question 1:** who drives Force India VJM10, a Formula One racing car previous driven by Nico Hülkenberg?
	Sub-question 2: which driver is born 17 September 1996?
	Multi-hop question: who is born 17 September 1996 and drives Force India VJM10, a Formula One racing car previous driven by Nico Hülkenberg?
PLAR w/ Planning z_2 $p(z_2 \mid c,a)=0.11$	**Sub-question 1:** Who currently drives in Fomula One for Force India?
	Sub-question 2: Who joined Force India after Nico Hülkenberg left?
	Multi-hop question: Who joined and drives for Force India after Nico Hülkenberg left?

Probing Pre-Trained Language Models for Disease Knowledge

Israa Alghanmi, Luis Espinosa-Anke, Steven Schockaert
Cardiff University, United Kingdom
{alghanmiia,espinosa-ankel,schockaerts1}@cardiff.ac.uk

Abstract

Pre-trained language models such as ClinicalBERT have achieved impressive results on tasks such as medical Natural Language Inference. At first glance, this may suggest that these models are able to perform medical reasoning tasks, such as mapping symptoms to diseases. However, we find that standard benchmarks such as MedNLI contain relatively few examples that require such forms of reasoning. To better understand the medical reasoning capabilities of existing language models, in this paper we introduce DisKnE, a new benchmark for Disease Knowledge Evaluation. To construct this benchmark, we annotated each positive MedNLI example with the types of medical reasoning that are needed. We then created negative examples by corrupting these positive examples in an adversarial way. Furthermore, we define training-test splits per disease, ensuring that no knowledge about test diseases can be learned from the training data, and we canonicalize the formulation of the hypotheses to avoid the presence of artefacts. This leads to a number of binary classification problems, one for each type of reasoning and each disease. When analysing pre-trained models for the clinical/biomedical domain on the proposed benchmark, we find that their performance drops considerably.

1 Introduction

Pre-trained language models (LMs) such as BERT (Devlin et al., 2019) are currently the de-facto architecture for solving most NLP tasks, and their prevalence in general language understanding tasks is today indisputable (Wang et al., 2018, 2019). Beyond generic benchmarks, it has been shown that LMs are also extremely powerful in domain-specific NLP tasks, e.g., in the biomedical domain (Lewis et al., 2020). While there are several reasons why they are preferred over standard neural architectures, one important (and perhaps less obvious) reason is that LMs capture a substantial amount of world knowledge. For instance, several authors have found that LMs are able to answer questions without having access to external resources (Petroni et al., 2019; Roberts et al., 2020), or that they exhibit commonsense knowledge (Forbes et al., 2019; Davison et al., 2019). To analyze the capabilities of LMs in a more systematic way, there is a growing interest in designing probing tasks, which are now common across the NLP landscape, e.g., for word and sentence-level semantics (Paperno et al., 2016; Conneau et al., 2018). In this paper we focus on (generic and specialized) LMs in the biomedical domain, and ask the following question: what kinds of medical knowledge do pre-trained LMs capture? More specifically, we focus on *disease knowledge*, which encompasses for instance the ability to link symptoms to diseases, or treatments to diseases.

Among the several biomedical LMs (i.e. LMs that have been pre-trained on biomedical text corpora) that exist today, some of the most prominent are SciBERT (Beltagy et al., 2019), BioBERT (Lee et al., 2020) and ClinicalBERT (Alsentzer et al., 2019). Rather than architectural features, these models differ from each other mostly in the pre-training corpora: SciBERT was trained from scratch on scientific papers; BioBERT is an adapted version of BERT (Devlin et al., 2019), which was fine-tuned on PubMed articles as well as some full text biomedical articles; and ClinicalBERT was initialized from BioBERT and further fine-tuned on MIMIC-III notes (Johnson et al., 2016), which are clinical notes describing patients admitted to critical care units. These LMs have enabled impressive results on various reading comprehension benchmarks for the medical domain, such as MedNLI (Romanov and Shivade, 2018) and MEDIQA-NLI (Abacha et al., 2019) for Natural Language Infer-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3023–3033
August 1–6, 2021.

ence (NLI), and PubMedQA (Jin et al., 2019b) for QA. As an example, Wu et al. (2019) achieved an accuracy of 98% on MEDIQA-NLI, which might suggest that medical NLI is essentially a solved problem. This would be exciting, as medical NLI intuitively requires a wealth of medical knowledge, much of which is not available in structured form.

However, a closer inspection of MedNLI, the most well-known medical NLI benchmark, reveals three important limitations, namely: (1) only few test instances actually require *medical disease* knowledge, with instances that (only) require terminological and lexical knowledge (e.g. understanding acronyms or paraphrases) being more prevalent; (2) training and test examples often cover the same diseases, and thus it cannot be determined whether good performance comes from the capabilities of the pre-trained LM itself, or from the fact that the model can exploit similarities between training and test examples; and (3) hypothesis-only baselines perform rather well on MedNLI, which shows that this benchmark has artefacts that can be exploited, similarly to general-purpose NLI benchmarks (Poliak et al., 2018).

We therefore propose DisKnE (Disease Knowledge Evaluation), a new benchmark for evaluating biomedical LMs. This dataset explicitly addresses the three limitations listed above and thus constitutes a more reliable testbed for evaluating the disease knowledge captured by biomedical LMs. DisKnE is derived from MedNLI and is organized into two top-level categories, which cover instances requiring medical and terminological knowledge respectively. The medical category is furthermore divided into four sub-categories, depending on the type of medical knowledge that is required.

We empirically analyse the performance of existing biomedical LMs, as well as the standard BERT model, on the proposed benchmark. Our results show that all the considered LMs struggle with NLI examples that require medical knowledge. We also find that the relative performance of the pre-trained models differs across medical categories, where the best performance is obtained by ClinicalBERT, BioBERT, SciBERT or BERT depending on the category and experimental setting. Conversely, for examples that are based on terminological knowledge, overall performance is much higher, with relatively little difference between different pre-trained models. The contributions of this paper are as follows[1]:

- We introduce a new benchmark to assess the disease-centred knowledge captured by pre-trained LMs, organised into categories that reflect the type of reasoning that is needed, and with training-test splits that avoid leakage of disease knowledge.

- We analyze the performance of several clinical/biomedical BERT variants on each of the considered categories. We find that all considered models struggle with examples that require medical disease knowledge.

- We find that without canonicalizing the hypotheses, hypothesis-only baselines achieve the best results in some categories. This shows that the original MedNLI dataset suffers from annotation artefacts, even within the set of entailment examples.

2 Related Work & Background

Knowledge Encoded in LMs There is a rapidly growing body of work that is focused on analyzing what knowledge is captured by pre-trained LMs. A recurring challenge in such analyses is to separate the knowledge that is already captured by a pre-trained model from the knowledge that it may acquire during a task-specific fine-tuning step. A common solution to address this is to focus on zero-shot performance, i.e. to focus on tasks that require no fine-tuning, such as filling in a blank (Davison et al., 2019; Talmor et al., 2020). As an alternative strategy, Talmor et al. (2020) propose to analyse the performance of models that were fine-tuned on a small training set. Other work has focused on extracting structured knowledge from pre-trained LMs. Early approaches involved manually designing suitable prompts for extracting particular types of relations (Petroni et al., 2019). Recently, however, several authors have proposed strategies that automatically construct such prompts (Bouraoui et al., 2020; Jiang et al., 2020; Shin et al., 2020). Finally, Bosselut et al. (2019) proposed to fine-tune LMs on knowledge graph triples, with the aim of then using the model to generate new triples.

---

LMs for Biomedical Text As already mentioned in the introduction, a number of pre-trained LMs have been released for the biomedical domain. Several authors have analyzed the performance of these models, and the impact of including different types of biomedical corpora in particular. For instance, Peng et al. (2019) proposed an evaluation framework for biomedical language understanding (BLUE). They obtained the best results with a BERT model that was pre-trained on PubMed abstracts and MIMIC-III clinical notes. Another large-scale evaluation of biomedical LMs has been carried out by Lewis et al. (2020). To evaluate the biomedical knowledge that is captured in pre-trained LMs, as opposed to acquired during training, Jin et al. (2019a) freeze the transformer layers during training. They find that when biomedical LMs are thus used as fixed feature extractors, BioELMo outperforms BioBERT. Most closely related to our work, He et al. (2020) recently also highlighted the limited ways in which biomedical LMs capture disease knowledge. To address this, they proposed a pre-training objective which relies on a weak supervision signal, derived from the structure of Wikipedia articles about diseases. Other authors have suggested to include structured knowledge, e.g. from UMLS, during the pre-training stage of BERT-based models (Michalopoulos et al., 2020; Hao et al., 2020). Another strategy is to inject external knowledge into task-specific models (rather than at the pre-training stage), for instance in the form of definitions (Lu et al., 2019) or again UMLS (Sharma et al., 2019). Kearns et al. (2019) presented a related approach to our work in which they categorize each sentence pair according to the tense and focus (e.g. medication, diseases, procedures, location) of the hypothesis, with the aim of providing a detailed examination of MEDIQA-NLI. Based on this categorization, they compare the performance of Enhanced Sequential Inference Model (ESIM) using ClinicalBERT, Embeddings of Semantic Predications (ESP), and cui2vec. However, their analysis was limited to the MEDIAQ-NLI test set, whereas we include entailment examples from the entire MedNLI and MEDIQA-NLI datasets. Moreover, we focus specifically on the ability of LMs to distinguish between closely related diseases, and we move away from the NLI setting to avoid training-test leakage and artefacts.

Adversarial NLI Several Natural Language Inference (NLI) benchmarks have been found to contain artefacts that can be exploited by NLP systems to perform well without actually solving the intended task (Poliak et al., 2018; Gururangan et al., 2018). In particular, it has been found that strong results can often be achieved by only looking at the hypothesis of a (premise, hypothesis) pair. In response to this finding, several strategies for creating harder NLI benchmarks have been proposed. One established approach is to create adversarial stress tests (Naik et al., 2018; Glockner et al., 2018; Aspillaga et al., 2020), in which synthetically generated examples are created to specifically test for phenomena that are known to confuse NLI models. This may, for instance, involve the use of WordNet to obtain nearly identical premise and hypothesis sentences, in which one word is replaced by an antonym or co-hyponym. In this paper, we rely on a somewhat similar strategy, using UMLS to replace diseases in hypotheses. As another strategy to obtain hard NLI datasets, Nie et al. (2020) used human annotators to iteratively construct examples that are incorrectly labelled by a strong baseline model. While the aforementioned works are concerned with open-domain NLI, some work on creating adversarial datasets for the biomedical domain has also been carried out. In particular, Araujo et al. (2020) studied the robustness of systems for biomedical named entity recognition and semantic text similarity, by introducing misspellings and swapping disease names by synonyms. To the best of our knowledge, no adversarial NLI datasets for the biomedical domain have yet been proposed.

3 Dataset Construction

In this section, we describe the process we followed for constructing DisKnE. As we explain in more detail in Section 3.1, this process involved filtering the entailment instances from the MedNLI and MEDIQA-NLI datasets, to select those in which the hypothesis expresses that the patient has (or is likely to have) a particular target disease. These instances were then manually categorized based on the type of knowledge that is needed for recognizing the validity of the entailment. Section 3.2 discusses our strategy for generating negative examples, which were obtained in an adversarial way, by replacing diseases occurring in entailment examples with similar ones. Details of the resulting training-test splits are provided in Section 3.3. In a

Category	# inst.	Premise	Hypothesis
Symptoms → Disease	112	The patient developed neck pain while training with increasing substernal heaviness and left arm pain together with sweating.	The patient has symptoms of acute coronary syndrome
Treatments → Disease	60	The patient started on Mucinex and Robitussin.	The patient has sinus disease
Tests → Disease	116	Cardiac enzymes recorded CK 363, CK-MB 33, TropI 6.78	The patient has cardiac ischemia
		A large R hemisphere ICH was revealed when the patent had head CT	The patient has an aneurysm
Procedures → Disease	70	Bloody fluid was removed by pericardiocentesis	The patient has hemopericardium.
Terminological	259	The patient has urinary tract infection	The patient has a UTI
		The patient has high blood pressure	Hypertension
		Transfusions in the past could be the cause of the patient having hepatitis C	The patient has hepatitis C

Table 1: Considered categories of disease-focused entailment pairs.

final step, we canonicalize the hypotheses of all examples, as explained in Section 3.4. Note that the benchmark we propose consists of binary classification problems (i.e. predicting entailment or not), rather than the standard ternary NLI setting (i.e. predicting entailment, neutral, or contradiction), which is motivated by the fact that natural contradiction examples are hard to find when focusing on disease knowledge.

3.1 Selecting Entailment Pairs

We started from the set of all entailment pairs (i.e. premise-hypothesis pairs labelled with the *entailment* category) from the full MedNLI and MEDIQA-NLI datasets. We used MetaMap to find those pairs whose hypothesis mentions the name of a disease, and to retrieve the UMLS CUI (Concept Unique Identifier) code corresponding to that disease. We then manually identified those pairs, among the ones whose hypothesis mentions a disease, in which the hypothesis specifically expresses that the patient has that disease. For instance, in this step, a number of instances were removed in which the hypothesis expresses that the patient does not have the disease. The remaining cases were manually assigned to categories that reflect the type of disease knowledge that is needed to identify that the hypothesis is entailed by the premise. The considered categories are described in Table 1, which also shows the number of (positive) examples we obtained and illustrative examples[2]. The primary distinction we make is between examples that need medical knowledge and those that need terminological knowledge. The former category is divided into four sub-categories, depending on the type of inference that is needed. First, we have the *symptoms-to-disease* category, containing examples where the premise describes the signs or symptoms exhibited by the patient, and the hypothesis mentions the corresponding diagnosis. Second, we have the *treatments-to-disease* category, where the premise instead describe medications (or other treatments followed by the patient). The third category, *tests-to-disease*, involves instances where the premise describes lab tests and diagnostic tools such as X-rays, CT scans and MRI. Finally, the *procedures-to-disease* category has instances where the premise describes surgeries and therapeutic procedures that the patient underwent. In the *terminological* category, the disease is mentioned in both the premise and hypothesis, either as an abbreviation, a synonym or within a rephrased sentence.

3.2 Generating Examples

The process outlined in Section 3.1 only provides us with positive examples. Unfortunately, MedNLI and MEDIQA-NLI contain only few negative examples (i.e. instances of the *neutral* or *contradiction* categories) in which the hypothesis expresses that the patient has some disease. For this reason, rather than selecting negative examples from these datasets, we generate negative examples by corrupting the positive examples. In particular, to generate negative examples, we replace the disease

---

[2] For data protection reasons, we only provide synthetic examples, which are different from but similar in spirit to those from the original MedNLI dataset.

X from a given positive example by other diseases $Y_1, ..., Y_n$ that are similar to X, but not ancestors or descendants of X in SNOMED CT (Donnelly et al., 2006). To identify similar diseases, we have relied on cui2vec (Beam et al., 2020), a pre-trained clinical concept embedding that was learned from a combination of insurance claims, clinical notes and biomedical journal articles. Apart from the requirement that the diseases $Y_1, ..., Y_n$ should be similar to X, it is also important that they are sufficiently common diseases, as including unusual diseases would make the corresponding negative examples too easy to detect. For this reason, we only consider the diseases that occur in the hypothesis of other positive examples as candidates for the negative examples. Specifically, among these set of candidate diseases, we selected the $n = 10$ most similar ones to X, which were not descendants or ancestors of X in SNOMED CT (as ancestors and descendants would not necessarily invalidate the entailment). This resulted in a total of 4133 examples requiring medical knowledge and 2639 examples requiring terminological knowledge.

3.3 Training-Test Splits

Because our focus is on evaluating the knowledge captured by pre-trained language models, we want to avoid overlap in the set of diseases in the training and test splits. In other words, if the model is able to correctly identify positive examples for a target disease X, this should be a reflection of the knowledge about X in the pre-trained model, rather than knowledge that it acquired during training. However, any single split into training and test diseases would leave us with a relatively small dataset. For this reason, we consider each disease X in isolation. Let $\mathcal{E}$ be the set of all positive examples, obtained using the process from Section 3.1. Furthermore, we write $\mathcal{E}_X$ for the set of those examples from $\mathcal{E}$ in which the target disease in the hypothesis is X. Finally, we write $neg(X)$ for the set $\{Y_1, ..., Y_n\}$ of associated diseases that was selected to construct negative examples, following the process from Section 3.2.

For each target disease X, we define a corresponding test set Test_X and training set Train_X as follows. Test_X contains all the positive examples from $\mathcal{E}_X$. Moreover, for each $e \in \mathcal{E}_X$ and each $Y \in neg(X)$ we add a negative example $e_{X \to Y}$ to Test_X which is obtained by replacing the occurrence of X by Y. If the word before the occurrence of X is *a* or *an*, we modify it depending on whether Y starts with a vowel or consonant. The positive examples in Train_X consist of all examples from $\mathcal{E}$ in which X is not mentioned. Note that we also remove examples in which these diseases are only mentioned in the premise. Furthermore, we check for occurrences of all the synonyms of these diseases that are listed in UMLS. The process of creating the training and test set for a given target disease X is illustrated in Figure 1.

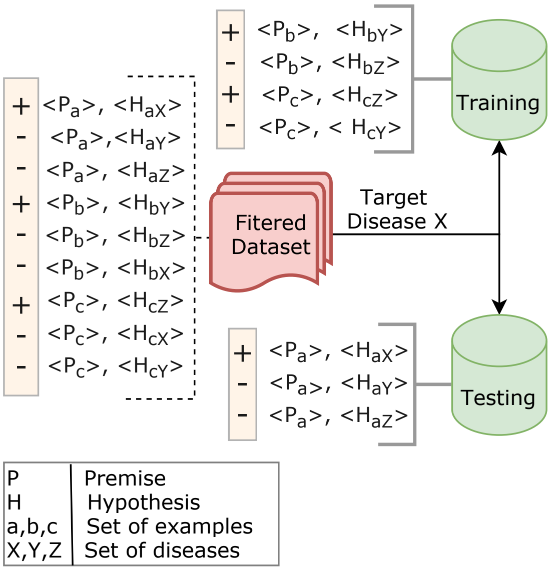

Figure 1: Illustration of training-test splitting process.

3.4 Canonicalization

We noticed that the way in which a given hypothesis expresses that "the patient has disease X" is correlated with the type of the disease. For this reason, as a final step, we canonicalize the hypotheses in the dataset. Specifically, we replace each hypothesis by the name of the corresponding disease X. Several hypotheses in the dataset already have this form. By converting the other hypotheses in this format, we eliminate any artefacts that are present in their specific formulation.

4 Experiments

We experimentally compare a number of pre-trained biomedical LMs on our proposed DisKnE benchmark. In Section 4.1, we first describe the considered LMs and the experimental setup. The main results are subsequently presented in Section 4.2. This is followed by a discussion in Section 4.3.

4.1 Experimental Setup

Pre-trained LMs. To understand to what extent the pretraining data of an LM affects its performance on our fine-grained evaluation of disease knowledge, we used the following BERT variants:

BERT We use the BERT$_{\text{base}}$-cased model (Devlin et al., 2019).

BioBERT Lee et al. (2019) proposed a model based on BERT$_{\text{base}}$-cased, which they further trained on biomedical corpora. We use the version where PubMed and PMC were utilized for this further pre-training.

ClinicalBERT Alsentzer et al. (2019) introduced four BERT model variants, trained on various clinical corpora. We use the version that was initialized from BioBERT and trained on MIMIC-III notes afterwards.

SciBERT Beltagy et al. (2019) introduced a BERT model variant that was trained from scratch on approximately 1.14M scientific papers from semantic scholar, 82% of which were biomedical articles. The full text of the papers was used for training. We use the cased version.

Training Details. For fine-tuning, model hyperparameters were the same across all BERT variants such as the random seeds, batch size and the learning rate. In this study, we fix the the learning rate at 2e-5, batch size of 8 and we set the maximum number of epochs to 8 with the use of early stopping. We used 10% of the training set as validation split.

Evaluation Protocol. We analyze the results per disease and per category in terms of F1 score for the positive class, reporting results for all diseases that have at least two positive examples for the considered category. To this end, for each disease X, we start from its corresponding training-test split, which was constructed as explained in Section 3.3. To show the results for a particular category, we remove from the test set all the examples that do not belong to that category.

4.2 Results

The main results are shown in Tables 2–6. A number of clear observations can be made. First, the results for the terminological category are substantially higher than the results for the other categories, which suggests that the masked language modelling

objective, which is used as the main pre-training task in all the considered LMs, may not be ideally suited for learning medical knowledge. Second, recall that the main difference between the considered biomedical LMs comes from the corpora that were used for pre-training them. As the results for the terminological category (Table 6) reveal, the inclusion of domain-specific corpora does not seem to benefit their ability to model biomedical terminology, as similar results for this category are obtained with the standard BERT model, which was pre-trained on Wikipedia and a corpus of books and movie scripts. For the *Symptoms* → *Disease* category, we see that ClinicalBERT outperforms the other biomedical LMs, although the standard BERT model actually achieves the best performance overall. The results suggest that ClinicalBERT is better at distinguishing between relatively rare diseases, but that the focus on encyclopedic text benefits BERT for more common diseases. Intuitively, we can indeed expect that the encyclopedic style of Wikipedia focuses more on symptoms of diseases than scientific articles, which might focus more on treatments, procedures and diagnostic tests. This is also in accordance with the findings from He et al. (2020), who obtained promising results with a disease-centric LM pre-training task that relies on Wikipedia. On the *Procedures* → *Disease* and *Tests* → *Disease* categories, we can see that SciBERT achieves the best results, with a particularly wide margin on the *Procedures* → *Disease* category. Finally, for the *Treatments* → *Disease* category, the relatively poor performance of BERT stands out, which conforms with the aforementioned intuition that scientific articles put more emphasis on procedures, treatments and tests. BioBERT achieves the best results, although the performance of the other biomedical LMs is quite similar.

4.3 Discussion

Which LM model? Several published works have found ClinicalBERT to outperform the other considered biomedical LMs on biomedical NLP tasks (Alsentzer et al., 2019; Kearns et al., 2019; Hao et al., 2020). In our results, however, SciBERT achieves the most consistent performance, clearly outperforming ClinicalBERT on the *Procedures* → *Disease* and *Test* → *Disease* categories, while performing similar to ClinicalBERT on the remaining categories. However, rather than providing a blanket recommendation for SciBERT, our fine-grained analysis highlights the fact that different models have different strengths. The most surprising finding, in this respect, is the performance of the standard BERT model, which achieves the best results on the *Symptoms* → *Disease* category and

Dataset Artefacts. As already reported by Romanov and Shivade (2018), the original MedNLI dataset has a number of annotation artefacts, which mean that hypothesis-only baselines can perform well. In our dataset, we tried to address this by only using entailment examples, and creating negative examples by corrupting these. However, without canonicalizing the hypotheses, we found that hypothesis-only baselines were still performing rather well. This is shown in Table 7, which summarizes the results we obtained for a version of our dataset without canonicalization, i.e. where the full hypotheses are provided, and the canonicalized version, where the hypotheses were replaced by the disease name only. The table shows results for the standard ClinicalBERT model, as well as for a hypothesis-only variant, which is only given the hypothesis. As can be seen, without canonicalization, the hypothesis only baseline performs similarly to the full model, even outperforming it in a few cases, with the exception of the *Terminological* category where a clear drop in performance for the hypothesis-only baseline can be seen. In contrast, for the canonicalized version of the dataset, we can see that the hypothesis only baseline, which only gets access to the name of the disease in this case, under-performs consistently and substantially. Note that the hypothesis-only baseline still achieves a non-trivial performance in most cases, noting that an uninformed classifier that always predicts true would achieve an F1 score of 0.167. However, this simply shows that the model has learned to prefer frequent diseases over rare ones.

Adversarial Examples. A key design choice has been to select negative examples from the diseases that are most similar to the target disease. To analyse the impact of this choice, we carried out an experiment in which negative examples were instead randomly selected. As before, we only consider diseases that are present in the dataset, and we ensure that negative examples are not ancestors or descendants of the target disease in SNOMED CT. The results are presented in Table 8. As expected, the results are overall higher than those from the main experiment. More surprisingly, this easier setting benefits some models more than others. The relative performance of ClinicalBERT in particular is now clearly better, with this model achieving the best results for *Symptoms* → *Disease*. Furthermore, the standard BERT model now clearly underperforms the biomedical LMs, except for *Procedures* → *Disease* where it outperforms ClinicalBERT and BioBERT.

5 Conclusion

We have proposed DisKnE, a new benchmark for analysing the extent to which biomedical language models capture knowledge about diseases. Positive examples were obtained from MedNLI and MEDIQA-NLI, by manually identifying and categorizing hypotheses that express that the patient has some disease. Negative examples were selected to be similar to the target disease. To prevent shortcut learning, the hypotheses were canonicalized, such that models only get access to the name of the disease that is inferred. Our empirical analysis shows that existing biomedical language models particularly struggle with cases that require medical knowledge. The relative performance on the different categories suggests that different (biomedical) LMs have complementary strengths.

AUGVIC: Exploiting BiText Vicinity for Low-Resource NMT

Tasnim Mohiuddin[*] [¶], **M Saiful Bari** [*][¶], and **Shafiq Joty**[¶][†]

Abstract

The success of Neural Machine Translation (NMT) largely depends on the availability of large bitext training corpora. Due to the lack of such large corpora in low-resource language pairs, NMT systems often exhibit poor performance. Extra relevant monolingual data often helps, but acquiring it could be quite expensive, especially for low-resource languages. Moreover, domain mismatch between bitext (train/test) and monolingual data might degrade the performance. To alleviate such issues, we propose AUGVIC, a novel data augmentation framework for low-resource NMT which exploits the vicinal samples of the given bitext without using any extra monolingual data explicitly. It can diversify the in-domain bitext data with finer level control. Through extensive experiments on four low-resource language pairs comprising data from different domains, we have shown that our method is comparable to the traditional back-translation that uses extra in-domain monolingual data. When we combine the synthetic parallel data generated from AUGVIC with the ones from the extra monolingual data, we achieve further improvements. We show that AUGVIC helps to attenuate the discrepancies between relevant and distant-domain monolingual data in traditional back-translation. To understand the contributions of different components of AUGVIC, we perform an in-depth framework analysis.

1 Introduction

Neural Machine Transaltion (NMT) has shown impressive performance in high-resource settings, even claiming to achieve parity with human professional translators (Hassan et al., 2018; Popel et al., 2020). Most successful NMT systems have billions of parameters (Lepikhin et al., 2021). They generally work well only when a good amount of parallel training data is available and perform poorly in low-resource conditions (Koehn and Knowles, 2017; Guzmán et al., 2019). However, majority of the languages are low-resourced despite being used by large portion of world population. Hence, improving low-resource MT quality has been of great interests to the MT researchers.

There have been several attempts to extend the success of NMT in high-resource settings to low-resource language pairs that have a relatively small amount of available parallel data. Most of these methods mainly focus on leveraging extra monolingual data through back-translation (Sennrich et al., 2016) and self-training (He et al., 2020), or translation knowledge transfer through parallel data involving other assisting language pairs (Firat et al., 2016a,b; Johnson et al., 2017; Neubig and Hu, 2018).[1] Large scale pre-training is another recent trend to utilize large monolingual data for NMT (Liu et al., 2020). However, very few work has considered low-resource NMT without using auxiliary data or other pivot languages.

In the presence of a sufficient amount of in-domain monolingual data, back-translation (BT) has proved to be quite successful (Edunov et al., 2018). In this approach, a reverse intermediate model is trained on the original parallel data, which is later used to generate synthetic parallel data by translating sentences from target-side monolingual data into the source language. However, when there are scarcity of in-domain data which indeed a common situation in many low-resource settings, the success of BT may be limited (Chen et al., 2019).

Another understudied problem with BT is the issue with *domain mismatch* (Edunov et al., 2020). To elaborate, let us consider two scenarios: (i) the training and testing data come from the same or relevant domains (*e.g.,* News), and (ii) the test domain (News) is different from the training domain (*e.g.,*

Subtitles). In the former case, we can foresee two problems. First, if we use out-of-domain monolingual data which is abundant, it might misguide the model and move it far away from the actual test distribution. Second, even if the monolingual data is from a domain similar to that of the training/testing data, there might be differences in topics, modality, style, etc., which might induce noise.

For the latter scenario, even if the monolingual data comes from the similar domain as the test data (News), the corresponding (reverse) translations will be noisy as the intermediate model would be trained on a different domain (Subtitles). Consequently, these noisy pseudo-parallel data will induce noise during training and might cause the model to perform worse (Wang et al., 2018). On the other hand, using in-domain (Subtitles) monolingual data in back-translation will not give enough diversity to cover the test domain (News).

In this work, inspired by the Vicinal Risk Minimization principle (Chapelle et al., 2001), we propose AUGVIC, a novel method to **aug**ment **vic**inal samples around the bitext distribution. Instead of using extra monolingual data, AUGVIC aims to leverage the vicinal samples of the original bitext, thereby enlarging the support of the training bitext distribution to improve model generalization. The main advantage is that the resulting distribution remains close to the original distribution and can be controlled at a finer level (Figure 1).

With the goal of training a source-to-target NMT system, AUGVIC augments vicinal samples in the target language. The vicinal samples are generated by predicting the masked tokens of a target bitext sentence using a pretrained large-scale language model. To generate synthetic bitext data from these augmented vicinal samples through a reverse intermediate (target-to-source) model, we propose two different methods: the first one is based on the traditional BT, while the second one leverages the original source sentence as a guide. Finally, we train the source-to-target model by combining the original parallel data with the synthetic bitext.

In order to demonstrate the effectiveness and robustness of AUGVIC, we conduct extensive experiments on four low-resource language pairs comprising data from different domains. Our results show significant improvements over the bitext baselines with 2.76 BLEU gains on an average on eight different translation tasks without using any extra monolingual data. AUGVIC also complements traditional BT with additive gains when extra monolingual data is used. We also show AUGVIC's efficacy in bridging the gap between in-domain and out-of-domain performance in traditional back-translation with monolingual data. We carried out an ablation study to understand the contribution of the diversity factor in our proposed framework. We open-source our framework at https://ntunlpsg.github.io/project/augvic/.

2 Related Work

Two lines of studies are relevant to our work.

Low-resource NMT Although the main focus of investigation and improvement in NMT has been in high-resource settings, there has been a recent surge of interest in low-resource MT. However, achieving satisfactory performance in low-resource settings turns out to be challenging for NMT systems (Koehn and Knowles, 2017). Recent research has mainly focused on creating and cleaning parallel (Ramasamy et al., 2014; Islam, 2018) and comparable data (Tiedemann, 2012), utilizing bilingual lexicon induction (Conneau et al., 2017; Artetxe et al., 2018; Mohiuddin and Joty, 2019, 2020; Mohiuddin et al., 2020), fine-grained hyperparameter tuning (Sennrich and Zhang, 2019), and using other language pairs as pivot (Cheng et al., 2017; Kim et al., 2019).

Another avenue of research follows multilingual translation, where translation knowledge from high-resource language pairs are exploited by training a single NMT system on a mix of high-resource and low-resource language pairs (Firat et al., 2016a,b; Kocmi and Bojar, 2018; Gu et al., 2018; Neubig and Hu, 2018; Guzmán et al., 2019). Zoph et al. (2016) proposed a variant where they pretrain NMT system on a high-resource language pair before finetuning on a target low-resource language pair.

Data Augmentation for NMT Till now, one of the most successful data augmentation strategies in NMT is back-translation (BT) (Sennrich et al., 2016; Hoang et al., 2018), which exploits target-side monolingual data. Edunov et al. (2018) investigated BT extensively and scaled the method to millions of target-side monolingual sentences. Caswell et al. (2019) explored the role of noise in noised-BT and proposed to use a tag for back-translated source sentences. Besides BT, self-training is another data augmentation strategy for NMT which leverages source-side monolingual data (He et al.,

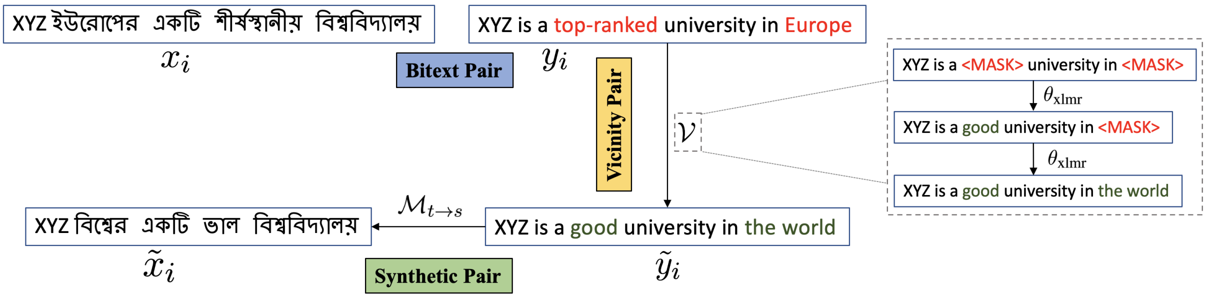

Figure 1: Illustration of AUGVIC steps for Bengali-to-English translation system. Here (x_i, y_i) is the original bitext pair, $\tilde{y}_i$ is a vicinal sample of y_i, and $(\tilde{x}_i, \tilde{y}_i)$ is a synthetic pair where $\tilde{x}_i$ is generated by a reverse intermediate translation system $\mathcal{M}_{t\to s}$. Right side of the figure shows the successive steps of vicinal sample generation.

2020). Large scale multilingual pre-training followed by bitext fine-tuning is a recent trend to utilize monolingual data for NMT, which is shown to be beneficial (Arivazhagan et al., 2019; Liu et al., 2020; Zhu et al., 2020; Lepikhin et al., 2021).

Apart from using extra monolingual data, Xie et al. (2017) show that data noising is an effective regularization method for NMT, while Wu et al. (2019) use noised training. In low-resource settings, Fadaee et al. (2017) augment bitext by replacing a common word with a low-frequency word in the target sentence, and change its corresponding word in the source sentence to improve the translation quality of rare words. Wang et al. (2018) propose an unsupervised data augmentation method for NMT by replacing words in both source and target sentences based on hamming distance. Gao et al. (2019) propose a method that replaces words with a weighted combination of semantically similar words. Recently, Nguyen et al. (2020) propose an in-domain augmentation method by diversifying the available bitext data using multiple forward and backward models. In their follow-up work (Nguyen et al., 2021), they extend the idea to unsupervised MT (UMT) using a cross-model distillation method, where one UMT model's synthetic output is used as input for another UMT model.

Summary Most of the previous work on improving BT involve either training iteratively or combining BT with self-training using monolingual data blindly without noticing the distributional differences between the monolingual and bitext data. In contrast, in AUGVIC we systematically parameterize the generation of new training samples from the original parallel data. Moreover, the combination of our augmented vicinal samples with monolingual data makes the NMT models more robust and attenuates the prevailing distributional gap.

3 Method

Let s and t denote the source and target languages respectively, and $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{N}$ denote the bitext training corpus containing N sentence pairs with x_i and y_i coming from s and t languages, respectively. Also, let $\mathcal{M}_{s\to t}$ is an NMT model that can translate sentences from s to t, and $\mathcal{D}_{\text{mono}}^{t} = \{y_j\}_{j=1}^{M}$ denote the monolingual corpus in the target language t containing M sentences.

3.1 Traditional Back-Translation

Traditional back-translation (Sennrich et al., 2016) leverages the target-side monolingual corpus. With the aim to train a source-to-target model $\mathcal{M}_{s\to t}$, it first trains a reverse intermediate model $\mathcal{M}_{t\to s}$ using the given bitext $\mathcal{D}$, and use it to translate the extra target-side monolingual data $\mathcal{D}_{\text{mono}}^{t}$ into source language. This yields a synthetic bitext corpus $\mathcal{D}_{\text{syn}} = \{\mathcal{M}_{t\to s}(y_j), y_j)\}_{j=1}^{M}$. Then a final model $\mathcal{M}_{s\to t}$ is trained on $\{\mathcal{D} \cup \mathcal{D}_{\text{syn}}\}$ usually by upsampling $\mathcal{D}$ to keep the original and synthetic bitext pairs to a certain ratio (generally 1:1).

3.2 AUGVIC: Exploiting Bitext Vicinity

For low-resource languages, the amount of available parallel data is limited, hindering training of a good MT system. Moreover, the target language pairs can be quite different (*e.g.,* morphologically, topic distribution) from the high-resource ones, making the translation task more difficult (Chen et al., 2019). Also, acquiring large and relevant monolingual corpora in the target language is difficult in low-resource settings and can be quite expensive. The domain mismatch between the monolingual and bitext data is another issue with the traditional back-translation as mentioned in §1.

With the aim to improve model generalization, the core idea of AUGVIC is to leverage the *vicinal* samples of the given bitext rather than using extra monolingual data. The addition of bitext vicinity also alleviates the domain mismatch issue since the augmented data distribution does not change much from the original bitext distribution. Figure 1 shows an illustrative example of AUGVIC, which works in three basic steps to train a model:

(i) Generate vicinal samples $\tilde{y}_i$ of the target sentences (y_i) in the bitext data $\mathcal{D}$.

(ii) Produce source-side translations $\tilde{x}_i$ of the vicinal samples to generate synthetic bitext $\tilde{\mathcal{D}}$.

(iii) Train the final source-to-target MT model $\mathcal{M}_{s\rightarrow t}$ using $\{\mathcal{D} \cup \tilde{\mathcal{D}}\}$.

AUGVIC, however, is not mutually exclusive to the traditional back-translation and can be used together when relevant monolingual data is available. In the following, we describe how each of these steps are operationalized with NMT models.

3.2.1 Generation of Vicinal Samples

We first generate vicinal samples for each eligible target sentence y_i in the bitext $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{N}$. Let $\mathcal{V}(\tilde{y}_i|y_i)$ denote the vicinity distribution around y_i, we create a corpus of vicinal samples as:

$$\tilde{y}_i \sim \mathcal{V}(\tilde{y}_i|y_i) \qquad (1)$$

We generate vicinal samples for sentences having lengths between 3 and 100, and $\mathcal{V}$ can be modeled with existing syntactic and semantic alternation methods like language model (LM) augmentation (Kobayashi, 2018; Wu et al., 2018; Shi et al., 2020; Bari et al., 2021), paraphrase generation (Li et al., 2018), constrained summarization (Laban et al., 2020), and similar sentence retrieval (Du et al., 2020). Most of these methods are supervised requiring extra annotations. Instead, in AUGVIC, we adopt an unsupervised LM augmentation, which makes the framework more robust and flexible to use. Specifically, we use a pretrained XLM-R masked LM (Conneau et al., 2020a) parameterized by θ_{xlmr} as our vicinal model. Thus, the vicinity distribution is defined as $\mathcal{V}(\tilde{y}_i|y_i, \theta_{\text{xlmr}})$.

Note that we treat the vicinal model as an external entity, which is not trained/fine-tuned. This disjoint characteristic gives our framework the flexibility to replace θ_{xlmr} even with a better monolingual LM for a specific target language, which in turn makes AUGVIC extendable to utilize stronger LMs that may come in the future.

In a masked LM, one can mask out a token at any position and ask the model to predict at that position. For a meaningful and informed augmentation, we mask out the tokens *successively* (one at a time) up to a required number determined by a diversity ratio, $\rho \in (0, 1)$. For a sentence of length ℓ, the successive augmentation can generate at most $(2^{\ell} - 1) \times k$ vicinal samples, where k is the number of output tokens chosen for each masked position. We use $k = 1$, and pick the one with the highest probability ensuring that it does not match the original token at the masked position. The diversity ratio (ρ) controls how much diverse the vicinal samples can be from the original sentence, and is selected using one of the following two ways:

- **Fixed diversity ratio** Here we use a fixed value for ρ, and select $t = \ell \times \rho$ tokens to mask out. We then generate new vicinity samples by predicting new tokens in those masked positions.
- **Dynamic diversity ratio** Instead of using a fixed value, in this approach we set the diversity ratio dynamically taking the sentence length into consideration. This allows finer-level control for diversification — the longer the sentence is, the smaller should its diversification ratio be. The intuition is that for long sentences, a larger value of ρ will produce vicinal samples which will be far away from the original sample. Specifically, we use the following piece-wise function to find the number of tokens to mask out dynamically:

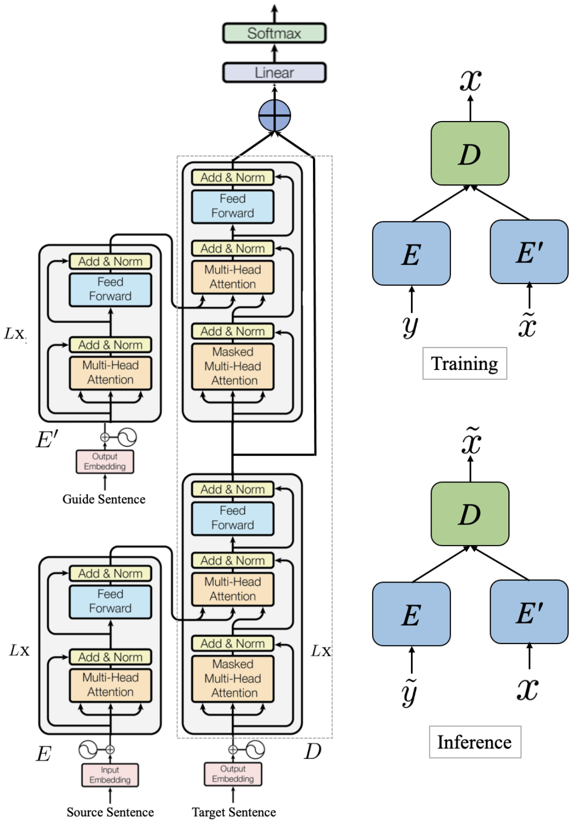
$$t = \begin{cases} \max(\ell \times a, t_{\text{min}}) & ;\text{if } \ell \leq 20 \\ \min(\frac{\ell}{h} \times b, t_{\text{max}}) & ;\text{otherwise} \end{cases} \qquad (2)$$

where t_{min} and t_{max} are hyperparameters and represent the minimum and maximum number of tokens to be replaced by the masked LM. The other hyperparameters a, b, and h play the same role as the diversity ratio ρ.

Since we predict tokens for replacement one at a time, we can make the prediction in any of the permutation order of t. So, the maximum number of possible augmentation for a sentence of length ℓ is $\gamma = \binom{\ell}{t} \times t!$. We perform *stochastic sampling* from the distribution of γ to select N' vicinal samples. We have added an analysis on the effect of diversity ratio ρ in AUGVIC in §5.5.

3.2.2 Generation of Synthetic Bitext Data

Our objective is to train a source-to-target MT model $\mathcal{M}_{s\rightarrow t}$. So far, we have the bitext $\mathcal{D} =$



(a) (b)

Figure 2: (a) Our proposed model for guided back-translation; (b) its training and inference method.

$\{(x_i, y_i)\}_{i=1}^{N}$ and target-side monolingual data $\tilde{\mathcal{D}}^t = \{\tilde{y}_j\}_{j=1}^{N'}$ which are vicinal to the original target in $\mathcal{D}$. We need a reverse intermediate target-to-source MT model $\mathcal{M}_{t\rightarrow s}$ to translate $\tilde{y}_j$ into $\tilde{x}_j$, which will give us the synthetic bitext data $\tilde{\mathcal{D}}$. For this, we experiment with two different models.

(*a*) Pure Back-Translation (PBT) This is similar to back-translation (§3.1), where we first train the reverse MT model $\mathcal{M}_{t\rightarrow s}$ using the given bitext $\mathcal{D}$. We then use $\mathcal{M}_{t\rightarrow s}$ to translate the target-side vicinal samples $\tilde{y}_j \sim \tilde{\mathcal{D}}^t$ into $\tilde{x}_j$. This gives a synthetic bitext $\tilde{\mathcal{D}} = \{(\tilde{x}_j, \tilde{y}_j)\}_{j=1}^{N'}$. We use the Transformer architecture (Vaswani et al., 2017) as our reverse intermediate NMT model $\mathcal{M}_{t\rightarrow s}$.

(*b*) Guided Back-Translation (GBT) In the illustrative example (Figure 1), we can identify three kinds of pairs: (i) the bitext (x_i, y_i), (ii) the vicinal $(y_i, \tilde{y}_i)$, and (iii) the synthetic pair $(\tilde{x}_i, \tilde{y}_i)$. Here, y_i is the original translation of source sentence x_i and $\tilde{y}_i$ is the vicinal sample, which can be seen as a perturbation of y_i. Hence, we can assume that $\tilde{x}_i$ will also be similar to (perturbed) x_i. Our goal is to leverage this extra relational knowledge to improve the translation quality of $\tilde{x}_i$ when generating the synthetic bitext $\tilde{\mathcal{D}}$. Specifically, we use the original source x_i as a guide for generating the synthetic translation $\tilde{x}_i$ of the target-side vicinal sample $\tilde{y}_i$.

$$\tilde{x}_i = \mathcal{M}_{t\rightarrow s}(\tilde{y}_i | x_i) \tag{3}$$

For this, we propose a model based on the Transformer architecture which has two encoders - one for the source sentence (E) and another for the guide sentence (E'), and a decoder (D) (Figure 2). We use the same architecture with the exception that now we have two identical encoders (E and E'). Both the encoders have a stack of L layers, while the decoder has $(L + 1)$ layers.

Training & Inference: We train this model with a dataset of triplets containing $(y, \tilde{x}, x)$, where (x, y) comes from the original bitext and $\tilde{x}$ is a vicinal sample of x to guide the decoder in generating x. Each of the first L layers of the decoder performs cross-attention on $E(y)$ resulting in decoder states $D^{(L)}(x_{<t}|y)$ at time step t, while the final decoder layer attends on $E'(\tilde{x})$ resulting in a second set of decoder states $D^{(L+1)}(x_{<t}|y, \tilde{x})$. The two sets of decoder states are then interpolated by taking a convex combination before passing it to a linear layer followed by the Softmax token prediction.

$$\lambda D^{(L)}(x_{<t}|y) + (1 - \lambda) D^{(L+1)}(x_{<t}|y, \tilde{x}) \tag{4}$$

where λ is a hyperparameter that controls the relative contributions from the two encoders, $E(y)$ and $E'(\tilde{x})$, in generating x by the decoder D.

To generate the synthetic bitext $\tilde{D}$, we need to translate $\tilde{y}$, which will be guided by x. So during *inference*, we feed $\tilde{y}$ to E and x to E' to autoregressively generate $\tilde{x}$ with beam search decoding.

3.2.3 Training of the Final Model

We combine the original bitext $\mathcal{D}$ and the synthetic bitext $\tilde{\mathcal{D}}$ generated from the previous step to train our final source-to-target model $\mathcal{M}_{s\rightarrow t}$. We use the standard Transformer as our final model.

4 Experimental Setup

4.1 Datasets and Evaluation Metrics

We conduct experiments on four low-resource language pairs: English (En) to/from Bangla (Bn), Tamil (Ta), Nepalese (Ne), and Sinhala (Si). Table 1 presents the source of the collected datasets and their domains for each language pair.

Pair	Data-Source	Train & Dev	Test
En-Bn	Islam (2018)	Mixed	Mixed
En-Ta	Ramasamy et al. (2014)	News, Bible, Cinema	News, Bible, Cinema
En-Ne	Guzmán et al. (2019)	Bible, GV, PTB, Ubuntu	Wikipedia
En-Si	Guzmán et al. (2019)	Opens subtitles, Ubuntu	Wikipedia

Table 1: Sources and domains of the datasets.

Even though the En-Bn dataset size is relatively small (∼ 72K pairs), the quality of the bitext is rich, and it covers a diverse set of domains including literature, journalistic texts, instructive texts, administrative texts, and texts treating external communication. Here the distributions in train and test splits are about the same. For En-Ta, the train and test domains are similar, mostly coming from the news (∼ 66.43%). For En-Ne and En-Si, we use the datasets from (Guzmán et al., 2019), where the train and test domains are different. Although these two datasets are comparatively larger (∼ 600K pairs each), the quality of the bitext is poor, requiring further cleaning and deduplication.

Table 2 presents the dataset statistics after deduplication where the last column specifies the number of augmented data by our method AugVic (§3.2.1). For a fair comparison with the traditional back-translation, we experiment with the same amount of target-side monolingual data from three domains: news, wiki, and gnome. We collected and cleaned News, Wiki, and Gnome datasets from News-crawl, Wiki-dumps, and Gnome localization guide, respectively. For some languages, the amount of specific domain monolingual data is limited, where we added additional monolingual data of that language from Common Crawl.

Following previous work (Guzmán et al., 2019; Nguyen et al., 2020), we report the tokenized BLEU (Papineni et al., 2002) when translating from English to other languages, and detokenized SacreBLEU (Post, 2018) when translating from other languages to English for all our experiments,.

Pair	Train	Dev	Test	Augmented (AugVic/Mono)
En-Bn	70,854	500	500	≈ 460K
En-Ta	166,851	1000	2000	≈ 1300K
En-Ne	234,514	2559	2835	≈ 1500K
En-Si	571,213	2898	2766	≈ 1500K

Table 2: Dataset statistics after deduplication.

4.2 Baselines

We compare AugVic with the following baselines:

(i) Bitext baseline is the model trained with the bitext given with the dataset.

(ii) Upsample baseline Here we upsample the bitext to the same amount of AugVic's data.

(iii) Diversification baseline Nguyen et al. (2020) diversifies the original parallel data by using the predictions of multiple forward and backward NMT models. Then they merge the augmented data with the original bitext on which the final NMT model is trained. Their method is directly comparable to AugVic, as both methods diversify the original bitext, but in different ways.

4.3 Model Settings

We use the Transformer (Vaswani et al., 2017) implementation in Fairseq (Ott et al., 2019). We follow the basic architectural settings from (Guzmán et al., 2019), which establishes some standards for low-resource MT. For low-resource "Bitext baseline", they use a smaller (5-layer) Transformer architecture as the dataset is small, while for larger datasets (*e.g.,* with additional synthetic data) they use a bigger (6-layer) model.[2] To keep the architecture the same in the respective rows (Table 3), we use a 6-layer model for "Upsample baseline" and 5-layer for "Bitext baseline". More specifically, for datasets with less than a million bitext pairs, we use an architecture with 5 encoder and 5 decoder layers, where the number of attention heads, embedding dimension, and inner-layer dimension are respectively 8, 512, and 2048. Otherwise, we use a larger Transformer architecture with 6 encoder and 6 decoder layers with the number of attention heads, embedding dimension, and inner-layer dimension of 16, 1024, and 4096, respectively.

After deduplication, we tokenize non-English data using the Indic NLP Library.[3] We use the sentencepeiece library[4] to learn the joint Byte-Pair-Encoding (BPE) of size 5000 symbols for each of

the language pair over the raw English and tokenized non-English bitext training data.

We tuned the hyper-parameters a, b, h, t_{min}, t_{max} in Eq. 2 and λ in Eq. 4 by small-scale experiments on the validation-sets. We found $a = 0.5$, $b = 2.5$, $h = 10$, $t_{min} = 1$, and $t_{max} = 20$ work better. We tuned λ within the range of 0.5 to 0.9. In general, we observe that for smaller sentences (length $<=$ 20), 50-60% successive-token-replacement works better while for longer sentences (length $>$ 20), 20-30% token-replacement performs better.

Following Guzmán et al. (2019), we train all the models upto a maximum epoch of 100 with early-stopping enabled based on the validation loss. We use the beam-search-decoding for inference. All the reported results for AugVic use dynamic diversity ratio for generating vicinal samples unless otherwise specified.

5 Results and Analysis

In this section, we present our results and the analysis of our proposed methods.

5.1 Comparison with Bitext & Diversification

Table 3 presents the BLEU scores on the eight translation tasks. First, we compare our model AugVic with the model trained on the original parallel data (Bitext). AugVic consistently improves the performance over all the tested language pairs, gaining about $+2.76$ BLEU scores on average. Specifically, AugVic achieves the absolute improvements of 4.28, 5.78, 1.35, 2.39, 1.88, 2.31, 1.70, and 1.82 over the Bitext for En-Bn, Bn-En, En-Ta, Ta-En, En-Ne, Ne-En, En-Si, and Si-En, respectively.

For a fair comparison, in another experiment, we upsample the bitext data to make it similar to the amount of AugVic's data. From the *Upsample* results (with a 6-layer architecture) reported in Table 3, we see that even though it increases the BLEU scores for En to/from $\{$Bn, Ta$\}$, it has negative impacts on En to/from $\{$Ne, Si$\}$ where it degrades the performance. Overall, AugVic achieves 1.75 BLEU score improvements on an average over the Upsample baseline.

The comparison with the diversification strategy proposed by Nguyen et al. (2020) reveals that AugVic outperforms their method by 0.84 BLEU scores on average. To be specific, our method gets 0.49, 0.85, 0.19, 0.14, 0.77, 1.75, 1.46, and 1.07 absolute BLEU improvements over their approach for En-Bn, Bn-En, En-Ta, Ta-En, En-Ne, Ne-En, En-Si, and Si-En, respectively.

The data diversification method of Nguyen et al. (2020) relies heavily on the performance of base models (Bitext). From Table 3, we see that the performance of base models are poor for En to/from $\{$Ne, Si$\}$, which impacts their augmented data generation process (diversification). However, the better performance of AugVic in those languages indicates that vicinal samples generated in our method are more diverse with better quality and less prone to the noise in base models.

5.2 Vicinal Samples with Extra Relevant Monolingual Data

We further explore the performance of AugVic by experimenting with the traditional back-translation method (§3.1) using the same amount of monolingual data. To perceive the variability, we choose to experiment with extra monolingual data from two *relevant* but different sources - newscrawl (BT-Mono (News)) and Wikipedia (BT-Mono (Wiki)). From the results in Table 3, we see that standard back-translation improves the scores in both cases, proving that extra relevant monolingual data helps

Interm. BT system	**En-Bn** →	←	**En-Ta** →	←	**En-Ne** →	←	**En-Si** →	←
Pure BT	18.03	26.96	12.93	28.68	**6.47**	**10.65**	**3.66**	**9.27**
Guided BT	**18.18**	**27.35**	**13.17**	**29.05**	4.81	8.62	2.16	7.71

Table 4: Comparison between two **interm**ediate reverse back-translation **(BT)** systems in AugVic.

BT-mono Domain	**Data**	**En-Bn** →	←	**En-Ta** →	←
	Bitext	13.21	21.18	11.58	26.29
News (relevant)	+ BT	18.81	27.11	13.51	29.38
	+ AugVic+ BT	19.98	28.14	13.87	30.15
gnome (distant)	+ BT	17.14	26.05	12.55	27.91
	+ AugVic+ BT	18.86	27.56	13.59	29.89

Table 5: Effect of relevant and distant domain monolingual data in back-translation with AugVic. We use *News* as "relevant" and *gnome* as "distant" domain.

for low-resource MT significantly.

To understand the exclusivity of the vicinal samples of AugVic from the external related monolingual data, we perform another set of experiments where we added both the AugVic's augmented data with the extra monolingual data and trained along with the Bitext data. From Table 3, we see that the combination of datasets improves the BLEU scores by 1.02 and 0.73 on average on the two relevant data sources (News and Wiki). From this, we can conclude that vicinal samples of AugVic make the NMT models more robust in the presence of the relevant monolingual data and can be used together when available.

5.3 Pure vs. Guided: Which One is Better?

For all the results of AugVic presented in Table 3, we use the pure back-translation (BT) method (§3.2.2(a)) as the reverse intermediate model. We compare the performance of the guided BT (§3.2.2(b)) with the pure BT method as the reverse intermediate model in Table 4. From the results, we observe that the guided BT achieves better results in En↔ {Bn, Ta}, while the pure BT achieves better in En↔ {Ne, Si} translation tasks.

We investigated why the guided BT performed poorly in En↔ {Ne, Si} tasks, and found that compared to the En-Bn and En-Ta bitexts, the original bitexts of En-Ne and En-Si languages are very noisy (*e.g.,* bad sentence segmentation, code-mix data), which propagates further noise while using the target translation as a guide for translating the vicinal samples. The diminishing results while upsampling in these two languages (Table 3) supports this claim. From these results, we can say that the better the original bitext quality is, the better the synthetic bitext will be for the guided BT.

5.4 AugVic with Relevant and Distant-domain Monolingual Data

To verify how traditional back-translation and AugVic perform with with monolingual data from related vs. distant domains, we perform another set of experiments on En to/from {Bn, Ta}. For both the language pairs (§4.1), *News* can (roughly) be considered as relevant compared to *gnome*,[5] which can be considered as distant domain. We use *pure BT* as the intermediate reverse back-translation system for generating synthetic data in AugVic in this set of experiments.

From Table 5, we see that traditional back-translation (+ BT) improves the BLEU scores over the Bitext by 4.14 and 2.85 on average for relevant- and distant-domain monolingual data, respectively, yielding higher gains for relevant domain, as expected. The addition of vicinal data by AugVic (+ AugVic+ BT) further improves the scores in both cases; interestingly, the relative improvements are higher in the distant-domain case. Specifically, the average BLEU score improvements over Bitext for relevant- and distant-domain data with AugVic+BT are 4.97 and 4.41, respectively. Comparing this with BT only, the BLEU score difference between relevant and distant domains has been reduced from 1.29 to 0.56. This indicates that AugVic helps to bridge the domain gap between relevant and distant-domain distributions in traditional BT with monolingual data.

In principle, for vicinal samples, the synthetic-pair generation capability of the reverse intermediate target-to-source MT model should be better than generating from an arbitrary monolingual data as it could be a distant distribution compared to the bitext. Judging by the amount of diverse data used for training the language model, we can safely assume that it is a diverse knowledge source (Conneau et al., 2020b) compared to the training bitext samples. Data that performs well on the reverse

---

[5] http://opus.nlpl.eu/GNOME.php

intermediate target-to-source MT system can be extrapolated from the knowledge-base as vicinal-distribution with the controlled diversity ratio function (Eq. 2). Moreover, to achieve more diversity, the use of multiple different language models is also compatible in AUGVIC.

5.5 Effect of Diversity Ratio in AUGVIC

For monolingual data, it could be challenging to identify domain discrepancy with the training/testing bitext data, and there is no parameter in the traditional BT method to control this distributional mismatch. However, in AUGVIC we can control the distributional drift of the generated vicinal samples from the original training distribution by varying the diversity ratio ρ.

Theoretically, it is possible to sample the same distribution using dynamic and static diversity. However, dynamic diversity is more flexible to perform hyperparameter-tuning and to prevent potential outliers. The term l/h in Eq. 2 represents pseudo-segmentation (h segments) of a large sentence of length l, and b represents the same intuition as ρ. Apart from these, t_{min} and t_{max} prevents irregular-samples: (i) t_{min} ensures that there should be at least some changes in the augmented sample, (ii) t_{max} makes sure that the generated-samples from LM do not diverge too much from the vicinity.

To understand the effect of the diversity ratio in AUGVIC, we perform another set of experiments. We choose to use En to/from {Bn, Ne} for this experiments, where we selected at most two vicinal samples from each of the target sentence in original bitext. We investigate the effect of both *dynamic* and *fixed* diversity ratio in AUGVIC's vicinal sample generation (§3.2.1). For fixed diversity ratio we use ρ values 0.1, 0.3, 0.5, and 0.8, while for dynamic diversity ratio we use $a = 0.5, b = 2.5$, and $h = 10$ for controlling the diversity.

We present these experimental results in Table 6, from where we see that the dynamic diversity ratio performs better in three out of four tasks. For the fixed diversity ratio, we see the variation in results for different values of ρ. In all the four tasks, the diversity ratio $\rho = 0.8$ gives the least scores. On average, we get the better results with $\rho = \{0.3, 0.5\}$. These experiments suggest that higher diversity values may induce noise and lower diversity values may not diversify the data enough to benefit the final NMT model.

AUGVIC **diversity ratio**	**En-Bn** →	←	**En-Ne** →	←
Dynamic	**17.69**	**26.61**	**6.21**	10.25
Fixed				
$\rho = 0.1$	17.34	25.98	5.98	10.03
$\rho = 0.3$	17.52	26.19	6.19	10.36
$\rho = 0.5$	17.48	26.49	6.05	**10.38**
$\rho = 0.8$	17.19	25.01	5.82	9.89

Table 6: Effect of diversity ratio ρ while generating vicinal samples in AUGVIC (§3.2.1).

6 Conclusion

We have presented an in-domain data augmentation framework AUGVIC by exploiting the bitext vicinity for low-resource NMT. Our method generates vicinal samples by diversifying sentences of the target language in the bitext in a novel way. It is simple yet effective and can be quite useful when extra in-domain monolingual data is limited.

Extensive experiments with four low-resource language pairs comprising data from different domains show the efficacy of AUGVIC. Our method is not only comparable with traditional back-translation with in-domain monolingual data, it also makes the NMT models more robust in the presence of relevant monolingual data. Moreover, it bridges the distributional gap for out-of-domain monolingual data when using together.

Abstract

Generative linguistic steganography mainly utilized language models and applied steganographic sampling (stegosampling) to generate high-security steganographic text (stegotext). However, previous methods generally lead to statistical differences between the conditional probability distributions of stegotext and natural text, which brings about security risks. In this paper, to further ensure security, we present a novel provably secure generative linguistic steganographic method **ADG**, which recursively embeds secret information by **A**daptive **D**ynamic **G**rouping of tokens according to their probability given by an off-the-shelf language model. We not only prove the security of ADG mathematically, but also conduct extensive experiments on three public corpora to further verify its imperceptibility. The experimental results reveal that the proposed method is able to generate stegotext with nearly perfect security.

1 Introduction

Steganography is the technology of hiding secret information within an innocent natural carrier (such as image (Hussain et al., 2018), audio (Mishra et al., 2018), video (Liu et al., 2019), text (Krishnan et al., 2017), etc) in order to avoid eavesdropping. Steganography differs from cryptography in that cryptography only conceals the content of secret information, whereas steganography even conceals its very existence, which makes it more secure and reliable in some scenarios (Anderson and Petitcolas, 1998).

Natural language is suitable as a carrier of steganography by virtue of its high robustness in transmission (Ziegler et al., 2019). Unlike digital images or digital audio which is sensitive to distortions like compression, cropping, blurring or pixel-wise dropout, text can usually be transmitted losslessly through different kinds of public channels. Nevertheless, text generally has low entropy and lacks sufficient redundancy for information hiding (Sharma et al., 2016), which often results in low embedding capacity of linguistic steganography. For example, in traditional modification-based methods (such as synonym substitution (Xiang et al., 2014, 2018) and spelling transformation (Shirali-Shahreza, 2008)), where secret information is encoded by slightly modifying an existing covertext, the options for modification can be very limited to keep the text fluent enough so as not to arouse suspicions.

In recent years, powered by the advanced technology of deep learning and natural language processing, language models based on neural networks have made significant progress in generating fluent text (Radford et al., 2019; Brown et al., 2020), which bring new vitality to linguistic steganography and facilitate the investigation of generation-based methods (Fang et al., 2017; Yang et al., 2018a; Dai and Cai, 2019; Ziegler et al., 2019; Yang et al., 2020a; Zhou et al., 2021). The generative linguistic steganography directly transform secret information into innocuous-looking steganographic text (stegotext) without any covertext. Using an off-the-shelf language model, secret information can be encoded in the selection of token at each time step autoregressively during the generation procedure, which greatly alleviates the drawback of low embedding capacity. However, previous methods inevitably introduce distortions during generation. The imperceptibility of generative linguistic steganography still needs further optimization.

In this paper, we aim to further improve the imperceptibility of generative linguistic steganography. The contributions of this work are the following:

1. We present **ADG** (**A**daptive **D**ynamic

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3046–3055
August 1–6, 2021.

Grouping), a novel generative linguistic steganographic method based on off-the-shelf language models, which groups the tokens adaptively in accordance with their probability at each time step to embed secret information dynamically in the generated stegotext.

2. We discuss the security of ADG and give mathematical proof, which reveals that the proposed method is provably secure.
3. Through quantitative analysis, we derive satisfactory experimental results in terms of both imperceptibility and embedding capacity, which further verifies the effectiveness of ADG.

Our code is available at `https://github.com/Mhzzzzz/ADG-steganography`.

2 Formalism

2.1 Notation

We use lowercase letters in bold type (e.g. $\boldsymbol{a}$) to denote vectors, normal lowercase letters (e.g. a) to denote scalars and uppercase letters (e.g. A) to denote sets. We use the symbol $|A|$ to denote the size of a set. Calligraphic letters denote neural models (e.g. $\mathcal{A}$). Both English letters and Greek letters are adopted. We use $p(\cdot)$ and $q(\cdot)$ to denote distributions and $f(\cdot)$ to denote functions, which are usually shortened to p, q and f. Subscripts and superscripts are used to tell the different variables/distributions/functions apart.

2.2 Generative Linguistic Steganography

Language modeling is a task to estimate the joint distribution of serialized natural language $p_{LM}(\boldsymbol{w})$, where $\boldsymbol{w}$ is a sequence of n tokens $[w_1, w_2, ..., w_n]$ and each token belongs to the vocabulary Σ. For an autoregressive language model $\mathcal{L}$, the output is usually factorized as a product of conditional distribution of the current token

$$\begin{aligned} p_{LM}(\boldsymbol{w}) &= p_{LM}(w_1, w_2, ..., w_n) \\ &= p_{LM}(w_1) \cdot \prod_{t=2}^{n} p_{LM}(w_t | w_1, ..., w_{t-1}). \end{aligned} \tag{1}$$

According to Simmons (1984), it is usually supposed that Alice (sender) wants to send a secret message $\boldsymbol{m} \sim \text{Uniform}(\{0,1\}^l)$ to Bob (receiver) through a public channel monitored by Eve (adversary). In generative linguistic steganography, they share an *embedding* algorithm f_{emb} which takes a language model $\mathcal{L}$ and the secret message $\boldsymbol{m}$ as input and then outputs *stegotext* $\boldsymbol{y}$ to transmit. They also share a corresponding *extraction* algorithm f_{ext}, which is the inverse mapping of f_{emb} that is able to recover the secret message $\boldsymbol{m}$ according to the language model $\mathcal{L}$ and the received stegotext $\boldsymbol{y}$.

2.3 Imperceptibility

In order to avoid raising Eve's suspicions, stegotext $\boldsymbol{y}$ is required to be fluent enough and statistically indistinguishable from natural innocuous text $\boldsymbol{x}$, which we call *covertext*. Cachin (1998) proposed the *information-theoretic security* of steganography to measure the statistical imperceptibility quantitatively, which is defined as the Kullback-Leibler divergence (KL divergence) between the distributions of covertext $\boldsymbol{x}$ and stegotext $\boldsymbol{y}$. The distortion of generative linguistic steganography is two-fold: one is introduced by the bias of the language models, which is the gap between the true distribution of natural text $p_{true}(\boldsymbol{x})$ and the modeled distribution $p_{LM}(\boldsymbol{x})$; the other is introduced by f_{emb}. Instead of directly sampling from the modeled distribution, the embedding algorithm f_{emb} actually provides a special way to sample from $p_{LM}(\boldsymbol{y})$, which we call steganographic sampling (stegosampling). It is equivalent to sampling from a modified distribution $q(\boldsymbol{y})$ produced by an implicit language model $\mathcal{L}'$. In a word, the latter distortion is the gap between $p_{LM}(\boldsymbol{y})$ and $q(\boldsymbol{y})$, which can also be regarded as the gap between the conditional distributions $p_{LM}(y_t|y_{<t})$ and $q(y_t|y_{<t})$. We simply use p_{LM} and q to refer to the conditional distributions in the rest of this paper.

3 Related Work

In the early stage, some researchers investigated rule-based approaches or using Markov Chains to achieve generative linguistic steganography (Wayner, 1992; Chapman and Davida, 1997; Chapman et al., 2001; Chapman and Davida, 2002; Dai et al., 2010; Moraldo, 2014; Luo et al., 2016; Yang et al., 2018b). However, these methods followed a simplistic pattern and are hard to guarantee the grammatical correctness and the semantic fluency of the generated stegotext.

With the development of deep learning, language models based on neural networks show great performance on automatic text generation. The pattern of generating stegotext with neural language models has been widely accepted. Fang et al. (2017)

proposed a linguistic steganographic method that randomly partitioned the vocabulary Σ into 2^b bins $[B_1, B_2, ..., B_{2^b}]$ and each one contained $|\Sigma|/2^b$ tokens. At each time step, they selected the token with the highest probability within the bin according to the $b-$bit secret information to be embedded. Yang et al. (2018a) improved the embedding algorithm by building the mapping from secret information to tokens dynamically at each time step rather than statically in advance. Concretely, the top 2^k tokens with the highest probability were encoded by Huffman coding algorithm. Then they took the token which has the same code as the secret information. Dai and Cai (2019) proposed *patient-Huffman*, which was an improved version of Yang et al. (2018a) that sacrificed embedding capacity for imperceptibility. They first calculated the distortion (total variation distance or KL divergence) between q and p_{LM} and then only used Huffman coding embedding algorithm to embed secret information when the distortion was less than a preset threshold δ. Otherwise they directly sampled a token to avoid high distortion occasions. Ziegler et al. (2019) employed arithmetic coding to embed secret information. They truncated the top h likely tokens and left out the low-probability long-tails. Then the tokens are encoded by arithmetic coding algorithm and selected according to the secret information. Compared with other coding algorithm, arithmetic coding has higher compression rate, which results in less damage to conditional probability distribution p_{LM} and helps to improve imperceptibility.

4 ADG Methodology

According to the analysis in Section 2.3, the distortion of generative linguistic steganography includes the bias of the language model $\mathcal{L}$ and the damage to the conditional distribution caused by the embedding algorithm f_{emb}. The former is not our research priority. With the development of automatic text generation, the former distortion can be gradually minimized. In this paper, we mainly pay attention to the latter distortion. We aim to seek an optimal solution theoretically and experimentally.

Given an off-the-shelf language model, how can we embed secret information to the generated tokens? Unlike previous works that encoded the conditional distribution by lossless coding algorithm, we achieve this goal in a novel way by grouping. Through mathematical analysis and proof, we propose a provably secure method ADG, which does little damage to the conditional distribution and is nearly equivalent to directly sampling from the full distribution. In this section, we investigate the security of steganography by grouping and give detailed descriptions of the proposed method.

4.1 Steganography by Grouping

Steganography by grouping is to group all tokens in the vocabulary into several groups, so that each group represents a unique secret message. E.g. we can Tokens belonging to the target group are able to make up the stegotext. In such a way, Bob reads each token in the sequence in turn and performs the same grouping operation to extrapolate which groups the current token belongs to, thereby extracting the corresponding secret information. The key question is: how to group the tokens at each time step to ensure an optimal imperceptibility? We have the following assumption.

Assumption 1. *For secret information in the form of uniformly distributed bitstream, adaptively grouping the vocabulary into* u *groups (*$u = 2^r, r \in N, r \leq \log_2 |\Sigma|$*) with equal probability will ensure the optimal imperceptibility.*

Proof. Assuming that the discrete conditional probability distribution p_{LM} is arbitrarily partitioned into u groups to embed r-bit secret information. p_{ij} denotes the probability of the j-th token in the i-th group. η_i and n_i denote the total probability and the size of the i-th group respectively. Then we have

$$\sum_{j=1}^{n_i} p_{ij} = \eta_i, \sum_{i=1}^{u} \eta_i = 1. \tag{2}$$

Our goal is to figure out the grouping algorithm to achieve the best imperceptibility, i.e. to minimize the gap between p_{LM} and q. First of all, starting from the modeled distribution $p_{LM} = [..., p_{ij}, ...]$, we calculate the equivalent distribution q. The probability of each token is firstly normalized within its group ($1/\eta_i$) and then multiplied by the selected probability of the group, which is $1/u$ since secret information is uniformly distributed. Therefore, q has the following form

$$q = [..., p_{ij}/u\eta_i, ...]. \tag{3}$$

We measured the gap between the two distributions with KL divergence, which is

$$D_{KL}(p_{LM}||q) = \sum p_{LM} \log \frac{p_{LM}}{q}$$

$$
\begin{aligned}
&= \sum_{i=1}^{u}\sum_{j=1}^{n_i} p_{ij}\log\frac{p_{ij}}{p_{ij}/u\eta_i} \\
&= \sum_{i=1}^{u}\sum_{j=1}^{n_i} p_{ij}\log(u\eta_i) \\
&= \sum_{i=1}^{u}\log(u\eta_i)\sum_{j=1}^{n_i} p_{ij} \\
&= \sum_{i=1}^{u}\eta_i\log(u\eta_i). \qquad (4)
\end{aligned}
$$

Therefore, the KL divergence between the two distributions is a function of the vector $\boldsymbol{\eta} = [\eta_1, \eta_2, ..., \eta_u]$.

Next, we will prove Assumption 1 in two steps.

[1]. Considering the auxiliary function $f_{aux}(\eta) = \eta\log(u\eta)$, $(0 \leq \eta \leq 1)$, we firstly analyse its concavity and convexity on the domain of definition. For every $\eta_1, \eta_2 \in (0,1)$ and $0 \leq \lambda \leq 1$,

$$
\begin{aligned}
& f_{aux}(\lambda\eta_1 + (1-\lambda)\eta_2) \\
& - \lambda f_{aux}(\eta_1) - (1-\lambda)f_{aux}(\eta_2) \\
& = (\lambda\eta_1 + (1-\lambda)\eta_2)\log(u(\lambda\eta_1 + (1-\lambda)\eta_2)) \\
& - \lambda(\eta_1\log(u\eta_1)) - (1-\lambda)(\eta_2\log(u\eta_2)) \\
& = \lambda\eta_1\log\frac{\lambda\eta_1 + (1-\lambda)\eta_2}{\eta_1} \\
& + (1-\lambda)\eta_2\, log\frac{\lambda\eta_1 + (1-\lambda)\eta_2}{\eta_2} \\
& \leq \lambda(\eta_1(\frac{\lambda\eta_1 + (1-\lambda)\eta_2}{\eta_1} - 1)) \\
& + (1-\lambda)\eta_2(\frac{\lambda\eta_1 + (1-\lambda)\eta_2}{\eta_2} - 1) \\
& = \lambda(\lambda\eta_1 + (1-\lambda)\eta_2 - \eta_1) \\
& + (1-\lambda)(\lambda\eta_1 + (1-\lambda)\eta_2 - \eta_2) \\
& = \lambda(\lambda-1)\eta_1 + \lambda(1-\lambda)\eta_2 \\
& + (1-\lambda)\lambda\eta_1 - (1-\lambda)\lambda\eta_2 \\
& = 0.
\end{aligned}
\qquad (5)
$$

As a result, $f_{aux}(\eta)$ is convex over $(0,1)$.

[2]. Then, when generalizing to u variables $\eta_1, \eta_2, ..., \eta_u$, $\sum_{i=1}^{u}\eta_i = 1$, according to Jensen's inequality (Jensen et al., 1906), there is

$$
\begin{aligned}
& \frac{\sum_{i=1}^{u} f_{aux}(\eta_i)}{u} = \frac{\sum_{i=1}^{u}\eta_i\log(u\eta_i)}{u} \\
& \geq f_{aux}(\frac{\sum_{i=1}^{u}\eta_i}{u}) = \frac{1}{u}\sum_{i=1}^{u}\eta_i\log(\sum_{i=1}^{u}\eta_i) = 0.
\end{aligned}
\qquad (6)
$$

The equality sign holds if and only if

$$\eta_1 = \eta_2 = ... = \eta_u. \qquad (7)$$

It means that $D_{KL}(p_{LM}||q) = \sum_{i=1}^{u} f_{aux}(\eta_i)$ takes the minimum value 0 when each component of $\boldsymbol{\eta}$ is equal, in which case p_{LM} and q are equivalent and that achieves the optimal information-theoretic security defined by Cachin (1998). □

Therefore, we basically construct the idea of our embedding algorithm, that is, to adaptively group the vocabulary into multiple groups at each time step, so that each group is assigned approximately the same probability. In practice, since the probability distribution is discrete, the probability of groups may not be absolutely equal. Firstly, we determine the number of groups u to be its maximum value $2^{\lfloor -\log_2 p_{max} \rfloor}$, where p_{max} is the highest probability in p_{LM}. Secondly, since the time complexity of solving the global optimal solution of equal grouping is unacceptable, we implement a suboptimal solution in ADG, as demonstrated in Algorithm 1. In line 10, we employ binary search algorithm to select the token that has the nearest probability of a given value. Our implementation enables us to obtain a unique grouping result for any p_{LM}, which ensures that the secret information can be extracted accurately and completely at the receiving end.

4.2 Recursion and Pruning

After obtaining the grouping results, we can select the group according to the next $\log u$ bits of secret information to be embedded and simply sample a token in the group to generate stegotext. As a matter of fact, we can also continue grouping the obtained groups to further enlarge the embedding capacity and recursively grouping the new groups until it is impossible to be equally participated (the normalized p_{max} of the current group is greater than 0.5). In order to improve the efficiency of the recursive grouping, we employ pruning strategy to remove the redundant grouping operations. We only need to recursively group the selected groups every time in accordance with the secret information to be embedded. In this manner, the amount of secret information embedded in each token is adjusted dynamically according to its probability distribution.

To sum up, at each time step, the proposed ADG embedding algorithm first conducts the equal

Algorithm 1: Suboptimal solution of equal grouping.

```
Data: vocabulary $\Sigma$, distribution $p_{LM}$
Result: set of groups $G$
list of tokens = sorted $(p_{LM})$;
$p_{max}$ = probability of the first token;
$u = 2^{\lfloor -\log_2 p_{max} \rfloor}$;
mean = $1/u$;
for ($i = 1; i \leq u - 1; i$ ++) do
    $G_i$ = [the first token];
    remove the first token;
    while $\sum$ probability of $G_i$ < mean do
        $\varepsilon$ = mean $- \sum$ probability of $G_i$;
        select a token with the nearest
          probability of $\varepsilon$;
        if probability of the token $- \varepsilon < \varepsilon$
          then
            append the token to $G_i$;
            remove the token;
        end
        else
            break;
        end
    end
    mean = $\frac{\text{probability of the rest tokens}}{u - i}$;
end
append the rest tokens to $G_u$;
$G = [G_1, G_2, ..., G_u]$;
```

grouping algorithm adaptively according to the conditional distribution, and then recursively repeats the operation on the selected group dynamically according to the secret information, until it is indivisible. At last, we normalize the probability of the last selected group and sample a token to generate the stegotext. We have proved the security of equal grouping algorithm. Obviously, it can also be extended to the recursive manner of ADG, which means the proposed method is provably secure.

4.3 Information Extraction

The extraction algorithm is basically the inverse process of the embedding algorithm. For an exactly successful extraction, Alice and Bob have to share the same language model, vocabulary and grouping algorithm. At each time step, Bob is supposed to recursively operate the same grouping algorithm as Alice do, and then select the group contains the current token in the stegotext. The index of the selected groups reveal the embedded secret information.

5 Experimental Results and Analysis

In this section, we evaluate the performance of ADG in terms of both embedding capacity and imperceptibility. Details of our experiments and the analysis of the results are present in the following subsections.

5.1 Datasets

We evaluated the performance of ADG on three public corpora, namely "Large Movie Review Dataset" (**Movie**) (Maas et al., 2011), "All the News" (**News**)[1] and "Sentiment140" (**Tweet**) (Go et al., 2009). Large movie review dataset is originally built for binary sentiment classification, containing 100,000 movie reviews in total crawled from IMDb[2]. "All the news" is a collection of publications of mainstream news media. Sentiment140 is also used in sentiment analysis tasks, which contains 1,600,000 tweets extracted from Twitter[3].

We converted the raw text to lowercase and removed HTML tags and most punctuations, then segmented it into sentences with NLTK tools (Loper and Bird, 2002). We filtered out sentences with length below 5 or above 200. For the convenience of training and evaluation, any token occurring less than 10 times was mapped to a special token "_UNK". We also added "_BOS" and "_EOS" at the beginning and end of each sentence to help training. Sentences in a batch were padded to the same length with a special padding token "_PAD". Finally, we divided the preprocessed corpora into training set and test set according to the ratio of 9:1. Statistics are demonstrated in Table 3.

5.2 Implementation Details

In experiments, we utilized LSTMs (Hochreiter and Schmidhuber, 1997) for word-level generation. We stacked 2 LSTM layers and the model was implemented with Pytorch (Paszke et al., 2017). The dimension of word embedding was set to be 350. Hidden states in LSTM were set to be 512-dimensional vectors. In the training procedure, we applied SGD algorithm together with Adam

(Kingma and Ba, 2014) to train the language model. Learning rate was set to be 0.001. The SGD update direction was computed using a batch of 32 training samples. They were both trained for 30 epochs on one GeForce GTX 1080 GPU. In the generation procedure, we adopted the model performing best on test sets. All generated sentences must be longer than 5 and shorter than 200.

5.3 Baselines

We rebuilt Fang et al. (2017) (**Bins**), Yang et al. (2018a) (**Huffman**), Dai and Cai (2019) (**Patient-Huffman**) and Ziegler et al. (2019) (**Arithmetic**) as baselines. For fair comparison, we rebuilt all the baselines with the same language models. For Bins, we set b to be 1, 2, 3, 4, 5 and the corresponding number of bins was 2, 4, 8, 16, 32. For Huffman, we built Huffman tree with the top 2, 4, 8, 16, 32 likely tokens. For Patient-Huffman, we measured the distortion by KL divergence and restricted the threshold δ to 1, 1.5, 2 with top 8 tokens. For Arithmetic, we truncated the conditional distribution at $h = 100, 200, 300$. In each case, we generated 1,000 stegotext. We randomly chose same amount of covertext from the test sets for further evaluation.

5.4 Metrics

The metrics we utilized to evaluate the performance on embedding capacity and imperceptibility are listed as follows.

Embedding Rate (**ER**): It is the average amount of information that one single token can carry, and is in unit of *bits per word* (*bpp*). Embedding rate is a metric to indicate the embedding capacity. Higher is better.

KL Divergence between the implicit distribution q and the modeled distribution p_{LM} (**$\mathbf{KLD}_1$**): It reflects the gap introduced by the embedding algorithm. Lower is better and the unit is *bit*.

KL Divergence between the statistical distributions of the sentence embedding of covertext and stegotext (**$\mathbf{KLD}_2$**): It indirectly reflects the overall information-theoretic security. We mapped all stegotext and covertext to fixed length dense vectors $\boldsymbol{v_x}$ and $\boldsymbol{v_y}$ by third-party sentence vectorization tool (Le and Mikolov, 2014), and assumed that the resulting vectors of covertext and stegotext both obey isotropic Gaussian distribution. Then KLD_2 is computed by

$$\begin{aligned} & D_{KL}(p(\boldsymbol{v_x})\|p(\boldsymbol{v_y})) \\ & \approx \sum (\log \frac{\boldsymbol{\sigma_y}}{\boldsymbol{\sigma_x}} + \frac{\boldsymbol{\sigma_x}^2 + (\boldsymbol{\mu_x} - \boldsymbol{\mu_y})^2}{2\boldsymbol{\sigma_y}^2} - \frac{1}{2}), \end{aligned} \tag{8}$$

where $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$ are the mean and standard deviation of sentence vectors. We set the dimension of sentence vectors to be 100. Lower is better and the unit is *bit*.

Detection Accuracy: It reflects the anti-steganalysis ability of steganographic methods. Ste-

ganalysis is the technology used by Eve to detect hidden information in stegocarriers, which is the opposite direction of steganography. In our experiment, we employed linguistic steganalysis approaches based on Fasttext (Yang et al., 2019) (**Acc**$_1$) and TextCNN (Yang et al., 2020b) (**Acc**$_2$). We took stegotext as positive samples and covertext as negative samples. We conducted 10-fold cross validation and reported the average accuracy. Closer to 50% is better.

Effective Embedding Rate: It is a new metric we proposed to evaluate the comprehensive performance of steganographic algorithms. It is defined to be calculated by

$$\text{EER} = 2 \times (1 - Acc) \times \text{ER}, \tag{9}$$

meaning that if the stegotext has a certain probability of being detected, the average amount of secret information actually transmitted should be discounted accordingly. For mathematical rigorousness and completeness, if $Acc < 0.5$, we assign $1 - Acc$ to Acc. In extreme cases where the stegocarriers are completely natural, the detection accuracy should be 50% and EER is equal to ER. On the contrary, stegocarriers with 100% detection accuracy cannot carry a single bit. We calculated this metric with the accuracy results obtained by the two aforementioned steganalysis method (**EER**$_1$, **EER**$_2$). Higher is better and the unit is *bpp*.

5.5 Results and Analysis

The results of KLD$_1$ and KLD$_2$ are listed in Table 1. KLD$_1$ measures the distortion between q and p_{LM}, which is introduced by the embedding algorithm ADG. KLD$_2$ estimates the overall information-theoretic security that also considers the deviation of language models. In terms of KLD$_1$, we found that the proposed method ADG outperforms all baselines and it is very close to the optimal value 0 (stochastic sampling), which means generating stegotext by ADG is almost equivalent to normal generation with the language models. The results of KLD$_2$ are also advantageous, indicating that the generated stegotext is statistically consistent with the covertext. We noticed that some baselines can also perform well on KLD$_2$ (e.g. Patient-Huffman ($\delta = 1.0$)). However, they have a crucial flaw in embedding capacity.

Table 2 demonstrates the results of anti-steganalysis, where we found the tendency coheres with that of KLD$_1$ and KLD$_2$. The proposed method ADG outperforms all baselines on the three corpora and it is very close to the optimal value 0.5, which further confirms its imperceptibility. Besides, we also illustrated some examples of stegotext generated by ADG in Table 5 for qualitative

	Sadly you will be missing so much.
	I do n't think the peach ice cream last night was good.

study. We found that the stegotext is fluent enough, with correct grammar and coherent semantics.

Finally, taking both embedding capacity and imperceptibility into account, we investigated effective embedding rate listed in Table 4. It can be concluded that our method has excellent comprehensive performance, which outperforms all baselines. In general, the experimental results indicate that the proposed method ADG is able to resist both perceptual and statistical steganalysis of Eve, meanwhile ensure a remarkable embedding rate, which reveals its effectiveness.

6 Conclusion

Previous works of generative linguistic steganography inevitably introduce distortions to the distribution estimated by off-the-shelf language models. In this paper, we attempted to achieve provably secure generative linguistic steganography during the procedure of stegotext generation. We proposed ADG, which embeds secret information by adaptive dynamic grouping. According to the mathematical proof and extensive experiments conducted on three public corpora, we found that the proposed method is provably secure and capable of generating fluent stegotext with high embedding capacity and high imperceptibility. We hope our investigation of provably secure generative linguistic steganography can be leveraged as a building block for future research.

Abstract

Commonsense generation is a challenging task of generating a plausible sentence describing an everyday scenario using provided concepts. Its requirement of reasoning over commonsense knowledge and compositional generalization ability even puzzles strong pre-trained language generation models. We propose a novel framework using retrieval methods to enhance both the pre-training and fine-tuning for commonsense generation. We retrieve prototype sentence candidates by concept matching and use them as auxiliary input. For fine-tuning, we further boost its performance with a trainable sentence retriever. We demonstrate experimentally on the large-scale CommonGen benchmark that our approach achieves new state-of-the-art results.[1]

1 Introduction

The understanding of commonsense knowledge in human language has been acknowledged as a critical component for artificial intelligence systems. In recent years, many new tasks and datasets are proposed to assess NLP model's ability of commonsense reasoning (Yu et al., 2020). SWAG (Zellers et al., 2018) is a task of inferring the upcoming event based on a partial description using commonsense. CommonsenseQA (Talmor et al., 2019) is a commonsense question answering dataset built from ConceptNet. Recently, Lin et al. (2020) propose CommonGen, a new challenge for evaluating model's ability of generative commonsense reasoning.

Concept Set #1:
dog, frisbee, catch, throw
Gold Target Sentences:
A dog leaps to catch a thrown frisbee. The dog catches the frisbee when the boy throws it. A man throws away his dog 's favorite frisbee expecting him to catch it in the air.
Concept Set #2:
lake, shore, canoe
Gold Target Sentences:
Canoe on a shore of lake. Canoe on shore with rainbow across the lake. Several canoes parked in the grass on the shore of a lake.

Table 1: Two concept sets and their gold corresponding sentences from CommonGen dataset.

CommonGen requires the system to construct a plausible sentence based on several concepts related to an everyday scenario. Two examples for this task are shown in Table 1. The task is challenging because the system needs to organize provided concepts into the most plausible scenario, avoid violation of commonsense, and ensure the generated sentence is grammatically correct. Existing approaches fine-tune pre-trained encoder-decoder models for description construction with concatenated concepts as input.

Fan et al. (2020) propose a retrieve-and-generation method for commonsense generation which uses a prototype candidate sentence as auxiliary input. However, their retriever is non-trainable and only works for the fine-tuning process. In this work, we extend this idea and propose a novel framework for commonsense generation by using retrieval method for enhancing both the pre-training and fine-tuning stages. Furthermore, we design a trainable prototype sentence retriever to further boost generation performance.

We conduct experiments on CommonGen (Lin et al., 2020) benchmark dataset. It contains 35,141 concept sets and 79,051 corresponding sentences. Each concept set is mapped to multiple corresponding sentences. Without any model modification or complex fusion of knowledge graphs, our approach

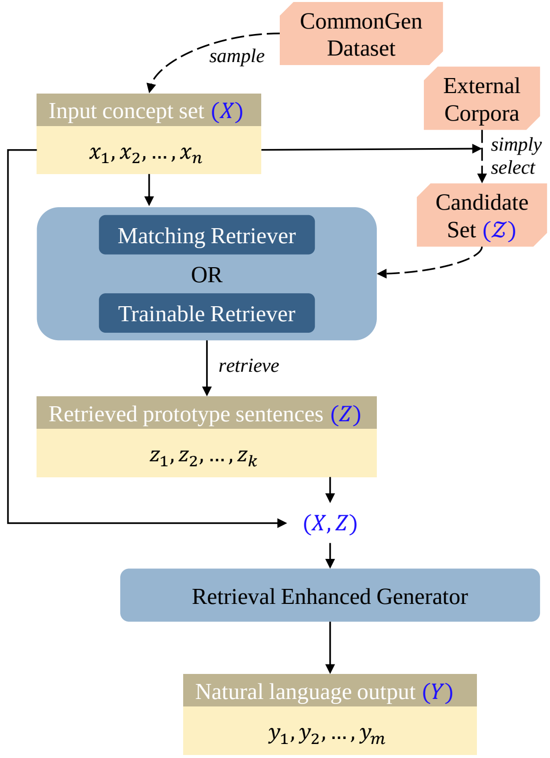

Figure 1: The overall framework of Retrieved Enhanced Model for Commonsense Generation.

achieves new state-of-the-art results on CommonGen on several metrics, including BLEU, CIDEr and SPICE.

2 Method

We frame CommonGen challenge as a sequence-to-sequence task and adopt T5 (Raffel et al., 2020), a powerful pre-trained encoder-decoder model, as our base model. Fan et al. (2020) find concepts-related sentences in external corpora can benefit relational reasoning for CommonGen. We extend this idea by proposing retrieval-enhanced T5 (RE-T5) which equips original T5 with a trainable retriever for selecting prototype sentences based on given concepts. Meanwhile, referring to (Zhou et al., 2021), we design a pre-training task for CommonGen which continue to pre-train RE-T5 on pseudo concept sets extracted from external corpora. We also use a retriever in this pre-training stage.

Formally, given a concept set $X = \{x_1, x_2, \ldots, x_n\}$, where x_i represents the i-th concept and n is the number of concepts, our goal is to generate a natural language output of tokens $Y = \{y_1, y_2, \ldots, y_m\}$, which describes a common scenario in our daily life, using all given concepts in X.

2.1 Retrieval

Since external corpora have lots of scenario knowledge to describe the relationship between concepts (Fan et al., 2020), we retrieve sentences related to input concepts to help the model perform better commonsense reasoning. First, given an input concept set, we extract all sentences from external corpora that contain at least two concepts in the input X as candidate set $\mathcal{Z}$. Then, we design two retrieval models, *matching retriever* and *trainable retriever*, to further retrieve k prototype sentences $Z = \{z_1, z_2, \ldots, z_k\}, Z \subseteq \mathcal{Z}$ as auxiliary input context for RE-T5.

Matching Retriever The *matching retriever* first orders candidate sentences by the number of contained concepts. Then it simply samples k sentences starting from sentences that contained the most concepts as the auxiliary input.

Trainable Retriever In order to retrieve more useful sentences from the sentence candidate set, we design a *trainable retriever*, which predicts scores to rank these candidates, and then select top-k sentences as additional context. The scorer is built based on BERT (Devlin et al., 2019), a pre-trained language model usually used for language understanding. Given a concept set X and a candidate sentence z_i, our trainable retriever first concatenate them into a text input:

$$\texttt{[CLS]}\, X \,\texttt{[SEP]}\, z_i \,\texttt{[SEP]}$$

where `[CLS]` and `[SEP]` are special symbols in BERT.

We pass this into BERT, which generates an output vector for each input token. We take the output vector corresponding to `[CLS]` which is used as the aggregated representation of the input sequence (denoted $\boldsymbol{c}$) into a linear layer with sigmoid activation to obtain the binary classification output y_c.

$$y_c = \sigma(\boldsymbol{W}_c \boldsymbol{c} + b_c) \tag{1}$$

where $\boldsymbol{W}_c$ is a projection matrix and b_c is a bias.

To train this retriever, for each concept set in CommonGen training set, we use its paired sentence as a positive example and we randomly sample another sentence, also from the training set, as a negative example. Then, we adopt cross entropy loss for this binary classification. The top-k scored sentences with the highest scores will be selected as the auxiliary input Z.

Model	BLEU-4	CIDEr	**SPICE**	SPICE(v1.0)
GPT-2 (Radford et al., 2019)	26.833	12.187	23.567	25.90
BERT-Gen (Bao et al., 2020)	23.468	12.606	24.822	27.30
UniLM (Dong et al., 2019)	30.616	14.889	27.429	30.20
BART (Lewis et al., 2020)	31.827	13.976	27.995	30.60
T5-base (Raffel et al., 2020)	18.546	9.399	19.871	22.00
T5-large (Raffel et al., 2020)	31.962	15.128	28.855	31.60
EKI-BART (Fan et al., 2020)	35.945	16.999	29.583	32.40
KG-BART (Liu et al., 2021)	33.867	16.927	29.634	32.70
CALM(T5-base) (Zhou et al., 2021)	-	-	-	33.00
RE-T5 (ours)	**40.863**	**17.663**	**31.079**	**34.30**

Table 2: Test results on CommonGen benchmark. All results except CALM are based on the latest human references(v1.1). v1.0 indicates evaluation with old evaluation protocol.[2]

We will describe how these two retrievers are used in CommonGen pre-training and fine-tuning stages.

2.2 Pre-training

To enhance model's ability of commonsense reasoning, we design a pre-training task for RE-T5 which is similar to original CommonGen task. In more details, given a sentence from external corpora, we first use spaCy (Honnibal et al., 2020) to tag the sentences with part-of-speech and extract *Verb*, *Noun* and *Proper Nouns* as pseudo concept phrases. We then only keep phrases in ConceptNet (Speer et al., 2017) and remove concept-sets that appear in CommonGen's testset. We use the original sentence as the target sentence, and constructs a pre-training task of using RE-T5 to generate this sentence given pseudo concepts.

Due to the extraction method for pseudo concepts, when retrieving prototype sentences, for each concept set in pre-training data, we have a large candidate set $\mathcal{Z}$ with an excessive number of candidate sentences. This leads to a long inference time for using the trainable retriever. Thus, due to speed consideration and also to introduce a degree of randomness into pre-training, we use the *matching retriever* to retrieve k sentences as auxiliary input Z.

After retrieval, RE-T5 takes the concatenation of input concepts and retrieved prototype sentences as input, and the original sentence as output.

2.3 Fine-tuning

At fine-tuning stage, we use *trainable retriever* to score sentences from candidate set $\mathcal{Z}$ and select top k sentence as additional context Z. Similar to pre-training, RE-T5 takes the concatenation of input concepts and retrieved prototype sentences as input, and the original sentence as output.

3 Experiments

3.1 Experiments Settings

Dataset CommonGen is a benchmark dataset designed to diagnose whether a model has the ability of generative commonsense reasoning (Lin et al., 2020). This dataset contains 32,651/993/1,497 concept sets for training/development/test, and the numbers of corresponding sentences are 67,389/4,018/7,644. We use BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Banerjee and Lavie, 2005), CIDEr (Vedantam et al., 2015) and SPICE (Anderson et al., 2016) as evaluation metrics. Because SPICE correlates the most with human evaluation (Lin et al., 2020), we take SPICE as the primary metric.

External Corpora To be consistent with the distribution of the CommonGen dataset, we use VATEX (Wang et al., 2019), Activity (Krishna et al., 2017), SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018) as external corpora. We sample 500k sentences from these corpora to construct our pre-training dataset. Meanwhile, these datasets are also used as our sentence pool for the retrieval module. For both the pre-training and fine-tuning, all sentences that appear in the CommonGen targets are not used as retrieval sentences candidates.

Baselines We compare RE-T5 with several baseline systems. GPT-2, BERT-Gen, UniLM, BART, and T5 are pre-trained language models tested in

---

[2] `https://inklab.usc.edu/CommonGen/leaderboard.html`

Concept Set: trailer shirt side sit road
T5: A man sits on the side of a trailer and a shirt.
Matching Retriever: (1)Two guys in red shirts are sitting on chairs, by the side of the road, behind that open trailer. (2)Two men, one wearing a straw cone hat, blue shirt, talking with a guy in a tan sunhat, red plaid shirt, both with baskets in front of them, sitting on the side of a dirt road. (3)An older guy with a tan shirt and hat sitting on the side of a road with bricks all around him and a small green bowl on the side. **RE-T5(matching retriever)**: a man in a tan shirt sits on the side of a road.
Trainable Retriever: (1)Two guys in red shirts are sitting on chairs, by the side of the road, behind that open trailer. (2)Teenagers in matching shirts stand at the side of the road holding trash bags. (3)A man in a white shirt and black pants standing at the side or the road. **RE-T5(trainable retriever)**: a man in a white shirt and black pants sits on the side of a trailer on the road.

Table 3: An example of sentences retrieved by different retrievers and sentences generated based on them.

(Lin et al., 2020). They are all fine-tuned on CommonGen training set with concatenated concepts as input and description sentence as output. EKI-BART (Fan et al., 2020) is a retrieve-and-generate framework for CommonGen, where they use a simple retriever to enhance pre-trained BART (Lewis et al., 2020). KG-BART (Liu et al., 2021) augment BART with Knowledge Graph on both the encoder and decoder side and continue to pre-train BART with a masked concept token generation task. CALM (Zhou et al., 2021) designs several self-supervised strategies encouraging model to focus on concept-centric information.

Implementation Details We adopt the T5-base as the generation model and BERT-base as the trainable retriever in fine-tuning. We use the Huggingface Transformer (Wolf et al., 2020) for model implementation. For pre-training phase, we use the AdamW optimizer (Loshchilov and Hutter, 2019) with an initial learning rate of 2e-6, weight decay 0.01, adam epsilon 1e-6, and a warmup fraction of 0.01. The model is pre-trained for 3 epochs, with batch size of 16, and gradient accumulation of 4 batches. For fine-tuning, the models are optimized using AdamW with an initial learning rate of 5e-5, batch size 64, gradient accumulation 3 and warmup fraction 0.01, and trained for 20 epochs. Meanwhile, the BERT-base scorer is optimized using AdamW optimizer with an initial learning rate 2e-5, batch size 64, and the model is trained for 3 epochs. For the number of the retrieved sentences k, we experimentally choose 3. All experiments are conducted using 4 V100 with 32 GB memory.

Model	**SPICE**
Retrieve (only)	29.60
T5	30.80[3]
T5 + *MR*	33.60
T5 + *MR* + pretrain	33.90
RE-T5 (T5 + *TR* + pretrain)	**34.30**

Table 4: Ablation results on the test set of CommonGen with T5-base as a backbone model. Note that *MR* denotes *Matching Retriever* and *TR* denotes *Trainable Retriever*.

3.2 Results

Table 2 shows results of different approaches on the CommonGen testset. RE-T5 outperforms all previous approaches by a large margin in all metrics and sets a new state of the art. RE-T5 combines the generation flexibility of pre-trained language models with the interpretability and modularity of a retrieval-based approach. Unlike EKI-BART (Fan et al., 2020) and KG-BART (Liu et al., 2021), RE-T5 enjoys strong results without model architecture modification. It is worth noting that although T5-base baseline does not perform as well as BART (Lewis et al., 2020) baseline, our method still outperforms the two improved BART-based methods mentioned above. RE-T5 demonstrates that for state-of-the-art performance, neither model modification nor complex fusion of knowledge graphs is necessary, only a simple and effective trainable retriever is needed.

---

[3] This is our reproduced result of T5-base. The difference from the result on the leaderboard is also observed in other papers (Zhou et al., 2021; Fan et al., 2020).

Ablation Study We conduct ablation experiments as shown in Table 4. First, we can see that RE-T5 model outperforms the backbone T5 model by a large margin in all metrics, with 3.5 improvement in the main metric SPICE. The second line of Table 4 shows that, although large-scale pre-trained language models have been shown to learn and store a substantial amount of the world knowledge implicitly from the massive text corpora (Petroni et al., 2019), the retrieved sentences from external corpora can still explicitly expose lots of scenario knowledge to describe the relationship between concepts. The third line indicates that further pre-training with data augmentation is helpful to improve the performance of the model. In addition, the last line demonstrates that a trainable scorer can capture more helpful knowledge for the model for commonsense generation.

Example Analysis Through the example in Table 3, we can observe that the baseline model T5 generates a sentence without concept *"road"*, and the juxtaposition between *"trailer"* and *"shirt"* in this sentence is not in line with common sense. For both *matching retriever* and *trainable retriever*, the retrieved sentences remind the model not to forget the concept *"road"*, in addition to providing the relationship between *shirt* and *person*. Since *matching retriever* randomly retrieves sentences based on the number of concepts they contain, it tends to retrieve longer sentences to contain as many concepts as possible, which may confuse the model and thus ignore some concepts, for example, the sentence generated by RE-T5 (matching retriever) in this example is missing the concept *"trailer"*. RE-T5 (trainable retriever) can solve the above problems and generate a sentence that is fluent and in line with common sense.

4 Conclusions

In this paper, we empirically investigated RE-T5, which utilizes a trainable retriever to retrieve sentences from external corpora to enhance the generative commonsense reasoning capability of pre-trained language models, such as T5. The state-of-the-art result achieved by RE-T5 on CommonGen benchmark demonstrates that a simple yet effective trainable retriever can be a useful addition to pre-trained language models for commonsense generation. For future work, we would like to explore the possibility of extending this simple and effective retrieval-based method to more tasks. In addition, we will also try training a more advanced retrieval model to further improve the performance of commonsense generation.

Abstract

Recently, Text-to-SQL for multi-turn dialogue has attracted great interest. Here, the user input of the current turn is parsed into the corresponding SQL query of the appropriate database, given all previous dialogue history. Current approaches mostly employ end-to-end models and consequently face two challenges. First, dialogue history modeling and Text-to-SQL parsing are implicitly combined, hence it is hard to carry out interpretable analysis and obtain targeted improvement. Second, SQL annotation of multi-turn dialogue is very expensive, leading to training data sparsity. In this paper, we propose a novel decoupled multi-turn Text-to-SQL framework, where an utterance rewrite model first explicitly solves completion of dialogue context, and then a single-turn Text-to-SQL parser follows. A dual learning approach is also proposed for the utterance rewrite model to address the data sparsity problem. Compared with end-to-end approaches, the proposed decoupled method can achieve excellent performance without any annotated in-domain data. With just a few annotated rewrite cases, the decoupled method outperforms the released state-of-the-art end-to-end models on both SParC and CoSQL datasets.

1 Introduction

Text-to-SQL has lately become an interesting research topic along with the high demand to query a database using natural language (NL). Standard large database format can only be accessed with Structured Query Language (SQL), which requires certain special knowledge from users, hence lowering the accessibility of these databases. Text-to-SQL tasks, however, greatly minimize this gap and allow the query based on NL. Previous work on Text-to-SQL mostly focuses on single-turn utterance inference, evaluated on context-independent Text-to-SQL benchmarks. Nevertheless, in practice, the users usually need to interact with the Text-to-SQL system step-by-step to address their query purpose clearly. Under such conversation scenarios, the co-reference and information ellipses are always present, shown in Figure 1. Recently proposed methods are mostly end-to-end, which endeavors to design a suitable model to encode the dialogue context and infer the corresponding SQL based on the whole dialogue context. The main limitation of the end-to-end multi-turn Text-to-SQL models lies in their extreme reliance on annotated multi-turn Text-to-SQL data. The large-scale multi-turn Text-to-SQL data is time-consuming and expensive. The annotators not only need to be SQL experts but also have to infer the complete and exact query intent of the latest utterance of the speaker.

tasks: utterance rewrite and single-turn Text-to-SQL. In recent years, these two individual tasks are both well-studied. The utterance rewrite task aims to generate the latest semantic-completion question based on the dialogue context. The single-turn Text-to-SQL task aims to parse the semantic-completion question to a SQL, where the state-of-the-art methods (Shi et al., 2020; Yu et al., 2020b; Chen et al., 2021; Rubin and Berant, 2021) can achieve over 70% exact match accuracy on Spider (Yu et al., 2018) (a cross-domain single-turn Text-to-SQL dataset) and even achieve more than 80% on easier Text-to-SQL benchmarks (Dahl et al., 1994; Zhong et al., 2017). However, there is no rewrite data on the existing multi-turn Text-to-SQL benchmarks and the existing utterance rewrite datasets normally pay more attention to the co-reference problem but ignore the information ellipses. Due to the limitation of the in-domain annotated rewrite data, we further propose a dual learning method to make comprehensive use of the unlabeled multi-turn data to learn a reliable rewrite model. Our proposed framework DELTA is evaluated on both the SParC (Yu et al., 2019b) and CoSQL datasets (Yu et al., 2019a), the two existing large-scale benchmark for the multi-turn Text-to-SQL task.

Contributions are highlighted below:

- We propose a decoupled parsing framework for the multi-turn Text-to-SQL task, whose annotated data is much easier to collect. Even without any in-domain multi-turn Text-to-SQL data, the decoupled parsing method can achieve encouraging results on multi-turn Text-to-SQL benchmarks.

- The decoupled framework includes an utterance rewrite model which is adapted from the pretrained BART (Lewis et al., 2020), with a newly implemented dual learning method to make comprehensive use of the unlabeled multi-turn data. Our adapted rewrite model achieves new state-of-the-art performance on the utterance rewrite benchmarks.

- With fully labeled multi-turn Text-to-SQL data, our decouple parsing method outperforms all the released end-to-end multi-turn Text-to-SQL model.

2 Decoupled Parsing Framework

In this section, we elaborate our decoupled parsing framework, which consists of two phases: 1) an *utterance rewrite model* (Section 2.1), to generate semantic-completion question based on the dialogue context; 2) a *single-turn Text-to-SQL parser* (Section 2.2), which is fed with the rewritten question to predict the corresponding SQL query. To further improve the rewrite model performance, we propose a dual learning method to make use of large-scale unlabeled data, which is detailed in Section 3.

2.1 Phase-I: BART as Rewrite Model

We leverage the pretrained BART (Lewis et al., 2020), which is a Transformer-based encoder-decoder architecture, as the utterance rewrite model. This idea is inspired by its success on the text generation tasks, including question answering and summarization. Along with the success of pretrained language models, the Transformer architecture has been widely applied in natural language process (NLP) tasks. Transformer aims to encode a sequence $X = [x_i]_{i=1}^n$ with the *self-attention* mechanism (Vaswani et al., 2017). Assume that $[\mathbf{x}_i^{(l)}]_{i=1}^n$ is the representation of the sequence X at (l)-th Transformer layer. The next Transformer takes the following operations with H attention heads:

$$
\begin{aligned}
\alpha_{ij}^{(h)} &= \operatorname*{softmax}_j \left(\frac{\mathbf{x}_i^{(l)} \mathbf{W}_Q^{(h)} \left(\mathbf{x}_j^{(l)} \mathbf{W}_K^{(h)} \right)^\top}{\sqrt{d_z/H}} \right), \\
\mathbf{z}_i &= \Big\Vert_{h=1}^{H} \sum_{j=1}^{n} \alpha_{ij}^{(h)} \mathbf{x}_j^{(l)} \mathbf{W}_V^{(h)}, \\
\bar{\mathbf{x}}_i^{(l+1)} &= \mathrm{LN}\left(\mathbf{x}_i^{(l)} + \mathbf{z}_i \right), \\
\mathbf{x}_i^{(l+1)} &= \mathrm{LN}\left(\bar{\mathbf{x}}_i^{(l+1)} + \mathrm{FFN}\left(\bar{\mathbf{x}}_i^{(l+1)} \right) \right), \qquad (1)
\end{aligned}
$$

where h is the head index, d_z is the hidden dimension, $\alpha_{ij}^{(h)}$ is attention probability, $\Vert$ denotes the concatenation operation, $\mathrm{LN}(\cdot)$ is layer normalization (Ba et al., 2016) and $\mathrm{FFN}(\cdot)$ is a feed-forward network consists of two linear transformations.

Similar to other large-scale pretrained language models, BART also uses a standard Transformer-based sequence-to-sequence architecture, where the encoder is the bidirectional Transformer and the decoder is the auto-regressive Transformer. BART's pretraining method reconstructs the original text from its corrupted text. In its essence, BART is a denoising autoencoder, which is applicable to a very wide range of NLP tasks. In our utterance rewrite task, both the co-reference and information ellipses can be regarded as the corrupted noise of an utterance. Based on this idea, BART can be an appropriate method to denoise the co-reference and information ellipses. In addition, the rewrite data in the public multi-turn Text-to-SQL benchmarks are lacking. Therefore, we propose a dual learning method to learn a reliable rewrite model with large-scale unlabeled dialogue data. The details are introduced in Section 3.

2.2 Phase-II: RATSQL as Parsing Model

Given a natural language question and a schema for a relational database, the goal of Text-to-SQL parser is to generate the corresponding SQL query. Regarding the single-turn Text-to-SQL parsing model, we directly use the current state-of-the-art RATSQL model (Wang et al., 2020). RATSQL provides a unified framework, which is based on a relation-aware Transformer (RAT), to encode the question and the corresponding schema. The relation-aware Transformer is an important extension to the traditional transformer, which takes the input sequence as a labeled, directed, fully-connected graph. The pairwise relations between input elements are considered in RAT. RAT incorporates the relation information in Equation 1. The edge from element $\mathbf{x}_i$ to element $\mathbf{x}_j$ is represented by vector $\mathbf{r}_{ij}$, which is represented as biases incorporated in the Transformer layer, as follows:

$$\alpha_{ij}^{(h)} = \underset{j}{\operatorname{softmax}} \left(\frac{\mathbf{x}_i^{(l)} \mathbf{W}_Q^{(h)} \left(\mathbf{x}_j^{(l)} \mathbf{W}_K^{(h)} + \mathbf{r}_{ij} \right)^{\top}}{\sqrt{d_z / H}} \right),$$

$$\mathbf{z}_i = \Big\Vert_{h=1}^{H} \sum_{j=1}^{n} \alpha_{ij}^{(h)} \left(\mathbf{x}_j^{(l)} \mathbf{W}_V^{(h)} + \mathbf{r}_{ij} \right).$$

The relations among the Text-to-SQL input elements can be categorized into three types: intra-question, question-schema, and intra-schema. The intra-question relation means both tokens are the elements of the question. The question-schema relations are normally named by schema linking, which is used to represent the matching degree between the question token and the schema token. The intra-schema relations include the relation types of the relational database: primary key, foreign key, etc. However, these relations within the input elements are independent of the domain information of the database. Incorporating the domain-independent relations into the representation of the Text-to-SQL input is thus beneficial to the Text-to-SQL parser generation.

During decoding, the SQL query is first represented as an abstract syntax tree (AST) following a well-designed grammar. Followed by that, the AST is flattened as a sequence by the deep-first search (DFS) method. RATSQL uses the LSTM to generate the flattened AST sequence. The generated actions defined by the grammar has two structures: (1) it expands the last generated node into a grammar rule, called APPLYRULE or when completing a leaf node; (2) alternatively, it selects a column/table from the schema, called SELECTCOLUMN and SELECTTABLE.

3 Dual Learning for Utterance Rewrite

Due to the limitation of the in-domain annotated rewrite data, we propose a semi-supervised learning method via dual learning to make full use of the unlabeled multi-turn data to learn a reliable rewrite model. In this section, we first introduce the primal and dual tasks of the utterance rewrite. We then demonstrate the dual learning algorithm for utterance rewrite in detail, where a large amount of unlabeled utterance rewrite data participate in optimizing the primal and dual models under the dual learning framework.

3.1 Primal and Dual Tasks

In a conversation scenario, the co-reference and information ellipses are always present in the user's expressions (Androutsopoulos et al., 1995). Recently, Liu et al. (2020a) make a significant step to analyze the co-reference and ellipsis phenomenon at the fine-grained level. Co-reference has been divided into five types according to the existing pronoun: *Bridging Anaphora*, *Definite Noun Phrases*, *One Anaphora*, *Demonstrative Pronoun*, and *Possessive Determiner*. Ellipsis has been characterized by its intention: *Continuation* and *Substitution*. where the substitution can be further classified into 4 types: *explicit* vs. *implicit* and *schema* vs. *operator*. The detailed introduction of these fine-grained types refers to (Liu et al., 2020a).

The primal task aims to denoise the above co-reference and ellipsis and generate a semantic-completion utterance $c^{(t)} = [c^{(t,i)}]_{i=1}^{n}$ based on the utterance $x^{(t)} = [x^{(t,i)}]_{i=1}^{m}$ at the t-th turn and the dialogue history $h = [x^{(j)}]_{j=1}^{t-1}$. We directly use the pretrained BART as the rewrite model (named **rewriter**). We further concatenate the dialogue history and the latest utterance as the input of the rewriter, where they are separated by the special

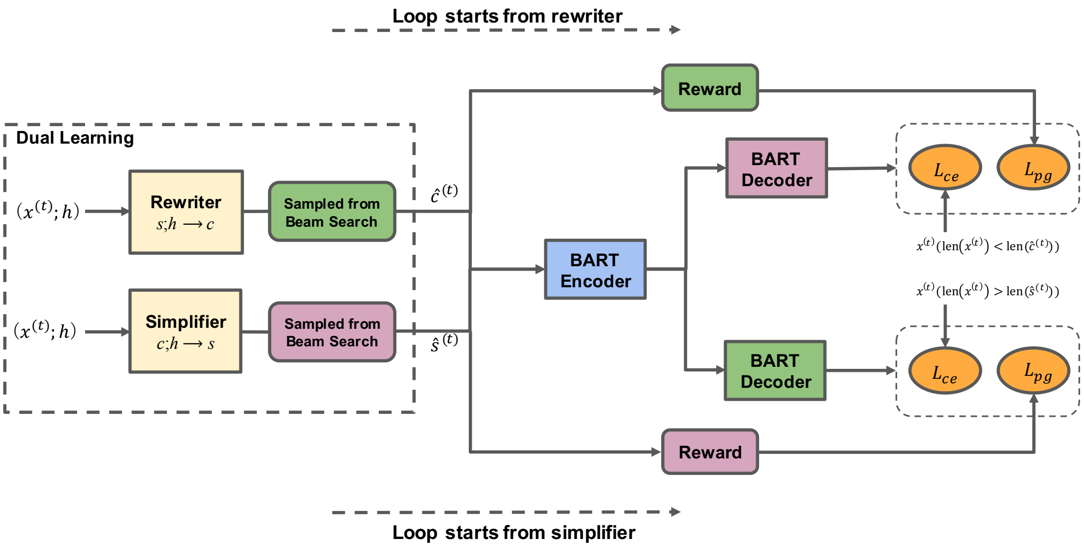

Figure 2: The dual learning architecture of the utterance rewrite task. Rewriter and Simplifier represent the dual models: rewrite model and simplification model. Both two models are initiated by pretrained BART. During the dual learning closed-loop game, two models are updated by policy gradient loss (L_{pg}) and cross-entropy loss (L_{ce}).

token "</s>". The dual task is to generate a simplified expression based on the latest utterance and the dialogue history. The simplified expression contains the above co-reference and ellipsis as more as possible without changing the original semantic meaning of the dialogue. Similar to the rewriter, we use the pretrained BART as the initial simplification model (named **simplifier**).

3.2 Dual Learning Algorithm

Under the dual learning framework, the dual models can be regarded as two agents in a closed-loop game. The game starts with one of the dual agents. The output of the start agent will be scored by an external reward function. Since the reward feedback is non-differentiable, the start agent is optimized by the policy gradient method (Sutton et al., 1999). The end agent is fed with the output of the start agent, where the end agent aims to reconstruct the initial input of the start agent. Thus, the end agent can be optimized by maximum likelihood estimation (MLE). Before deep-diving into the dual learning algorithm, we first introduce the definitions of the dual framework for the utterance rewrite.

3.2.1 Definition

Suppose we have unlabeled dialogue data $\mathcal{D}_u = \{(x^{(t)}; h)\}$. There are two dual models: rewriter with parameter Θ_c and simplifier with parameter Θ_s. Two language models ($\mathrm{LM}_c(\cdot)$ and $\mathrm{LM}_s(\cdot)$) are used to evaluate the quality of the generated utterances by rewriter and simplifier respectively. Both two language models are fine-tuned from GPT-2 model (Radford et al., 2019). $\mathrm{LM}_c(\cdot)$ is trained with semantic-completion Spider dataset. $\mathrm{LM}_s(\cdot)$ is trained from multi-turn Text-to-SQL data (SParC and CoSQL), where the utterances at the first turn are removed. There is an external single-turn Text-to-SQL parser $\mathrm{RATSQL}(\cdot)$, which parses a question into a SQL query. Next, we will introduce the strategy of agent optimization under dual learning framework.

3.2.2 Loop Starts from Rewriter

As shown in Fig. 2, we sample an unlabeled dialogue data $(x^{(t)}; h)$ from $\mathcal{D}_u$. The rewriter generates k possible rewritten formats $[\hat{c}_i^{(t)}]_{i=1}^k$ with beam search mechanism. There are two-level external reward functions to evaluate the quality of generated $\hat{c}_i^{(t)}$: token-level reward and sentence-level reward.

Token-level Reward To reserve the schema information of the database mentioned in original utterance $x^{(t)}$, the generated token $\hat{c}_i^{(t,j)}$ will get $+0.1$ reward at j-th step when it is database-related token mentioned in $x^{(t)}$. To decrease the co-reference phenomenon in the rewritten utterance, we punish the generated pronoun words (e.g., it, their, and so on) with -0.1. Otherwise, the generated tokens will get zero points.

Sentence-level Reward We first use the pretrained language model $\mathrm{LM}_c(\cdot)$ to evaluate the quality of the rewritten utterance with $r_{\mathrm{LMc}} = \log(\mathrm{LM}_c(\hat{c}_i^{(t)}))/\mathrm{len}(\hat{c}_i^{(t)})$, where $\mathrm{len}(\hat{c}_i^{(t)})$ denotes the number of the tokens in $\hat{c}_i^{(t)}$. In practice, the rewritten utterance $\hat{c}_i^{(t)}$ can be directly evaluated by the user, who does not need any SQL background. The user can give an indicated score (0 or 1) to evaluate whether $\hat{c}_i^{(t)}$ meets his/her real intent. Instead, we feed the rewritten utterance $\hat{c}_i^{(t)}$ into Text-to-SQL parser and get the corresponding SQL query with $\hat{q} = \mathrm{RATSQL}(\hat{\mathrm{c}}_{\mathrm{i}}^{(\mathrm{t})})$. If $\hat{q}$ equals to the golden SQL, we can say the rewritten utterance meets the user's intent ($r_{\mathrm{u}} = 1$) and vise versa ($r_{\mathrm{u}} = 0$). The final sentence-level reward of $\hat{c}_i^{(t)}$ is represented as $r_i^c = r_{\mathrm{LMc}} + r_{\mathrm{u}}$.

For the j-th token in the rewritten utterance $\hat{c}_i^{(t)}$, its accumulated reward can be represented as $R_i^{(t,j)} = r_i^{(t,j)} + \sum_{l=j+1}^{m} \lambda^{l-j} r_i^{(t,l)}$, where λ is discount rate, $r_i^{(t,j)}$ means the j-th token reward of the rewritten utterance and the final token reward equals to the sentence-level reward $r_i^{(t,m)} = r_i^c$. The rewriter can be optimized by policy gradient method as:

$$L_{pg}(\Theta_c) = -\sum_{i,j=1}^{k,m} R_i^{(t,j)} \log\left(P(\hat{c}_i^{(t,j)} | (x^{(t)}; h); \Theta_c)\right).$$

To force the simplifier to reconstruct the original input $x^{(t)}$ as similar as possible, the simplifier can be optimized with maximum likelihood estimation (MLE) as:

$$L_{ce}(\Theta_s) = -\log\left(P(x^{(t)} | (\hat{c}_i^{(t)}; h); \Theta_s)\right).$$

Noting that $x^{(t)}$ could be a semantic-completion utterance. It is not reasonable to force the simplifier to reconstruct a semantic-completion utterance. Thus, we first compare the length of the original utterance $\mathrm{len}(x^{(t)})$ with the length of the rewritten one $\mathrm{len}(\hat{c}_i^{(t)})$. Only when $\mathrm{len}(x^{(t)}) < \mathrm{len}(\hat{c}_i^{(t)})$, we optimize the simplifier with MLE.

3.2.3 Loop Starts from Simplifier

As shown in Fig. 2, we also sample an unlabeled dialogue data $(x^{(t)}; h)$ from $\mathcal{D}_u$. The simplifier generates k possible simplified formats $[\hat{s}_i^{(t)}]_{i=1}^k$ with beam search mechanism evaluated by two-level external reward functions.

Token-level Reward To decrease the schema information mentioned in original utterance $x^{(t)}$, the generated token $\hat{s}_i^{(t,j)}$ will get -0.1 punishment at j-th step when it is database-related token mentioned in $x^{(t)}$ and history h. To encourage the co-reference phenomenon in the simplified utterance, we award the pronoun words with $+0.1$ reward. Otherwise, the generated tokens will get zero points.

Sentence-level Reward We only use the pre-trained language model $\mathrm{LM}_s(\cdot)$ to evaluate the quality of the simplified utterance with $r_{\mathrm{LMs}} = \log(\mathrm{LM}_s(\hat{s}_i^{(t)}))/\mathrm{len}(\hat{s}_i^{(t)})$, where $\mathrm{len}(\hat{s}_i^{(t)})$ denotes the number of the tokens in $\hat{s}_i^{(t)}$.

For the j-th token in the simplified utterance $\hat{s}_i^{(t)}$, its accumulated reward is represented as $R_i^{(t,j)} = r_i^{(t,j)} + \sum_{l=j+1}^{m} \lambda^{l-j} r_i^{(t,l)}$, where $r_i^{(t,j)}$ means the j-th token reward of the simplified utterance and the final token reward equals to the sentence-level reward $r_i^{(t,m)} = r_{\mathrm{LMs}}$. Similar to the first loop in Section 3.2.2, the simplifier and the rewriter can be optimized with policy gradient method and MLE respectively:

$$L_{pg}(\Theta_s) = -\sum_{i,j=1}^{k,m} R_i^{(t,j)} \log\left(P(\hat{s}_i^{(t,j)} | (x^{(t)}; h); \Theta_s)\right),$$

$$L_{ce}(\Theta_c) = -\log\left(P(x^{(t)} | (\hat{s}_i^{(t)}; h); \Theta_c)\right).$$

Noting that only when $\mathrm{len}(x^{(t)}) > \mathrm{len}(\hat{s}_i^{(t)})$, we optimize the rewriter with MLE.

4 Experiments

Series of experiments are conducted to validate our proposed utterance rewrite model and the decoupled framework. We first validate the pretrained BART's performance on the utterance rewrite benchmarks. Then, the multi-turn Text-to-SQL with the decoupled parsing method (DELTA) are experimented on the limited utterance rewrite data. Finally, we analyze the interpretability of the decoupled parsing method through the case study.

4.1 Experimental Setup

Datasets&Metrics Our proposed rewrite model is validated on two utterance rewrite datasets: TASK (Quan et al., 2019) and CANARD (Elgohary et al., 2019a). We employ the widely used automatic metrics BLEU, ROUGE, EM (Exact Match) and rewrite F-score as our evaluation metrics. **BLEU**$_n$(**B**$_n$) and **ROUGE**$_n$(**R**$_n$) are used to calculate the similarity and the overlapping at the n-grams level between predictions and golden

Table 2: The question match accuracy and interaction match accuracy on SParC and CoSQL datasets. Since the test datasets are not public, RichContext has not evaluated by the dataset owner.

ones. **EM** means the exact match rate, where the prediction exactly equals to the golden. Rewrite F-score $\mathcal{F}_n$ is calculated on the collection of n-grams that contain at least one word from the context. Our decoupled parsing method is evaluated on two multi-turn Text-to-SQL tasks: SParC and CoSQL. Following (Yu et al., 2019b), with **Question Match** and **Interaction Match** as the metrics. Question match means the predicted SQL equals the golden one for each question, while Interaction match indicates the predicted SQL queries of all the questions in an interaction are correct.

Implementation Details Our implementation is based on PyTorch (Paszke et al., 2019) and HuggingFace's (Wolf et al., 2020) Transformers library. We reproduce RATSQL with the same setup presented in (Wang et al., 2020), where the encoder consists of eight relation-aware Transformer (RAT) layers. When fine-tuning the BARTs (rewriter and simplifier) on the utterance rewrite datasets, we use the AdamW as the optimizer with the learning rate 2e-6. At the dual learning and co-training period, we set the learning rate as 1e-6. Specifically, BARTs mentioned above refer to $\mathrm{BART}_{\mathrm{large}}$. The discount rate λ in the dual learning method is 1.

4.2 Experimental Results

4.2.1 BART as Rewrite Model

For the rewrite task, we compared the pretrained BART with state-of-the-art rewrite models: L-Ptr-Gen (See et al., 2017), GECOR (Quan et al., 2019), and RUN (Liu et al., 2020b). Table 1 shows the experimental results on TASK and CANARD datasets. As indicated, using the BART as rewrite model surpasses the best baseline RUN by a large margin on all the metrics. Even for the most challenging metric **EM**, the BART exceeds the previous best model by 5.0 points on TASK. The BART also obtains a large boost on CANARD, which improves the state-of-the-art by 4.1 points and 6.8 points on B_4 and R_L respectively. The above experimental results demonstrate the superiority of the BART as the rewrite model.

4.2.2 DELTA for Decoupled Parsing

Regarding the multi-turn Text-to-SQL task, we compared the decoupled parsing method with all the released end-to-end multi-turn Text-to-SQL models: EditSQL (Zhang et al., 2019), RichContext (Liu et al., 2020a), IGSQL (Cai and Wan, 2020), and R^2SQL (Hui et al., 2021).

Since there is no utterance rewrite data on SParC and CoSQL datasets, we randomly sample 10% dialogues on these two datasets and annotate them as the rewrite in-domain data. There are 741 annotated turns and 695 annotated turns on SParC and CoSQL respectively. At the Phase-I, we first use the rewrite in-domain data to warm-up the rewrite model and simplification model, where their encoders share the parameters inspired by (Lample et al., 2018). Then, we use the rest of 90% di-

Precedent Question	Current Question	Rewritten Question	Predicted SQL	Status
how many people live in asia ?	what about the largest gnp among them ?	~~how many people live~~ what is the country in asia that is the largest gnp ~~among them~~ ?	SELECT country.Population FROM country WHERE country.Continent= 'value' ORDER BY country.GNP ESC LIMIT 1	Fail in Phase-I

alogues as unlabeled data to further improve the rewrite model with the dual learning method, detailed in Section 3. At the Phase-II, we first use the single-turn Text-to-SQL data (Spider) to warm-up the RATSQL parser. Since there is an annotation gap[1] between Spider and multi-turn Text-to-SQL datasets, we use the annotated Text-to-SQL data on the SParC and CoSQL to fine-tune the pretrained RATSQL parser, where the multi-turn dialogue data are rewritten as single-turn data by the rewrite model trained in Phase-I. Table 2 shows that our proposed decoupled framework (DELTA+Dual) gets a considerable performance boost on SParC and CoSQL datasets.

4.2.3 Ablation Study

We conducted an ablation study to analyze the contribution of our proposed decoupled parsing framework on the SParC dataset. To compare with our proposed dual learning method on rewrite task, we examined another semi-supervised learning method co-training (Blum and Mitchell, 1998), which uses the pretrained rewrite model to annotate the unlabeled data and add these pseudo-labeled data to improve the original rewrite model iteratively. To fairly compare with the dual learning method, we only use the pseudo labeled rewrite data that are correctly predicted by the RATSQL parser at each iteration of the co-training method. As shown in Table 4, our proposed dual learning method outperforms the co-training method at row (1). To further validate the effect of the dual learning method, we remove the dual learning part in the Phase-I. Compared with our adapted dual learning method at row (2), the above two variants have a significant performance degradation, which demonstrates the superiority of the dual learning method on rewrite task.

Compared with the end-to-end multi-turn Text-to-SQL models, our proposed decoupled parsing framework even does not require any annotated multi-turn in-domain data. We first evaluate the performance of the decoupled method without any Text-to-SQL parsing in-domain data at row (3). There are 3.9 points and 4.1 points degradation on question match accuracy and interaction match accuracy respectively, which is caused by the annotation gap between Spider and SParC. We further drop our annotated rewrite in-domain data at row (4) and warm-up the rewrite model and simplification model with TASK and CANARD datasets. As shown in Table 4, we can find the decoupled parsing framework still gets 42.1% question match accuracy without any annotated multi-turn in-domain data. Lastly, we just remove the Phase-I (rewrite

---

[1] For example, "Tell me how many rooms cost more than 120, for each different decor." is annotated as "SELECT decor, count(*) FROM Rooms WHERE basePrice > 120 GROUP BY decor" in SParC. It is tend to be annotated as "SELECT count(*) FROM Rooms WHERE basePrice > 120 GROUP BY decor" in Spider.

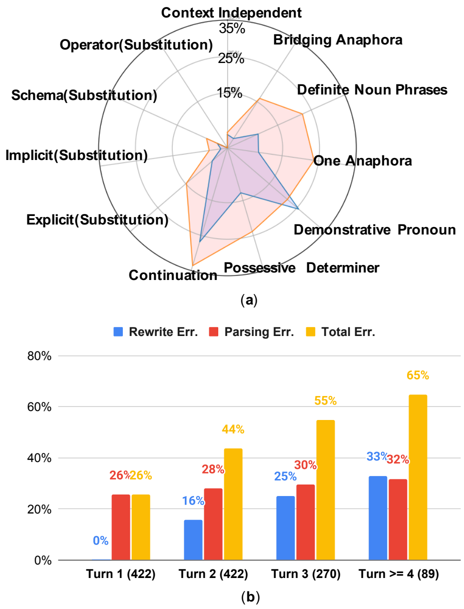

Figure 3: The rewrite error analysis (**a**) in the fine-grained level and the error rate of the two decoupled models (**b**) at turn-wise level.

model) at row (5), where the RATSQL parser is trained on Spider and fine-tuned with multi-turn Text-to-SQL data. It can be regarded as the baseline of all the ablations, which only gets 34.5% question match accuracy.

4.3 Case Analysis

Compared with end-to-end multi-turn Text-to-SQL models, our decoupled parser can generate the intermediate rewritten utterance, which is easier to understand for the user than a SQL query. As introduced in Section 3.2.2, the feedback of the user can be used to optimize the rewrite model. Additionally, our decoupled parser is more convenient in data collection compared with end-to-end methods, which does not require annotators' familiarization with SQL to rewrite an utterance. When collecting single-turn Text-to-SQL data, the annotator does not need to consider the dialogue context. It is also costly to collect the dialogue data on the SQL query task.

Table 3 displays three cases parsed by our proposed decoupled method. We can pinpoint exactly which phase the error occurred under decoupled parsing framework. Through fine-grained error analysis, the bottleneck of multi-turn parser can be found accurately. Thus, we can target to optimize the bottleneck individually. Figure 3(**a**) shows the error rate of the utterance rewrite model (DELTA+Dual) on SParC development dataset at a fine-grained level. The orange line denotes the error rate on the individual co-reference or ellipsis type. The blue line denotes the overall error ratio. We can see that most rewrite errors happen on the co-reference side, especially at *Demonstrative Pronoun* type. For the ellipsis, *Continuation* type is a serious problem. Figure 3(**b**) shows the error ratios that happen in the rewrite model (Phase-I) or in the parsing model (Phase-II). We can find that at the first three turns the parsing model is still the bottleneck. After the third turn, the rewrite model gets a bigger error rate. The error rate of the rewrite model is more sensitive than the parser with turn increased. We can conclude that we need more annotated rewrite data, especially with *Continuation* type and *Demonstrative Pronoun* type.

5 Related Work

Utterance Rewrite Recently, the utterance rewrite has raised large attention. Some works use the sequence-to-sequence architecture with copy mechanism (Elgohary et al., 2019b; Quan et al., 2019; Rastogi et al., 2019) to solve the incomplete question problem. Liu et al. (2019) decompose the utterance rewrite model as two-phase subtasks: split and recombine. The split and recombine models are both learned from the well-designed reward function by the policy gradient method. Borrowing the idea from image segmentation, Liu et al. (2020b) formulate the utterance rewrite as the semantic segmentation task, where the rewrite model is implemented with UNet (Ronneberger et al., 2015). For the downstream task, the utterance rewrite has been successfully used in dialogue state tracking (DST) tasks (Rastogi et al., 2019; Han et al., 2020). Yu et al. (2020a) propose a rule-based and self-supervised learning method to generate weakly-supervised rewrite data, which are used to fine-tune GPT-2. Different from the previous works, we directly use the pretrained BART, which is a denoising autoencoder, as the utterance rewrite model.

End-to-End Text-to-SQL Parser EditSQL (Zhang et al., 2019) proposes an Edit-based model that reuses the SQL query generated from the previous step to alleviate the pressure of the increasing turns. RichContext (Liu et al., 2020a) conducts an exploratory study on semantic parsing in context and performs a fine-grained analysis. IGSQL (Cai and Wan, 2020) presents a schema interaction graph encoder to capture the historical information of database schema items. R^2SQL (Hui et al., 2021) presents a dynamic graph framework that employs dynamic memory decay mechanisms to introduce inductive bias to construct enriched contextual relation representation at both utterance and token level.

Dual Learning Dual learning method is first proposed to improve neural machine translation (NMT) (He et al., 2016). The dual learning mechanism enables a pair of dual systems to automatically learn from unlabeled data through a closed-loop game. The idea of dual learning has been applied into various tasks, such as Question Answer (Tang et al., 2017)/Generation (Tang et al., 2018), Image-to-Image Translation (Yi et al., 2017), Open-domain Information Extraction/Narration (Sun et al., 2018), Text Simplification (Zhao et al., 2020), Semantic Parsing (Cao et al., 2019; Zhu et al., 2020a; Cao et al., 2020) and dialogue state tracking (Chen et al., 2020c).

6 Conclusion and Future Work

In this paper, we propose a decoupled parsing framework (DELTA+Dual) to solve the multi-turn Text-to-SQL task. The previous end-to-end multi-turn Text-to-SQL models rely on large-scale multi-turn data. DELTA can achieve considerable performance without any multi-turn Text-to-SQL data. We adapt the pretrained BART as the rewrite model and achieve new state-of-the-art performance on the utterance rewrite benchmarks. We further propose an efficient dual learning method to make full use of unlabeled dialogue data. On the challenging multi-turn Text-to-SQL benchmarks, DELTA surpasses all the released end-to-end models with fully labeled data. In the future, we will try to reformulate the decoupled parsing method as a multitask, where the rewrite model and Text-to-SQL model are trained simultaneously. The proposed DELTA is also easy to extend to the other conversational semantic parsing tasks, like dialogue state tracking (Chen et al., 2020b; Zhu et al., 2020b; Chen et al., 2020a).

Abstract

Relational fact extraction aims to extract semantic triplets from unstructured text. In this work, we show that all of the relational fact extraction models can be organized according to a graph-oriented analytical perspective. An efficient model, a**D**jacency l**I**st o**R**iented r**E**lational fa**CT** (**DIRECT**), is proposed based on this analytical framework. To alleviate challenges of error propagation and sub-task loss equilibrium, DIRECT employs a novel adaptive multi-task learning strategy with dynamic sub-task loss balancing. Extensive experiments are conducted on two benchmark datasets, and results prove that the proposed model outperforms a series of state-of-the-art (SoTA) models for relational triplet extraction.

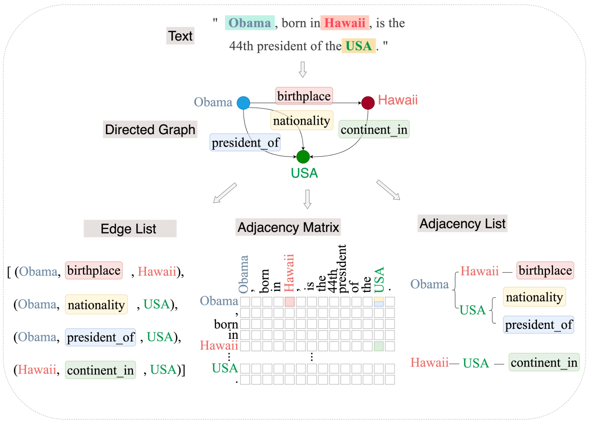

Figure 1: Example of exploring the relational fact extraction task from the perspective of directed graph representation method as output data structure.

1 Introduction

Relational fact extraction, as an essential NLP task, is playing an increasingly important role in knowledge graph construction (Han et al., 2019; Distiawan et al., 2019). It aims to extract relational triplet from the text. A relational triplet is in the form of $(subject, relation, object)$ or (s, r, o) (Zeng et al., 2019). While various prior models proposed for relational fact extraction, few of them analyze this task from the perspective of output data structure.

As shown in Figure 1, the relational fact extraction can be characterized as a directed graph construction task, where graph representation flexibility and heterogeneity accompany additional benefaction. In practice, there are three common ways to represent graphs (Gross and Yellen, 2005):

Edge List is utilized to predict a sequence of triplets (edges). The recent sequence-to-sequence based models, such as NovelTagging (Zheng et al., 2017), CopyRE (Zeng et al., 2018), CopyRL (Zeng et al., 2019), and PNDec (Nayak and Ng, 2020), fall into this category.

Edge list is a simple and space-efficient way to represent a graph (Arifuzzaman and Khan, 2015). However, there are three problems. First, the triplet overlapping problem (Zeng et al., 2018). For instance, as shown in Figure 1, for triplets (Obama, nationality, USA) and (Obama, president_of, USA), there are two types of relations between the "Obama" and "USA". If the model only generates one sequence from the text (Zheng et al., 2017), it may fail to identify the multi-relation between entities. Second, to overcome the triplet overlapping problem, the model may have to extract the triplet element repeatedly (Zeng et al., 2018), which will increase the extraction cost. Third, there could be an ordering problem (Zeng et al., 2019): for multiple triplets, the extraction order could influence the model performance.

Adjacency Matrices are used to predict matrices that represent exactly which entities (vertices) have semantic relations (edges) between them. Most early works, which take a pipeline ap-

proach (Zelenko et al., 2003; Zhou et al., 2005), belong to this category. These models first recognize all entities in text and then perform relation classification for each entity pair. The subsequent neural network-based models (Bekoulis et al., 2018; Dai et al., 2019), that attempt to extract entities and relations jointly, can also be classified into this category.

Compared to edge list, adjacency matrices have better relation (edge) searching efficiency (Arifuzzaman and Khan, 2015). Furthermore, adjacency matrices oriented models is able to cover different overlapping cases (Zeng et al., 2018) for relational fact extraction task. But the space cost of this approach can be expensive. For most cases, the output matrices are very sparse. For instance, for a sentence with n tokens, if there are m kinds of relations, the output space is $n \cdot n \cdot m$, which can be costly for graph representation efficiency. This phenomenon is also illustrated in Figure 1.

Adjacency List is designed to predict an array of linked lists that serves as a representation of a graph. As depicted in Figure 1, in the adjacency list, each vertex v (key) points to a list (value) containing all other vertices connected to v by several edges. Adjacency list is a hybrid graph representation between edge list and adjacency matrices (Gross and Yellen, 2005), which can balance space and searching efficiency[1]. Due to the structural characteristic of the adjacency list, this type of model usually adopts a cascade fashion to identify subject, object, and relation sequentially. For instance, the recent state-of-the-art model CasRel (Wei et al., 2020) can be considered as an exemplar. It utilizes a two-step framework to recognize the possible object(s) of a given subject under a specific relation. However, CasRel is not fully adjacency list oriented: in the first step, it use $subject$ as the key; while in the second step, it predicts $(relation, object)$ pairs using adjacency matrix representation.

Despite its considerable potential, the cascade fashion of adjacency list oriented model may cause problems of sub-task error propagation (Shen et al., 2019), i.e., errors from ancestor sub-tasks may accumulate to threaten downstream ones, and subtasks can hardly share supervision signals. Multitask learning (Caruana, 1997) can alleviate this problem, however, the sub-task loss balancing problem (Chen et al., 2018; Sener and Koltun, 2018) could compromise its performance.

Based on the analysis from the perspective of output data structure, we propose a novel solution, a**D**jacency l**I**st o**R**iented r**E**lational fa**CT** extraction model (**DIRECT**), with the following advantages:

- For efficiency, DIRECT is a fully adjacency list oriented model, which consists of a shared BERT encoder, the Pointer-Network based subject and object extractors, and a relation classification module. In Section 3.4, we provide a detailed comparative analysis[2] to demonstrate the efficiency of the proposed method.

- From the performance viewpoint, to address sub-task error propagation and sub-task loss balancing problems, DIRECT employs a novel adaptive multi-task learning strategy with the dynamic subtask loss balancing approach. In Section 3.2 and 3.3, the empirical experimental results demonstrate DIRECT can achieve the state-of-the-art performance of relational fact extraction task, and the adaptive multi-task learning strategy did play a positive role in improving the task performance.

The major contributions of this paper can be summarized as follows:

1. We refurbish the relational fact extraction problem by leveraging an analytical framework of graph-oriented output structure. To the best of our knowledge, this is a pioneer investigation to explore the output data structure of relational fact extractions.

2. We propose a novel solution, DIRECT[3], which is a fully adjacency list oriented model with a novel adaptive multi-task learning strategy.

3. Through extensive experiments on two benchmark datasets[3], we demonstrate the efficiency and efficacy of DIRECT. The proposed DIRECT outperforms the state-of-the-art baseline models.

2 The DIRECT Framework

In this section, we will introduce the framework of the proposed DIRECT model, which includes a shared BERT encoder and three output layers: subject extraction, object extraction, and relation classification. As shown in Figure 2, DIRECT is fully adjacency list oriented. The input sentence is firstly fed into the subject extraction module to

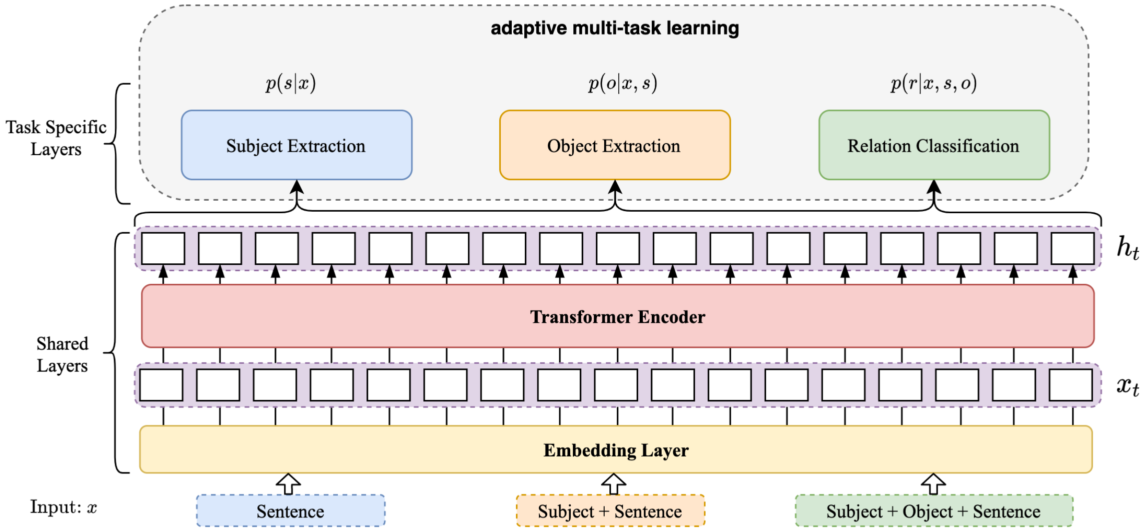

Figure 2: An overview of the proposed DIRECT framework

extract all subjects. Then each extracted subject is concatenated with the sentence, and fed into the object extraction module to extract all objects, which can form a set of subject-object pairs. Finally, the subject-object pair is concatenated with sentence, and fed into the relation classification module to get the relations between them. For balancing the weights of sub-task losses and to improve the global task performance, three modules share the BERT encoder layer and are trained with an adaptive multi-task learning strategy.

2.1 Shared BERT Encoder

In the DIRECT framework, the encoder is used to extract the semantic features from the inputs for three modules. As aforementioned, we employ the BERT (Devlin et al., 2019) as the shared encoder to make use of its pre-trained knowledge and attention mechanism.

The architecture of the shared method is shown in Figure 2. The lower embedding layer and transformers (Vaswani et al., 2017) are shared across all the three modules, while the top layers represent the task-specific outputs.

The encoding process is as follows:

$$\mathbf{h}^t = \text{BERT}(\mathbf{x}^t) \tag{1}$$

where $\mathbf{x}^t = [w_1, ..., w_n]$ is the input text of task t and $\mathbf{h}^t$ is the hidden vector sequence of the input. Due to the limited space, the detailed architecture of BERT please refer to the original paper (Devlin et al., 2019).

2.2 Subject and Object Extraction

The subject and object extraction modules are motivated by the Pointer-Network (Vinyals et al., 2015) architecture, which are widely used in Machine Reading Comprehension (MRC) (Rajpurkar et al., 2016) task. Different from MRC task that only needs to extract a single span, the subject and object extractions need to extract multiple spans. Therefore, in the training phase, we replace $softmax$ function with $sigmoid$ function for the activation function of the output layer, and replace cross entropy (CE) (Goodfellow et al., 2016) with binary cross entropy (BCE) (Luc et al., 2016) for the loss function. Specifically, we will perform independent binary classifications for each token twice to indicate whether the current token is the start or the end of a span. The probability of a token to be start or end is as follows:

$$p^t_{i,\text{start}} = \sigma(\mathbf{W}^t_{\text{start}} \cdot h_i + \mathbf{b}^t_{\text{start}}) \tag{2}$$

$$p^t_{i,\text{end}} = \sigma(\mathbf{W}^t_{\text{end}} \cdot h_i + \mathbf{b}^t_{\text{end}}) \tag{3}$$

where h_i represents the hidden vector of the i_{th} token, $t \in [s, o]$ represents subject and object extraction respectively, $\mathbf{W}^t \in \mathbb{R}^{h\times 1}$ represents the trainable weight, $\mathbf{b}^t \in \mathbb{R}^1$ is the bias and σ is $sigmoid$ function.

During inference, we first recognize all the start positions by checking if the probability $p^t_{i,\text{start}} > \alpha$, where α is the threshold of extraction. Then, we identify the corresponding end position with the largest probability $p^t_{i,\text{end}}$ between two neighboring start positions. Concretely, assuming $\text{pos}_{j,\text{start}}$ is the start position of the j_{th} span, the corresponding end position is:

$$\text{pos}_{j,\text{end}} = \underset{\text{pos}_{j,\text{start}} <= i < \text{pos}_{j+1,\text{start}}}{\text{argmax}} \; p^t_{i,\text{end}} \tag{4}$$

Though the overall structure is similar, the inputs for subject and object extraction are different. When extracting the subject, only the original sentence needs to be input:

$$\mathbf{x} = [w_1, ..., w_n] \tag{5}$$

$$\text{input}^s = [[\text{cls}], \mathbf{x}, [\text{sep}]] \tag{6}$$

where w_i represents the i_{th} token of the original sentence.

Meanwhile, the object extraction is based on the corresponding subject. To form the input, the subject s and the original sentence x are concatenated with $[sep]$ as follows:

$$\text{input}^o = [[\text{cls}], s, [\text{sep}], \mathbf{x}, [\text{sep}]] \tag{7}$$

2.3 Relation classification

The output layer of relation classification is relatively simple, which is a normal multi-label classification model. The $[cls]$ vector obtained by BERT encoder is used as the sentence embedding. A fully connected layer is used for the nonlinear transformation, and perform multi-label classification to predict relations of the input subject-object pair. The detailed operations of relation classification are as follows:

$$\mathbf{P}^r = \sigma(\mathbf{W}^r \cdot h_{[\text{cls}]} + \mathbf{b}^r) \tag{8}$$

where $\mathbf{P}^r \in \mathbb{R}^c$ is the predicted probability vector of relations, σ is $sigmoid$ function, $\mathbf{W}^r \in \mathbb{R}^{h \times c}$ and $\mathbf{b}^r \in \mathbb{R}^c$ are the trainable weights and bias, h is the hidden size of encoder, c is the number of relations, and $h_{[\text{cls}]}$ denotes the hidden vector of the first token [cls]. The input for relation classification task is as follows:

$$\text{input}^r = [[\text{cls}], s, [\text{sep}], o, [\text{sep}], \mathbf{x}, [\text{sep}]] \tag{9}$$

2.4 Adaptive Multi-task Learning

In DIRECT, subject extraction module, object extraction module, and relation classification module can be considered as three sub-tasks. As aforementioned, if we train each module directly and separately, the error propagation problem would reduce the task performance. Meanwhile, three independent encoders would consume more memory. Therefore, we use multi-task learning to alleviate this problem, and the encoder layer is shared across three modules.

Algorithm 1: Adaptive Multi-task Learning with Dynamic Loss Balancing

```
Initialize model parameters $\Theta$ randomly;
Load pre-trained BERT parameters for
  shared encoder;
Prepare the data for each task $t$ and pack
  them into mini-batch: $D^t$, $t \in [s, o, r]$ ;
Get the number of batch for each task: $n^t$;
Set the number of epoch for training:
  $epoch_{max}$;
for $epoch$ in $1, 2, ..., epoch_{max}$ do
    1. Merge all the datasets:
      $D = D^s \cup D^o \cup D^r$;
    2. Shuffle D;
    3. Initialize EMA for each task $v^t = 1$
      and its decay $\epsilon = 0.99$ ;
    for $b^t$ in $D$ do
        // $b^t$ is a mini-batch of $D^t$ ;
        4. Compute loss: $l^t(\Theta)$ ;
        5. Update EMA:
          $v^t = (1 - \epsilon) \cdot \sum(l^t) + \epsilon \cdot v^t$ ;
        6. Calculate and normalize the
          weights: $w^t = (v^t/n^t)/(v^r/n^r)$ ;
        7. Update model $\Theta$ with gradient:
          $\nabla(w^t \cdot \bar{l}^t)$ ;
    end
end
```

However, applying multi-task learning could be challenging in DIRECT, due to the following problems:

- The input and output of the three modules are different, which means we cannot simply sum up the loss of each task.

- How should we balance the weights of losses for three sub-task modules?

These issues can affect the final results of multi-task training (Shen et al., 2019; Sener and Koltun, 2018).

In this work, based on the architecture of MT-DNN (Liu et al., 2019b), we propose a novel adaptive multi-task learning strategy to address the above problems. The algorithm is shown as Algorithm 1. Basically, the datasets are firstly split into mini-batches. A batch is then randomly sampled to calculate the loss. The parameters of the shared encoder and its task-specific layer are updated accordingly. Especially, the learning effect of each task t is different and dynamically changing during training. Therefore, an approach of adaptively adjusting the weights of task losses is applied. The sum of sub-task's loss $\sum l^t$ is utilized to approximate its optimization effect. The adaptive weight adjusting strategy ensures that the more room a sub-task has to be optimized, the more weight its loss will receive. Furthermore, an exponential moving average (EMA) (Lawrance and Lewis, 1977) is maintained to avoid the drastic fluctuations of loss weights. Last but not least, to make sure that each task has enough influence on the shared encoder, the weight of the sub-task will be penalized according to the training data amount of each sub-task.

3 Experiments

3.1 Dataset and Experiment Setting

Datasets. Two public datasets are used for evaluation: **NYT** (Riedel et al., 2010) is originally produced by the distant supervision approach. There are 1.18M sentences with 24 predefined relation types in NYT. **WebNLG** (Gardent et al., 2017) is originally created for Natural Language Generation (NLG) tasks. (Zeng et al., 2018) adopts this dataset for relational triplet extraction task. It contains 246 predefined relation types. There are different versions of these two datasets. To facilitate comparison evaluation, we use the datasets released by (Zeng et al., 2018) and follow their data split rules.

Besides the basic relational triplet extraction, recent studies are focusing on the relational triplet overlapping problem (Zeng et al., 2018; Wei et al., 2020). Follow the overlapping pattern definition of relational triplets (Zeng et al., 2018), the sentences in both datasets are divided into three categories, namely, Normal, EntityPairOverlap (EPO), and SingleEntityOverlap (SEO). The statistics of the two datasets are described in Table 1.

Category	NYT		WebNLG	
	Train	Test	Train	Test
Normal	37013	3266	1596	246
EPO	9782	978	227	26
SEO	14735	1297	3406	457
ALL	56195	5000	5019	703

Table 1: Statistics of Dataset NYT and WebNLG. Note that a sentence can belong to both EPO class and SEO class.

Baselines: the following strong state-of-the-art (SoTA) models have been compared in the experiments.

- NovelTagging (Zheng et al., 2017) introduces a tagging scheme that transforms the joint entity and relation extraction task into a sequence labeling problem. It can be considered as edge list oriented.
- CopyRE (Zeng et al., 2018) is a seq2seq based model with the copy mechanism, which can effectively extract overlapping triplets. It has two variants: CopyRE$_{\text{one}}$ employs one decoder; CopyRE$_{\text{mul}}$ employs multiple decoders. CopyRE is also edge list oriented.
- GraphRel (Fu et al., 2019) is a GCN (graph convolutional networks) (Kipf and Welling, 2017) based model, where a relation-weighted GCN is utilized to learn the interaction between entities and relations. It is a two phases model: GraphRel$_{\text{1p}}$ denotes 1st-phase extraction model; GraphRel$_{\text{2p}}$ denotes full extraction model. GraphRel is adjacency matrices oriented.
- CopyRL (Zeng et al., 2019) combines the reinforcement learning with a seq2seq model to automatically learn the extraction order of triplets. CopyRL is edge list oriented.
- CasRel (Wei et al., 2020) is a cascade binary tagging framework, where all possible subjects are identified in the first stage, and then for each identified subject, all possible relations and the corresponding objects are simultaneously identified by a relation specific tagger. This work recently achieves the SoTA results. As aforementioned, CasRel is partially adjacency list oriented.

Evaluation Metrics: following the previous work (Zeng et al., 2018; Wei et al., 2020), different models are compared by using standard micro Precision (Prec.), Recall (Rec.), and F1-score[4]. An extracted relational triplet (subject, relation, object) is regarded as correct only if the relation and the heads of both subject and object are all correct.

Implementation Details. The hyper-parameters are determined on the validation set. To avoid the evaluation bias, all reported results from our method are averaged results for 5 runs. More implementation details are described in

---

[4] In this study, the results of baseline models are all self-reported results from their original papers. Meanwhile, the experimental results of our proposed model are the average of five runs.

Appendix section 6.1.

3.2 Results and Analysis

Relational Triplet Extraction Performance. The task performances on two datasets are summarized in Table 2. Based on the experiment results, we have the following observations and discussions:

- The proposed DIRECT model outperformed all baseline models in terms of all evaluation metrics on both datasets, which proved DIRECT model can effectively address the relational triplet extraction task.
- The best-performed model (DIRECT) and runner-up model (CasRel) were both adjacency list oriented model. These two models overwhelmingly outperformed other models, which indicated the considerable potential of adjacency list (as the output data structure) for improving the task performance.
- To further compare the relation extraction ability of DIRECT and CasRel, we took a closer look at the extraction performance of relational triplet elements from these two models. As shown in Table 3[5], DIRECT outperformed CasRel in terms of all relational triplet elements on both datasets. These empirical results suggested that, for relational triplet extraction, a fully adjacency list oriented model (DIRECT) may have advantages over a partially oriented one (CasRel).

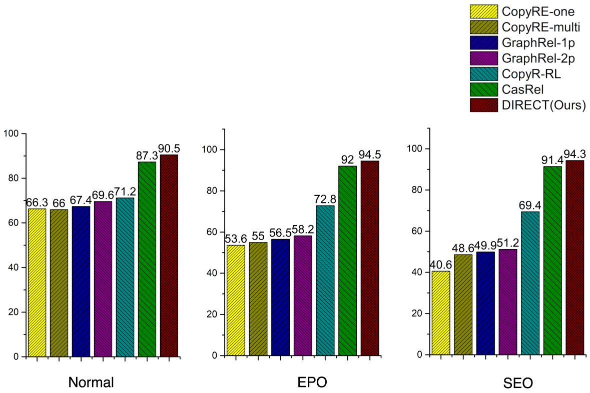

Figure 3: F1 score of extracting relational triples from sentences with different overlapping patterns on NYT dataset.

Ability in Handling The Overlapping Problem. The relational facts in sentences are often complicated. Different relational triplets may have overlaps in a sentence. To verify the ability of our models in handling the overlapping problem, we conducted further experiments on NYT dataset. Figure 3 illustrated of F1 scores of extracting relational triplets from sentences with different overlapping patterns. DIRECT outperformed all baseline models in terms of all overlapping patterns. These results demonstrated the effectiveness of the proposed model in solving the overlapping problem.

Ability in Handling Multiple Relation Extraction. We further compared the model's ability of extracting relations from sentences that contain multiple triplets. The sentences in NYT and WebNLG were divided into 5 categories. Each category contained sentences that had 1,2,3,4 or ≥ 5 triplets. The triplet number was denoted as N. As shown in Table 4:

- DIRECT achieved the best performance for all triplet categories on both datasets. These experimental results demonstrated our model had an excellent ability in handling multiple relation extraction.
- In both NYT and WebNLG datasets, when the sentences contained more triplets, the leading advantage of DIRECT became greater. This observation indicated that DIRECT was good at solving complex relational fact extraction.

3.3 Ablation Study

To validate the effectiveness of components in DIRECT, We implemented several model variants for ablation tests[6]. The results of the comparison on NYT dataset are shown in Table 5. In particular, we aim to address the following two research questions:

RQ1: Is it possible to improve the model performance by sharing the parameters of extraction layers?

RQ2: Did the proposed adaptive multi-task learning strategy improve the task performance?

Effects of Sharing Extraction Layer Parameters (RQ1). As described in Section 2, the structures of subject extraction and object extraction output layers are exactly the same. To answer RQ1, we merged the subject extraction and object extraction layers into one entity extraction layer by sharing the parameters of output layers of these two modules, denoted as $\mathbf{DIRECT_{shared}}$. From the results of Table 5, we can observe that, sharing the parameters of output layers of two extraction modules would reduce the performance of the model.

---

[5] More detailed results with Precision and Recall are provided in Appendix section 6.2.

[6] Due to the length limitation, we list two main ablation experiments, the rest will be provided in the Appendix section 6.2.

Method	Category	NYT			WebNLG		
		Prec.	Rec.	F1	Prec.	Rec.	F1
NovelTagging(Zheng et al., 2017)	EL	62.4	31.7	42.0	52.5	193.	28.3
CopyRE$_{\text{One}}$(Zeng et al., 2018)	EL	59.4	53.1	56.0	32.2	28.9	30.5
CopyRE$_{\text{Mul}}$(Zeng et al., 2018)	EL	61.0	56.6	58.7	37.7	36.4	37.1

Method	Element	NYT	WebNLG
CasRel	s	93.5	95.7
	o	93.5	95.3
	r	94.9	94.0
DIRECT(Ours)	s	**95.4**	**97.3**
	o	**96.4**	**96.4**
	r	**97.8**	**97.4**

Table 3: F1-score for extracting elements of relational triplets on NYT and WebNLG datasets.

A possible explanation is that, although the output of these two modules is similar, the semantics of subject and object are different. Hence, directly sharing the output parameters of two modules could lead to an unsatisfactory performance.

Effects of Adaptive Multi-task Learning (RQ2). As described in Section 2, the adaptive multi-task learning strategy with the dynamic sub-task loss balancing approach is proposed for improving the task performance. To answer RQ2, we replaced the adaptive multi-task learning strategy with an ordinary learning strategy. In this strategy, the losses of three sub-tasks were computed with equal weights, denoted as **DIRECT**$_{\textbf{equal}}$. From the results of Table 5, we can observe that, by using adaptive multi-task learning, DIRECT was able to get a 1.5 percentage improvement on the F1-score. This significant improvement indicated that adaptive multi-task learning played a positive role in the balance of sub-task learning and can improve the global task performance.

3.4 Graph Representation Efficiency Analysis

Based on the amount estimation of predicted logits[7], we conduct a graph representation efficiency analysis to demonstrate the efficiency of the proposed method[8].

For each graph representation category, we choose one representative algorithms. **Edge List**: CopyRE (Zeng et al., 2018); **Adjacency Matrices**: MHS (Bekoulis et al., 2018); **Adjacency List**: CasRel (partially) (Wei et al., 2020) and the proposed DIRECT (fully).

The averaged predicted logits estimation for one sample[9] of different models on two datasets are shown in Table 6. MHS is adjacency matrices oriented, it has the most logits that need to be predicted. Since CasRel is partially adjacency list oriented, it needs to predict more logits than DIRECT. Theoretically, as an edge list oriented, the predicted logits of CopyRE should be the least. But, as described in Section 1, it needs to extract the entities repeatedly to handle the overlapping problem. Hence, its graph representation efficiency could be worse than our model. The structure of our model is simple and fully adjacency list oriented. Therefore, from the viewpoint of predicted logits estimation, DIRECT is the most representative-efficient model.

4 Related Work

Relation Fact Extraction. In this work, we show that all of the relational fact extraction models can be unified into a graph-oriented output structure analytical framework. From the perspective of graph representation, the prior models can be divided into three categories. **Edge List**, this type of model usually employs sequence-to-sequence fashion, such as NovelTagging (Zheng et al., 2017),

---

[7] Numeric output (0/1) of the last layer

[8] From the graph representation perspective, when a method requires fewer logits to represent the graph (set of triples), it will reduce the model fitting difficulty.

[9] The theoretical analysis of predicted logits for different models are described in Appendix section 6.4.

CopyRE (Zeng et al., 2018), CopyRL (Zeng et al., 2019), and PNDec (Nayak and Ng, 2020). Some models of this category may suffer from the triplet overlapping problem and expensive extraction cost. **Adjacency Matrices**, many early pipeline approaches (Zelenko et al., 2003; Zhou et al., 2005; Mintz et al., 2009) and recent neural network-based models (Bekoulis et al., 2018; Dai et al., 2019; Fu et al., 2019), can be classified into this category. The main problem for this type of model is the graph representation efficiency. **Adjacency List**, the recent state-of-the-art model CasRel (Wei et al., 2020) is a partially adjacency list oriented model. In this work, we propose DIRECT that is a fully adjacency list oriented relational fact extraction model. To the best of our knowledge, few previous works analyze this task from the output data structure perspective. GraphRel (Fu et al., 2019) employs a graph-based approach, but it is utilized from an encoding perspective, while we analyze it from the perspective of output structure. Our work is a pioneer investigation to analyze the output data structure of relational fact extraction.

Multi-task Learning. Multi-task Learning (MTL) can improve the model performance. (Caruana, 1997) summarizes the goal succinctly: *"it improves generalization by leveraging the domain-specific information contained in the training signals of related task."* It has two benefits (Vandenhende et al.): (1) multiple tasks share a single model, which can save memory. (2) Associated tasks complement and constrain each other by sharing information, which can reduce overfitting and improve global performance. There are two main types of MTL: hard parameter sharing (Baxter, 1997) and soft parameter sharing (Duong et al., 2015). Most of the multi-task learning is done by summing the loses directly, this approach is not suitable for our case. When the input and output are different, it is impossible to get two losses in one forward propagation. MT-DNN (Liu et al., 2019b) is proposed for this problem. Furthermore, MTL is difficult for training, the magnitudes of different task-losses are different, and the direct summation of losses may lead to a bias for a particular task. There are already some studies proposed to address this problem (Chen et al., 2018; Guo et al., 2018; Liu et al., 2019a). They all try to dynamically adjust the weight of the loss according to the magnitude of the loss, the difficulty of the problem, the speed of learning, etc. In this study, we adopt MT-DNN's framework, and propose an adaptive multi-task learning strategy that can dynamically adjust the loss weight based on the averaged EMA (Lawrance and Lewis, 1977) of the training data amount, task difficulty, etc.

5 Conclusion

In this paper, we introduce a new analytical perspective to organize the relational fact extraction models and propose DIRECT model for this task.

Unlike existing methods, DIRECT is fully adjacency list oriented, which employs a novel adaptive multi-task learning strategy with dynamic sub-task loss balancing. Extensive experiments on two public datasets, prove the efficiency and efficacy of the proposed methods.

6 Appendix

6.1 Implementation Details

We adopted the pre-trained BERT model [BERT-Base-Cased][10] as our encoder, where the number of Transformer layers was 12 and the hidden size was 768. The token types of input were always set to 0.

We used Adam as our optimizer and applied a triangular learning rate schedule as suggested by original BERT paper. In addition, we adopted a lazy mechanism for optimization. Different from the momentum mechanism of ordinary Adam optimizer (Kingma and Ba, 2015) that updated the output layer parameters for all tasks, this lazy-Adam mechanism wouldn't update the parameters of non-current tasks.

The dacay rate ϵ of EMA was set to 0.99 as default. The max sequence length was 128.

The other hyper-parameters were determined on the validation set. Notably, considering our special decoding strategy, we raised the threshold of extraction to 0.9 to balance the precision and the recall. The threshold of relation classification was set to 0.5 as default. The hyper-parameter setting was listed in Table 7.

Our mthod were implemented by Pytorch[11] and run on a server configured with a Tesla V100 GPU, 16 CPU, and 64G memory.

Hyper-parameter	NYT	WebNLG
Learning Rate	8e-5	1e-4
Epoch Num.	15	60
Batch Size	32	16

6.2 Supplementary Experimental Results

Ablation Study. To validate the effectiveness of components in DIRECT, We implemented several model variants for ablation tests respectively. For experimental fairness, we kept the other components in the same settings when modifying one module.

- **DIRECT$_{\textbf{shared}}$**, we merged the subject extraction and object extraction layers into one entity extraction layer by sharing the parameters of output layers of these two modules.
- **DIRECT$_{\textbf{equal}}$**, we replaced the adaptive multi-task learning strategy with an ordinary learning strategy. In this strategy, the losses of three sub-tasks were computed with equal weights, denoted as **DIRECT$_{\textbf{equal}}$**.
- **DIRECT$_{\textbf{threshold}}$**, we simply recognized all the start and end positions of entities by checking if the probability $p^t_{i,\text{start/end}} > \alpha$, where α was the threshold of extraction.
- **DIRECT$_{\textbf{adam}}$**, we used ordinary Adam as optimizer.

Method	NYT		
	Prec.	Rec.	F1
DIRECT$_{\text{shared}}$	92.1	91.6	91.9
DIRECT$_{\text{equal}}$	90.6	91.3	91.0
DIRECT$_{\text{threshold}}$	92.8	92.0	92.4
DIRECT$_{\text{adam}}$	92.1	**92.9**	92.5
DIRECT	**92.9**	92.1	**92.5**

Table 8: Results of model variants for ablation tests.

From the results of Table 8, we can observe that:

1. Sharing the parameters of output layers of subject and object extraction modules would reduce the performance of the model.
2. Compared to ordinary multi-task learning strategy, by using adaptive multi-task learning, DIRECT was able to get a 1.5 percentage point improvement on F1-score.
3. There would be a slight drop in performance, if we just used a simple threshold policy to recognize the start and end positions of an entity.
4. Despite the difference in precision and recall, there was no significant difference between these two optimizers (ordinary-Adam & lazy-Adam) for the task.

Results on Extracting Elements of Relational Triplets. The complete extraction performance of relational triplet elements from DIRECT and CaslRel are listed in Table 9. DIRECT outperformed CasRel in terms of all relational triplet elements on both datasets. These empirical results

suggest that, for relational triplet extraction, a fully adjacency list oriented model (DIRECT) may have advantages over a partially oriented one (CasRel).

Results of Different Methods under Exact-Match Metrics. In experiment section, we followed the match metric from (Zeng et al., 2018), which only required to match the first token of entity span. Many previous works adopted this match metric (Fu et al., 2019; Zeng et al., 2019; Wei et al., 2020).

In fact, our model is capable of extracting the complete entities. Therefore, we collected papers that reported the results of exact-match metrics (requiring to match the complete entity span). The following strong state-of-the-art (SoTA) models have been compared:

- CopyMTL (Zeng et al., 2020) is a multi-task learning framework, where conditional random field is used to identify entities, and a seq2seq model is adopted to extract relational triplets.
- WDec (Nayak and Ng, 2020) fuses a seq2seq model with a new representation scheme, which enables the decoder to generate one word at a and can handle full entity names of different length and overlapping entities.
- PNDec (Nayak and Ng, 2020) is a modification of seq2seq model. Pointer networks are used in the decoding framework to identify the entities in the sentence using their start and end locations.
- Seq2UMTree (Zhang et al., 2020) is a modification of seq2seq model, which employs an unordered-multi-tree decoder to to minimize exposure bias.

The task performances on NYT dataset are summarized in Table 10. The proposed DIRECT model outperformed all baseline models in terms of all evaluation metrics. This experimental results further confirmed the efficacy of DIRECT for relational fact extraction task.

6.3 Complexity Analysis of Graph Representations

For a graph $G = (V, E)$, $|V|$ denotes the number of nodes/entities and $|E|$ denotes the number of edges/relations. Suppose there are m kinds of relations, $d(v)$ denotes the number of edges from node v.

- Edge List Complexity
  - Space: $O(|E|)$
  - Find all edges/relations from a node: $O(|E|)$
- Adjacency Matrices Complexity
  - Space: $O(|V| \cdot |V| \cdot m)$

Category	Method	Theoretical	NYT	WebNLG
Edge List	CopyRe	$4kl + kr$	329	712
Adjacency Matrices	MHS	llr	57369	26518
Adjacency List (Partially)	CasRel	$2l + 2slr$	3084	15836
Adjacency List (Fully)	DIRECT	$2l + 2sl + or$	238	542

Table 11: Graph representation efficiency based on the theoretical logits amount and the estimated logits amount on two benchmark datasets.

  - Find all edges/relations from a node: $O(|V| \cdot m)$

- Adjacency List Complexity

  - Space: $O(|V| + |E|)$

  - Find all edges/relations from a node: $O(d(v))$

6.4 Graph Representation Efficiency Analysis

Based on the amount estimation of predicted logits[12] $(0/1)$, we conduct a graph representation efficiency analysis to demonstrate the efficiency of proposed method[13].

For each graph representation category, we choose one representative model algorithms. **Edge List**: CopyRE (Zeng et al., 2018); **Adjacency Matrices**: MHS (Bekoulis et al., 2018); **Adjacency List**: CasRel (partially) (Wei et al., 2020) and DIRECT (fully).

Formally, for a sentence whose length is l (l tokens), there are r types of relations, k denotes the number of triplets. Suppose there are s keys (subjects) and o values (corresponding amount of object-based lists) in adjacency list. The theoretical logits amount and the estimated logits amount on two benchmark datasets (NYT and WebNLG) are shown in Table 11. From the viewpoint of predicted logits estimation, DIRECT is the most representative-efficient model.

---

[12] Numeric output of the last layer

[13] As aforementioned, from the graph representation perspective, when a method requires fewer logits to represent the graph (set of triples), it will reduce the model fitting difficulty.

Self-Supervised Document Similarity Ranking via Contextualized Language Models and Hierarchical Inference

Abstract

We present a novel model for the problem of ranking a collection of documents according to their semantic similarity to a source (query) document. While the problem of document-to-document similarity ranking has been studied, most modern methods are limited to relatively short documents or rely on the existence of "ground-truth" similarity labels. Yet, in most common real-world cases, similarity ranking is an unsupervised problem as similarity labels are unavailable. Moreover, an ideal model should not be restricted by documents' length. Hence, we introduce SDR, a self-supervised method for document similarity that can be applied to documents of arbitrary length. Importantly, SDR can be effectively applied to extremely long documents, exceeding the $4,096$ maximal token limit of Longformer. Extensive evaluations on large documents datasets show that SDR significantly outperforms its alternatives across all metrics. To accelerate future research on unlabeled long document similarity ranking, and as an additional contribution to the community, we herein publish two human-annotated test-sets of long documents similarity evaluation. The SDR code and datasets are publicly available [1].

1 Introduction

Text similarity ranking is an important task in multiple domains, such as information retrieval, recommendations, question answering, and more. Recent approaches based on Transformer language models such as BERT (Devlin et al., 2019) benefit from effective text representations, but are limited in their maximum input text length. Hence, developing techniques for long-text or document level matching is an emerging research field (Jiang et al., 2019).

In this work, we present SDR, a self-supervised method for document-to-document similarity ranking that can be effectively applied to extremely long documents of arbitrary length and does not require similarity labels. SDR employs a self-supervised pre-training phase that leverages: (1) a masked language model that fine-tunes *contextual word* embeddings to specialize in a given domain and (2) a contrastive loss on sentence pairs, assembled by inter-and intra-sampling, that encourages the model to produce enhanced text embeddings for similarity. Similarity inference is achieved by producing per-sentence embeddings followed by a two-staged hierarchical scoring.

Our contributions are as follows: (1) we present SDR, a novel method for document-to-document similarity that can effectively operate on long documents of arbitrary length and does not require similarity labels. We evaluate SDR and report its performance on two large datasets of documents, showcasing its ability to rank documents better than other state-of-the-art alternatives. (2) to accelerate future research, we publish two long-document similarity datasets annotated by human experts.

2 Related Work

Semantic similarity has been studied in many fields, such as computer vision (Parmar et al., 2018; Huang et al., 2017), recommender systems (Wang and Fu, 2020; Barkan et al., 2020a, 2021; Malkiel et al., 2020), and natural language processing (Devlin et al., 2019; Reimers and Gurevych, 2019; Mikolov et al., 2013). Recently, transformer-based Language Models (LMs) ushered significant performance gains in various natural language understanding tasks, but mainly on relatively short texts (Devlin et al., 2019; Liu et al., 2019). These models are usually pre-trained on the Masked Language Modeling (MLM) objective followed by a down-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3088–3098
August 1–6, 2021.

stream task-specific fine-tuning process (Wang et al., 2018). However, most models employ a battery of self-attention operations, which scale *quadratically* with the sequence length rendering extremely inefficient for long documents containing pages of text.

To mitigate scale challenges, the Longformer (Beltagy et al., 2020) model has been proposed which employs local windowed attention unit that restrains the computation and space to scale *linearly* with the sequence length. However, computation complexity still depends on the sequence length. Moreover, it entails a linear space complexity (memory usage). Therefore, in practice, the propagation of extremely long sequences remains infeasible and the maximal input of the Longformer is capped at $4,096$ tokens only, far less than many real-world long documents.

Apart from the aforementioned scale limitations on the model's input, in the case of computing pair-wise similarities between a large number of documents, the above models also suffer from an exhaustive inference process: Longformer and BERT score pairs of items in a unified feed-forward process, by which each pair of two items is fed to the model in order to produce a single pair-wise score (as opposed to scoring based on the individual item embeddings). Such inference technique, impose $O(N^2)$ feed-forward operations (Barkan et al., 2020b), compared to just $O(N)$ in SDR.

An additional challenge of Transformer-based LMs is the fact that their raw vector representations is known to perform poorly on semantic textual similarity tasks (Reimers and Gurevych, 2019). As a result, specific methods for text similarity tasks have been proposed. A prominent example for such methods is the SBERT model (Reimers and Gurevych, 2019). SBERT employs a novel fine-tuning procedure that encourages representations of similar sentences be closer in terms of the cosine similarity, substantially improving their ability to capture semantic similarity. Yet, SBERT still toils from the aforementioned complexity challenges and is unable to handle long-documents.

Recently, several works proposed long-document processing and retrieval techniques using labeled data. Cohan et al. (2020) introduced SPECTER, a model for producing document-level embedding of scientific documents. SPECTER employs a novel objective that uses paper citations as a proxy for similarity. Similarly, the Cross-Document Attention (CDA) model (Zhou et al., 2020) and the Cross-Document Language Model (CDLM) (Caciularu et al., 2021) suggest equipping language models with cross-document information for document-to-document similarity tasks. All the above methods rely on supervision, either during the pre-training phase or during fine-tuning. However, in the general case, document-to-document similarity (as well as most similarity tasks), is performed in unsupervised settings where no labels (or citations) are available.

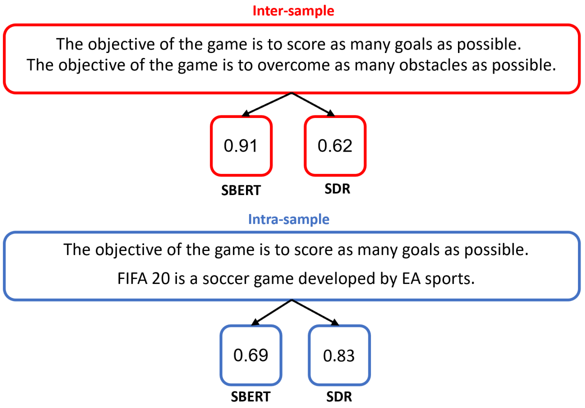

Figure 1: A representative inter- and intra-samples, along with cosine similarity scores retrieved by SBERT and SDR. Top: Inter-sampling from two documents associated with games of different categories. SBERT scores the sentences with a higher cosine value than the one retrieved by SDR. Bottom: attaching the anchor sentence with a sentence sampled from the same paragraph (and document). SDR and SBERT are reversed, where SDR yields a higher score that is more faithful to the sentences' underlying semantics and topic.

Another line of work consists of hierarchically learning single document representations. For example, Hierarchical Attention Networks (HANs) incorporate words and sentences into the final document representation showing competitive performance in different tasks involving long document encoding (Yang et al., 2016; Sun et al., 2018). More recently, Yang et al. (2020) and Jiang et al. (2019) investigated hierarchical models based on recurrent neural networks or BERT (Devlin et al., 2019) leading to state-of-the-art results in *supervised* document similarity challenges. These hierarchical models employ a bottom-up approach in which a long body of text (a document) is represented as an aggregation of smaller components i.e., paragraphs, sentences, and words. As opposed to these works, SDR exploits a document's hierarchical structure while avoiding compressing it into a single representation. This enables SDR to preserve more relevant information, leading to the superior results presented in Sec. 4. Importantly, SDR is *unsupervised* and does not require similarity labels or further fine-tuning.

3 The SDR Model

We present the problem setup followed by a description of the SDR model, its training and inference.

3.1 Problem Setup

Given a collection of documents $D = \{d_1, \ldots, d_n\}$ and a source document $s \in D$, the goal is to quantify a score that would allow us to rank all the other documents in D according to their semantic similarity with the source document s. In this work, we assume that document similarity labels are not supplied. Therefore, we propose a self-supervision loss that utilizes labels that we invent - this is a proxy to the ultimate similarity labels (if were given).

3.2 Training

SDR adopts the RoBERTa language model as a backbone, and, following Gururangan et al. (2020a), continues the pre-training of the RoBERTa model on D. Unlike RoBERTa, the SDR training solely relies on negative and positive sentence-pairs produced by inter- and intra-document sampling, respectively.

Specifically, the SDR training propagates sentence-pairs sampled from D. The sentence-pairs are sampled from the same paragraph with probability 0.5 (intra-samples), otherwise from different paragraphs taken from the different documents (inter-samples). The sentences in each pair are then tokenized, aggregated into batches, and randomly masked in a similar way to the RoBERTa pre-training paradigm. The SDR objective comprises a dual-term loss. The first term is the standard MLM loss adopted from Devlin et al. (2019). Denoted by $\mathcal{L}_{MLM}$. The MLM loss allows the model to specialize in the domain of the given collection of documents (Gururangan et al., 2020b).

The second loss term is the contrastive loss (Hadsell et al., 2006). Given a sentence pair (p, q) propagated through the model, we compute a feature vector for each sentence by average pooling the token embeddings associated with each sentence separately. The tokens embedding are the output of the last encoder layer of the model. The contrastive loss is then applied to the pair of feature vectors and aims to encourage the representations of intra-samples to become closer to each other while pushing inter-samples further away than a predefined positive margin $m \in R^+$.

Formally, the contrastive loss is defined as follows:

$$\mathcal{L}_C = \begin{cases} 1 - C\left(f_p, f_q\right) & y_{p,q} = 1 \\ \max\left(0, C\left(f_p, f_q\right) - (1-m)\right) & y_{p,q} = 0 \end{cases} \tag{1}$$

where f_p, f_q are the pooled vectors extracted from the tokens embedding of sentence p and q, respectively. $y(p, q) = 1$ indicates an intra-sample (sentence-pair sampled from the same paragraph), otherwise negative (sentence-pair from different documents). $C(f_p, f_q)$ measures the angular distance between f_p and f_q using the Cosine function:

$$C\left(f_p, f_q\right) = \frac{f_p^T f_q}{|f_p|\,|f_q|} \tag{2}$$

A demonstration of the inter-and intra-sampling procedure associated with the cosine scores produced by SDR can be found in Fig.1. The figure presents a representative sample as a motivation for SDR sampling and contrastive loss, where SDR is shown to score sentences in a way that is more faithful to their underlying topic and semantics. Importantly, as the inter-samples represent sentences that were randomly sampled from different documents, it is not guaranteed that their semantics would oppose each other. Instead, it is likely that those sentences are semantically uncorrelated while obtaining some level of opposite semantics only in rare cases. Therefore, instead of pushing negative samples to completely opposite directions, we leverage the contrastive loss in a way that encourages orthogonality between inter-samples while avoiding penalizing samples with negative scores. Hence, in our experiments, we set $m \triangleq 1$, which encourages inter-samples to have a cosine similarity that is less than or equal to 0, and do not penalize pairs with negative cosine scores.

Finally, both loss terms are combined together yielding the total loss

$$\mathcal{L}_{total} = \mathcal{L}_{MLM} + \mathcal{L}_C \tag{3}$$

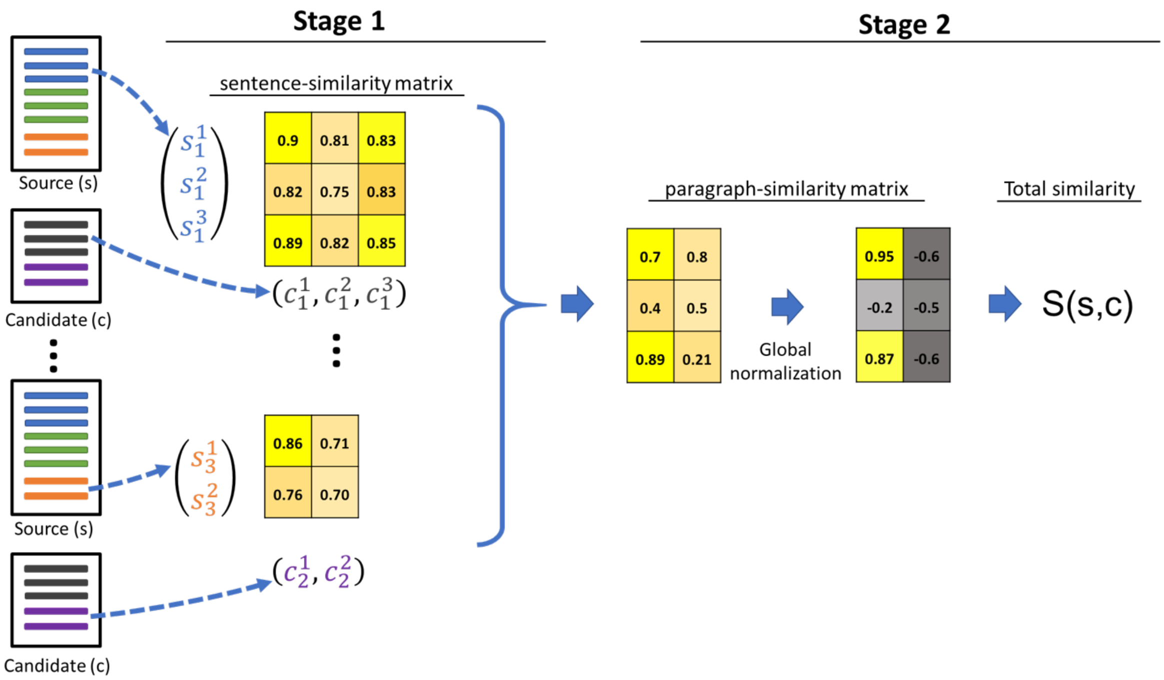

Figure 2: A schematic illustration of the SDR inference. Given a source and candidate documents, and for each paragraph-pair, SDR decomposes the paragraphs into sentences and maps each sentence into a vector. In the first stage, a sentence-similarity matrix is computed for each paragraph-pair. In the second stage, paragraph-similarity scores are inferred for all pairs and aggregated into a paragraph-similarity matrix. The matrix is then globally normalized and reduced into a total score, estimating the cumulative similarity between the two documents.

3.3 Inference

Let $s \in D$ be a source document composed of a sequence of paragraphs $s = (s_i)_{i=1}^{\widetilde{n}}$, where each paragraph comprises a sequence of sentences $s_i = (s_i^k)_{k=1}^{i^*}$, and i^* denotes the number of sentences in s_i. Similarly, let $c \in D$ be a candidate document, c can be written as $c = (c_j)_{j=1}^{m}$, where $c_j = (c_j^r)_{r=1}^{j^*}$. The SDR inference scores the similarity between s and every other candidate document c by calculating two-staged hierarchical similarity scores. The first stage operates on sentences to score the similarity between paragraph-pairs, and the second operates on paragraphs to infer the similarity between two documents. In SDR, we first map each document in D into a sequence of vectors by propagating its sentences through the model. Each sentence is then transformed into a vector by average pooling the token embeddings of the last encoder layers' outputs. Next, for each candidate document $c \in D$, SDR iterates over the feature vectors associated with the sentences in s and c and composes a *sentence-similarity matrix* for each paragraph-pair from both documents. Specifically, for each paragraph-pair $(s_i, c_j) \in s \times c$, SDR computes the cosine similarity between every pair of sentence embedding from $s_i \times c_j$, forming a sentence-similarity matrix. Focusing on the (k, r) cell of this matrix, $1 \leq k \leq i^*$, $1 \leq r \leq j^*$, the sentence-similarity matrix can be expressed as:

$$M_{ij}^{kr} \triangleq C(s_i^k, c_j^r) \tag{4}$$

Calculated for each paragraph pair $(s_i, c_j) \in s \times c$, the paragraph-similarity scores are then aggregated into a *paragraph-similarity matrix*. Focusing on the (i, j) cell, the matrix can be expressed as:

$$P_{ij}^{sc} \triangleq \frac{\sum_{k=1}^{i^*} \max\limits_{0 \leq r \leq j^*} M_{ij}^{kr}}{i^*} \tag{5}$$

The motivation behind the similarity scores in Eq. 5 is that similar paragraph-pairs should incorporate similar sentences that are more likely to correlate under the cosine metric, due to the properties of the contrastive loss employed throughout SDR training. In order to rank all the documents in the dataset, we compute the above paragraph-similarity matrix for every candidate document $c \in D$. The resulted paragraph-similarity matrices are then globally normalized. Each row i in P_{ij}^{sc} is z-score normalized by a mean and standard deviation computed from the row i values of P_{ij}^{sc} across all candidates $c \in D$.

The motivation behind this global normalization is to refine the similarity scores by highlighting the ones of the most similar paragraph-pairs and negatively scores the rest. Throughout our early experiments, we observed that different paragraph-pairs incorporate sentences with different distributions of cosine scores, where some source paragraphs may yield a distribution of cosine values with a sizeable margin compared to other paragraphs. This can be attributed to the embedding space, for which some regions can be denser than others.

Finally, a total similarity score is inferred for each candidate c, using the above paragraph-similarity matrix. The total similarity score aims to quantify the cumulative similarity between s and c. To this end, we aggregate all paragraph-similarity scores for each paragraph in s as follows:

$$\mathcal{S}(s,c) = \frac{\sum_{i=1}^{\tilde{n}} \max_{1\leq j\leq m} \left[\text{NRM}(P_{ij}^{sc})\right]_{i,j}}{n} \quad (6)$$

where NRM is the global normalization explained above. The essence of Eq.6 is to match between the most similar paragraphs from s and c, letting those most correlated paragraph-pairs contribute to the total similarity score between both documents. Finally, the ranking of the entire collection d can be obtained by sorting all candidate documents according to $\mathcal{S}(s,c)$, in a descending order.

It is important to notice that (1) in SDR inference, we do not propagate documents-pairs through the language model (which is computationally exhaustive). Instead, the documents are separately propagated through the model. Then, the scoring solely requires applications of non-parametric operations[2]. (2) both SDR training and inference operate on sentences and therefore do not suffer from discrepancies between the two phases.

4 Experiments

4.1 Datasets

We conducted our experiments over two datasets excerpted from Wikipedia. For each of the Wikipedia-based datasets, we provide a human-annotated test set of similarity labels. Examples from the datasets are provided in Fig. 3.

Wikipedia video games (WVG) The Wikipedia video games dataset[3] consists of 21,935 articles reviewing video games from all genres and consoles. Each article consists of a different combination of sections, such as summary, gameplay, plot, production, etc. For this dataset, we publish ground-truth similarity annotations, crafted by a domain expert, for $\sim$ 90 source game articles. For each source, the expert annotated $\sim$ 12 articles of similar games. Examples for the ground-truth similarities are: (1) Grand Theft Auto - Mafia, (2) Burnout Paradise - Forza Horizon 3.

Wikipedia wine articles (WWA) Wikipedia wines[4] dataset consists of 1635 articles from the wine domain. This dataset consists of a mixture of articles discussing different types of wine categories, brands, wineries, grape varieties, and more. The ground-truth similarities were crafted by a human sommelier who annotated 92 source articles with $\sim$10 similar articles, per source. Examples for ground-truth expert-based similarities are: (1) Dom Pérignon - Moët & Chandon, (2) Pinot Meunier - Chardonnay.

4.2 Quantitative Metrics

We evaluated the performance of SDR, the baselines, and ablations using the MPR,MRR and HR@k metrics:

Mean Percentile Rank (MPR) The mean percentile rank is the average of the percentile ranks for every sample with ground truth similarities in the dataset. Given a sample s, the percentile rank for a true recommendation r is the rank the model gave to r divided by the number of samples in the dataset. MPR evaluates the stability of the model, i.e, only models where all ground truth similarities had a high rank by the model will have a good score.

Mean Reciprocal Rank (MRR) The mean reciprocal rank is the average of the best reciprocal ranks for every sample with ground truth similarities in the dataset. Given a sample with M_s ground truth similarities we first mark the rank of each ground truth recommendation by the model and then take the reciprocal of the *best* (lowest) rank.

Hit Ratio at k (HR@k) HR@k evaluates the percentage of true predictions in the top k retrievals

made by the model, where a true prediction corresponds a candidate sample from the ground truth annotations.

4.3 Baseline models

We compare SDR with the following baselines:

Latent Dirichlet Allocation (LDA) LDA (Blei et al., 2003) is one of the renowned algorithms for topic modeling and text-matching. LDA assumes that documents are generated by sampling from a distribution of latent topics, where each topic can be described by another distribution defined over the vocabulary. For every LDA experiment, we perform a grid search with $1,000$ different configuration of hyper-parameters. The reported performance corresponds to the model with the highest topic coherence value (Newman et al., 2010).

BERT and Longformer For BERT (Devlin et al., 2019) and Longformer (Beltagy et al., 2020) (see Sec. 2), we evaluate two different variants. First, we employ the publicly available pre-trained weights of the models. Second, we continue the pre-training of the models over the corpora induced by the datasets, applying our proposed method associated with each model. We used only the "large" architectures during all the experiments.

SBERT The SBERT model (Reimers and Gurevych, 2019) utilizes a fine-tuning approach that produces semantically meaningful embeddings under a cosine-similarity metric.

We evaluate SBERT model under two inference configurations (1) using the original weights trained on the NLI dataset (Bowman et al., 2015), and (2) after fine-tuning with the pseudo labels presented in Sec. 3.2.

4.4 Inference Methods

To compare SDR with the above baselines, which are restricted by a maximal sequence length, we follow previous procedures (Reimers and Gurevych, 2019; Beltagy et al., 2020) and report the performance of four different inference techniques applied on the output embeddings of the different models :

- **CLS** - use the special CLS token embedding of the N^5 first tokens.
- **FIRST** - use the mean of the embeddings of the N first tokens.
- **ALL** - propagating the entire document in

---

[5] N is the maximal sequence length the model supports in one forward pass.

		Video games				Wines			
Architecture	**Inference**	**MPR**	**MRR**	**HR@10**	**HR@100**	**MPR**	**MRR**	**HR@10**	**HR@100**
LDA	-	94.1%	31.8%	8.8%	28.1%	83.7%	23.4%	8.7%	41.3%

Table 1: Similarity results evaluated on the video games (left), movies (middle) and wines (right) datasets from wikipedia, based on expert annotations. The second column specifies the applied inference method, as described in Section 4.4. SBERT_{V} refers to the vanilla SBERT (without continuing training on each dataset by utilizing our pseudo-labels).

chunks, then use the mean of the embeddings of all the tokens in the sample.

- **SDR_{inf}** - use the hierarchical SDR inference described in Sec. 3.3.

4.5 Results

The results over the document similarity benchmarks are depicted in Tab. 1. The scores are based on the ground-truth expert annotations associated with each dataset. The results indicate that SDR outperforms all other models by a sizeable margin. Recall that the underlying LMs we evaluated (BERT, Longformer) were pre-trained on the MLM objective. This makes them hard to generate meaningful embeddings suitable for probing similarity using the Cosine-similarity metric, as previously discussed in Sec. 2. Comparing to the best variant of each model, SDR presents absolute improvements of ∼7-12% and ∼11-13% in MPR, and MRR, respectively, and across all datasets.

SBERT, as opposed to the underlying models above, presents a cosine similarity-based loss during training. Compared to SDR, we observe that a fine-tuned SBERT, which utilizes the pseudo-labels introduced in Sec. 3.2, shows inferior results across all datasets, yielding -3% MPR, -5% MRR and -2% HR@10 in the Video games. This can be attributed to SBERT's cosine loss, that constantly penalizes negative pairs to reach a cosine score of -1. For uncorrelated sentence-pairs, such property can hinder the convergence of the model. See the below ablation analysis for more details. We observe that SBERT's suffers from an additional degradation in performance when applied with the original SBERT weights, yielding -6% MPR and -8% MRR. This can be attributed to the importance of continue training on the given dataset at hand.

Notably, as shown in the table, applying the SDR inference to other baseline language models improves their performance by a significant margin. This is another evidence of our inference's advantage over other methods, especially as we observe sizeable gains across all baseline models and datasets.

Inspecting SBERT results, we see that the SDR_{inf} gains increase in all metrics, yielding an increase of at least +3% MPR, +4% MRR, +6% HR@10 and +7% HR@100. This can be attributed to the importance of the hierarchical evaluation

	Video games		Wines	
Seed / Model	Dead Island	Mafia III	Hagafen Cellars	Champagne
SDR	1. Dead Island: Riptide	1. Mafia II	1. Golan Heights Winery	1. Champagne Krug
	2. Dying Light	2. Saints Row 2	2. Manischewitz	2. Sparkling wine
	3. Dead Rising 4	3. Grand Theft Auto V	3. Barkan Wine Cellars	3. Champagne Krug
SBERT	1. Fallout 3	1. Red Dead Redemption 2	1. Petit Rouge	1. Moët & Chandon
	2. Dead Rising 3	2. Dark Souls II	2. Roter Veltliner	2. Chardonnay
	3. Wasteland 2	3. Battlefield	3. Trisaetum Winery	3. Chasselas
BERT	1. The Outer Worlds	1. The Godfather	1. Domaine Dujac	1. Roter Veltliner
	2. Metro Exodus	2. Dark Souls	2. Petri Wine	2. Table wine
	3. Rage 2	3. Code Vein	3. Blue Nun	3. Champagne wine region

Table 2: Similarity predictions for the Wikipedia video games (WVG) and Wikipedia wine articles (WWA) datasets. For each of the shown recommendations, a domain expert rated the similarity with the source document. Red, yellow, and green indicate poor, mediocre, and high similarity (respectively).

for long documents and indicate the struggle transformers have in embedding long text into a single vector. Importantly, SDR outperforms SBERT by a significant margin, even when SBERT is applied with SDR_{inf}. This is due to SDR training, which incorporates the contrastive loss for promoting orthogonality between negative sentence-pairs.

Table 2 presents qualitative results on randomly chosen samples from the WWA and WVG datasets. We compare SDR with the top two baselines associated with the highest scores in the Wikipedia evaluations, namely SBERT and BERT. Similarly to the evaluation scheme presented for the quantitative experiments, we employ a self-supervised training for SBERT, with the same pseudo-labels as in SDR training. In Tab. 2, we observe that SDR correctly understands the essence of the article, as finding *Grand Theft Auto V* similar to *Mafia III*, or *Sparkling wine* similar to *Champagne*. As to SBERT results, we see that the model fails to grasp the article's underlying topic in 50% of the predictions. For example, SBERT matches between *Battlefield* and *Mafia III*, or *Chasselas* and *Champagne*. This can be attributed to the fact that SBERT does not apply a hierarchical inference and struggles to compress the entire document representation in one vector. This becomes especially crucial in very long documents, which are common in the WVG dataset. In BERT, we observe document similarity predictions of relatively poor quality. For example, for *Hagafen Cellars* BERT retrieves *Blue Nun*, or for *Champagne* it matches *Table wine*. The relative degradation in performance can be attributed to the BERT pre-training procedure, which inherently does not optimize text embedding under a well-defined metric.

The above results highlight the benefit obtained by the SDR model, which utilizes a hierarchical inference, along with a self-supervised training procedure that embeds sentences under a well-defined similarity metric.

4.6 Ablation Study

We performed an ablation study to asses the effectiveness of SDR. To that end, we used the video games dataset, described in Sec. 4.1. The following ablations are considered:

- No hierarchical inference - the embeddings of the first N tokens of each document are averaged, producing one embedding vector per document. These embeddings are compared via the cosine function to score the similarity between documents. This is similar to the scoring procedure from (Reimers and Gurevych, 2019).
- Paragraph-level inference - the paragraph-similarity matrix is computed directly using the first N tokens of each paragraph. This variant neglects the sentence-similarity matrix from stage 1 2 of the inference mechanism. The scoring proceeds by stage 2 of the inference, as described in Sec. 3.3.
- No training - the BERT pre-trained weights are used and applied with the proposed hierarchical inference (i.e., we do not employ additional pre-training on the given collection of documents).
- Global normalization - the SDR inference is applied without globally normalizing the paragraph-similarity matrix.

	Video games		
	MPR	**MRR**	**HR@10**
(i) No hierarchical inference	96.3%	52.4%	20.1%
(ii) Paragraph-level inference	97.4%	58.5%	22.8%
(iii) No training	87.1%	28.2%	7.0%
(iv) No normalization	97.3%	63.2%	22.6%
(v) No contrastive loss	91.5%	46.0%	14.5%
Full method	**97.4%**	**64.0%**	**23.6%**

Table 3: Ablation study results.

- No contrastive loss - the SDR training is applied without the contrastive loss term (solely using the MLM objective).
- Standard cosine loss - the SDR training employs a contrastive loss with a margin of $m = 2$. This is equivalent to the standard Cosine-Similarity loss, that reinforces negative and positive samples to cosine scores of -1 and 1, respectively.

The results depicted in Tab.3 indicate that our proposed hierarchical inference is highly beneficial, even compared to a paragraph-level inference, that it is crucial to employ the proposed training in the way it is done in SDR, and that it is better to apply global normalization.

Particularly noticeable is the contrastive loss, whose gain is present in both (ii) and (iii), for which the biggest degradation in the results took place. Another significant improvement is due to the hierarchical inference, with a leap of 11% in MPR by applying paragraph-level inference, and another 9% by applying the two-stage hierarchy.

4.7 Implementation details

SDR and all other transformer-based baselines utilize the Huggingface package [6]. In our transformer-based baselines experiments, we use the best-published model configuration associated with each variant. To split the paragraphs into sentences as suggested in SDR, we used the NLTK package [7], resulting in an average sentence length of 16 tokens. We use a train-validation split of 90%-10% to evaluate the MLM and cosine similarity accuracy during training.

For LDA modeling and similarity evaluation, we used the implementation of the Gensim package[8]. We conduct a hyperparameter search, based on the topic coherence score, to find the best LDA parameters for each dataset.

For SBERT we used the official package[9], with the released fine-tuned weights for the STS task. All our experiments were conducted using a single Tesla V100 32GB card, with a batch size of 8 both for training and evaluation.

5 Conclusions

In this work, we presented Self-Supervised Document Similarity Ranking (SDR), a novel self-supervised model for document similarity, supporting extremely long documents. Documents' similarities are extracted via a hierarchical bottom-up scoring procedure, which preserves more semantic information, leading to superior similarity results. For our evaluations, we assembled two manually-labeled test-sets using expert annotations, that will be made publicly available to expedite future research on long-document similarities.

Abstract

Recent years have seen many breakthroughs in natural language processing (NLP), transitioning it from a mostly theoretical field to one with many real-world applications. Noting the rising number of applications of other machine learning and AI techniques with pervasive societal impact, we anticipate the rising importance of developing NLP technologies for social good. Inspired by theories in moral philosophy and global priorities research, we aim to promote a guideline for social good in the context of NLP. We lay the foundations via the moral philosophy definition of social good, propose a framework to evaluate the direct and indirect real-world impact of NLP tasks, and adopt the methodology of global priorities research to identify priority causes for NLP research. Finally, we use our theoretical framework to provide some practical guidelines for future NLP research for social good.[1]

1 Introduction

Advances on multiple NLP fronts have given rise to a plethora of applications that are now integrated into our daily lives. NLP-based intelligent agents like Amazon Echo and Google Home have entered millions of households (Voicebot, 2020). NLP tools are now prevalent on phones, in cars, and in many daily services such as Google search and electronic health record analysis (Townsend, 2013).

In the current COVID-19 context, NLP has already had important positive social impact in the face of a public health crisis. When the pandemic broke out, Allen AI collected the CORD-19 dataset (Wang et al., 2020) with the goal of helping public health experts efficiently sift through the myriad of COVID-19 research papers that emerged in a short time period. Subsequently, NLP services such as Amazon Kendra were deployed to help organize the research knowledge around COVID-19 (Bhatia et al., 2020). The NLP research community worked on several problems like the question-answering and summarization system CAiRE-COVID (Su et al., 2020), the expressive interviewing conversational system (Welch et al., 2020) and annotation schemas to help fight COVID-19 misinformation online (Alam et al., 2020; Hossain et al., 2020).

As NLP transits from theory into practice and into daily lives, unintended negative consequences that early theoretical researchers did not anticipate have also emerged, from the toxic language of Microsoft's Twitter bot Tay (Shah and Chokkattu, 2016), to the leak of privacy of Amazon Alexa (Chung et al., 2017). A current highly-debated topic in NLP ethics is GPT-3 (Brown et al., 2020), whose risks and harms include encoding gender and racist biases (Bender et al., 2021).

It is now evident that we must consider the negative and positive impacts of NLP as two sides of the same coin, a consequence of how NLP and more generally AI pervade our daily lives. The consideration of the negative impacts of AI has engendered the recent and popular interdisciplinary field of AI ethics, which puts forth issues such as algorithmic bias, fairness, transparency and equity with an aim to provide recommendations for ethical development of algorithms.

Highly influential works in AI ethics include (Buolamwini and Gebru, 2018; Mitchell et al., 2019; Raji et al., 2020; Chen et al., 2019; Blodgett et al., 2020). AI for social good (AI4SG) (Tomašev et al., 2020) is a related sub-field that benefits from results of AI ethics and while keeping ethical principles as a pre-requisite, has the goal of creating positive impact and addressing society's biggest challenges. Work in this space includes (Wang et al., 2020; Bhatia et al., 2020; Killian et al., 2019; Lampos et al., 2020).

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3099–3113
August 1–6, 2021.

Active conversations about ethics and social good have expanded broadly, in the NLP community as well as the broader AI and ML communities. Starting with early discussions in works such as (Hovy and Spruit, 2016; Leidner and Plachouras, 2017), the communities introduced the first workshop on ethics in NLP (Hovy et al., 2017) and the AI for social good workshop (Luck et al., 2018), which inspired various follow-up workshops at venues like ICML and ICLR. The upcoming NLP for Positive Impact Workshop (Field et al., 2020) finds inspiration from these early papers and workshops. In 2020, NeurIPS required all research papers to submit broader impact statements (Castelvecchi, 2020; Gibney, 2020). NLP conferences followed suit and introduced optional ethical and impact statements, starting with ACL in 2021 (Association for Computational Linguistics, 2021).

With the growing impact of our models in daily lives, we need comprehensive guidelines for following ethical standards to result in positive impact and prevent unnecessary societal harm. (Tomašev et al., 2020) provide general guidelines for successful AI4SG collaborations through the lens of United Nations (UN) sustainable development goals (SDGs) (United Nations, 2015) and (Hovy and Spruit, 2016; Leidner and Plachouras, 2017) begin the ethics discussions in NLP. However, there is room for iteration in terms of presenting a comprehensive picture of NLP for social good, with an evaluation framework and guidelines. At the moment, researchers eager to make a beneficial contribution need to base their research agenda on intuition and word of mouth recommendations, rather than a scientific evaluation framework.

To this end, our paper presents a modest effort to the understanding of social good, and sketches thinking guidelines and heuristics for NLP for social good. Our main goal is to answer the question:

> Given a specific researcher or team with skills s, and the set of NLP technologies $\boldsymbol{T}$ they can work on, what is the best technology $t \in \boldsymbol{T}$ for them to optimize the social good impact I?

In order to answer this overall question, we take a multidisciplinary approach in our paper:

- §2 relies on theories in moral philosophy to approach what is social good versus bad (i.e., the sign and rough magnitude of impact I for a *direct* act a);
- §3 relies on causal structure models as a framework to estimate I for $t \in \boldsymbol{T}$, considering that t can be an *indirect* cause of impact;
- §4 relies on concepts from global priorities research and economics to introduce a high-level framework to choose a technology t that optimizes the social impact I;
- §5 applies the above tools to analyze several example NLP directions, and provides a practical guide on how to reflect on the social impact of NLP.

We acknowledge the iterative nature of a newly emerging field in NLP for social good, requiring continuing discussions on definitions and the development of ethical frameworks and guidelines. Echoing the history of scientific development (Kuhn, 2012), the goal of our work is not to provide a perfect, quantitative, and deterministic answer about how to maximize social good with our NLP applications. The scope of our work is to take one step closer to a comprehensive understanding, through high-level philosophies, thinking frameworks, together with heuristics and examples.

2 What is social good?

Defining social good can be controversial. For example, if we define saving energy as social good, then what about people who get sick because of not turning on the air-conditioner on a cold day? Therefore, social good is context-dependent, relevant to *people*, *times*, and *states of nature* (Broome, 2017). This section is to provide a theoretical framework about the social impact I for a direct act a.

2.1 Moral philosophy theories

We can observe that for some acts, it is relatively certain to judge whether the impact is positive or negative. For example, solving global hunger is in general a positive act. Such judgement is called intuitionalism (Sidgwick, 1874), a school of moral philosophy.

There are many areas of social impact that cannot receive consensus by intuitions. To find analytical solutions to these debatable topics, several moral philosophies have been proposed. We introduce below three categories of philosophical perspectives to judge moral laws (Kagan, 2018), and provide the percentage of professional philosophers who support the theory (Bourget and Chalmers, 2014):

1. Deontology: emphasizes duties or rules, endorsed by 25.9% philosophers;
2. Consequentialism: emphasizes consequences of acts, endorsed by 23.6% philosophers;
3. Virtue ethics: emphasizes virtues and moral character, endorsed by 18.2% philosophers.

Note that the above three schools, deontology, consequentialism, and virtue ethics, follows the standard textbook introductions for normative ethics in the analytic philosophy tradition. It is also possible for future research to consider different perspectives while defining social good.

A practical guide for using these philosophies. The three perspectives provide us dimensions to think about the impact I of an act a, so that the final decision is (hopefully) more reliable than one single thought which is subject to biases. Such decomposition practices are often used in highly complicated analyses (e.g., business decisions), such as radar charts to rate a decision/candidate or SMART goals.

A practical guide for using moral philosophies to judge an act a is to think along each of the three perspectives, collect estimations of how good the act a is from the three dimensions, and merge them. For example, using NLP for healthcare to save lives can be good from all three perspectives, and thus it is an overall social good act.

When merging judgements from the above philosophical views, there can be tradeoffs, such as sacrificing one life for five lives in the Trolley problem (Thomson, 1976), which scores high on consequentialism but low on deontology and virtue ethics. One solution by the moral uncertainty theory (MacAskill et al., 2020) is to favor acts with more balanced judgements on all criteria, and reject acts that are completely unacceptable on any criterion.

2.2 Principles for future AI

Many agencies from academia, government, and industries have proposed principles for future AI (Jobin et al., 2019), which can be regarded as a practical guide by *deontology*. Zeng et al. (2019) surveyed the principles of the governance of AI proposed by 27 agencies. The main areas are as follows (with keywords):

- Humanity: beneficial, well-being, human right, dignity, freedom, education, human-friendly.
- Privacy: personal information, data protection, explicit confirmation, control of the data, notice and consent.
- Security: cybersecurity, hack, confidential.
- Fairness: justice, bias, discrimination.
- Safety: validation, test, controllability.
- Accountability: responsibility.
- Transparency: explainable, predictable, intelligible.
- Collaboration: partnership, dialog.
- Share: share, equal.
- AGI: superintelligence.

3 Evaluating the indirect impact of NLP

Given the general moral guide to judge an act with *direct* impacts, we now step towards the second stage – understanding the downstream impact of scientific research which typically has *indirect* impacts. For example, it is not easily tractable to estimate the impact of some linguistic theories. To sketch a solution, this section will first classify NLP tasks by the dimension of theory→application, and then provide an evaluation framework for I of a technology t that may have indirect real-life impacts.

3.1 Classifying tasks from upstream to downstream

To evaluate each NLP research topic, we propose four stages in the *theory→application* development, as shown in Figure 1, and categorize the 570 long papers from ACL 2020[2] according to the four stages in Figure 2. Details of the annotation are in Appendix A. The four stages are as follows.

Stage 1. Fundamental theories. Fundamental theories are the foundations of knowledge, such as linguistic theories by Noam Chomsky. In ACL 2020, the most prevalent topic for papers in Stage 1 is linguistics theory in Figure 2.

Stage 2. Building block tools. Moving one step from theory towards applications is the research on building block tools, which serves as important building blocks and toolboxes for downstream technologies. The most frequently researched Stage-2 topics at ACL 2020 are information extraction, model design, and interpretability (in Figure 2).

---

[2] `https://www.aclweb.org/anthology/events/acl-2020/#2020-acl-main`

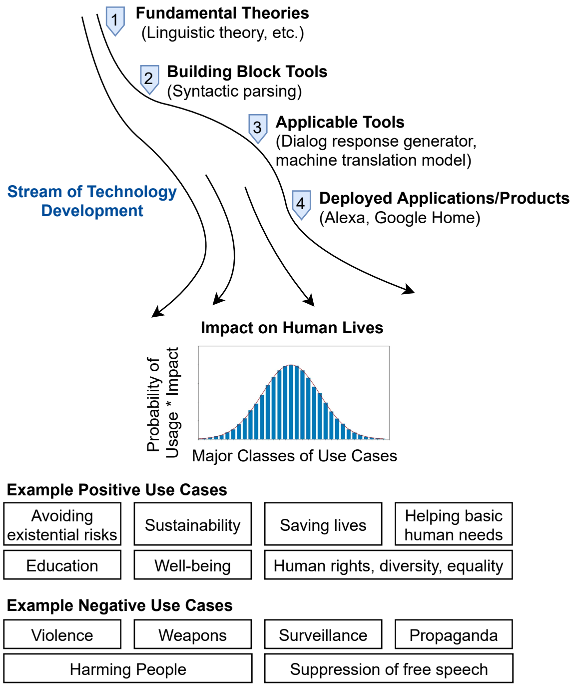

Figure 1: Stream of technology development from theory to application with end impacts. The end impacts are a distribution of use cases and their corresponding weighted impacts.

Stage 3. Applicable tools. Applicable tools are pre-commercialized NLP systems which can serve as the backbones of real-world applications. This category includes NLP tasks such as dialog response generation, question answering, and machine translation. The most common research topics in this category are dialog, machine translation, and question answering (in Figure 2).

Stage 4. Deployed applications/products. Deployed applications often build upon tools in Stage 3, and wrap them with user interfaces, customer services, and business models. Typical examples of Stage-4 technologies include Amazon Echo, Google Translate, and so on. The top three topics of ACL 2020 papers in this category are ways to address misinformation (e.g., a fact checker for news bias), dialog, and NLP for healthcare.

3.2 Estimating impact

***Direct* impacts of Stage-4 technologies.** A direct impact of NLP development is allowing users more free time. This is evident in automatic machine translation, which saves the effort and time of human translators, or in NLP for healthcare, which allows doctors to more quickly sift through patient history. Automatic fake news detection frees up time for human fact-checkers, to aid them in more quickly detecting fake news through the increasing number of digital news articles being published.

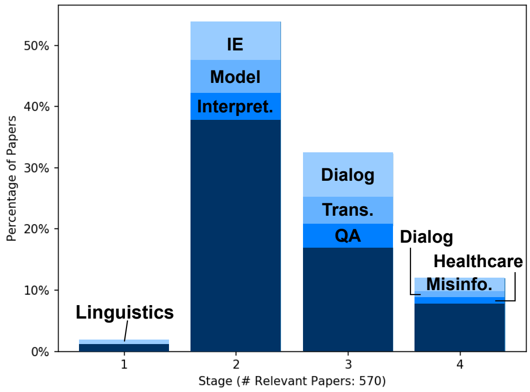

Figure 2: Distribution of ACL 2020 papers by the four stages. For each stage, we highlight the top several topics of the papers. We only list the top one topic for Stage 1 due to visual space limit. Abbreviations of technologies include Information Extraction (IE), Interpretability (Interpret.), machine translation (Trans.), question answering (QA), and misinformation (Misinfo.).

The impact of more user free time is varied. In the case of healthcare, NLP can free up time for more personalized patient care, or allow free time for activities of choice, such as spending time on passion projects or more time with family. We recognize these varied impacts of NLP deployment, and recommend user productivity as one way to measure it.

Note that there can be positive as well as negative impact associated with rising productivity, and the polarity can be decided according to Section 2.1. Typical positive impacts of NLP technology include better healthcare and well-being, and in some cases it indirectly helps with avoiding existential risks, sustainability, and so on. Typical negative impacts include more prevalent surveillance, propaganda, breach of privacy, and so on. For example, intelligent bots can improve efficiency at work (to benefit economics), and bring generally better well-being for households, but they might leak user privacy (Chung et al., 2017).

Thus, estimating the overall end impact of a technology t in the Stage 4 needs to accumulate over a set of aspects $\boldsymbol{AS}$:

$$I(t) = \sum_{as \in \boldsymbol{AS}} \text{scale}_{as}(t) \cdot \text{impact}_{as}(t) \,, \qquad (1)$$

where $\text{scale}_{as}(t)$ is the usage scale of applications of technology t used in the aspect as, and

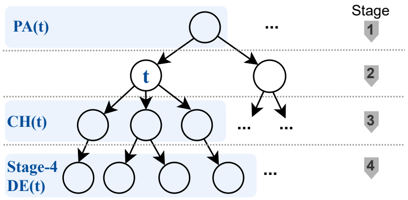

Figure 3: Viewing the theory→application process with a structural causal model.

$\text{impact}_{as}(t)$ is the impact of t in this aspect.

***Indirect* impacts of early stage technologies.** Although the direct impact of Stage-4 technologies can be estimated by Eq. (1), it is difficult to calculate the impact of a technology in earlier stages (i.e., stage 1-3).

We can approach the calculation of indirect impacts I of an early-stage technology t by a structural causal model. As shown in the causal graph $\mathcal{G}$ in Figure 3, each technology t is in a causal chain from its parent vertex set $\text{PA}(t)$ (i.e., upstream technologies that directly causes the invention of t), to its children vertex set (i.e., downstream technologies directly resulting from t). Formally, we denote a directed (causal) path in $\mathcal{G}$ as a sequence of distinct vertices $(t_1, t_2, \ldots, t_n)$ such that $t_{i+1} \in \text{CH}(t_i)$ for all $i = 1, \ldots, n-1$. We call t_n a descendant of t_1. After enumerating all paths, we denote the set of all descendants of t as $\text{DE}(t)$. Specifically, we denote all descendant nodes in Stage 4 as $\text{Stage-4 DE}(t)$.

Hence, the impact of any technology t is the sum of impact of all its descendants in Stage 4:

$$I(t) = \sum_{x \in \text{Stage-4 DE}(t)} p(x) \cdot c_x(t) \cdot I(x) \,, \quad (2)$$

where $p(x)$ is the probability that the descendent technology x can be successfully developed, $c_x(t)$ is the contribution of t to x, and $I(x)$ can be calculated by Eq. (1). This formula can also be interpreted from the light of do-calculus (Pearl, 1995) as $P(X|\text{do}(t)) - P(X)$, for $X \in \text{Stage-4 DE}(t)$, which means the effect of intervention $\text{do}(t)$ on Stage 4 descendants.

Note that Eq. (1) and (2) are meta frameworks, and we leave it to future work to utilize these for assessing the social impact of their work.

3.3 Takeaways for NLP tasks

With the growing interest of AI and NLP publication venues (e.g., NeurIPS, ACL) in ethical and broader impact statements, it will be useful and important for researchers to have practical guidelines on evaluating the impact of their NLP tasks.

We first introduce some thinking steps to estimate the impact of research on an NLP task t:

(S1) Classify the NLP task t into one of the four stages (§3.1)

(S2) If t is in Stage 4, think of the set of aspects $\boldsymbol{AS}$ that t will impact, the scale of applications, and aspect-specific impact magnitude. Finally, estimate impact using Eq. (1).

(S2') If t is in Stage 1-3, think of its descendant technologies, their success rate, and the contribution of t to them. Finally, estimate impact using Eq. (1) and (2).

Next, we introduce some high-level heuristics to facilitate fast decisions:

(H1) For earlier stages (i.e., Stage 1-2), it is challenging to quantify the exact social impact. Their overall impact tends to lean towards positive as they create more knowledge that benefits future technology development.

(H2) Developers of Stage-4 technologies should be the most careful about ethical concerns. Enumerate the use cases, and estimate the scale of each usage by thinking of the stakeholders, economic impact, and users in the market. Finally, evaluate the final impact before proceeding. (E.g., if the final impact is very negative, then abandon or do it with restrictions).

(H3) For Stage-3 technologies, if their Stage-4 descendants are tractable to enumerate and estimate for their impacts, then aggregate the descendants' impacts by Eq. 2. Otherwise, treat them like (H1).

4 Deciding research priority

There are many directions for expansion of our efforts for social good; however, due to limited resources and availability of support for each researcher, we provide a research priority list. In this section, we are effectively trying to answer the overall question proposed in Section 1. Specifically, we adopt the practice in the research field *global priorities* (GP) (MacAskill, 2015; Greaves and McAskill, 2017). We first introduce the high-level decision-making framework in Section 4.1, and then formulate these principles using technical terms in Section 4.2.

4.1 Important/Neglected/Tractable (INT) framework

Our thinking framework to address the research priority follows the practice of existing cost-benefit analysis in GP (MacAskill, 2015; Greaves and McAskill, 2017), which aligns with the norms in established fields such as development economics, welfare economics, and public policy.

We draw an analogy between the existing GP research and NLP for social good. Basically, GP addresses the following problem: given, for example, 500 billion US dollars (which is the annual worldwide expenditure on social good), what priority areas should we spend on? Inspired by this practical setting, we form an analogy to NLP research efforts, namely to answer the question proposed in Section 1 about how to attribute resources and efforts on NLP research for social good.

The high-level intuitions are drawn from the Important/Neglected/Tractable (INT) framework (MacAskill, 2015), a commonly adopted framework in global priorities research on social good. Assume each agent has something to contribute (e.g., money, effort, etc.). It is generally effective to contribute to important, neglected, and tractable areas.

4.2 Calculation of priority

Although the INT framework is commonly used in practice of many philanthropy organizations (MacAskill, 2015), it will be more helpful to formulate it using mathematical terms and economic concepts. Note that the terms we formulate in this section can be regarded as elements in our proposed thinking framework, but they are not directly calculable.[3]

Our end goal is to estimate the cost-effectiveness of contributing a unit time and effort of a certain researcher or team to research on the technology t. So far we have a meta framework to estimate the impacts I brought by successful development of a technology t. And we introduce the notations in Table 1.

Notation	Meaning
r	An NLP researcher or research group
$\boldsymbol{T}(r)$	The set of NLP topics that the researcher can pursue (limited by skills, resources, and passion)
t	An NLP technology
$I(t)$	Social impacts brought by successful development of t
$\text{prog}(t)$	The current progress of t
$p(t; r)$	Probability that research in t succeeds based on the skills of the researcher r
$p(t; r)I(t)$	Expected social impact of the researcher r's work on t
$\Delta t(r)$	Improvement of t per unit resource (incl. time, effort, money, etc.) of the researcher r

Table 1: Notations and their corresponding meanings used for cost-effectiveness calculation.

For a researcher r, the action set per unit resource is $\{\Delta t | t \in \boldsymbol{T}(r)\}$. Equivalently speaking, they can intervene at a node t by the amount of $\Delta t(r)$ in the structured causal graph $\mathcal{G}$ in Figure 3.

The first useful concept is $p(t; r)I(t)$, **the expected social impact** of research on a technology t. Here the success rate $p(t; r)$ is crucial because most research does not necessarily produce the expected outcome. However, if the impact of a technology can be extremely large (for example, prevention of extinction has impact near positive infinity), then even with a very little success rate, we should still devote considerable efforts into it.

The second concept that is worth attention is **the marginal impact** (Pindyck et al., 1995) of one more unit of resources of the researcher r into the technology t, calculated as

$$\Delta I(t; r) := I(\text{prog}(t) + \Delta t(r)) - I(\text{prog}(t)) \ . \quad (3)$$

For example, if the field associated with the technology is almost saturated, or if many other researchers working on this field are highly competent, then, for a certain research group, blindly devoting time to the field may have little marginal impact. However, on the other hand, if a field is important but neglected, the marginal impact of pushing it forward can be large. This also explains why researchers are passionate about creating a new research field.

The third useful concept is **the opportunity cost** (Palmer and Raftery, 1999) to devote researcher r's resources into the technology t instead of a possibly more optimal technology $t^{\star}$. Formally,

---

[3] We adapted these terms from GP. Such terms to estimate priority has been successfully used by real-world social good organizations, e.g., GiveWell, Global Priorities Institute, the Open Philanthropy Project (a foundation with over 10 billion USD investment), ReThink Priorities, 80,000 Hours Organization. In the long run, the NLP community may potentially benefit from aligning with GP's terminology. Still, we do not recommend applying our framework in high-stake settings yet, since it serves only as a starting point currently.

the opportunity cost is calculated as

$$t^{\star}(r) := \arg\max_{x} \Delta I(x(r)), \quad (4)$$

$$\mathrm{Cost}(t; r) := \Delta I(t^{\star}(r); r) - \Delta I(t; r)\ , \quad (5)$$

where $t^{\star}$ is the optimal technology that can bring the largest expected improvement of social impact. The opportunity cost conveys the important message that we should not just do *good*, but do the *best*, because the difference from good to best can be a large loss.

Estimating the variables. Note that the frameworks we have proposed so far are at the meta level, useful for guiding thought experiments, and future research. Exact calculations are not possible with the current state of research in NLP for social good, although achievable in the future.

A practical insight is that NLP researchers estimate the impact of their research via qualitative explanations (natural language) or rough quantitative ones. For example, the introduction section of most NLP papers or funding proposals is a natural language-based estimation of the impact of the research. Such estimations can be useful to some extent (Hubbard and Drummond, 2011), although precise indicators of impact can motivate the work more strongly.

We can also borrow some criteria from effective altruism, a global movement that establishes a philosophical framework, and also statistical calculations of social good. One of the established metrics for calculating impact is called the "quality-adjusted life years" (QALYs) proposed by MacAskill (2015). QALYs count the number of life years (calibrated by life quality such as health conditions) that an act helps to increase.

5 Evaluating NLP tasks

In this section, we will first try to categorize the current state of NLP research for social good based on ACL 2020 papers, and then highlight NLP topics that are aligned with the UN's SDGs. We will conclude with a practical checklist and case studies of common NLP tasks using this checklist.

5.1 Current state of NLP research for social good – ACL 2020 as a case study

We want to compare the ideal priority list with the current distribution of NLP papers for social good. As a case study of the current research frontier, we plot the topic distribution of the 89 ACL 2020 papers that are related to NLP for social good in Figure 4. We also show the portion of papers by the 10 countries with the most social-good papers. Our annotation details are in Appendix A.

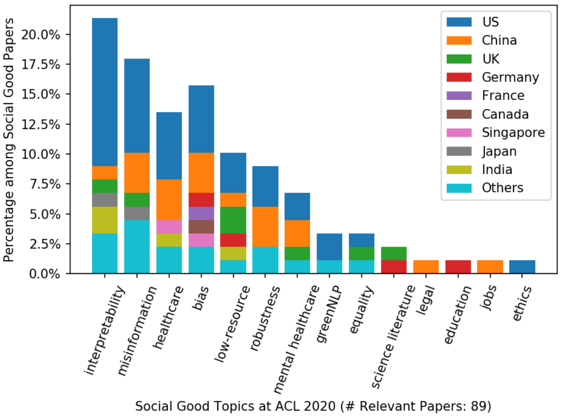

Figure 4: Social good topics at ACL 2020 by countries.

Illustrated in Figure 4, most social-good papers work on interpretability, tackling misinformation (e.g., fact-checking for news), and healthcare (e.g., to increase the capacity of doctors). In terms of countries, the US has the most papers on interpretability, and no papers on NLP for education, NLP for legal applications, and some other topics. China has few papers on interpretability, although interpretability is the largest topic. India has no papers on fighting misinformation, although it is the second largest topic. Only 5 countries have publications across more than two social good topics. Please refer to Appendix B for more analyses such as social-good papers by academia vs. industries.

However, compared with the UN's SDGs (United Nations, 2015), the current NLP research (at least in the scope of ACL conference submissions) lacks attention to other important cause areas such as tackling global hunger, extreme poverty, clean water and sanitation, and clean energy. There are also too few research papers on NLP for education, although education is the 4th most important area in SDGs.

One cause of this difference is *value misalignment*. Most NLP research is supported by stakeholders and funding agencies, which have a large impact on the current research trends or preferences in the NLP community. The perspective from social good with a framework to calculate the priority list has still not reached many in the NLP community.

Although we do not have data on expenditure

Cause	Annual Spending (USD)
Global R&D	1.5 trillion (UNESCO, 2017)
Luxury Goods	1.3 trillion (D'arpizio et al., 2015)
US Social Welfare	900 billion (Ferrara, 2011)
Climate Change	>300 billion (Buchner et al., 2014)
Global Poverty	>250 billion (Todd, 2017)
Nuclear Security	1-10 billion (Todd, 2017)
Pandemic Prevention	1 billion (Todd, 2017)
AI Safety Research	10 million (Todd, 2017)

Table 2: Annual spending of the cause areas.

Priority	**Example NLP research topics**
Poverty	• Predicting povery by geo-located Wikipedia articles (Sheehan et al., 2019) • Parsing fund applicant profiles (proposed)
Hunger	• NLP for agriculture (Yunpeng et al., 2019) • NLP for food allocation (proposed)
Health & Well-being	• NLP to analyze clinical notes (Dernoncourt et al., 2017a,b; Luo et al., 2018; Gopinath et al., 2020; Leiter et al., 2020a,b) • NLP for psychotherapy and counseling (Biester et al., 2020; Xu et al., 2020; Pérez-Rosas et al., 2019) • NLP for happiness (Asai et al., 2018; Evensen et al., 2019) • Assistive speech generation (proposed)
Education	• NLP for educational question answering (Atapattu et al., 2015; Lende and Raghuwanshi, 2016) • Improving textbooks (Agrawal et al., 2010) • Automated grading (Madnani and Cahill, 2018; Taghipour and Ng, 2016) • Plagiarism detection (Chong et al., 2010) • Tools for learners with disabilities (proposed)
Equality	• Interpretability (Köhn, 2015; Belinkov et al., 2017; Nie et al., 2020) • Ethics of NLP (Hovy and Spruit, 2016; Stanovsky et al., 2019; Sap et al., 2019) • NLP for low-resource languages (Zoph et al., 2016; Kim et al., 2017) • NLP on resource-limited devices (Sun et al., 2020) • NLP tools that signal bias in human language and speech (proposed)
Clean water	• Raising public awareness of water sanitation (proposed)
Clean energy	• Green NLP (Strubell et al., 2019; Schwartz et al., 2020) • NLP to analyze cultural values regarding climate change (Jiang et al., 2017; Koenecke and Feliu-Fabà, 2019) • Cross-cultural models of climate change perceptions (proposed)

Table 3: Top priorities and some NLP research related to each of them. This list may not be exhaustive. We also propose a high-impact research problem in each of the areas which has received less attention so far.

in each NLP subarea, we can get a glimpse of the value misalignment in general. Table 2 shows the annual spending of some cause areas. Note that the ranking of the expenditure does not align with our priority list for social good. For example, luxury goods are not as important as global poverty, but luxury goods cost 1.3 trillion USD each year, almost five times the expenditure in global poverty.

5.2 Aligning NLP with social good

In this subsection, we list the top priorities according to UN's SDGs (United Nations, 2015). For each goal, in Table 3 we include examples of existing NLP research, and suggest potential NLP tasks that can be developed (labeled as (proposed)).

5.3 Checklist

As a practical guide, we compile the takeaways of this paper into a list of heuristics that might be helpful for future practioners of NLP for social good. To inspect the social goodness of an NLP research direction (especially in Stage 3-4), the potential list of questions to answer is as follows:

(Q1) What kind of people/process will be benefited from the technology?

(Q2) Does it enforce traditional structure of beneficiaries? I.e., what groups of underprivileged people can be benefited? (e.g., by gender, demographics, socio-economic status, country, native languages, disability type)

(Q3) Does it contribute to SDG priority goals such as poverty, hunger, health, education, equality, clean water, and clean energy?

(Q4) Can it directly improve quality of lives? E.g., how many QALYs might it result in?

(Q5) Does it count as (a) mitigating problems brought by NLP, or (b) proactively helping out-of-NLP social problems?

5.4 Case studies by the checklist

We conduct some case studies of NLP technologies using the checklist.

Low-resource NLP & machine translation. This category includes NLP on low-resource languages, such as NLP for Filipino (Sagum et al., 2019; Cruz et al., 2020), and machine translation in general. Because this direction expands the users of NLP technologies from English-speaking people to other languages, it benefits people speaking these languages (Q1), and helps to narrow the gap between English-speaking and non-English speaking end users (Q2), although it is still likely that people who can afford intelligent devices will benefit more than those who cannot. This category can contribute directly to goals such as equality and education, and indirectly to other goals because translation of documents in general helps the sharing of information and knowledge (Q3). It directly improves quality of lives, for example, for immigrants who may have difficulties with the local language (Q4). Thus, it counts as social good category (b) by (Q5).

Transparency, interpretability, algorithmic fairness and bias. Research in this direction can impact users who need more reliable decision-making NLP, such as the selection process for loans, jobs, criminal judgements, and medical treatments (Q1). It can shorten the waiting time of candidates and still make fair decisions regardless of spurious correlations (Q2) (Q4). It reduces inequality raised by AI, but not increasing equality over man-made decisions, at least by the current technology (Q2). Thus, it is social good category (a) by (Q5).

Green NLP. Green NLP reduces the energy consumption of large-scale NLP models. Although it works towards the goal of affordable and clean energy (Q3), it just neutralizes the negative impact of training NLP models, but not impacting out-of-NLP energy problems. Green NLP belongs to social good category (a) by (Q5). It does not have large impacts directly targeted at (Q1), (Q2) and (Q4).

QA & dialog. People who can afford devices embedded with intelligent agents can use it, which is about 48.46% of the global population (BankMyCell, 2021) (Q1). So this benefits people with higher socio-economic status, and benefits English speaking people more than others, not to mention job replacements for labor-intensive service positions (Q2). It does not contribute to priority goals except for education and healthcare for people who can afford intelligent devices (Q3). Nonetheless, it can improve the quality of lives for its user group (Q4). It can be regarded as social good of category (b) by (Q5).

Information extraction, NLP-powered search engine & summarization. This direction speeds up the information compilation process, which can increase the productivity in many areas. About 50% of the world population have access to the Internet and thus can use it (Meeker, 2019) (Q1) (Q2). This category indirectly helps education, and the information compilation process of other goals (Q3). It can largely improve the lives of its user group because people gather information very frequently (e.g., do at least one Google search every day) (Q4). Thus, it belongs to social good category (b) by (Q5).

NLP for social media. This category is beneficial for social scientists interested in the trends and culture, or companies and organizations interested in market analyses (Q1) (Q2). The benefits to social science can indirectly help evidence-based policy makers, despite the caveat of bleach of user privacy, and information manipulation (Q4). This direction has limited contribution to priorities such as poverty and hunger, because extremely poor population do not own devices to post on social media (Q3). It is social good category (b) by (Q5).

6 Conclusion

This paper presented a meta framework to evaluate NLP tasks in the light of social good, and proposed a practical guide for practitioners in NLP. We call for more attention towards awareness and categorization of social impact of NLP research, and we envision future NLP research taking on an important social role and contributing to multiple priority areas. We also acknowledge the iterative nature of this emerging field, requiring continuing discussions, improvements to our thinking framework and different ways to implement it in practice. We highlight that the goal of our work is to take one step closer to a comprehensive understanding of social good rather than introducing a deterministic answer about how to maximize social good with NLP applications.

Acknowledgments

We thank Bernhard Schoelkopf, Kevin Jin, and Qipeng Guo for insightful discussions on the main ideas and methodology of the paper. We thank Osmond Wang for checking the economic concepts in the paper. We also thank Chris Brockett for checking many details in the paper. We thank the labmates in the LIT lab at University of Michigan, especially Laura Biester, Ian Stewart, Ashkan Kazemi, and Andrew Lee for constructive feedback. We also thank labmates at the MIT MEDG group, especially William Boag and Peter Szolovits for their constructive feedback. We thank Jingwei Ni for the help with the annotation of the country and affiliation of the ACL 2020 papers.

Ethical and societal implications

Our paper establishes a framework to better understand the definition of social good in the context of NLP research, and lays out a recommended direction on how to achieve it. The contributions of our paper could benefit a focused, organized and accountable development of NLP for social good. The data used in our work is public, and without privacy concerns.

A ACL 2020 paper annotations

For the case study on ACL 2020 papers, such as Figure 2 and 4, we collect the 570 long papers at ACL 2020. An NLP researcher with four years of research experience conducted the entire annotation, so that the categorization is consistent across all papers.[4]

The first annotation task is to categorize all papers into one of the four stages in the theory→application development. We showed the annotator the description of the four stages in Section 3.1. Next, provided with the title, abstract, and PDF of each paper, the annotator was asked to annotate which of the four stages each paper belongs to. The annotator had passed a test batch before starting the large-scale annotation.

The second annotation task is to annotate the research topics of the papers related to social good at ACL 2020. If the paper has a clear social good impact (89 out of 570 papers), the annotator needs to classify the topic of the paper into one of the given categories: bias mitigation, education, equality, fighting misinformation, green NLP, healthcare, interpretability, legal applications, low-resource language, mental healthcare, robustness, science literature parsing, and others. For the other meta information such as countries, or academia vs. industry, we decide based on the information of the leading first author.

B More statistics about ACL 2020 papers

For the case study on ACL 2020 papers, we further investigate the following statistics.

Stage 1-4 by countries. Recall that in Figure 2 of the main paper, we plot the distributions of papers by the four stages, and highlight the most frequent topics in each stage. Additionally, it is also interesting to explore the distribution of stages for different countries. In Figure 5, we have the following observations:

China does not have Stage-1 papers (i.e., fundamental theories), although it has the second largest total number of papers. The reason might be that there are not many Chinese researchers on linguistic theories who publish at English conferences.

Most countries' number of papers in the four stages follows the overall trend (i.e., Stage-2 papers > Stage-3 papers > Stage-4 papers > Stage-1 papers), with a few exceptions. For example, China has almost the same number of papers in Stage 2 and 3, Germany has more papers in Stage 4 (i.e., deployed applications) than in Stage 3, and Canada has the most papers in Stage 3.

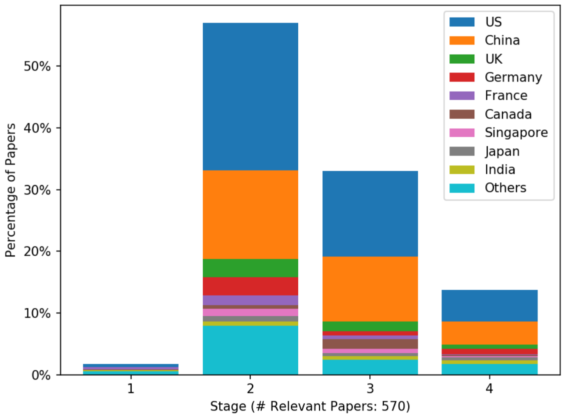

Figure 5: Stage 1-4 of ACL 2020 papers by countries.

Social good topics by academia vs. industry. As we call for more research attention to NLP for social good, it is important to understand the affiliations behind the current social good papers. A coarse way is to look at the affiliation of the first author, and inspect whether the main work of the paper is done by people from academia or industry.

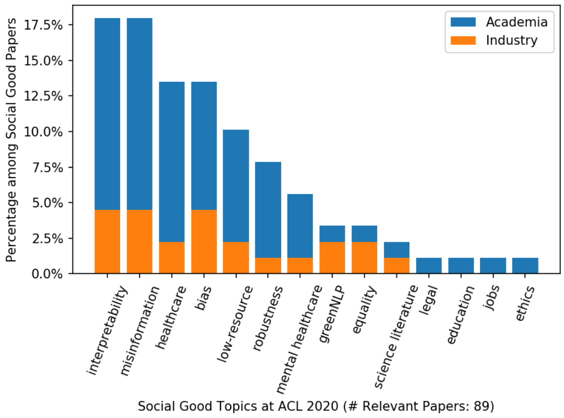

Figure 6: Social good topics at ACL 2020 by affiliations.

As in Figure 6, overall academia publishes several times more papers on social good than the industry. This ratio is higher than the average ratio of papers from academia out of all ACL 2020 papers (389 from academia out of 570). Industry does not have ACL 2020 papers on topics such as

---

[4] The annotation file has been uploaded to the softconf system.

NLP ethics. Note that using statistics from ACL papers alone could be limiting because researchers in academia typically present almost all research achievements through publications, but many industry researchers do not publish in public venues such as ACL, although their research may impact various products.

IgSEG: Image-guided Story Ending Generation

Abstract

In this work, we propose a new task called Image-guided Story Ending Generation (IgSEG). Given a multi-sentence story plot and an ending-related image, IgSEG aims to generate a story ending that conforms to the contextual logic and the relevant visual concepts. In contrast to the story ending generation task, which generates open-ended endings, the major challenges of IgSEG are to comprehend the given context and image sufficiently, and mine the appropriate semantics from the image to make the generated story ending informative, reasonable, and coherent. To address the challenges, we propose a Multi-layer Graph convolution and Cascade-LSTM (MGCL) based model which mainly comprises of two collaborative modules: i) a multi-layer graph convolutional network to learn the dependency relations of sentences and the logical clue of the context; ii) a multiple context-image attention module to generate the story endings by gradually incorporating textual and visual semantic concepts. Our MGCL is thus capable of building logically consistent and semantically rich story endings. To evaluate the proposed model, we modify the existing VIST dataset to obtain the VIST-Ending dataset. Empirically, our MGCL outperforms all the strong baselines on both automatic and human evaluation.

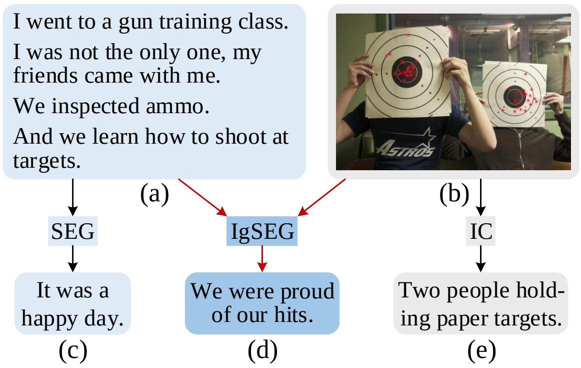

Figure 1: In SEG, existing methods tend to generate generic, safe, and inane story endings, e.g., (c). IgSEG is designed to generate specific, reasonable and informative endings induced by the given ending-related image. (d) is generated by the proposed MGCL model.

1 Introduction

As two challenging subtasks of story generation, the story ending generation (SEG) and visual storytelling (Huang et al., 2016; Zhao et al., 2018) have attracted more attention recently. The former generates text-based story endings (Zhao et al., 2018; Li et al., 2018; Guan et al., 2019). While, the latter generates photo-streams-based stories (Huang et al., 2016; Wang et al., 2018; Hu et al., 2020) or one-image-based stories (Gaur, 2019). Distinctly, both of them are input with single-modal information merely. Actually, people often confront with demands to handle multi-modal inputs for generating a sentence or paragraph, e.g., *comments generation given a news story and an image* and *picture composition with a leading paragraph*. However, to our best knowledge, the SEG task incorporating a context and an image is still under-explored.

Furthermore, due to the limited textual information of the story context, the generated endings of SEG models remain tending to be generic, safe, and inane. To make the generation of story endings more coherent, specific, and informative, we consider introducing visual information to enrich the generation of story endings. For example (cf. Figure 1), the story context (a) mainly narrates that the experience of someone went for gun training. The story ending generated by SEG (c) just talks about the feeling (e.g., *happy*) of the day, which seems to be generic, safe, and unattractive for lack of interesting events, imaginative conception, and evocative plots. Meanwhile, Image Captioning (e) generates the description of a given image (b) with-

out any story context plot. Here, we introduce the image to induce the development of the story plot and guide the generation of the ending. The image-guided story ending (d) is associated with the senior semantic (e.g., *proud*) and events (e.g., *hits*) from the visual information. Obviously, this ending seems to be high-quality compared with the one generated by SEG.

We herein propose an Image-guided Story Ending Generation (IgSEG) task, which aims at generating a story ending with contextual plots and an ending-related image. Models need to comprehend the story plots and the image information, and grasp the visual semantic concepts strongly related to the story plots (e.g., *event*, *behavior*, and *emotion*). The main challenges of this task are three-fold: *(i)* How to accurately select and capture appropriate visual concepts matching the development trend of the story plot from the image. *(ii)* How to fuse the language and visual information and model inter- and intra-modality relations efficiently. *(iii)* How to make the utmost of high-level semantics mined from the image to write coherent, semantically-informative, and imaginative story endings.

To capture the text contextual plots and merge visual features effectively, we propose a Multi-layer Graph convolution and Cascade-LSTM (MGCL) model. A multi-layer graph convolution module is constructed to capture and encode the clues information (e.g., dependency relations (Zhang et al., 2018)) hidden in context. In detail, following (Huang et al., 2021), for each sentence, we construct a graph over the dependency parsing tree and conduct convolutional operations by Graph Convolution Networks (GCN). We then employ attention mechanism to compress each graph as one node and deliver the node from low layer to high layer for aggregation of inter-sentence information. Furthermore, inspired by the work (Anderson et al., 2018), we design a Multiple Context-Image Attention (MCIA) module to merge the contextual features and the image features. Specifically, we apply attention mechanism to weight sentence features and image features separately, then concatenate and feed them to the next Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) cell. We perform experiments on the VIST-Ending (VIST-E) dataset which is modified from the VIST (Huang et al., 2016).

Our contributions can be summarized as follows:

- We define a new task termed IgSEG to generate coherent, specific, and informative story endings guided by an ending-related image. To our best knowledge, this is the first story generation task with multi-modal inputs.

- We propose a model called MGCL, which employs multi-layer graph convolutional operations to capture story contextual plots and multiple context-image attentions to merge visual features effectively.

- Experiments show that our model outperforms several strong baselines on the VIST-E dataset. Human evaluations show that our model can generate story endings with better grammaticality, logicality, and relevance.

2 Related Work

The IgSEG task is related to *(i)* Story Ending Generation (SEG) and *(ii)* Visual Storytelling (VIST). **SEG** (Zhao et al., 2018) is a subtask of story generation, which aims to understand the context and generate a coherent story ending. Many researchers have made great efforts on SEG. To improve the diversity and rationality of the generated story endings, (Li et al., 2018) tried to employ a Seq2Seq model based on adversarial training. Similarly, (Guan et al., 2019) made the model generate a reasonable ending by introducing external commonsense knowledge. Further, (Wang and Wan, 2019) adopted a transformer-based conditional autoencoder to capture contextual clues to improve coherence of story endings. (Guan et al., 2020) proposed a knowledge-enhanced pretraining approach for generating more reasonable stories. (Huang et al., 2021) proposed a multi-level GCN to capture the dependency relations of input sentences. Although previous studies have made great progress, due to the limitations of the SEG task itself, the generated endings tend to be generic and safe to some extent.

IgSEG is relevant to **VIST** as well. VIST aims to generate a coherent story according to an image stream. The main difficulty of VIST is how to generate image-relevant sentences. The previous works on VIST can be roughly divided into three categories. The first category focuses on designing specific model architectures to improve the quality of the generated stories (Kim et al., 2018; Wang et al., 2019). The second one generate more

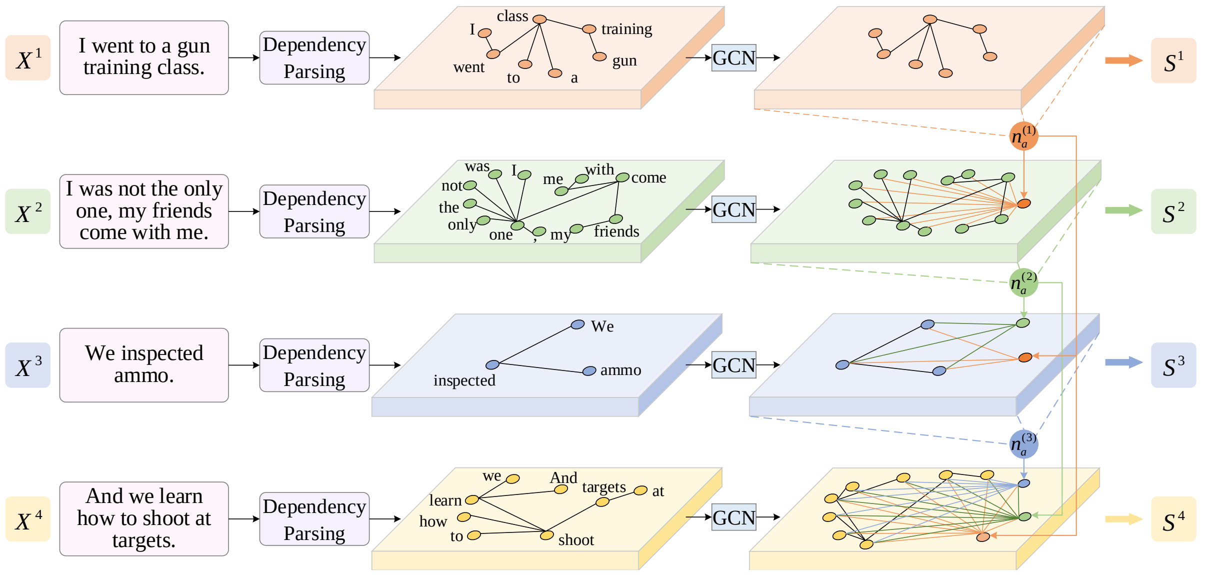

Figure 2: The Multi-layer Graph Convolutional Networks structure for context encoding. For intra-sentence information, each sentence is constructed as a graph over dependency parsing. For inter-sentence information, each graph is compressed as one node and is delivered to next layer. The output representation of each graph (i.e., S^1, S^2, S^3, S^4) are feed into decoder.

expressive output with reinforcement learning and adversarial training (Wang et al., 2018; Huang et al., 2019; Mo et al., 2019; Hu et al., 2020). The third one generates more common-sense stories by incorporating external knowledge. (Yang et al., 2019; Li et al., 2019; Wang et al., 2020; Jung et al., 2020).

However, the inputs of both SEG and VIST are single-modal information. The work on generating story endings given a textual sequence and an image simultaneously is unexplored. Therefore we propose the IgSEG task.

3 Methodology

3.1 Overview

The proposed IgSEG task aims to generate a story ending conforming the given contextual and visual information. Given a story context $X = \{X^1, X^2, \cdots, X^\mu\}$ and an ending-related image V, where $X^\mu = x_1^\mu x_2^\mu \cdots x_c^\mu$ represents the μ-th sentence with c words, IgSEG aims at generating a story ending $E = y_1 y_2 \cdots y_m$ with m words.

To generate the contextual-consistent and image-related story endings, we propose a Multi-layer Graph convolutional networks and Cascade-LSTM (MGCL) model based on the encoder-decoder framework. In the encoder, we propose a Multi-layer Graph Convolutional Networks (MGCN) over dependency trees to learn the context representation (cf. Figure 2), and we extract the image features with ResNet-152 (He et al., 2016). When decoding, we generate the story ending with the cascaded LSTM framework. Specifically, we employ Top-Down LSTM to joint the context features and image features. And we devise a Multiple Context-Image Attention (MCIA) module to grasp the image-related context and contextual-relevant information of image for text generation. We will introduce each part of MGCL below.

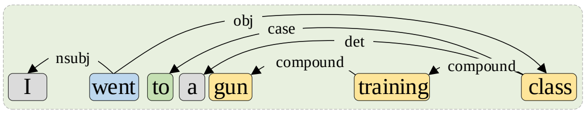

Figure 3: Dependency parsing of a sentence.

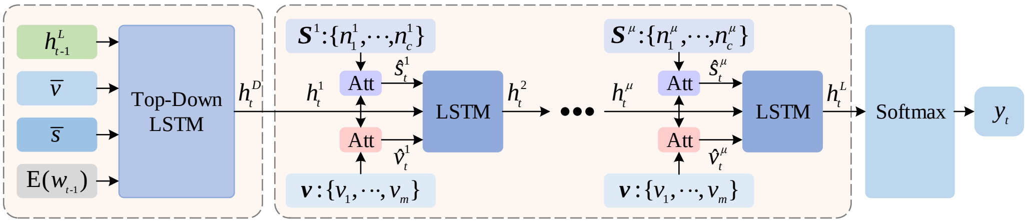
3.2 Story Context Representation

Graph Construction We parse the sentences with Stanford Dependency tool (De Marneffe et al., 2014) (cf. Figure 3). To capture the relations of words in a sentence, we construct a graph G over the dependency parsing tree for each sentence. Regarding the words x as nodes $\mathcal{O}^k$, the word representation n_i as node feature, and the corresponding relations on the dependency parsing tree as edges ξ^k, the graph G^k of k-th sentence (k=1,2,3,4) can be constructed:

$$G^k = (\mathcal{O}^k, \xi^k). \tag{1}$$

Multi-Layer GCN To deliver inter-sentence information, we utilize attention mechanism to weight



(a) TD (b) MCIA

Figure 4: Illustration of the Cascade-LSTM framework. The Cascade-LSTM consists of TD and MCIA modules. The MCIA module consists of μ LSTM. The $\bar{v}$ denotes the mean-pooled image features, the $\bar{s}$ denotes the mean-pooled context features. The symbol "$\cdots$" denotes the omitted parts of MCIA module.

each node and sum them together as a new node $n_a^{(k)}$ for the $(k+1)$-th layer GCN (cf. Figure 2):

$$\boldsymbol{S}^k = [n_1^k \cdots n_c^k], \tag{2}$$

$$\theta = softmax(W_0^k \boldsymbol{S}^k + b_0^k), \tag{3}$$

$$n_a^k = \sum_{i=1}^{n} \theta n_i^k, \tag{4}$$

where n_i^k denotes the features of the i-th word of the k-th sentence, W_0 and b_0 are trainable parameters.

After updating the nodes of $(k+1)$-th layer GCN, the graph G^{k+1} structure is represented by a $(\lambda+k)\times(\lambda+k)$ adjacency matrix $\boldsymbol{A}^{k+1} = \{A_{ij}, (i,j) \in (\lambda+k)\}$. The corresponding value A_{ij} is 1 if the relation exists between node i and node j, otherwise it is 0. The representations of node i and its neighbor node $j \in \phi(i)$ are n_i^{k+1} and n_j^{k+1}, respectively. To obtain the correlation score w_{ij}^{k+1} between node i and node j, we learn a connected layer over concatenation of nodes features:

$$w_{ij}^{k+1} = w_{k+1}^T \sigma\left(W_1^{k+1}[n_i^{k+1}; n_j^{k+1}] + b_1^{k+1}\right), \tag{5}$$

where w_{k+1}, W_1^{k+1}, and b_1^{k+1} are trainable parameters, σ is the non-linear activation function, $(\cdot)^T$ denotes transpose operation, and $[;]$ denotes the concatenation operation.

We apply the softmax function over the correlation score w_{ij} to obtain the weight α_{ij}:

$$\alpha_{ij}^{k+1} = \frac{\exp(w_{ij}^{k+1})}{\sum_{j\in\phi(i)} \exp(w_{ij}^{k+1})}. \tag{6}$$

In the adjacency matrix $\boldsymbol{A}^{k+1}$, the value is α_{ij}^{k+1} if the relation exists between node i and node j, otherwise is 0. The A_{ij}^{k+1} can be denoted as:

$$A_{ij}^{k+1} = \begin{cases} \alpha_{ij}^{k+1} & \text{nodes } i,j \text{ are related} \\ 0 & \text{nodes } i,j \text{ are unrelated} \end{cases}. \tag{7}$$

For each node of the $(k+1)$-th GCN layer, we update the $(h+1)$-th representation of node n_i^{h+1} with aggregating the representations of h-th neighboring nodes n_j^h. This procedure is denoted as:

$$n_i^{h+1} = \sigma(A_{ii}n_i^h + \sum_{j\in\phi(i)} A_{ij}(W_2^h n_j^h + b_2^h)), \tag{8}$$

where W_2^h and b_2^h are trainable parameters. By l updates, the output S^{k+1} of GCN is denoted as:

$$\boldsymbol{S}^{k+1} = [n_1^{k+1} \cdots n_c^{k+1}]. \tag{9}$$

3.3 Decoder

The inputs of the decoder are the context features $\boldsymbol{S} = \left\{\boldsymbol{S}^k\right\}_{k=1}^4$ and the image features $\boldsymbol{v}$ extracted with the pre-trained model ResNet152 (He et al., 2016), as shown in Figure 4.

Top-Down LSTM (TD) Following previous work (Anderson et al., 2018), we employ Top-Down LSTM to incorporate the visual information (cf. Figure 4(a)). We operate LSTM over a single time step in the decoder with the following notation:

$$h_t = \mathrm{LSTM}(x_t, h_{t-1}) \tag{10}$$

where x_t is the input vector of LSTM and h_t is the output vector. The inputs of TD module x_t^D consists of the previous output h_{t-1}^L of MCIA module, the mean-pooled image features $\bar{v}$, and the embedding of the previously generated word $E(w_{t-1})$, where t denotes the current time step.

To incorporate the context information, we modify the original inputs of TD. Firstly, we calculate the mean-pooled context features $\bar{s}$:

$$\bar{s} = \frac{1}{\mu}\frac{1}{c}\sum_{k=1}^{\mu}\sum_{i=1}^{c} n_i^k, \tag{11}$$

where μ denotes the number of sentences, c denotes the number of words of each sentence, n_i^k denotes the representation of the i-th word of the k-th sentence. Then, the vector x_t^D is denoted as:

$$x_t^D = [h_{t-1}^L; \bar{s}; \bar{v}; E(w_{t-1})]. \tag{12}$$

Multiple Context-Image Attention (MCIA) To merge the context features and image features, we devise the MCIA module. The MCIA module consists of four LSTM layers (cf. Figure 4(b)), which share all the parameters. The output h_t^D of TD is input to the MCIA module. Given the output h_t^k of $(k-1)$-th LSTM layer in MCIA module ($h_t^1 = h_t^D$), at each time step, we calculate the normalized attention weight $a_{i,t}^k$ for each of word representations n_i^k of the k-th sentence:

$$a_{i,t}^k = (w_a^k)^T \tanh(W_a^k n_i^k + W_a^{hk} h_t^k), \tag{13}$$

where w_a^k, W_a^k, and W_a^{hk} are trainable parameters. The convex combination of all words $\hat{s}_t^k$ can be calculated by n_i^k:

$$\beta_{i,t}^k = softmax(\boldsymbol{a}_t^k), \tag{14}$$

$$\hat{s}_t^k = \sum_{i=1}^{c} \beta_{i,t}^k n_i^k. \tag{15}$$

Likewise, we calculate the normalized weight $b_{i,t}^k$ for features v_i of each region of the image:

$$b_{i,t}^k = (w_b^k)^T \tanh(W_b^k v_i + W_b^{hk} h_t^k), \tag{16}$$

where w_b^k, W_b^k, and W_b^{hk} are trainable parameters. The convex combination of the image $\hat{v}_t^k$ can be calculated by the image features v_i:

$$\gamma_{i,t}^k = softmax(\boldsymbol{b}_t^k), \tag{17}$$

$$\hat{v}_t^k = \sum_{i=1}^{M} \gamma_{i,t}^k v_i, \tag{18}$$

where M denotes the the number of region of the image. We concatenate $\hat{s}_t^k$, $\hat{v}_t^k$, and h_t^k as inputs of the next LSTM layer:

$$x_t^{k+1} = [\hat{s}_t^k; h_t^k; \hat{v}_t^k]. \tag{19}$$

Given the output h_t^L of MCIA module, we calculate the conditional distribution over possible output words at each time step as follows:

$$p(y_t|y_{1:t-1}) = softmax(W_p h_t^L + b_p), \tag{20}$$

where W_p and b_p trainable parameters, and $y_{1:m}$ is the notation to refer to a sequence of words $(y_1, \cdots, y_m)$. Finally, the product of conditional distributions can be obtained by:

$$p(y_{1:m}) = \prod_{t=1}^{T} p(y_t|y_{1:t-1}). \tag{21}$$

4 Experiments

4.1 Dataset

To serve the IgSEG task, we modify the VIST dataset (Huang et al., 2016) to obtain a VIST-Ending (VIST-E) dataset, as shown in Table 1. Specifically, we keep the first four sentences, the ending sentence, and the last image of the photo stream of the VIST dataset. We have removed the stories which have corrupted images and rigmarole sentences over 40 words.

Dataset	Total	Training	Validation	Test
VIST	50,200	40,155	4,990	5,055
VIST-E	49,913	39,920	4,963	5,030

Table 1: Statistics of VIST and VIST-E.

4.2 Baselines

We compare our model with following models. **Seq2Seq** is a stack RNN-based model (Luong et al., 2015) with attention mechanisms. **Transformer** is a parallel model based solely on attention mechanisms (Vaswani et al., 2017). **IE+MSA** incorporates external knowledge with incremental encoding model for story ending generation(Guan et al., 2019). **T-CVAE** is a transformer-based conditional variational autoencoder for missing story plots generation (Wang and Wan, 2019). To adapt the IgSEG task, we rebuild above baselines by concatenating visual features as inputs. For fair comparison and testing our model, two variants of MGCL are created with the same inputs of the baselines. **MG+CIA**: We keep one Context-Image-Attention (CIA) unit in the decoder of MGCL. **MG+Trans**: We replace the decoder of MGCL with Transformer.

4.3 Evaluation Metrics

Automatic Evaluation We adopt four automatic metrics: **BLEU (B)** (Papineni et al., 2002) evaluates n-gram overlap between generated ending and a reference. **METEOR (M)** (Banerjee and Lavie, 2005) evaluates a generated sentence with

Model	B1	B2	B3	B4	M	C	R-L	Gram.	Logic.	Rele.
Seq2Seq†(Luong et al., 2015)	13.96	5.57	2.94	1.69	4.54	12.04	16.84	1.59	1.61	1.65
Transformer†(Vaswani et al., 2017)	17.18	6.29	3.07	2.01	6.91	12.75	18.23	3.01	2.15	1.96
IE+MSA†(Guan et al., 2019)	19.15	5.74	2.73	1.63	6.59	15.56	20.62	3.41	2.09	1.52
T-CVAE†(Wang and Wan, 2019)	14.34	5.06	2.01	1.13	4.23	11.49	15.51	1.89	1.76	1.25
MG+Trans† (ours)	19.43	7.47	3.92	2.46	7.63	14.42	19.62	3.46	2.77	2.60
MG+CIA† (ours)	20.91	7.46	3.88	2.35	7.29	19.88	21.12	2.80	2.35	1.97
MGCL (our full model)	**22.57**	**8.16**	**4.23**	**2.49**	**7.84**	**21.46**	**21.66**	**3.51**	**3.17**	**2.75**

Table 2: Experiments on the VIST-E dataset for the IgSEG task (p-value < 0.01). The **bold** / underline denotes the best and the second performance, respectively. † denotes the image features are directly concatenated.

Model	B2	B4	M	C	R-L
MGCL	**8.16**	**2.49**	**7.84**	**21.46**	**21.66**
w/o MGCN	7.11	2.03	7.23	20.26	19.74
w/o TD	5.18	1.04	6.74	10.33	18.93
w/o MCIA	7.17	2.17	7.13	17.62	19.75
w/o TD, MCIA	3.96	0.77	5.49	8.66	17.64

Table 3: Ablation studies. “w/o” means “without”.

direct word-ordering. **CIDEr (C)** (Vedantam et al., 2015) evaluates the similarity of a generated sentence against the references by human consensus. **ROUGE-L (R-L)** (Lin, 2004) is applied to find the length of the longest common subsequence.

Human Evaluation Considering the limitation of automatic evaluation and the complexity of the IgSEG task, it is necessary to conduct human evaluation. The criteria of human evaluation includes three aspects: **Grammaticality (Gram.)** (Wang and Wan, 2019) evaluates correct, natural, and fluent of the generated story endings. **Logicality (Logic.)** (Wang and Wan, 2019) evaluates whether the story endings are reasonable and coherent. **Relevance (Rele.)** (Yang et al., 2019) measures how relevant the generated story endings and the input images are. We randomly pick 100 generated story endings from test-set for each model and employ three professional annotators skills to make evaluation. Following (Yang et al., 2019), we apply a 5-grade marking system, with 5 as the maximum grade and 1 as the worst. The final results are the average of the scores given by the three annotators.

4.4 Experimental Settings

The dimension of word embedding is 300 from GloVe.6B (Pennington et al., 2014). The update times of each GCN is 5, the maximum number of nodes in GCN is 43. The hidden layer dimension of all LSTM is 512. The number of LSTM layer is 4 in MCIA module. The dimension of image features is $7 \times 7 \times 2048$ from ResNet-152 (He et al., 2016). During training on the VIST-E dataset, the epoch is set to 30 and the batch size is 128. The optimizer is Adam with an initial learning rate of 4e-4. All baselines keep their own default settings. The dropout rate is 0.5. Specially, inputs of Seq2Seq, Transformer, IE+MSA, and T-CVAE are concatenated with context representations and image features.

4.5 Result Analysis

Automatic and Manual Evaluation

We perform experiments on the VIST-E dataset comparing with several strong baselines, i.e., Seq2Seq, Transformer, IE+MSA, and T-CVAE.

The results of automatic and manual evaluation are shown in Table 2. We have done significant test comparing our model with these baselines by running all these models ten times. The results shows that our model significantly outperforms them with all p-values < 0.01. Specifically, our model implements an improvement of 8.66 / 5.39 / 3.42 / 8.23 / 3.14 / 1.66 over the Seq2Seq / Transformer / IE-MAS / T-CVAE / MG+Trans / MG+CIA on B1. As for B4, our model achieves an improvement of 0.8 / 0.48 / 0.86 / 1.36 / 0.03 / 0.14 over the Seq2Seq / Transformer / IE-MAS / T-CVAE / MG+Trans/ MG+CIA. With respect to M, our model outperforms the Seq2Seq / Transformer / IE-MAS / T-CVAE / MG+Trans / MG+CIA by 3.3 / 0.93 / 1.25 / 3.61 / 0.21 / 0.55. And for R-L, our model implements an improvement of 4.82 / 3.43 / 1.04 / 6.15 / 2.04 / 0.54 over the Seq2Seq / Transformer / IE-MAS / T-CVAE / MG+Trans / MG+CIA. The results show that our MGCL model can comprehend the context better with the MGCN module, and merge the context features and image features effectively with the MCIA module.

Our MGCL model also outperforms baselines on all manual evaluation. Compared with the best baseline, Gram. increases from 3.46 to 3.51, Logic.

Model	B1	B2	B4	M	R-L
Seq2Seq	14.27	4.27	1.05	6.02	16.32
Transformer	17.06	6.18	1.57	6.55	18.69
IE+MSA	20.11	6.62	1.68	6.87	**21.27**
T-CVAE	20.36	6.63	1.88	6.74	20.98
Plan&Write	20.92	5.88	1.44	7.10	20.17
KE-GPT2	**21.92**	**7.40**	1.90	**7.41**	20.58
MG+Trans (ours)	18.55	6.76	**2.33**	7.31	19.02
MGCL (ours)	20.27	6.26	1.81	6.91	21.01

Table 4: Experiments on the VIST-E dataset (plain text) for the SEG task. The **bold** / underline denotes the best and the second performance, respectively.

increases from 2.77 to 3.17, and Rele. increases from 2.60 to 3.75. It shows that our model can generate the more coherent and reasonable story endings than other baselines. Notably, our model has a good performance on Rele., which shows that MCIA module is helpful for enhancing the link of the generated story endings with the images.

Ablation Study To explore the effectiveness of our MGCL, we perform the ablation experiments on VIST-E (cf. Table 3). When removing the MGCN module and using the hidden features of the previous LSTM directly, the performance of our model drops 0.46 on B4, 0.61 on M, 1.2 on C, and 1.92 on R-L, respectively. When removing the MCIA and using hidden features of TD directly, the performance drops 0.32 on B4, 0.71 on M, 3.84 on C, and 1.91 on R-L, respectively. When removing TD and MCIA and using a LSTM unit to decoder, the performance drops 1.72 on B4, 2.35 on M, 12.8 on C, and 4.02 on R-L. All of the these show that the MGCN module and MCIA module can help to generate the more contextual-consistent and image-related story endings.

Comparison on SEG To verify the effectiveness of image guidance, we conduct experiments on VIST-E dataset removing the image. The automatic evaluation results are shown in Table 4. Compared with the corresponding results in Table 2, the Seq2Seq, Transformer, and our models have poor performance overall, which indicates the image is helpful for generating better endings. But for IE+MSA and T-CVAE model, they have poor performance when adding the image. One possible reason is that they are designed for the textual story generation specially, so it is hard to change to generate better story endings with an image. Further, we also conduct the SEG experiments with another two recent models, the Plan&Write model (Yao et al., 2019) and the pretrained language KE-GPT2 model (Guan et al., 2020). The results show that KE-GPT2 achieves the best performance on the plain text dataset, while our models are close to it.

Task	Noun	Verb	Adjective
IgSEG	11,659	11,050	6,508
SEG	9,808	9,027	5,835

Table 5: Statistics of Noun, Verb, and Adjective in the generated sentences of our MGCL model.

To research the quantity transformation of part of speech, we count the number of Noun, Verb, and Adjective in the generated story endings (cf. Table 5). With the guidance of image, the story endings achieves an improvement of 18.87%, 22.41%, and 11.53% on Noun, Verb, and Adjective, respectively. The results indicates that the MGCL model can enrich story endings on the IgSEG task.

4.6 Visualization and Case Study

To explicitly demonstrate our model, we present the visualization and case study (cf. Figure 5).

The context (Figure 5(a)) is mainly about people going to the seaside for a holiday. The context is encoded by the MGCN module, and fed with the image features together into the MCIA module. Key words are marked in red by our model, the darker means more important. The entities, events, and emotion (e.g., *We*, *go*, *trip*, and *exciting*) are assigned more attention weights by our model. It shows that our model can understand the semantic information of context sufficiently. Similarly, we present visualization for image (Figure 5(b)). The regions in darker red are where our model focuses on. Our model pays more attention to the regions with the important objects (e.g., *bridge*, *city*, and *sky*, which can be regarded as *view*). It shows that our model can also capture the vital visual concepts in the image. As shown in Figure 5(c), we present the cases of baselines on SEG and IgSEG, respectively. On SEG, the Seq2Seq model generates a long ending with repeat words , but it is still reasonable. The Transformer and T-CVAE generate the generic endings with positive sentiment. Our model generates the sentence describing how “we” ended the day, which is more interesting. On IgSEG, all the models generate the more specific endings where the visual concepts are mentioned. These cases show that our model can capture context-relevant image concepts and generate informative story plots.

X_1:Everyone was excited to be going on vacation.

X_2:We stopped at a memorial and spent our time reading about the history of it.

X_3:It was fourth of July that day, we were proud to be American.

X_4:We decided to go on a diving trip, it seemed exciting.

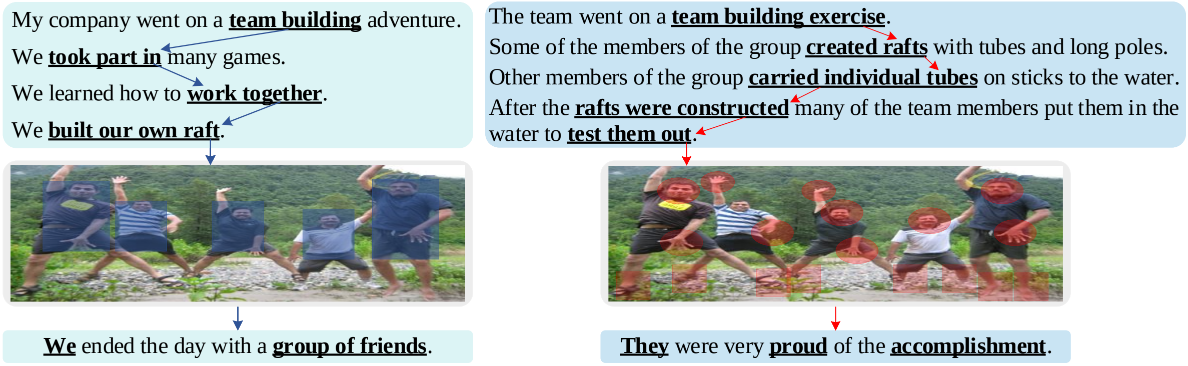
GT: We spent the rest of the day on the water, it was a great day!

(a) (b)

Model	SEG	IgSEG
Seq2Seq	At the end of the day, we went back to location location and view what a beautiful sky, it was a trip home from many times.	We went to the bridge.
Tramsformer	At the end of the day, we had a great time.	After that we decided to go back to the beach.
IE+MSA	We were all gone, but we had fun all the time.	We have the great time at the beach
T-CVAE	We were glad to be going to the future.	We these the tired enjoy my day in a nap.
MG+Trans(Ours)	We ended the day with a beautiful sunset.	It was a great day at the beach.
Ours[†]	We ended the day with a great view.	We have the great time at the beach.
Ours	We ended the day with a beautiful view of the water.	We ended the day by watching the **bridge** and enjoy the **view**.

(c)

Figure 5: Visualization and case study. The regions where are dark in color of sentences and images mean that model pays more attention to. GT denotes Ground True. (Best viewed in color)



My company went on a **team building** adventure.
We **took part in** many games.
We learned how to **work together**.
We **built our own raft**.

We ended the day with a **group of friends**.

The team went on a **team building exercise**.
Some of the members of the group **created rafts** with tubes and long poles.
Other members of the group **carried individual tubes** on sticks to the water.
After the **rafts were constructed** many of the team members put them in the water to **test them out**.

They were very **proud** of the **accomplishment**.

GT: In the end we all became friends.

(a)

GT: Even though they were wet at the end of the day they felt as sense of accomplishment

(b)

Figure 6: Different story context guided by the same ending-related image for IgSEG.

To vividly demonstrate the impact of image on IgSEG task, we show the generation cases (cf. Figure 6) which are offered the same ending-related image but the different story context. The content of image is that five people are very happy and jump in front of camera. The generated endings (a) and (b) are both coherent with their corresponding context. The context (a) has the logic chain (e.g., *team building* → *took part in games* → *work together* → *built raft*), and the context (b) has the logic chain (e.g., *team building* → *created raft* → *carried tubes* → *rafts test*). According to different logic chains, our model may focus on different regions of image and generate the story endings with the various semantics. The context (a) merely links to number of people in the image (e.g., *friends*), while the context (b) may be associated with people's postures and emotions (e.g., *dump* and *laugh* mean *proud*). To some extent, our MGCL model is able to capture some latent high-level semantics (e.g., *pride* and *celebration*) hidden in the image.

5 Conclusion

We propose a new task termed Image-guided Story Ending Generation. We transform the VIST dataset to VIST-Ending for IgSEG. We propose a MGCL model which uses a multi-layer graph convolutional networks to capture intra- and inter-sentence relations, a multiple context-image attention module to merge the context features and image features. Results on automatic and manual evaluation show that our model outperforms all the baselines.

Abstract

Query focused summarization (QFS) models aim to generate summaries from source documents that can answer the given query. Most previous work on QFS only considers the query relevance criterion when producing the summary. However, studying the effect of answer relevance in the summary generating process is also important. In this paper, we propose QFS-BART, a model that incorporates the explicit answer relevance of the source documents given the query via a question answering model, to generate coherent and answer-related summaries. Furthermore, our model can take advantage of large pre-trained models which improve the summarization performance significantly. Empirical results on the Debatepedia dataset show that the proposed model achieves the new state-of-the-art performance.[1]

Document: Interrogator Ali Soufan said in an April op-ed article in the New York Times: "It is inaccurate to say that Abu Zubaydah had been uncooperative [and that enhanced interrogation techniques supplies interrogators with previously unobtainable information]. Along with another f.b.i. agent and with several c.i.a. officers present I questioned him from March to June before the harsh techniques were introduced later in August. Under traditional interrogation methods he provided us with important actionable intelligence."
Query: Are traditional interrogation methods insufficient?
Summary: The same info can be obtained by traditional interrogations.

Table 1: An example of QFS. The input is a document and a corresponding query, and the highlight sentence is the answer from our QA module. We observe that the summary and the answers are very correlated.

1 Introduction

Query focused summarization (QFS) models aim to extract essential information from a source document(s) and organize it into a summary that can answer a query (Dang, 2005). The input can be either a *single* document that has multiple views or *multiple* documents that contain multiple topics, and the output summary should be focused on the given query. QFS has various applications (e.g., a personalized search engine that provides the user with an overview summary based on their query (Su et al., 2020b)).

Early work on the QFS task mainly focused on generating extractive summaries (Davis et al., 2012; Daumé III and Marcu, 2006; Feigenblat et al., 2017; Xu and Lapata, 2020b), which may contain unreadable sentence ordering and lack cohesiveness. Other work on abstractive QFS incorporated the query relevance into existing neural summarization models (Nema et al., 2017; Baumel et al., 2018). The closest work to ours was done by (Su et al., 2020a) and (Xu and Lapata, 2020a,b), who leveraged an external question answering (QA) module in a pipeline framework to take into consideration the answer relevance of the generated summary. However, they only used QA as distant supervision to retrieve relevant segments for generating the summary, but did not take into consideration the answer relevance in the generation model. As shown in the Table 1, the query focused summary is correlated to the answer extracted from the QA module.

On the other hand, recent neural summarization models (Paulus et al., 2017; Gehrmann et al., 2018; Zhang et al., 2020) have achieved remarkable performance in *generic* abstractive summarization by taking advantage of large pre-trained language

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3124–3131
August 1–6, 2021.

models (Lewis et al., 2019; Zhang et al., 2020). Yet, how to leverage these models and adapt them to the QFS task remains unexplored.

In this work, we propose QFS-BART, a BART-based (Lewis et al., 2019) framework for abstractive QFS that incorporates explicit answer relevance. We leverage a state-of-the-art QA model (Su et al., 2019) to predict the answer relevance of the given source documents to the query, then further incorporate the answer relevance into the BART-based generation model. We conduct empirical experiments on the Debatepedia dataset, one of the first large-scale QFS datasets (Nema et al., 2017), and achieve the new state-of-the-art performance on the ROUGE metrics compared to all previously published work.

Our contributions in this work are threefold:

- Our work demonstrates the effectiveness of the answer relevance score in neural abstractive QFS.
- We propose an effective method to incorporate the answer relevance score into the pre-trained language models which can produce more query-relevant summaries.
- Our model reaches the state-of-the-art performance on a single-document QFS dataset (Debatepedia), and brings substantial improvements over several strong baselines on two multi-document QFS datesets (DUC 2006, 2007).

2 Related Work

Abstractive summarization models aim to generate short, concise and readable text that extracts the salient information from a document. In the past few years, significant achievements (See et al., 2017; Liu and Lapata, 2019; Lewis et al., 2019; Dong et al., 2019) have been made in the *generic* abstractive summarization task which is attributed to the advanced neural architectures and the availability of large-scale datasets (Sandhaus, 2008; Hermann et al., 2015; Grusky et al., 2018).

QFS is a more complex task that aims to generate a summary according to the query and its relevant document(s). Nema et al. (2017) proposed an encode-attend-decode system with an additional query attention mechanism and diversity-based attention mechanism to generate a more query-relevant summary. Baumel et al. (2018) incorporated query relevance into a pre-trained abstractive summarizer to make the model aware of the query, while Xu and Lapata (2020a) discovered a new type of connection between generic summaries and QFS queries, and provided a universal representation for them which allows *generic* summarization data to be further exploited for QFS. Su et al. (2020b), meanwhile, built a query model for paragraph selection based on the answer relevance score and iteratively summarized paragraphs to a budget. Although Xu and Lapata (2020a) and Su et al. (2020b) utilized QA models for sentence- or paragraph- level answer evidence ranking, they did not make use of answer relevance to query-forcused generation.

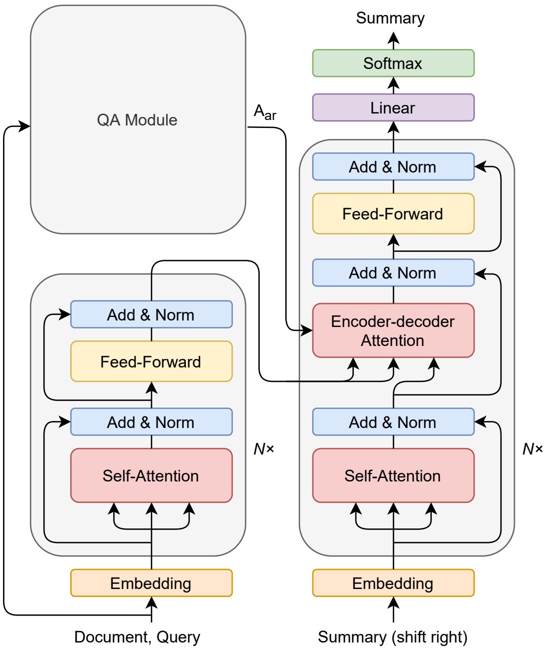

Figure 1: The framework of QFS-BART. The QA module calculates the answer relevance scores, and we incorporate the scores as explicit answer relevance attention to the encoder-decoder attention.

To the best of our knowledge, we are the first to leverage explicit answer relevance to abstractive QFS. In addition, our approach can be easily combined with pre-trained Transformers (Song et al., 2019; Dong et al., 2019; Lewis et al., 2019; Xiao et al., 2020), which have shown great success for the *generic* abstractive summarization task.

3 Methodology

In this section, we present our approach to incorporating the answer relevance into QFS. First, we introduce the method of generating answer relevance scores. Then, we describe our answer relevance attention in the Transformer-based model. Third, we introduce our QFS-BART model in which the decoder is composed of a stack of answer relevance decoding layers, as shown in Figure 1.

3.1 Answer Relevance Generation

In recent years, neural models (Yang et al., 2019a; Su et al., 2019) have shown remarkable achievements in QA tasks. In order to apply QA models to the QFS task, we use HLTC-MRQA (Su et al., 2019) to generate the answer relevance score for each word in context. The reason for choosing HLTC-MRQA is twofold: 1) it shows robust generalization and transferring ability on different datasets, and 2) the model shows great performance in QA tasks and significantly outperforms the BERT-large baseline by a large margin. The HLTC-MRQA is introduced as follows.

Based on XLNet (Yang et al., 2019b), HLTC-MRQA is fine-tuned on multiple QA datasets with an additional multilayer perceptron (MLP). Given a context that contains n words, the model outputs a distribution $s \in (0, 1)$ for each word's probability of being the start word of the answer and a probability distribution $e \in (0, 1)$ to be the end word of answer. To generate the answer relevance score r for each word, we calculate it by summing two distributions:

$$r = s + e, \tag{1}$$

where $r \in (0, 2)$.

3.2 Answer Relevance Attention

Scaled dot-product attention (Vaswani et al., 2017) is the core-component of the Transformer-based model:

$$Attention(Q, K, V) = softmax(\frac{QK^T}{\sqrt{d}}V), \tag{2}$$

where d is the dimension of the query matrix Q, key matrix K and value matrix V. The Transformer encoder is constructed by self-attention layers, where all of the keys, values and queries come from the input sequence. This makes each token in the input attend to all other tokens. The Transformer decoder layer is a combination of a self-attention layer and encoder-decoder attention layer. In the encoder-decoder attention layer, the query comes from the decoder's self-attention layer, and the key and value come from the output of the encoder. This allows every generated token to attend to all tokens in the input sequence.

In this work, we propose to incorporate the word-level answer relevance score as additional explicit encoder-decoder attention in the transformer decoder. Given a document with n tokens, we generate a summary with a maximum length of m tokens. Let $x^l \in \mathbb{R}^{n*d}$ denotes the output of the l-th transformer encoder layer and $y^l \in \mathbb{R}^{m*d}$ denotes the output of the l-th transformer decoder layer's self-attention layer. The encoder-decoder attention $\alpha^l \in \mathbb{R}^{m*n}$ can be computed as:

$$\alpha^l = softmax(\frac{(y^l W_Q)(x^l W_K)}{\sqrt{d_k}} + A_{ar}), \tag{3}$$

where W_Q and $W_K \in \mathbb{R}^{d_k * d_k}$ are parameter weights and $A_{ar} \in \mathbb{R}^{m*n}$ is our explicit answer relevance score. Since the original answer relevance score is an n-dimensional vector, we repeat it m times to generate an m by n attention matrix, which means our answer relevance attention is equal to all generated tokens.

3.3 QFS-BART

Generative pre-trained models (Dong et al., 2019; Lewis et al., 2019; Raffel et al., 2019) have shown remarkable performance in natural language generation (NLG), including text summarization. We choose to combine our answer relevance attention with BART (Lewis et al., 2019), a denoising autoencoder built with a sequence-to-sequence model, for two reasons: 1) BART achieves state-of-the-art performance on several summarization datasets (i.e. CNN/DailyMail (Hermann et al., 2015) and Xsum (Narayan et al., 2018)). 2) BART follows the standard Transformer encoder-decoder architecture, and we can easily combine the answer relevance as explicit attention to the encoder-decoder attention layers. In detail, we incorporate the same answer relevance attention for all Transformer decoder layers.

Domain adaption for natural language processing tasks is widely studied (Blitzer et al., 2007; Daumé III, 2009; Liu et al., 2020; Yu et al., 2021). Hua and Wang (2017) first studied the adaptation of neural summarization models and showed that the models were able to select salient information, even when trained on out-of-domain data. Inspired by this, we leverage a two-stage fine-tuning method for our QFS-BART. In the first stage, we directly fine-tune the original BART model with the Xsum

Models	ROUGE-1	ROUGE-2	ROUGE-L
Without Pre-training			
Transformer (Vaswani et al., 2017)	28.16	17.48	27.28
Transformer (CONCAT)	41.72	33.62	41.25
Transformer (ADD)	41.10	33.35	40.72
SD2* (Nema et al., 2017)	41.26	18.75	40.43
CSA Transformer* (Xie et al., 2020)	46.44	37.38	45.85
With Pre-training			
RSA Word Count* (Baumel et al., 2018)	53.09	16.10	46.18
QR-BERTSUM-TL* (Laskar et al., 2020)	57.96	**45.20**	57.05
BART-FT	57.98	43.62	56.30
QFS-BART	**59.02**	44.59	**57.44**

Table 2: ROUGE-F1 scores for Debatepedia QFS dataset. Results with * mark are taken from the corresponding papers. The previous work can be divided into two categories: 1) training the models from scratch, and 2) using pre-trained models and fine-tuning on a QFS dataset.

Document: Interrogator Ali Soufan said in an April op-ed article in the New York Times: “It is inaccurate to say that Abu Zubaydah had been uncooperative [and that enhanced interrogation techniques supplies interrogators with previously unobtainable information]. Along with another f.b.i. agent and with several c.i.a. officers present I questioned him from March to June before the harsh techniques were introduced later in August. Under traditional interrogation methods he provided us with important actionable intelligence.”
Query: Are traditional interrogation methods insufficient?

BART-FT: Al Qaeda detainee Abu Zubaydah has been cooperative under traditional interrogation.

QFS-BART: The same info can be obtained by traditional interrogation.

Gold: The same info can be obtained by traditional interrogations.

Table 3: A example taken from Debatepedia test set. The generated summary from **QFS-BART** is almost the same as the gold summary.

dataset, and in the second stage, we fine-tune our QFS-BART model with QFS datasets. All the parameters in the model are initialized from the first stage. In order to make the model capture both query relevance and answer relevance, the input text is formatted in the following way:

[CLS] document [SEP] query.

The answer relevance attention score for the document is generated by the QA model, and we take the maximum number in the document as the attention score for all the words in the query.

4 Experimental Setup

Datasets We use multiple QA datasets, including SQuAD (Rajpurkar et al., 2016), NewsQA (Trischler et al., 2016), TriviaQA (Joshi et al., 2017), SearchQA (Dunn et al., 2017), HotpotQA (Yang et al., 2018) and NaturalQuestions (Kwiatkowski et al., 2019) to train HLTC-MRQA, following Su et al. (2019). We evaluate our model on the Debatepedia dataset (Nema et al., 2017) and DUC2005-7 dataset (in Appendix).

Training Details For all the experiments, we use the BART-large version to implement our models. We use a mini-batch size of 32 and train all the models on one V100 16G. During decoding, we use beam search with the beam size of 4. We decode until an end-of-sequence token is emitted and early stop when the generated summary reaches to 48 tokens.

5 Results & Analysis

We compare our proposed QFS-BART model with the following models: 1) **Transformer** does not consider the queries in the Debatepedia dataset. 2) **Transformer (CONCAT)** concatenates the query and the document. 3) **Transformer (ADD)** adds the query encoded vector to the document encoder. 4) **SD2** adds a query attention model and a new diversity-based attention model to the encode-attend-decode paradigm. 5) **CSA Transformer** combines conditional self-attention (CSA) with Transformer. 6) **RAS Word Count** incorporates query relevance into a pre-trained abstractive summarization model. 7) **QR-BERTSUM-TL** presents a transfer learning technique with the Transformer-based BERTSUM model (Liu and Lapata, 2019). 8) **BART-FT** concatenates the document and query, and directly fine-tunes on the

Debatepedia dataset.

We adopt ROUGE score (Lin, 2004) as the evaluation metric. As shown in Table 2, QFS-BART significantly outperforms the models without pre-training. Compared with the models utilizing pre-training, ours improves the ROUGE-1 and ROUGE-L scores by a large margin.

5.1 Case Study

We present a case study comparing between the strong baseline BART-FT model, our QFS-BART model and the gold summary, shown in Table 3. It's clear that the baseline model tends to copy spans from the document which are not directly related to the query and the QFS-BART model produces a more query- and answer- related summary.

6 Conclusions

In this work, we propose QFS-BART, an abstractive summarization model for query focused summarization. We use a generalizing QA model to make explicit answer relevance scores for all words in the document and combine them to the encoder-decoder attention. We also leverage pre-trained model (e.g. BART) and two-stage fine-tuning method which further improve the summarization performance significantly. Experimental results show the proposed model achieves state-of-the-art performance on Debatepedia dataset and outperforms several comparable baselines on DUC 2006-7 datasets.

A Adapting QFS-BART to DUC 2005-7

DUC 2005-7 are datasets for the multi-document query focused summarization (QFS) task. As shown in the Table 4, the documents and summaries of the DUC datasets are extremely longer than those in the Debatepedia (Nema et al., 2017) dataset. We thus need to adapt the QFS-BART model to handle the multi-document scenario and produce longer output.

Datasets	**Document(s)**	**Query**	**Summary**
Debatepedia	66.40	11.16	9.97
DUC 2005	20058.12	26.60	243.56
DUC 2006	14330.14	23.30	246.84
DUC 2007	10759.17	21.57	243.94

Table 4: Average length of the input documents, queries and output summaries for the Debatepedia and DUC 2005-7 datasets. For the DUC datasets, we add up the lengths of all the documents related the same query

In this paper, we introduce a two-step architecture: 1) Retrieve answer-related sentences given the query, rank them by the confidence score (generated from Equation 4) and concatenate them. 2) Use our QFS-BART to produce an abstractive summary.

A.1 Answer Retrieving

We split documents into paragraphs and feed each paragraph to the QA model to get answer-related sentences. Then the sentences are ranked by the confidence score.

Document Segmentation The QA model selects one answer span given an input document, and the sentences that contain the span will be chosen as the answer-related sentences. Since we only retain the answer-related sentences as input to the next step, we set the maximum paragraph length to 300 words to avoid missing too much information in this step. Specifically, we feed text to the paragraph sentence by sentence until it reaches the maximum length.

Answer Relevance Ranking The paragraphs are fed to the QA model to generate answer-related sentences and the corresponding answer relevance scores. We align each sentence with a confidence score from the corresponding answer span. The confidence score is defined as:

$$confidence\_score = P_{start} + P_{end}, \qquad (4)$$

where P_{start} and P_{end} is two probability distributions over the tokens in the context. $P_{start}(i)$/$P_{end}(i)$ the probability of the i-th token is the start/end of the answer span in context.

A.2 Summary Generation

We use the answer-related sentences and their answer relevance scores as the input to the QFS-BART model. The DUC 2005 dataset is used as a development set to optimize the model, and we evaluate the performance on the DUC 2006-7 dataset. We compare our QFS-BART with the following models.

Models	**DUC 2006**			**DUC 2007**		
	1	**2**	**SU4**	**1**	**2**	**SU4**
LEAD	32.1	5.3	10.4	33.4	6.5	11.3
TEXTRANK	34.2	6.4	11.4	35.8	7.7	12.7
HLTC-MRQA	39.1	8.3	13.5	**40.6**	9.6	14.7
BART-CAQ*	38.3	7.1	12.9	40.5	9.2	14.4
BART-FT	38.9	8.5	13.9	40.4	**10.0**	**15.1**
QFS-BART	**39.4**	**8.6**	**14.1**	39.22	9.39	14.34

Table 5: ROUGE-F1 scores for DUC 2006-7 dataset. Results with * mark are taken from the corresponding papers.

LEAD (Xu and Lapata, 2020c) returns all leading sentences of the most recent document up to 250 words.

TEXTRANK (Mihalcea and Tarau, 2004) is a graph-based ranking model that incorporate two unsupervised methods for keyword and sentence extraction.

HLTC-MRQA truncates the ranked answer related sentences from our first step as the extractive summary.

BART-CQA (Su et al., 2020b) uses QA models for paragraph selection and iteratively summarizes paragraphs to 250 words.

We adopt ROUGE-F1 score (Lin, 2004) as the evaluation metric. As shown in Table 5, HLTC-MRQA significantly outperforms the LEAD and TEXTRANK baselines, which indicates the effectiveness of our answer retrieval. However, QFS-BART does not perform well on DUC 2006-7 datasets. We conjecture that the model can not converge to the task well with limited training samples (DUC 2005 contains only 300 samples).

Learning a Reversible Embedding Mapping using Bi-Directional Manifold Alignment

Abstract

We propose a Bi-Directional Manifold Alignment (BDMA) that learns a non-linear mapping between two manifolds by explicitly training it to be bijective. We demonstrate BDMA by training a model for a pair of languages rather than individual, directed source and target combinations, reducing the number of models by 50%. We show that models trained with BDMA in the "forward" (source to target) direction can successfully map words in the "reverse" (target to source) direction, yielding equivalent (or better) performance to standard unidirectional translation models where the source and target language is flipped. We also show how BDMA reduces the overall size of the model.

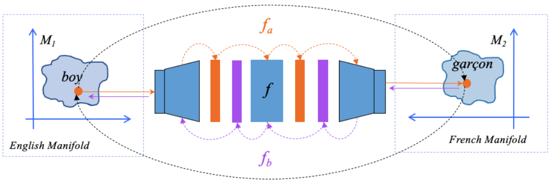

Figure 1: **Mapping vector spaces with Bi-Directional Manifold Alignment (BDMA).** f is the feedforward network. f_a and f_b are represent the forward and backward direction of flow through the network. In a shared BDMA network, the blue components represent network fully connected layers, orange are activation layers during forward network flow while purple represents activation layers in reverse flow. During reverse flow from output to input, the weight matrix is a transpose of weights during forward flow through the network.

1 Introduction

Learning continuous vector representations of embeddings is an expensive exercise as it requires a large quantity of free text to train *stable* representations (Sahin et al., 2017). Learning word embeddings in the English language is relatively easy since a model can make use of free text online from sources like *Wikipedia*, but it is challenging to learn embeddings for natural languages where the free text is limited (low-resource languages). Resource-constrained languages suffer from dual problems of reduced quality of embeddings and their vocabulary being small. Cross-lingual words embedding (CLWE) models alleviate this problem but are often linear mapping functions that align the source and target language manifolds, since non-linear mapping functions such as neural networks are unidirectional and known to perform poorly as compared to their linear counterparts (Ruder et al., 2019).

In this paper, we propose Bi-Directional Manifold Alignment (**BDMA**), which learns a *reversible*, non-linear mapping function between two manifolds. Inspired by CycleGAN (Zhu et al., 2017), we use a *cycle consistency* loss to optimize BDMA. We study BDMA in the context of cross-lingual lexicon induction and show that it offers solutions to two known problems: (1) that non-linear models are known to perform poorly in comparison to their linear counterparts (Ruder et al., 2019), and (2) most approaches perform unidirectional mapping only (from a source to target language), leading to an ever increasing set of translation models. We show how BDMA is a *generic* training method that uses different distance metrics (or losses) like MSE, cosine or RCSLS (Joulin et al., 2018) while training models cyclically.[1]

2 Bi-Directional Manifold Alignment

Consider two manifolds $M^s \in \mathbb{R}^{n \times d}$ (source domain) and $M^t \in \mathbb{R}^{m \times d}$ (target domain) that are vector space representations of words. The monolingual word embeddings are pretrained from a large corpus and may be created using different

methods. Let V^s and V^t be the respective vocabularies of the two languages. Hence $V^s = \{w_1^s \dots w_n^s\}$ and $V^t = \{w_1^t .. w_m^t\}$ are words in each vocabulary of size n and m. The distributed representations of words in each manifold are $M^s = \{m_1^s \dots m_n^s\}$ and $M^t = \{m_1^t \dots m_m^t\}$. We assume there is $V^p = \{w_1^p \dots w_c^p\}$, an available dictionary or parallel corpus of words for the given source/target pair.

2.1 Bi-Directional Loss Mechanism

We achieve bi-directional alignment by learning a mapping function is optimized with a *cyclic-consistency loss* (CCL). In Figure 1, the mapping function $f_a : M^s \to M^t$ to align the manifold M^s to M^t. We also use a backward mapping function $f_b : M^t \to M^s$ to align the manifold M^t to M^s. We refer to the parameters of both f_a and f_b as θ_f.

Our method is based on jointly minimizing the distance $\mathcal{D}$ between pairs of embeddings, and their mapped counterparts, from each manifold. We define our cycle consistency loss for a single training sample based on this distance function $\mathcal{D}$ as

$$\mathcal{L}_{\text{ccl}}^{\mathcal{D}}(i) = \mathcal{D}(f_a(m_i^s), m_i^t) + \mathcal{D}(f_b(m_i^t), m_i^s). \quad (1)$$

Following previous work (Xing et al., 2015), we include an *orthogonal loss* in the objective; we extend this loss function for a neural network by performing a **layerwise** orthogonal loss. For our full objective, we sum over all training instances and minimize over θ_f:

$$\mathcal{L}_{\text{ccl}} = \min_{\theta_f} \sum_{i \in V^p} \mathcal{L}_{\text{ccl}}^{\mathcal{D}}(i) + \sum_{w_j \in \theta_f} w_j w_j^T - I \quad (2)$$

where w_j are weights of layer j in the network. While Euclidean distance (mean squared error: $\mathcal{D} = \text{MSE}$) is a common way of computing distance in a manifold (Ruder et al., 2019; Artetxe et al., 2016), cosine or relaxed cross-domain similarity local scaling (RCSLS) (Joulin et al., 2018) distance functions have been shown to be effective for word and embedding alignment tasks. Our formulation works with these other computable distance functions. For example, while applying $\mathcal{D} = \text{MSE}$, and for ease omitting the orthogonal loss term $\sum_{w_j \in \theta_f} w_j w_j^T - I$, the loss is

$$\min_{\theta_f} \sum_{i \in V^p} \|f_a(m_i^s) - m_i^t\|_2^2 + \|f_b(m_i^t) - m_i^s\|_2^2 .$$

See Appendix D for similar formulations for $\mathcal{D} = \text{cosine}$, $\mathcal{D} = \text{RCSLS}$, and a combined distance function $\mathcal{D} = \text{cosine} + \text{RCSLS}$ (used in §3).

2.2 Forward - Reverse Network Flow

As described in §2.1, f_a and f_b represent the forward and reverse network flow. We represent the forward and reverse mapping with two networks that have shared or independent parameters. When the parameters are independent, two separate networks are trained simultaneously and optimized in order to learn the mapping between two languages. In Figure 1, the network parameters are shared in our model. The forward flow is shown in orange while reverse flow is depicted in purple.

Although the two networks share parameters, they cannot do so directly as the required shapes of each layer differ. In order to perform backward translation, reverse flow is enabled in the network by explicitly taking the **transpose of each layer** in the network (we use fully connected layers without bias vectors) making the network bi-directional or invertible. With our cycle consistency loss formulation, the model learns layers such that the transpose of the layer inverts the network.

3 Experiments & Analysis

We experiment with the **MUSE** dataset (Conneau et al., 2017). It consists of 110 bilingual dictionaries with separate training and test datasets for each language pair. The pairs contain polysemous words. When it comes to training BDMA, polysemous words can provide additional context to the model being trained while handicapping other baseline models. We filter out training pairs for polysemous words (source or target). The models are trained with 5000 unique pairs. We show two sets of experiments: (a) with a filtered evaluation set that contains 1500 unique pairs and (b) with the original evaluation dataset. We measure the performance of BDMA on two sets of languages: the low-resource languages *Russian* (Ru) and *Japanese* (Ja), and the high-resource languages *Spanish* (Es), *French* (Fr), *German* (De) and *Italian* (It).

In each table, ***s*** is the source language while ***t*** is the target language. → indicates the direction of mapping and training language pairs used from MUSE. For **reverse translation**, the model is trained with the *t* → *s* dataset and evaluated on the *s* → *t* test dataset—for example, the model trained on **En→Ru** is evaluated on **Ru→En**. P@1 measurements highlighted in **blue show the forward (training) direction** in which the model is trained and its adjacent non-colored measurement uses the **same model** to perform **reverse** translation.

Embeddings & Baselines. We use normalized and mean-centered FastText embeddings (Joulin et al., 2016), learned from language-specific Wikipedia. We train two types of translation models: (a) a linear mapping with a weight matrix $W \in \mathbb{R}^{d \times d}$ for a d-dimensional embedding, and (b) a 1 hidden layer feed forward network. For baseline comparisons, we retrain VECMAP (Artetxe et al., 2016, 2018), GeoMM (Jawanpuria et al., 2019) and RCSLS (Joulin et al., 2018). When possible, we compare with BLISS(R) (Patra et al., 2019), Joint Align (Wang et al., 2019), Cross-lingual Anchoring (Ormazabal et al., 2020) and LNMAP (Mohiuddin et al., 2020) using results previously reported for high resource languages. We train BDMA with a combination of cosine (`C`) and RCSLS (`R`) losses, and separate baseline methods for each language and translation direction pair.

3.1 Impact of Polysemy

In Table 1, we observe BDMA's performance translating words in high resource languages. BDMA's performance is better or equivalent in comparison to other methods. Additionally, we note that the translation model is trained with 5000 unique pairs while *Joint Align* (Wang et al., 2019) and *cross-lingual anchoring* (Ormazabal et al., 2020) are trained with the full MUSE training dataset for any given language pair which is greater than 5K.[2] Similarly, Table 2 shows the performance of different models on low resource languages compared to BDMA. BDMA with 1-H FFN performs better than a linear mapping with an overall increase as high as 2.82% while translating Japanese to English. The exception is for Hindi, where the performance drops by 3.8% (Hi → En). We see that the

model benefits from bidirectional training when there are polysemous words in the evaluation corpus, improving the network's ability to generalize.

3.2 Impact of Unique Vocabulary

Similar to the previous experiment, we analyze the impact of BDMA with an evaluation dataset of unique pairs for both high resource and low resource languages. In contrast to Table 1, Table 3 shows that both linear mapping and 1-H neural network are comparable to other baselines (except RCSLS) when there are no polysemous words. Adding additional layers to the network does not provide any benefit, which is consistent with findings from Søgaard et al. (2018) and Ruder et al. (2019) that a linear mapping performs well for these language pairs. Table 4 details experiments for the same under low resource language conditions. Although BDMA performs better for En → Ru and En → Ja, Hi → En continues to perform poorly. In contrast, its performance is comparable for *Portuguese* where the reduction is 1.13% (En → Pt) only.

Therefore, the 2 main benefits of BDMA are: (a) it creates a single bidirectional word translation model while keeping the performance of the model comparable to baseline, and (b) the 1-H FFN is a single network in comparison to LNMAP (which has 3), while Linear BDMA has the same number of parameters as all other methods in Table 1 and 2.

3.3 Importance of Training Direction

If the filtered training pairs do not contain polysemous words, why is the training direction important? This is because when the model is trained for a number of epochs, its optimal savepoint is chosen based on the forward translation performance for the given language pair direction. As seen in Table 2 and 4, the direction chosen to start model training can have an impact of forward and reverse translation performance. For example, the model training with *Ru → En* performs better than *En → Ru*.

Loss	Evaluation [$s \to t$] P@1			
	En→Ru	**Ru→En**	**En→Ja**	**Ja→En**
Linear Mapping ($s \to t$)				
`[M]`	54.66	66.26	21.93	16.26
`[C]`	55.00	66.46	52.22	40.38
`[R]`	51.80	67.53	38.51	39.53
`[C + R]`	55.80	68.66	53.59	38.52
Linear Mapping ($t \to s$)				
`[M]`	53.66	65.20	21.86	16.54
`[C]`	54.93	66.46	52.15	40.38
`[R]`	52.13	67.93	38.58	39.49
`[C + R]`	55.60	69.73	53.52	38.73
1-Hidden Layer Feedforward Network ($s \to t$)				
`[M]`	51.40	63.66	20.28	12.19
`[C]`	55.00	65.86	52.84	40.38
`[R]`	52.26	68.80	49.96	47.48
`[C + R]`	**57.20**	**70.20**	**54.07**	46.51
1-Hidden Layer Feedforward Network ($t \to s$)				
`[M]`	49.80	64.26	17.95	18.26
`[C]`	54.06	66.00	53.80	40.45
`[R]`	52.46	68.60	49.48	47.07
`[C + R]`	56.93	70.06	54.28	**47.07**

Table 5: **Precision @ 1 of BDMA with different losses.** An ablation study of the impact of different loss combinations while training a model with BDMA. `[M]` = MSE, `[C]` = cosine, `[R]` = RCSLS and `[C + R]` = cosine + RCSLS loss.

Ablation Study. In Table 5, we assess the impact of using (combinations of) MSE, cosine and RCSLS distance functions $\mathcal{D}$. A combined cosine and RCSLS loss (`[C + R]`) performs the best and provides consistent forward ($s \leftarrow t$) and reverse translation ($t \leftarrow s$) performance (within 0.5%).

4 Related Work

Over the years, many supervised methods have been proposed. Irvine and Callison-Burch (2013) learn a binary classifier for a language pair that predicts if a given word pair is a translation of each other or not. Artetxe et al. (2016) implement Procrustes alignment while normalizing and mean centering word embeddings. Xing et al. (2015) add an orthogonal loss while aligning manifolds. In Artetxe et al. (2018), additional pre- and post-processing steps are provided. Conneau et al. (2017) propose a new retrieval method called cross-domain similarity local scaling (CSLS) in order to reduce the "hubness" problem. Joulin et al. (2018) convert CSLS into a loss objective in order to optimize the translation matrix. An important challenge with linear mapping is that it assumes that source and target languages have a similar manifold structure; Søgaard et al. (2018) show this assumption is not true for many language pairs. Nakashole and Flauger (2018) show that transformations need to be non-linear and are dependent on the word's local neighborhood. Instead of learning a mapping between languages separately, Wang et al. (2019) jointly learn the monolingual and cross-lingual embeddings for the given language pair. Ormazabal et al. (2020) extend skip-gram to project source embeddings into a fixed target space and using them as anchors to iteratively learn the mapping.

Cyclic Loss for Reverse Translation. Xu et al. (2018) perform unsupervised word alignment using the cycle consistency loss while computing the sinkhorn distance between a forward and reverse translation network. Mohiuddin and Joty (2019) train a dual autoencoder-discriminator architecture and use a cyclic loss to train a bi-directional model. LNMAP (Mohiuddin et al., 2020) extends the autoencoder architecture with a 2 layer mapping to learn a non-isomorphic mapping between languages. Our work differs as we reduce the number of parameters in the model (as it contains the mapping only) while training an **invertible network** that can perform both forward and back translation.

5 Conclusion

We show how a non-linear mapping (invertible neural network) can be trained with a cyclic consistency loss, showing that a common isomorphic assumption is not strictly necessary (Søgaard et al., 2018). The network trained has fewer parameters in comparison to Mohiuddin et al. (2020) while providing equivalent or improved performance on the low-resource word translation task.

Appendix

In the following sections, we provide information about hyperparameter values for each network architecture, statistics about the dataset and results from additional experiments. The experiments are conducted on a NVIDIA K20 GPU with ≈ 4GB of RAM and NVIDIA V100 GPUs with 16GB of RAM. Each model is trained on a single GPU. Linear models can be trained on K20s and the larger 1-H-FFN are optimized on V100s.

A Hyperparameters

Following are the hyper-parameters used in our experiments:

Hyper-parameter	**Value**
`batch size`	128
`lr_decay`	0.98
`lr_shrink`	0.5
`map_beta`	0.001
`max_vocab`	200000

Table A1: Hyperparameters for BDMA experiments.

As seen in table A1, the maximum vocabulary (`max_vocab`) size is $200K$. The vocabulary is selected by taking $200K$ words that have the highest frequency. `map_beta` is the parameter that controls the contribution of the orthogonal loss to the overall loss function. The network is trained with an Adam optimizer (Kingma and Ba, 2014) having a learning rate of 0.0005. The word embeddings are preprocessed i.e. they are normalized and centered. The 1 hidden layer feedforward network used to perform alignment has a hidden layer size of 4096. The activation function of the hidden layer is `tanh`.

B CCL Correlation with Linear Mapping

As observed in equation 2.1, a linear relationship between source and target language embeddings can be learned by minimizing the squared loss between them. Although, in practice, an additional orthogonal constraint $\mathcal{L}_{ortho} = WW^T - I$ is added (Xing et al., 2015) as shown in the equation below:

$$\mathcal{L}_{\text{mse}} = \sum_{i \in V^p} \overbrace{\|f_a(m_i^s) - m_i^t\|_2^2}^{\mathcal{L}_{\text{mse}}^i} + (WW^T - I), \tag{3}$$

Minimizing $\mathcal{L}_{ortho}$ makes the linear mapping *implicitly* bidirectional able to map words from the target to source language. In comparison, $\mathcal{L}_{ccl}$ in equation 1 trains a non-linear neural network or linear mapping to be **explicitly** bidirectional. Thus $\mathcal{L}_{ccl}$ can be considered as an extension of $\mathcal{L}_{ortho}$.

Target Language	**Train**	**Test**
French	10872	2943
German	14677	3660
Italian	9657	2585
Spanish	11977	2975
Russian	10887	2447
Hindi	8704	2032
Japanese	7135	1799
Portuguese	11185	2827

Table A2: **MUSE Dictionary Size**. The table shows the *target* language, the number of pairs in the training and pairs present in the test dictionary where the *source* language is *English*.

Source Language	**Train**	**Test**
French	8270	2342
German	10866	2827
Italian	7364	2102
Spanish	8667	2416
Russian	7452	2069
Hindi	8001	1963
Japanese	6819	1952
Portuguese	7582	2148

Table A3: The table shows the *source* language, the number of pairs in the training and pairs present in the test dictionary where the *target* language is *English*.

C Dataset

MUSE (Conneau et al., 2017). As described in §3, the dataset has 110 bilingual dictionaries and contains pairs with *English* being the source or target language. Additionally, *Non-English* language pairs are available for European languages that includes *German*, *Spanish*, *French*, *Italian* and *Portuguese*. Each bilingual dataset has a vocabulary of 5000 unique source language words to train the translation model and 1500 unique words to evaluate them. Because the pairs are not unique and contain polysemous source words (the target word is always unique), the overall size of training and test dictionaries is greater than 5000 and 1500.

Tables A2 and A3 show the dataset size from the original MUSE dataset. The tables show that samples for different language pairs contain polysemous words that expand dataset size by 36.8% to 123.7% in comparison to BDMA (in table 2, 4 and 1) that is trained with 5000 unique pairs only.

D Additional Loss

In §2.1, we showcased how MSE is adapted for $\mathcal{L}_{\text{ccl}}$. Similarly, cosine and Relaxed CSLS loss can be modified for BDMA too. In an adapted version of cosine loss, we minimize the following:

$$\min_{\theta_f} \sum_{i \in V^p} (1 - |f_a(m_i^s) \cdot m_i^t|) + (1 - |f_b(m_i^t) \cdot m_i^s|)$$

In order to modify RCSLS (Joulin et al., 2018), we first take look at CSLS (Conneau et al., 2017) criteria for retrieval:

$$\begin{aligned} &\text{CSLS}(m_i^s, m_i^t) \\ &\quad = -2\cos(m_i^s, m_i^t) \\ &\qquad + \frac{1}{\text{k}} \sum_{m_j^t \in \mathcal{N}^t(\mathcal{W} \cdot m_i^s)} \cos(\mathcal{W} m_i^s, m_j^t) \\ &\qquad + \frac{1}{\text{k}} \sum_{m_j^s \in \mathcal{N}^s(\mathcal{W}^{\mathcal{T}} \cdot m_i^t)} \cos(m_j^s, \mathcal{W}^{\mathcal{T}} m_i^t)) \end{aligned} \tag{4}$$

where $\mathcal{N}^s(x)$ is the neighborhood of x in the source manifold and $\mathcal{N}^t(y)$ is the same in the target, k is the number of nearest neighbors and $\mathcal{W}$ is assumed to be orthogonal. Joulin et al. (2018) relax the cosine criteria in RCSLS i.e. $\cos(\mathcal{W} m_i^s, m_i^t) = {m_i^s}^{\mathcal{T}} \mathcal{W}^{\mathcal{T}} m_i^t$. Hence RCSLS becomes:

$$\begin{aligned} &\text{RCSLS}(m_i^s, m_i^t) \\ &\quad = -2{m_i^s}^{\mathcal{T}} \mathcal{W}^{\mathcal{T}} m_i^t \\ &\qquad + \frac{1}{\text{k}} \sum_{m_j^t \in \mathcal{N}^t(\mathcal{W} \cdot m_i^s)} {m_i^s}^{\mathcal{T}} \mathcal{W}^{\mathcal{T}} m_j^t \\ &\qquad + \frac{1}{\text{k}} \sum_{m_j^s \in \mathcal{N}^s(\mathcal{W}^{\mathcal{T}} \cdot m_i^t)} {m_j^s}^{\mathcal{T}} \mathcal{W}^{\mathcal{T}} m_i^t \end{aligned} \tag{5}$$

In BDMA, we replace the orthogonal matrix $\mathcal{W}$ with a mapping that is either linear or non-linear (neural network). RCSLS changes to:

$$\begin{aligned} \text{RCSLS}(m_i^s, m_i^t) &= -2 f_a(m_i^s) m_i^t \\ &+ \frac{1}{\text{k}} \sum_{m_j^t \in \mathcal{N}^t(f_a(m_i^s))} f_a(m_i^s) m_j^t \\ &+ \frac{1}{\text{k}} \sum_{m_j^s \in \mathcal{N}^s(f_b m_i^t)} m_j^s f_b(m_i^t) \end{aligned} \tag{6}$$

In equation 6, f_a and f_b are the forward and reverse flow projections of m_i^s and m_i^t respectively.

Probabilistic Graph Reasoning for Natural Proof Generation

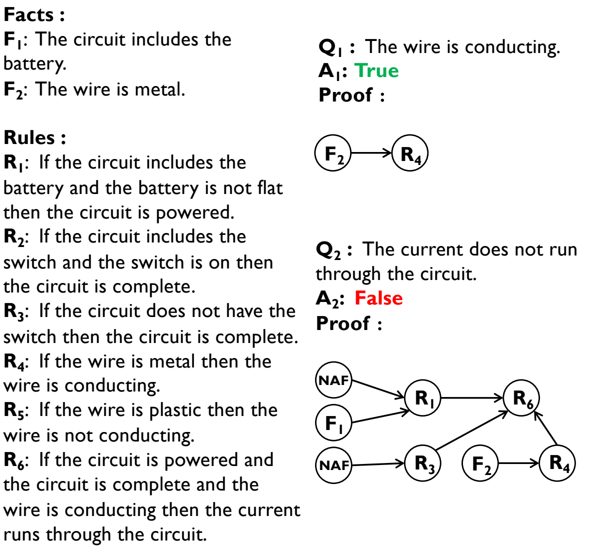
Abstract

In this paper, we investigate the problem of reasoning over natural language statements. Prior neural based approaches do not explicitly consider the inter-dependency among answers and their proofs. In this paper, we propose PRobr, a novel approach for joint answer prediction and proof generation. PRobr defines a joint probabilistic distribution over all possible proof graphs and answers via an induced graphical model. We then optimize the model using variational approximation on top of neural textual representation. Experiments on multiple datasets under diverse settings (fully supervised, few-shot and zero-shot evaluation) verify the effectiveness of PRobr, e.g., achieving 10%-30% improvement on QA accuracy in few/zero-shot evaluation. Our codes and models can be found at https://github.com/changzhisun/PRobr/.



Facts :
F_1: The circuit includes the battery.
F_2: The wire is metal.

Rules :
R_1: If the circuit includes the battery and the battery is not flat then the circuit is powered.
R_2: If the circuit includes the switch and the switch is on then the circuit is complete.
R_3: If the circuit does not have the switch then the circuit is complete.
R_4: If the wire is metal then the wire is conducting.
R_5: If the wire is plastic then the wire is not conducting.
R_6: If the circuit is powered and the circuit is complete and the wire is conducting then the current runs through the circuit.

Q_1 : The wire is conducting.
A_1: True
Proof :

Q_2 : The current does not run through the circuit.
A_2: False
Proof :

Figure 1: An example of reasoning over natural language statements. The goal is to predict the answer (true/false) and generate the proof graph.

1 Introduction

Automatic reasoning over explicitly provided knowledge has been a persistent goal of AI (Newell and Simon, 1956; McCarthy et al., 1960). Early approaches focus on reasoning over formal (logical or probabilistic) representations. However, automatically constructing and reasoning over formal representations remain challenging. To bypass these challenges, in this work, we investigate reasoning over natural language statements instead of formal representations.

Given a set of facts and rules and a query (expressed in natural language), we aim to predict the answer and provide proof to prove or disprove the query. For example, in Figure 1, there are two facts, six rules and two queries, each of which is expressed by natural language. To predict the true/false of each query, starting from the facts, we need to reason deductively by applying given rules until we can derive the truth value of the query. The process of deduction can be represented as a graph, whose node is either a fact, rule or special NAF node (explained in the Section 2.1). Generating answer and proof together makes a system easier to interpret and diagnose.

Recent work by PRover (Saha et al., 2020) first explored this problem through two modules: question answering and proof generation. It trains these two modules through implicit parameter sharing, and then uses integer linear programming (ILP) to enforce consistency constraints (only test time). It is difficult to ensure that the proof generation module contributes to the question answering module, because the proof is not explicitly involved in the answer prediction. Parameter sharing becomes more limited under few/zero-shot settings, as demonstrated in our experiments. We expect the proof to enhance the capability of question answering, especially under few/zero-shot settings. One

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3140–3151
August 1–6, 2021.

promising solution is to explicitly exploit more interaction between question answering and proof generation.

In this paper, we propose PRobr, a novel **prob**abilistic graph **r**easoning framework for joint question answering and proof generation. PRobr defines a joint distribution over all possible proof graphs and answers with an undirected *probabilistic graphical model* (PGM). It directly characterizes the interaction between proofs and answers. PGMs generally incur intractable learning and inference for the complex graph (Koller and Friedman, 2009). For example, computing normalization constant in PGMs using traditional probabilistic propagation algorithm (e.g.sum-product algorithm (Kschischang et al., 2001)) requires large time complexity. Therefore, we propose a variational approach to maximize the pseudolikelihood of joint distribution to optimize the model more efficiently. First, a variational distribution was introduced based on mean-field assumption. Then we maximize the pseudolikelihood of joint distribution given the output of variational distribution. At the same time, we align these two distributions using the training data. PRobr can be efficiently trained by stochastic gradient descent. Our contributions are summarized as follows[1]:

- We propose PRobr for joint question answering and proof generation, which defines a joint distribution over all possible proofs and answers with an undirected PGM to capture more dependencies.

- We present an efficient variational approximation method to learn PRobr.

- Experiments on several datasets verify the effectiveness of PRobr under multiple settings (supervised, few-shot, and zero-shot evaluation).

2 Task Definition

To reason over natural language statements, we design to answer the query and generate corresponding proof generation jointly. Figure 1 shows an example. Given a declarative query Q, and given relevant facts and rules (expressed in natural language), the task aims to predict the answer A (true/false) to the query Q based on the closed-world assumption (described in 2.1). Meanwhile, it generates a proof P (described in 2.2) to prove or disprove Q.

2.1 Semantics

We adopt the semantics of Datalog (Ceri et al., 1989) in this work. Following prior work (Clark et al., 2020), we make a closed-world assumption (CWA), which means a fact is true if it can be deduced based on a given context, and any fact not provable is assumed false. And we use negation as failure (NAF) (Clark, 1978), a rule of inference which allows one to deduce that `NOT S` is true if all possible proofs of a statement `S` fail. For example, in Figure 1, the `NAF` node before $\mathtt{R}_3$ represents "the circuit does not have the switch". Note that under this semantics, negative facts and negative rules are not allowed because of redundancy under the CWA assumption.

2.2 Formulations

A proof is a directed acyclic graph (Figure 1). Each node is either a fact, rule or special `NAF` node. Each edge directs from either a fact (or `NAF`) to a rule or a rule to another rule, which indicates that a fact is consumed by a rule, or another rule consumes a rule, respectively. For simplicity, let context $C = \{s_1, \ldots, s_n\}$ denote the collection of sentence, each of which is a fact or rule.

Proof Formulation We assign an indicator variable (0/1) for each possible node and edge, to vectorize the structure of a given proof P. Specifically, we introduce the indicator variables $V = \{V_i\}_{i=1}^{n}$ for each element s_i in the context C, and an indicator variable $E = \{E_{ij}\}_{i,j=1}^{n}$ $(i \neq j)$ for a possible edge connecting from node s_i to node s_j, where:

- $V_i = 1$ indicates s_i is in the proof P, while $V_i = 0$ means s_i is absent.

- $E_{ij} = 1$ indicates there is an edge directing from s_i to s_j, while $E_{ij} = 0$ means s_i cannot direct to s_j in the proof by an edge.

In addition, we assign a binary answer variable A to indicate the true value of the query. Figure 2a shows a simplified example, where context $C = \{s_1, s_2, s_3\}$, and the query can be decided as true by a very simple proof, consisting of only two nodes (s_1 and s_3) and a single edge (from s_1 to s_3). The proof can be represented by the following variables: $A = V_1 = V_3 = E_{13} = 1, V_2 = E_{12} = E_{21} = E_{23} = E_{31} = E_{32} = 0$.

---

(a) Proof graph and its induced random variables.

(b) Factor graph induced by the proof graph.

Figure 2: Joint probabilistic distribution by assigning indicator variables for the answer and proof. The solid circles and lines in 2a indicate that these corresponding statements and edges are in the final proof graph.

3 Approach

We introduce the proposed framework PROBR, which jointly provides the answer to the given query over natural contexts and generates corresponding proof. Different from PROVER that makes independence assumption, PROBR can capture more dependencies between the proof and answer. PROBR defines a joint distribution over all possible proofs and answers with an undirected graphical model (Section 3.1), and we use neural networks to parameterize each component (Section 3.2). To optimize PROBR efficiently, we adopt a variational approach to maximize the pseudolikelihood of joint distribution (Section 3.3). Finally, we introduce the strategy during inference (Section 3.4).

3.1 Overview

We start by formalizing joint question-answering module and proof-generation module in a probabilistic way. We clarify some notations as follows:

- A context $C = \{s_1, \ldots, s_n\}$, s_i is a sentence.
- A query Q.
- An answer variable A, it can take any value a in $\{0, 1\}$.
- Node variables $\mathcal{V} = \{V_i\}_{i=1}^{n}$, each V_i can take any value v_i in $\{0, 1\}$.
- Edge variables $\mathcal{E} = \{E_{ij}\}_{i,j=1}^{n}$ $(i \neq j)$, each E_{ij} can take any value e_{ij} in $\{0, 1\}$.
- Let $Y \triangleq (A, \mathcal{E}, \mathcal{V})$ denote all output variables.

In our notation, we use uppercase letters for variables (e.g., Y, A, V_i, E_{ij}) and lowercase letters for variables that take values (e.g., y, a, v_i, e_{ij}).

Given a context C and a query Q, PROBR tries to assign true/false values for all variables, including answer variable A, node variables V and edge variables E. We define a joint distribution over all possible Y, officially denoted as $p(Y)$: [2]

$$p(Y = y) \propto \Phi^A(a) \prod_i \Phi_i^V(v_i, a) \prod_{i,j} \Phi_{ij}^E(v_i, v_j, e_{ij}, a) \quad (1)$$

Different from PROVER that makes independent assumption, such a factorization of Equation 1 can characterize the interaction between the variables V_i, V_j, E_{ij} and A. Figure 2b shows the factor graph of joint distribution $p(Y)$ for the example in Figure 2a. Theoretically, when we have the ground truth y^*, [3] we can minimize the following objective:

$$\mathcal{L}_{\text{joint}} = -\log p(Y = y^*) \quad (2)$$

However, the normalization constant of $p(Y)$ is hard to calculate due to high-order factors of large size (RHS of Equation 1). In this paper, we provide a variational-based solution to optimize objective $\mathcal{L}_{\text{joint}}$ (Section 3.3).

3.2 Parameterization

We use neural networks to parameterize each potential function of Equation 1: Φ^A, Φ_i^V and Φ_{ij}^E.

Text Representation Network Given a context C and a query Q, to obtain a contextual representations, we use RoBERTa (Liu et al., 2019) as our backbone network following (Clark et al., 2020; Saha et al., 2020). The input to RoBERTa is the concatenation of C and Q, separated by `[SEP]` tokens, denoted as: `[CLS]`, C, `[SEP]`, `[SEP]`, Q, `[SEP]`.

---

[2] We drop the input variables for clarity.

[3] We use $*$ to indicate the ground truth in the text.

Potential Function for the Answer (Φ^A) After the RoBERTa encoding, we can get the global representation of the entire input through the first token [`CLS`], denoted as $h_{[\texttt{CLS}]}$. To score the possible values of variable A, i.e. 0 or 1, we use a multilayer perceptron (MLP) as a nonlinear transformation:

$$\begin{bmatrix} \Phi^A(A=0) \\ \Phi^A(A=1) \end{bmatrix} = \mathrm{MLP}_1(h_{[\texttt{CLS}]}) \in \mathbb{R}^2$$

Potential Function for Statements (Φ_i^V) For each sentence s_i (a fact or a rule), we compute the sentence representation h_{s_i} by performing a mean pool of the all token representation based on the output of RoBERTa. It is worth noting that `NAF` is a special fact, we calculate $h_{\texttt{NAF}}$ through linear transformation on $h_{\texttt{CLS}}$. To score the possible values of variables (V_i, A), we also use another MLP as a score function:

$$\begin{bmatrix} \Phi_i^V(V_i=0, A=0) \\ \Phi_i^V(V_i=0, A=0) \\ \Phi_i^V(V_i=0, A=0) \\ \Phi_i^V(V_i=1, A=1) \end{bmatrix} = \mathrm{MLP}_2(h_{s_i}) \in \mathbb{R}^4,$$

where the dimension 4 indicates the number of possible values for the combination of variables V_i and A. We share the parameters of MLP_2 across all sentences.

Potential Function for Statement Relations (Φ_{ij}^E) For each sentence pair (s_i, s_j), we obtain the sentence pair representation h_{s_i,s_j}, by concatenating h_{s_i} and h_{s_j} with their element-wise difference (directionality). To score four variables (V_i, V_j, E_{ij}, A) simultaneously, similarly, we use a new MLP as score function:

$$\begin{bmatrix} \Phi_{ij}^E\begin{pmatrix} V_i=0, V_j=0, \\ E_{ij}=0, A=0 \end{pmatrix} \\ \vdots \\ \Phi_{ij}^E\begin{pmatrix} V_i=1, V_j=1, \\ E_{ij}=1, A=1 \end{pmatrix} \end{bmatrix} \begin{matrix} = \mathrm{MLP}_3(h_{s_i,s_j}) \\ \in \mathbb{R}^{16}, \end{matrix}$$

$$h_{s_i,s_j} = h_{s_i} \oplus h_{s_j} \oplus (h_{s_i} - h_{s_j}),$$

where $\oplus$ is the vector concatenation, and the dimension 16 indicates the number of possible values for the combination of four variables (V_i, V_j, E_{ij}, A). We also share the parameters of MLP_3 across all sentence pairs.

3.3 Learning the Model

To tackle the challenge of optimizing $\mathcal{L}_{\text{joint}}$ (Equation 2), we adopt the widely used pseudolikelihood as an alternative objective for optimization (Richardson and Domingos, 2006), bypassing the calculation of the normalization constant.

Pseudolikelihood Given a set of variable Y, the pseudolikelihood of Y is defined as:

$$p_{\text{pseduo}}(Y) = \prod_{y \in Y} p(y|Y_{-y}) =$$
$$p(A|\mathcal{E}, \mathcal{V}) \prod_i p(V_i|Y_{-V_i}) \prod_{i,j} p(E_{ij}|Y_{-E_{ij}})$$

When we have the ground truth y^*, we can minimize the following objective:

$$\mathcal{L}_{\text{pseudo}} = -\log p_{\text{pseudo}}(Y = y^*)$$

However, it is difficult to decode the optimal assignments based on the pseudolikelihood (Equation 3). There is a rich body of literature on how to decoding in a sampling way (Chapter 12 (Salakhutdinov, 2014)). In this paper, however, we choose a modern approach using variational approximation.

Variational Approximation We approximate pseudolikelihood of Y with a mean-field (Opper and Saad, 2001) variational distribution $q(Y)$, in which $y \in Y$ is independent of each other. Similarly, we parameterize each independent distribution with a neural network. Formally, $q(Y)$ is formulated as below:

$$q(Y) = q(A) \prod_i q(V_i) \prod_{i,j} q(E_{ij}),$$

$$\begin{bmatrix} q(A=0) \\ q(A=1) \end{bmatrix} = \mathrm{Softmax}\left(\mathrm{MLP}_4(h_{[\texttt{CLS}]})\right) \in \mathbb{R}^2,$$

$$\begin{bmatrix} q(V_i=0) \\ q(V_i=1) \end{bmatrix} = \mathrm{Softmax}\left(\mathrm{MLP}_5(h_{s_i})\right) \in \mathbb{R}^2,$$

$$\begin{bmatrix} q(E_{ij}=0) \\ q(E_{ij}=1) \end{bmatrix} = \mathrm{Softmax}\left(\mathrm{MLP}_6(h_{s_i,s_j})\right) \in \mathbb{R}^2.$$

Once the variational distribution $q(Y)$ is obtained, it can provide conditions for pseudolikelihood $p(y|Y_{-y})$, thus avoiding the sampling process to obtain the optimal assignments. In the optimization process, we adopt the simple strategy to update the parameters of p and q.

- For node and edge variables, we optimize

$$\mathcal{L}_{\text{node}} = -\sum_i \log q(V_i = v_i^*),$$

$$\mathcal{L}_{\text{edge}} = -\sum_{i,j} \log q(E_{ij} = e_{ij}^*).$$

- For the answer variable, we optimize

$$\mathcal{L}_{\text{qa}} = -\log p(A = a^*|\hat{\mathcal{E}}, \hat{\mathcal{V}}),$$

where $\hat{\mathcal{E}} = \{\hat{e}_{ij}\}, \hat{\mathcal{V}} = \{\hat{v}_i\}$ are the predictions of variational model [4].

The final objective is to minimize:

$$\mathcal{L}_{\text{final}} = \mathcal{L}_{\text{qa}} + \mathcal{L}_{\text{node}} + \mathcal{L}_{\text{edge}}$$

Overall, PROBR is a mixture of independent (variational) model and undirected graphical model through some reasonable approximations. Our final optimized distribution can be decomposed as directed graphical model $q(\mathcal{V})q(\mathcal{E})p(A|\mathcal{E}, \mathcal{V})$, where $q(\mathcal{V}), q(\mathcal{E})$ adopts the independent factorized probability, and $p(A|\mathcal{E}, \mathcal{V})$ is implied by the undirected graphical model (Equation 1). In this way, PROBR enjoys the advantage of global normalization (undirected graphical model) and is easier to optimize (directed graphical model).

Discussion Another way to achieve consensus between $q(Y)$ and $p_{\text{pseudo}}(Y)$ is to directly optimize the KL divergence:

$$\mathcal{L}_{\text{kl}} = \sum_{y \in Y} \text{KL}\left(q(y)||p(y|Y_{-y})\right)$$

However, $\mathcal{L}_{\text{kl}}$ does not bring any improvement for supervised learning (Section 4.6), hence we exclude it during training. PROBR can be easily extended to semi-supervised learning scenario by using this $\mathcal{L}_{\text{kl}}$ term. Specifically, minimize the $\mathcal{L}_{\text{final}}$ for the labeled data; and minimize the $\mathcal{L}_{\text{kl}}$ for the unlabeled data. We save this for future work.

3.4 Inference

After training, for nodes and edges, we choose the predictions of the variational model, and for answers, we choose the prediction of the joint model based on the output of variational model. In addition, we also employ the Integer Linear Programming (ILP) to enforce consistency constraints following (Saha et al., 2020).

4 Experiments

To evaluate the effectiveness and generality of our PROBR model, we conduct both fully supervised learning, few-shot learning, and zero-shot learning over several datasets[5] against two baselines: RuleTakers and PROVER[6].

4.1 Datasets and Metrics

We use three datasets (DU0-DU5, Birds-Electricity, ParaRules) introduced by (Clark et al., 2020).

DU0-DU5 DUd (d=0,1,2,3,5) are five synthetic datasets, each containing 100k queries with theories expressed in templated English, proof graphs expressed in natural language, and answers described as *True/False*. Answers require reasoning up to depth d for queries in DUd.

Birds-Electricity This dataset is a test-only dataset of 5k samples in total. It describes birds and electric circuit, which was used to evaluate the out-of-distribution performance of the models.

ParaRules ParaRules is a dataset generated and paraphrased from sampled theories (facts + rules). It contains 40k queries against ≈2k theories, where the original templated English facts and rules are creatively paraphrased into more diverse natural language by crowdsourcing. For example, the fact "Dave is cold" can be rephrased as"After Dave got wet in the rain, he feels cold"; the rule "If someone is nice then they are young" can be rephrased into "A person described as being nice will certainly be young". Different from DUd and Birds-Electricity dataset composed of synthetic language, ParaRules can better test models' reasoning ability over human-like language.

Metrics We evaluate the performance considering both answers and proofs. For answers, we evaluate the **QA Accuracy** (**QA**). For proofs, we evaluate the **Proof Accuracy** (**PA**), and PA refers to the fraction of examples where generated proof matches exactly with the gold proof. We also report **Full Accuracy** (**FA**) to denote the faction of examples where both the answer and the proof are exactly correct.

4.2 Fully Supervised Learning

For the supervised setting, we train PROBR on the training split of the DU5 dataset with gold answer

---

[4] We also experiment with the gold proof to optimize $\mathcal{L}_{\text{qa}}$ (Section 4.6).

[5] https://allenai.org/data/ruletaker

[6] Please refer to supplementary materials for our hyper-parameter and computing infrastructure. For RuleTakers and PROVER, we directly adopt results reported in their papers if exist, and for extra setting beyond papers, we reproduce the baselines using provided codes and parameters:https://github.com/swarnaHub/PRover.

Table 2: Few-shot performance comparison among PROVER and PROBR on test split of DU5 after training on partial DU5 samples. (Two types of training samples, RC: queries from randomly reserved contexts; RQ: randomly reserved queries.)

and gold proof and evaluate on the test split of DU5. We evaluate above metrics of varying depths d against two state-of-the-art baselines: RuleTakers (Clark et al., 2020) and PROVER (Saha et al., 2020), showed in Table 1. For RuleTakers and PROVER, we directly adopt the results reported in their paper. Note that RuleTakers can not generate a proof, so we only report the PA and FA on PROVER and PROBR. The corresponding validation set results can be found in the supplementary materials .

Overall, at each depth, PROBR generates comparable or superior QA accuracy to baselines. And for 88.8% of test examples, PROBR can generate exact proofs and answers. Similar to PROVER, the full accuracy matches the proof accuracy for PROBR, showing that in this fully supervised setting, full accuracy depends on proof accuracy at each depth. The predicted answer is always correct when the corresponding proof is correct. Actually, answering predicting is much easier than a proof generation.

When increasing depth, PROBR provides accurate answers without any loss in QA performance. It becomes harder to generate correct proofs for both PROVER and PROBR, while PROBR outperforms PROVER by 7 points of proof accuracy (65.1% → 72.2%) at depth 5.

4.3 Few-shot Learning

We explore the few-shot learning ability of PROBR against PROVER by reducing training data size. For the sake of comparison, we follow the same setting in (Saha et al., 2020), that is, randomly reserve 30k, 10k, 1k queries of overall 69762 training queries to train the model, denoted as "RQ".

It's worth noting that in the DU5 training dataset, several queries can be asked from a shared context. To better explore the ability when varying the amount of training data, we conduct another set of experiments, denoted as "RC". Specifically, we first randomly select context that appeared in the DU5 training dataset by a varying percentage, i.e., 10%, 5%, 1%, and then reserve training samples where the query is asked from the selected context. Results of both "RQ" and "RC" are showed in Table 2.

Generally speaking, proof generation is harder to improve with increased training data, while QA performance improves rapidly by enlarging the training size. PROBR widely defeats PROVER on QA accuracy in each setting in Table 2. Surprisingly, PROBR achieves 88.2% QA accuracy when training with only 700 samples (RC-1%). Overall, PROBR has a more stable ability for question answering when varying training data; however, PROVER's QA accuracy drops sharply when lacking training data. This is because that PROBR considers the joint distribution over all possible proofs and answers, and can better learn to reason over natural language statements. While as for proof accuracy, even if in some settings, PROBR loses to PROVER (RC-1%), we will soon discover that PROVER overfits to the small training data (Section 4.4 and 4.5).

Another interesting observation is that the full accuracy is not always consistent with the proof accuracy in few-shot learning, which is different from the observation in Section 4.2. Furthermore, we find that the gap between **PA** and **FA** when using PROBR is much smaller than that of PROVER. This is because PROVER trains in a multi-task way, where the question answering module and proof generation module could make independent errors, especially when training data is not enough. But PROBR can better utilize limited data to reason, which again verifies the effectiveness of PROBR.

Test	Cnt	QA			PA		FA	
		RT	PV	PB	PV	PB	PV	PB

Table 3: Zero-shot performance comparison among RuleTakers, PROVER, and PROBR on Birds-Electricity dataset after training on DU5.

4.4 Zero-shot Evaluation

Following previous work (Clark et al., 2020; Saha et al., 2020), we evaluate the out-of-distribution (OOD) performance of PROBR against baselines on six sub-datasets of Birds-Electricity. We conduct zero-shot experiments using DU5-trained models, which means that the model does not see any bird-domain or any electricity-domain samples during training. Results are showed in Table 3.

For QA accuracy, PROBR outperforms PROVER and RuleTakers obviously in all of sub-datasets. As for proof accuracy, PROBR performs better when the depth of the out-of-domain sample ≤ 3, while there is a PA drop compared to PROVER when testing on E4. This is a very interesting thing: superficially, proof accuracy drops for complicated unseen queries, but the QA accuracy for out-of-domain queries improves a lot (11 points on E4: $84.8\% \rightarrow 95.6\%$). We save it for future work to explore the portability of the proof and how an out-of-domain proof can help with question answering.

Moreover, we evaluate the zero-shot performance after few-shot learning. In Table 4, we report the results when testing on Birds-Electricity after training the model only on partial DU5 (RC-k and RQ-k, described in 4.3) training partitions. As shown in Table 4, when testing zero-shot performance after few-shot learning, PROBR is well ahead of PROVER on QA accuracy. However, as for proof accuracy, PROBR seems worth than PROVER on the zero-shot test. Again we point out this amazing observation. This indicates that data from different domains might have different proof form. The well-learned proof from one domain might not be directly adopted to another, but, by training with PROBR, the well-learned proof from one domain can help answer out-of-distribution queries.

Table 5: Performance comparison between RuleTakers, PROVER, and PROBR when testing on DU5 after training on DU0, DU1, DU2, DU3, respectively.

4.5 Generalization Ability

Generalize to Unseen Depth We conduct experiments to explore how well PROBR can generate proofs and provide answers at depths unseen during training. Following PROVER, we train the model on the training splits of DU0, DU1, DU2, and DU3, respectively, and test the QA performance and proof performance on the overall DU5 test set. As DU5 contains queries with higher depth than those seen during training, we can evaluate the model's ability when generalized to higher depth.

As shown in Table 5, PROBR performs better than RuleTakers and PROVER on all of QA/PA/FA performance when training on D1, D2 and D3, especially a significant improvement on QA performance. PROBR shows a high and comparable QA performance when training only on depth=1 (97.7%), which demonstrates PROBR's superior generalization ability on depth. This means PROBR can perfectly answer complicated queries using only simple training samples, which reduces the cost of constructing training data.

Generalize to Complex Language We also evaluate the robustness of PROBR when generalized to more diverse natural language. Following (Clark et al., 2020; Saha et al., 2020), we train our model on the combined training partitions of DU3

Table 7: Performance comparison between PRover and PRobr when testing on ParaRules test partitions after training on DU5 or partial DU5 (RC-k and RQ-k) training partitions.

and ParaRules, and then test on the ParaRules test partition. The results in Table 6 show that PRobr is more robust for human-like language.

To better test the generalization ability for complex natural language, we train the model only on DU5 or partial DU5 (RC-k and RQ-k, described in 4.3) training partitions and test on test split of ParaRules. This is a more convincing setup since the model will never see the human-like language but all templated language during training. Results are shown in Table 7. When testing on ParaRules after only training on DU5, PRobr outperforms PRover by nearly **30 points** on QA accuracy(53.6% → 82.8%). A similar trend is observed for training on RC-k and RQ-k datasets, where PRobr improves the QA accuracy when generalized to human-like natural language. And the change for proof accuracy is not significant between PRobr and PRover, which supports the observation in Section 4.3 and 4.4, that PRobr improves QA performance by joint question-answering and proof-generation learning, but not necessarily improve the proof performance.

4.6 Ablation Studies

We investigate the effect of training strategy and objective term $\mathcal{L}_{\text{kl}}$ for our model. Specifically we compare PRobr with the following three variants: 1) **PRobr + Gold**, that is, we replace predicted proofs with gold proofs when we optimize $\mathcal{L}_{\text{qa}}$ during training. 2) **PRobr + KL**, that is, we add $\mathcal{L}_{\text{kl}}$ between $q(Y)$ and $p_{\text{pseudo}}(Y)$ during training. 3)**PRobr + Gold + KL** means both. For PRobr and above three variants, we first train on DU5 or partial DU5 (RC-k) training splits respectively, and Figure 3 reports the QA accuracy on test split of DU5 (left), ParaRules test partitions (middle) and Birds-Electricity (right). We observe that PRobr always achieves the best QA accuracy on all of three test datasets (DU5, ParaRules, Birds-Electricity) after training on all of four datasets with varying size (RC-1%, RC-5%, RC-10%, RC-100%). And the other three model variants show inconsistent performance in different settings[7].

5 Related Work

Text Reasoning over Formal Representation Early work employs a pipeline of methods that converts free text into logic form first (semantic parsing), and then uses formal logical reasoning (Musen and Van der Lei, 1988). Due to the serious error propagation caused by semantic parsing (Zettlemoyer and Collins, 2005; Berant et al., 2013; Berant and Liang, 2014), researchers focus on developing theorem provers by combining the symbolic techniques with the differentiable learning from neural networks (Reed and de Freitas, 2016; Abdelaziz et al., 2020; Abboud et al., 2020), such as NLProlog (Weber et al., 2019), SAT solving (Selsam et al., 2019) and Neural programme (Neelakantan et al., 2016). To bypass this expensive and error-prone intermediate logical representation, reasoning over natural language statements in an end-to-end manner is promising.

Text Reasoning over Natural Language Natural logic (MacCartney and Manning, 2009) focuses on semantic containment and monotonicity by incorporating semantic exclusion and implicativity. Subsequently, Clark et al. (2020) proposes to use a Transformer-based model to emulate deductive reasoning and achieves high accuracy on synthetically generated data. PRover (Saha et al., 2020)

---

[7] For more details, please refer to the supplementary materials.

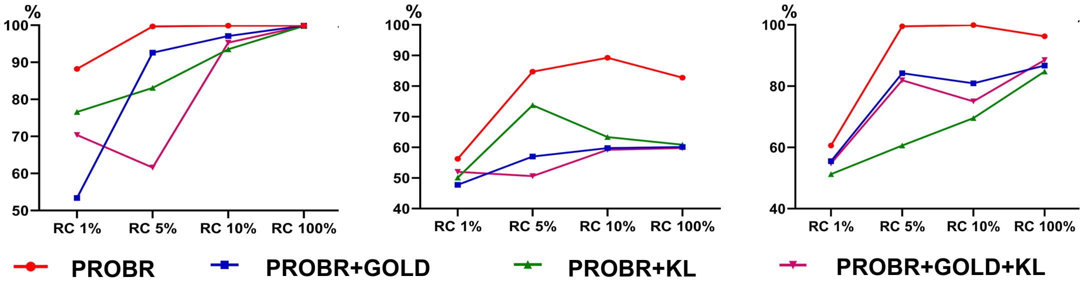

Figure 3: QA accuracy compared among PRobr, PRobr + Gold, PRobr + KL, and PRobr + Gold + KL on DU5 test partition (left), on ParaRules test partitions (middle) and on Birds-Electricity dataset (right), after training on DU5 or partial DU5 (RC-k) training splits.

points out that a reasoning system should not only answer queries but also generate a proof. However, PRover adopts the multi-task learning framework in the training stage and cannot effectively capture the interactions between question answering and proof generation. Along this line, we explore more powerful joint models to achieve deep reasoning.

QA and NLI There are bAbI (Weston et al., 2016), QuaRTz (Tafjord et al., 2019), ROPES (Lin et al., 2019) and Hotpot QA (Yang et al., 2018) (QA datasets) involved in rule reasoning. However, for those datasets, implicit rules (i.e., which multi-hop chains are valid) need to be inferred from the training data. In our task, the rules of reasoning are given in advance. Compared with the Natural Language Inference (MacCartney and Manning, 2014), our task can be regarded as its deductive subset. In particular, NLI allows for unsupported inferences (Dagan et al., 2013).

6 Conclusion

In this work, we propose PRobr, a novel probabilistic graph reasoning framework for joint question answering and proof generation. PRobr defines a joint distribution over all possible answers and proofs, which can directly characterize the interaction between answers and proofs. Experiments prove the effectiveness of proposed PRobr.

Acknowledgement

The authors wish to thank the reviewers for their helpful comments and suggestions, the authors of RuleTakers for their datasets, and the authors of PRover for providing the source code.

DU2	89.3	**99.9**	72.6	**74.3**	72.3	**74.3**
DU3	98.3	**99.9**	79.4	**83.2**	79.4	**83.2**
DU5	99.3	**99.9**	88.0	**90.0**	88.0	**90.0**

Table 10: Performance comparison between PRover and PRobr development split of DU5 after training on DU0, DU1, DU2, DU3, respectively.

C Results of Ablation Studies

Table 11 lists the comparison results of PRobr and the three variants of PRobr (mentioned in Section 4.6). Regarding the Table 11, we have three observations:

1. In all ablation experiments, PRobr achieved the best **QA** performance, demonstrating that PRobr can capture critical information for question answering in a variety of settings. However, since some of the dataset are artificially synthesized, it is difficult to guarantee that PRobr will work in the real dataset as well. We leave it as future work.

2. In some cases, variant d) (**PRobr + Gold + KL**) outperforms PRobr in **PA** and **FA**. It shows the potential advantages of the KL term. In the future, we will explore proof generation in a semi-supervised learning scenario through this KL term.

3. When we compare the performance of the two models PRobr and **PRobr + Gold**, we can see that whether the predicted proof or the correct proof is used during training significantly affects the final performance. Applying some heuristic strategies may give better results, such as scheduled sampling (Bengio et al., 2015). We will try it in the future.

Abstract

In this paper, we consider a realistic scenario on stance detection with more application potential, i.e., zero-shot and few-shot stance detection, which identifies stances for a wide range of topics with no or very few training examples. Conventional data-driven approaches are not applicable to the above zero-shot and few-shot scenarios. For human beings, commonsense knowledge is a crucial element of understanding and reasoning. In the absence of annotated data and cryptic expression of users' stance, we believe that introducing commonsense relational knowledge as support for reasoning can further improve the generalization and reasoning ability of the model in the zero-shot and few-shot scenarios. Specifically, we introduce a commonsense knowledge enhanced model to exploit both the structural-level and semantic-level information of the relational knowledge. Extensive experiments demonstrate that our model outperforms the state-of-the-art methods on zero-shot and few-shot stance detection task.

1 Introduction

Stance detection aims to identify the text authors' attitudes or positions towards a specific topic as a category label from this set: {*Pro*, *Con*, *Neutral*} (Mohammad et al., 2016b, 2017). Conventionally, this task is designed to learn a target-specific classifier for prediction on the same topic. Afterward, cross-target stance detection comes out as a subclass of the initial generic stance detection, where the classifier is adapted from different but closely related topics (e.g., training classifier on "Hillary Clinton" and predicting on "Donald Trump") (Augenstein et al., 2016a). However, both target-specific and cross-target stance detection models (Du et al., 2017; Wei and Mao, 2019; Augenstein et al., 2016a; Zhang et al., 2020) require a large number of training examples with manual annotation, and annotating data for thousands of new topics is time-consuming and expensive.

Topic: Stability **Stance:** Pro

Text: Tenure does not mean a teacher cannot lose their job. It requires due process before termination. Before tenure is achieved, a teacher can be fired without due process. In the Atlanta School District administrators, fearing that low test scores would cost them their jobs, instructed teachers to change student test responses. Without tenure and due process, teachers risked being fired if they didn't follow instructions.

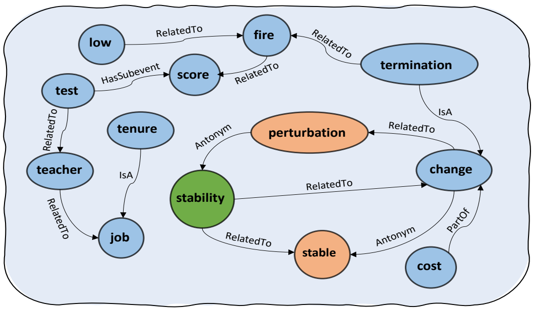

Figure 1: An example where the topic isn't contained in the text. Entity mentions in the text and the topic are highlighted. We omit the reverse edges in the relation graph for clarity.

In this paper, we focus on zero-shot and few-shot stance detection (Allaway and McKeown, 2020), a task to classify stances for a large number of topics with no or very few training examples. A key challenge for zero-shot and few-shot stance detection is the generalization ability of the models. However, most of the previous approaches (Xu et al., 2018; Augenstein et al., 2016b; Wei and Mao, 2019; Wei et al., 2019) for stance detection have relied on only the training data, which fails to achieve satisfactory results in zero-shot and few-shot scenarios. Another prominent challenge is the implicit expression of the users' stance, where the topic does not always appear in the document, resulting

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3152–3157
August 1–6, 2021. ©2021 Association for Computational Linguistics

in the difficulty of directly establishing a connection between the topic and the document. Take Figure 1 as an example, the topic "*Stability*" is not mentioned in the document, where the relational knowledge can supplement the lack of explicit inferential evidence such as (*stability, Antonym, perturbation*) and (*perturbation, RelatedTo, change*) etc. Despite attempting to introduce the external word-level semantic and emotion knowledge (Cambria et al., 2018) about each word of the document, Zhang et al. (2020) neglect the global relationship between the topic and the document.

To further tackle the above challenges, we propose to bring in commonsense knowledge from external structural knowledge base ConceptNet (Speer et al., 2017). We believe that the relational knowledge graph extracted from ConceptNet can promote the transmission of relational information between the document and the topic as well as the inference of corresponding stances, which can further reduce the dependency on annotated data. Specifically, we introduce a commonsense knowledge enhanced module based on Graph Convolution Networks (Kipf and Welling, 2017; Velickovic et al., 2018; Vashishth et al., 2020) to exploit both the structural-level and semantic-level information of the relation subgraph, which can further strengthen the generalization and reasoning capacities of the model. Extensive experiments show that our method outperforms the state-of-the-art models on the benchmark dataset for zero-shot and few-shot stance detection.

2 Methodology

2.1 Problem Formulation

Formally, $D = \{(x_i, t_i, y_i)\}_{i=1}^{N}$ denotes the zero-shot stance detection dataset which contains N exmples, where x_i is a document, t_i is the corresponding topic, and y_i is the stance label. The goal of the task is to obtain a stance label $\widetilde{y}$ given x_i and t_i. To bridge the document and the topic, we introduce an commonsense knowledge subgraph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ extracted from the external KG, where $\mathcal{V}$ is the subset of the concepts and $\mathcal{E}$ denotes the relations between concepts.

2.2 BERT Encoding

We employ the pre-trained language model BERT (Devlin et al., 2019) to encode the document x and topic t. Specifically, we concatenate x and t into one input sequence in the following format: [CLS] x [SEP] t [SEP]. Then, the input sequence is fed into BERT to obtain the contextual representations $\boldsymbol{X} = \{\boldsymbol{x}^1, \cdots, \boldsymbol{x}^m\}$ for the document and $\boldsymbol{T} = \{\boldsymbol{t}^1, \cdots, \boldsymbol{t}^n\}$ for the topic, where m and n is the length of the document and the topic respectively. Finally, we can get the average representations $\hat{\boldsymbol{x}}$ and $\hat{\boldsymbol{t}}$ of the document and the topic, respectively.

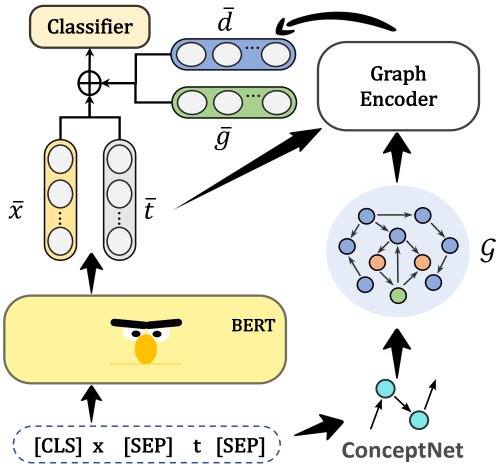

Figure 2: The architecture of our model.

2.3 Knowledge Graph Encoding with CompGCN

Before introducing our graph encoder, let's first describe the process of constructing the relational subgraph from the external knowledge graph. We adopt ConceptNet as our knowledge graph base G. ConceptNet consists of millons of relation triples, which contains 34 relations in total. Each triple is represented as $R = (u, r, v)$, where u is the head concept, r is the relation, and v is the tail concept. We match phrases in **documents** and **topics** to sets of mentioned concepts (C_d and C_t respectively) from the ConceptNet. To extract the relational subgraph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ from G, we find the two-hop directed paths from concepts in C_d to concepts in C_t. All concepts on the paths form the concepts set $\mathcal{V}$ and $\mathcal{E}$ is composed of all edges between concepts within $\mathcal{V}$. Moreover, we add reverse relations edge between any concept pair to improve the information flow.

Most of the existing research on GCNs mainly focuses on non-relational graphs. Thus, to incorporate commonsense relational knowledge, we utilize CompGCN (Vashishth et al., 2020), a variant of Graph Convolution Networks (GCNs), which jointly embeds both nodes and relations of the subgraph $\mathcal{G}$. The graph encoder consists of L-stacked

CompGCN layers. The features of nodes and relations are all initialized with **TransE** (Bordes et al., 2013) embeddings. We update node representations by aggregating the information from their neighbors and their relational edges. Formally, the update equation of nodes is defined as:

$$\boldsymbol{h}_v^{l+1} = f\left(\frac{1}{|\mathcal{N}(v)|} \sum_{(u,r)\in\mathcal{N}(v)} \boldsymbol{W}_u^l \phi(\boldsymbol{h}_u^l, \boldsymbol{h}_r^l)\right), \tag{1}$$

where f is an activation function, $\mathcal{N}(v)$ is the neighbors of the node v; $\boldsymbol{h}_u$, $\boldsymbol{h}_r$, and $\boldsymbol{h}_v$ are the representations of node u, node v and relation r.

Here, ϕ is a entity-relation composition operation based on the translational theory (Bordes et al., 2013) in the form of subtraction:

$$\phi(\boldsymbol{h}_u, \boldsymbol{h}_r) = \boldsymbol{h}_u - \boldsymbol{h}_r. \tag{2}$$

The relation embeddings are transformed as follows: $\boldsymbol{h}_r^{l+1} = \boldsymbol{W}_r^l \boldsymbol{h}_r^l$. After that, we obtain the node representations $\boldsymbol{H}_d$ and $\boldsymbol{H}_t$ of C_d and C_t, respectively. To aggregate reasonable relational information, we compute the average relational representation $\hat{\boldsymbol{d}}$ for C_d by performing scaled dot-product attention (Vaswani et al., 2017), with $\hat{\boldsymbol{t}}$ as the key and $\boldsymbol{H}_d$ as the query and value. Similarly, we get the average relational representation $\hat{\boldsymbol{g}}$ for C_t.

2.4 Stance Classification

We concatenate the representations of plain texts (i.e., $\hat{\boldsymbol{x}}$ and $\hat{\boldsymbol{t}}$) with the relational representations (i.e., $\hat{\boldsymbol{d}}$ and $\hat{\boldsymbol{g}}$) to make full use of the textual information and the graph structural information. Afterward, the concatenated representations are fed into a two-layer multi-layer perception (MLP) with a softmax function to predict the stance label:

$$\hat{y} = softmax(\text{MLP}([\hat{\boldsymbol{x}}; \hat{\boldsymbol{t}}; \hat{\boldsymbol{d}}; \hat{\boldsymbol{g}}])), \tag{3}$$

where [;] is vector concatenation operation.

Finally, the parameters of the network are trained using multi-class cross-entropy loss.

3 Experiments

3.1 Datasets and Evaluation Metrics

Different from the existing stance datasets (Mohammad et al., 2016a; Kobbe et al., 2020; Vamvas and Sennrich, 2020) including few topics (ranging from 6 to 194 topics), Allaway and McKeown (2020) present a new dataset for the zero-shot and few-shot stance detection, VAried Stance Topics (VAST), which consists of thousands of topics. The statistics of VAST are demonstrated in Table 1. Note that a document only belongs to one partition, which means that documents in the training set do not appear in the validation set or the test set, and vice versa. In addition, the zero-shot topics in the test set never appear in the training set, and the few-shot topics only contains few training data. Following the previous work (Allaway and McKeown, 2020), the macro average of F1-score is adopted as the evaluation metric.

Statistics	**Train**	**Dev**	**Test**
# Examples	13477	2062	3006
# Documents	1845	682	786
# Zero-shot Topics	4003	383	600
# Few-shot Topics	638	114	159

Table 1: Detailed statistics for VAST.

3.2 Experimental Settings

We employ the base version of BERT as the backbone. The graph encoder has two layers of CompGCN. We train our model on 1 GPU (Nvidia RTX TITAN, 24G) using Adam optimizer (Kingma and Ba, 2015) with an initial learning rate of 4e-5 and a batch size of 64. All documents are kept the first 200 words and the topic is the first 5 words. The best checkpoints are selected according to the evaluation metrics on the validation set. We repeat our model three times using different random seeds and report the averaged results. Our code will be released on Github.

We compare our model with the several state-of-the-art baselines: **BiCond** (Augenstein et al., 2016b), **CrossNet** (Xu et al., 2018), **SEKT** (Zhang et al., 2020), **BERT-joint** (Allaway and McKeown, 2020) and **TGA-Net** (Allaway and McKeown, 2020). The first three models are based on BiLSTM for cross-target stance detection. When training the latter two BERT-based models, Allaway and McKeown (2020) fixed the parameters of the BERT module. Hence, we extend two models **BERT-joint-ft** and **TGA-Net-ft**, in which BERT has been fine-tuned during the training process. Besides, we compare our model with **BERT-GCN**, which applies the conventional GCN (Kipf and Welling, 2017) only considering the node information aggregation.

3.3 Results and Discussions

Results of Different Scenarios The overall results of our model and baselines are shown in Table 2. To evaluate the effectiveness of our method on different scenarios, we categorize the results into three subsets: *Zero-Shot*, *Few-shot* and *All*. Our model outperforms all baselines by a large margin, which can demonstrate the importance of incorporating the rich commonsense knowledge in the form of relational graphs. Additionally, we observe that all BERT-based baselines perform worse on *pro* examples than on *con* examples for zero-shot topics. A possible explanation might be that there are more negative words in the con examples, which is easier to identify in terms of semantics. Conversely, our model brings a significant improvement on average for both zero-shot and few-shot topics, which indicates that the relational information from the external knowledge base can boost the generalization and reasoning ability. Compared to BERT-GCN only modeling the node aggregation, our model takes full advantage of the relational information to contribute much to the overall performance.

Furthermore, all BERT-based models perform better than other baseline methods. In presents that the pre-trained models possess more strong generalization capability because it learns from a large-scale unsupervised corpus. Besides, SEKT does not achieve effective improvement on VAST, probably because they only introduce the external semantic knowledge at the token level without explicitly considering the overall relationship between the topic and the document. And the token-level approach is difficult to transplant to BERT.

Results of Different Phenomena To further analyse the effectiveness of our model, we test it under five challenging phenomena in the VAST following (Allaway and McKeown, 2020): (1) **Imp**: examples with non-neutral labels, where the topic does not appear in the document, (2) **mlT**: documents having multiple examples with different topics, (3) **mlS**: documents having multiple examples with different and non-neutral labels, (4) **Qte**: documents with quotations, (5) **Sarc**: documents with sarcasm (Habernal et al., 2018). As shown in table 3, our model achieves the best performance on all difficult phenomena. In particular, the improvement on **Imp** demonstrates that introducing external relational knowledge can help the model better understand the relationship between the topic and the article. Besides, the external semantic-level information from the relational subgraph makes our model perform better on the special rhetorics (**Qte** and **Sarc**).

4 Conclusion

In this paper, we interpret the necessity of introducing commonsense knowledge for zero-shot and few-shot stance detection. We present a commonsense knowledge enhanced method, which facilitates the integration of the relational knowledge to further strengthen the generalization and reasoning capacities of the stance detection model. Extensive experiments show that our proposed model achieved state-of-the-art results.

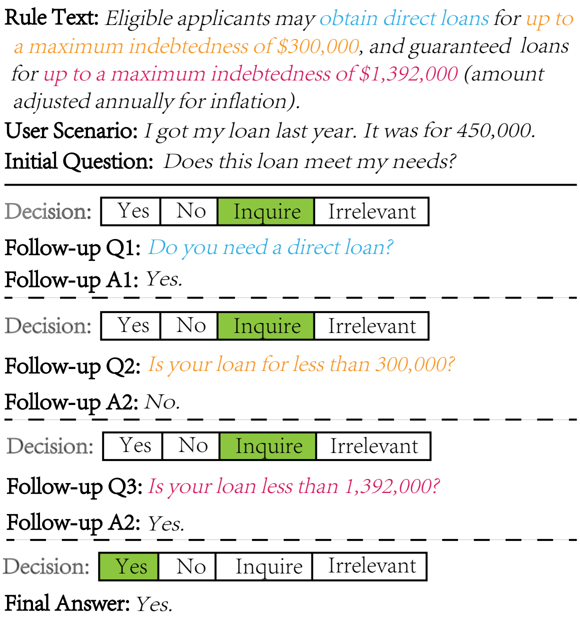
Abstract

Conversational Machine Reading (CMR) aims at answering questions in complicated interactive scenarios. Machine needs to answer questions through interactions with users based on given rule document, user scenario and dialogue history, and even initiatively asks questions for clarification if necessary. Namely, the answer to the task needs a machine in the response of either *Yes*, *No*, *Irrelevant* or to raise a follow-up question for further clarification. To effectively capture multiple objects in such a challenging task, graph modeling is supposed to be adopted, though it is surprising that this does not happen until this work proposes a dialogue graph modeling framework by incorporating two complementary graph models, i.e., explicit discourse graph and implicit discourse graph, which respectively capture explicit and implicit interactions hidden in the rule documents. The proposed model is evaluated on the ShARC benchmark and achieves new state-of-the-art by first exceeding the milestone accuracy score of 80%. The source code of our paper is available at `https://github.com/ozyyshr/DGM`

1 Introduction

Training machines to understand documents is the major goal of machine reading comprehension (MRC) (Hermann et al., 2015; Hill et al., 2016; Rajpurkar et al., 2016; Nguyen et al., 2016; Joshi et al., 2017; Rajpurkar et al., 2018; Choi et al., 2018; Zhang et al., 2018; Reddy et al., 2019; Zhang et al., 2020c, 2021). Especially, in the recent challenging conversational machine reading (CMR) task, the machine is required to read and interpret the given rule document and the user scenario, ask clarification questions, and then make a final decision (Saeidi et al., 2018). As an example shown in Figure 1. The user posts the scenario and asks a question concerning whether the loan meets the needs. Since the user cannot know the rule document, the information he/she provided may not be sufficient for the machine to decide. Therefore, a series of follow-up questions are asked by the machine until it can finally make a conclusion.



Rule Text: *Eligible applicants may obtain direct loans for up to a maximum indebtedness of $300,000, and guaranteed loans for up to a maximum indebtedness of $1,392,000 (amount adjusted annually for inflation).*
User Scenario: *I got my loan last year. It was for 450,000.*
Initial Question: *Does this loan meet my needs?*

Decision: Yes No [✓ Inquire] Irrelevant
Follow-up Q1: *Do you need a direct loan?*
Follow-up A1: *Yes.*

Decision: Yes No [✓ Inquire] Irrelevant
Follow-up Q2: *Is your loan for less than 300,000?*
Follow-up A2: *No.*

Decision: Yes No [✓ Inquire] Irrelevant
Follow-up Q3: *Is your loan less than 1,392,000?*
Follow-up A2: *Yes.*

Decision: [✓ Yes] No Inquire Irrelevant
Final Answer: *Yes.*

Figure 1: An example dialog from ShARC benchmark dataset (Saeidi et al., 2018). At each turn, the machine can give a decision regarding the initial question put up by the user. If the decision is *Inquire*, the machine will ask a clarification question to help with decision making. The corresponding rule document and the question are marked in the same color in the figure.

The major challenges for the conversational machine reading include the rule document interpretation, and reasoning with the background

knowledge, e.g., the provided rule document, user scenario and the input question. Existing works (Zhong and Zettlemoyer, 2019; Lawrence et al., 2019; Verma et al., 2020; Gao et al., 2020a,b) have made progress in improving the reasoning ability by modeling the interactions among rule document, user scenario and the other elements implicitly. As for rule document interpretation, most existing approaches simply split the rule document into several rule conditions to be satisfied. In general, they first track the entailment state of each rule condition for decision making and then form a certain under-specified rule span into a follow-up question.

However, the aforementioned cascaded methods tend to model in a holistic way, i.e. interpreting the rule document with other elements quite plainly, which have the following drawbacks. First, very little attention is paid to the inner dependencies of rule conditions such as the discourse structure and discourse relations (Qin et al., 2016, 2017; Bai and Zhao, 2018). Second, existing methods do not dig deep enough into mining the interactions between the rule document and other elements, especially user scenarios.

As seen, the interactions of elements in CMR is far more complicated than that of traditional MRC tasks. Therefore, we proposed a dialogue graph modeling (DGM) framework consisting of two complementary graphs to fully capture the complicated interactions among all the elements. Firstly, an explicit discourse graph is constructed by making use of discourse relations of elementary discourse units (EDUs) generated from rule documents to tackle explicit element interactions. User scenario representation is injected as a special global vertex, to bridge the interactions and capture the inherent dependency between the rule document and the user scenario information. Secondly, an implicit discourse graph is designed for digging the latent salient interactions among rule documents by decoupling and fusing mechanism. The two dialogue graphs compose the encoder of our model and feed fusing representations to the decoder for making decisions.

As to our best knowledge we are the first to explicitly model the relationships among rules and user scenario with Graph Convolutional Networks (GCNs) (Schlichtkrull et al., 2018). Experimental results show that our proposed model outperforms the baseline models in terms of official evaluation metrics and achieves the new state-of-the-art results on ShARC, the benchmark dataset for CMR (Saeidi et al., 2018). In addition, our model enjoys strong interpretability by modeling the process in an intuitive way.

2 Related Work

Conversational Machine Reading. Compared with traditional triplet-based MRC tasks that aim to answer questions by reading given document (Hermann et al., 2015; Hill et al., 2016; Rajpurkar et al., 2016; Nguyen et al., 2016; Joshi et al., 2017; Rajpurkar et al., 2018; Zhang et al., 2020a,b), our concerned CMR task (Saeidi et al., 2018) is more challenging as it involves rule documents, scenarios, asking clarification question, and making a final decision. The major differences lie in two sides: 1) machines are required to formulate follow-up questions for clarification before confident enough to make the decision, 2) machines have to make a question-related conclusion by interpreting a set of complex decision rules, instead of simply extracting the answer from the text. Existing works (Zhong and Zettlemoyer, 2019; Lawrence et al., 2019; Verma et al., 2020; Gao et al., 2020a,b) have made progress in improving the reasoning ability by modeling the interactions between the rule document and other elements. As a widely-used manner, the existing models commonly extracted the rule documents into individual rule items, and track the rule fulfillment for the dialogue states. As indicated in Gao et al. (2020b), improving the rule document representation remains a key factor to the overall model performance, because the rule documents are formed with a series of implicit, separable, and possibly interrelated rule items that the conversation should satisfy before making decisions. However, previous work only considered segmenting the discourse, and neglected the inner discourse structure/relationships between the EDUs (Gao et al., 2020b). Compared to existing methods, our method makes the first attempt to explicitly capture elaborate interactions among all the document elements, user scenarios and dialogue history updates.

Graph Modeling in MRC. Inspired by the impressive performance of GCN (Kipf and Welling, 2017; Luo and Zhao, 2020), efforts towards better performance on MRC utilizing GCNs have sprung up, such as BAG (Cao et al., 2019), GraphRel (Fu et al., 2019) and social information reasoning (Li and Goldwasser, 2019). Unlike the previous works who just apply the graph framework mechanically to turn the entire passage or document into a graph, the discourse graph we proposed is delicately designed to mine the relationships of multiple elements in CMR task and to facilitate information flow over the graph.

3 Model

As illustrated in Figure 2, our model mainly consists of three parts to generate the final answer.

1. Rule document is segmented into rule EDUs, which is then tagged discourse relationship by a pre-trained discourse parser.

2. In the encoding phase, taking segmented and preprocessed rule document and user scenario as input, we build two graphs over the segments (EDUs), in which the explicit discourse graph captures the interactions among rules and user scenarios with the support of tagged discourse relationship, while the implicit discourse graph mines latent salient interactions from the raw rule document.

3. For decoding, an interaction layer takes the combined representation generated by both explicit and implicit discourse graph of rule EDUs, initial question, user scenario and dialog history as inputs, and maps it into an entailment state of each rule EDU. With these rule fulfillment situation, we can make a decision among *Yes, No, Inquire and Irrelevant*. Once the decision is made to be *Inquire*, the model generates a follow-up question to clarify the under-specified rule span in the rule document.

The complete training procedure of DGM is shown in Algorithm 1.

3.1 Preprocessing

EDU Segmentation. We first separate the rule document into several units each containing exactly one condition. Here we follow DISCERN (Gao et al., 2020b) adopting the discourse segmenter (Li et al., 2018) to break the rule document into EDUs.

Discourse Relation. Unlike EDU segmentation which only concerns with constituency-based logical structures, discourse relation allows relations between the non-adjacent EDUs. There are in total 16 discourse relations according to STAC (Asher et al., 2016), namely, *comment, clarification-question, elaboration, acknowledgement, continuation, explanation, conditional, question-answer, alternation, question-elaboration, result, background, narration, correction, parallel and contrast*. We adopt a pre-trained discourse parser (Shi and Huang, 2019)[1] to decide the dependencies between EDUs and the corresponding relation types with the structured representation of each EDU.

Algorithm 1: DGM Algorithm

```
Input: word embeddings $E = \{e_1, .., e_n\}$,
       dimension of word embeddings $d$,
       token ids of rule document $I$,
       discourse relation $D$ of rule
       document, number of rule EDUs $n$
Output: Final decision in Yes/No/Irrelevant
        or a follow-up question
for $i$ in epochs do
    build explicit discourse graph $G(E, D)$
    $G_{n \times d} \leftarrow GCN(G)$
    build implicit discourse graph by
      calculating adjacent matrix $M_l$, $M_c$
    get rule EDU representation $C_{n \times d}$ by
      Eq.(6) and (7)
    combined representation for [RULE] $\tilde{r_i} \leftarrow$
      self-Attn$(C + G)_i$
    entailment state $f_i \leftarrow$ LINEAR$(\tilde{r_i})$
    make the decision $z$ by Eq.(10) based
      on $\tilde{r_i}$ and $f_i$
    if $z$ is Inquire then
        generate follow-up question
    return $z$ or follow-up question
```

3.2 Encoding Block

Embedding. We select the pre-trained language model (PrLM) model ELECTRA (Clark et al., 2020) for encoding. As shown in the figure, the input of our model includes rule document which has already be parsed into EDUs with explicit discourse relation tagging, user initial question, user scenario and the dialog history. Instead of inserting a `[CLS]` token before each rule EDU to get a sentence-level representation, we use `[RULE]` which is proved to enhance performance (Lee et al., 2020). Note that we also insert `[SEP]` between every two adjacent utterances.

Explicit Discourse Graph. We first construct the explicit discourse graph as a Levi graph (Levi, 1942) which turns the labeled edges into additional vertices. Suppose $G = (V, E, R)$ is the graph constructed in the following way: if utterance U_1 is the continuation of utterance U_2,

---

[1] This discourse parser gives a state-of-the-art performance on STAC so far

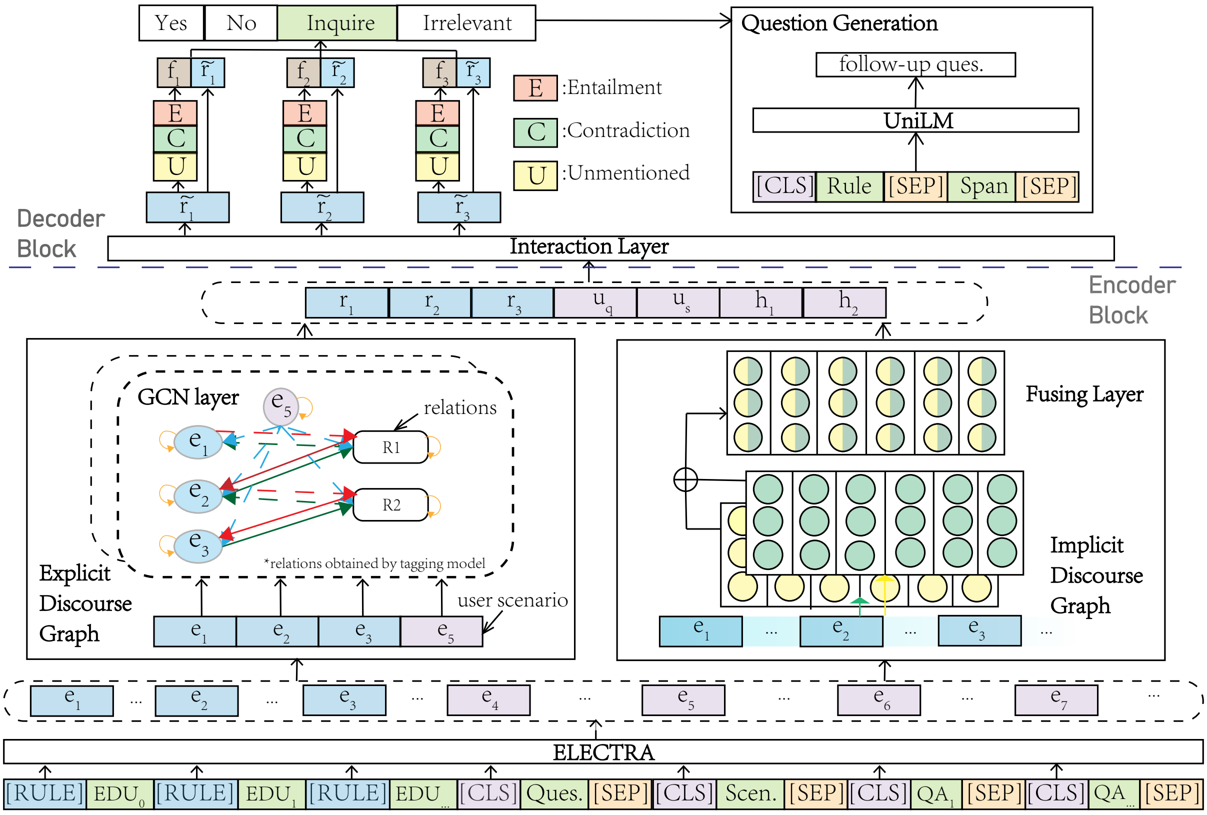

Figure 2: The overall structure for our proposed model. With segmented EDUs and tagged relations, the inputs including user initial question, user scenario and dialog history are sent for embedding and graph modeling to make the final decision. If the decision is *Inquire*, the question generation stage will be activated and use the under-specified span of rule document to generate a follow-up question.

we add a directed edge $e = (U_1, U_2)$ with relation R assigned to *Continuation*. The corresponding Levi graph can be expressed as $G = (V_L, E_L, R_L)$ where $V_L = V \cup R$. E_L is the set of edges with format $(U_1, Continuation)$ and $(Continuation, U_2)$. As for R_L, previous works such as (Marcheggiani and Titov, 2017; Beck et al., 2018) designed three types of edges $R_L = default, reverse, self$ to enhance information flow. Here with our settings, we extend it into six types: *default-in*, *default-out*, *reverse-in*, *reverse-out*, *self*, *global*, corresponding to the direction of the edges towards the relation vertices. An example of constructing Levi graph is shown in Figure 3. To construct the discourse structure of other elements, a global vertex representing user scenario is added and connected with all the other vertices.

We use a relational graph convolutional network (Schlichtkrull et al., 2018) to implement explicit discourse graph as the traditional GCN is not able to handle multi-relation graphs. For utterance and scenario vertices, we employ the encoding results of `[RULE]` and `[CLS]` in Section 3.1. For relation vertices, we look up in the embedding table to get the initial representation. Given the initial representation h_p^0 of every node v_p, the feed-forward or the message-passing process can be written as:

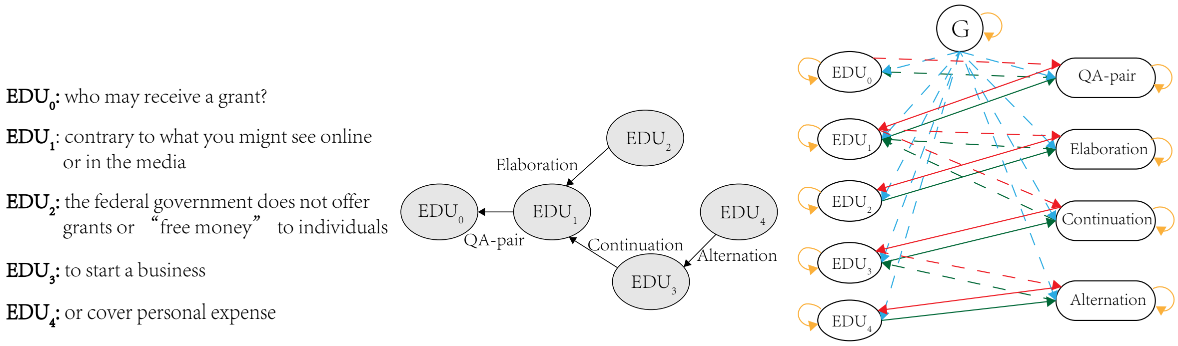
$$h_p^{(l+1)} = \text{ReLU}\Big(\sum_{r \in R_L} \sum_{v_q \in \mathcal{N}_r(v_p)} \frac{1}{c_{p,r}} w_r^{(l)} h_q^{(l)}\Big), \tag{1}$$

where $\mathcal{N}_r(v_p)$ denotes the neighbors of node v_p under relation r and $c_{p,r}$ is the number of those nodes. $w_r^{(l)}$ is the learnable parameters of layer l.

Because the total 16 relations cannot be treated equally, e.g. relation *Contrast* is much more important than the relation *Continuation*, we introduce the gating mechanism (Marcheggiani and Titov, 2017). The basic idea is to calculate a value between 0 and 1 for information passing control.

$$g_p^{(l)} = \text{Sigmoid}(h_p^{(l)} W_{r,g}), \tag{2}$$

where $W_{r,g}^{(l)}$ is a learnable parameter under relation type r of the l-th layer. Finally, the forward process



(a) separated EDUs (b) the original graph (c) the Levi graph

Figure 3: Processes turning a sample dialog into Levi graph representing discourse relations.

of gated GCN can be represented as:

$$h_p^{(l+1)} = \mathrm{ReLU}\Big(\sum_{r \in R_L} \sum_{v_q \in \mathcal{N}_r(v_p)} g_q^{(l)} \frac{1}{c_{p,r}} w_r^{(l)} h_q^{(l)}\Big), \tag{3}$$

Implicit Discourse Graph. Implicit discourse graph aims at digging the salient latent interactions inside rule document. Each token i in rule EDU is represented as a vertex in the graph. We use adjacent matrices to express implicit discourse graph. Two types of matrices M_l and M_c are introduced standing for local and contextualized information:

$$M_l[i,j] = \begin{cases} 0 & \text{if } I_i = I_j, \\ -\infty & \text{otherwise.} \end{cases} \tag{4}$$

$$M_c[i,j] = \begin{cases} 0 & \text{if } I_i \neq I_j, \\ -\infty & \text{otherwise.} \end{cases} \tag{5}$$

where I_i is the index of token i in EDU. Thus the information containing in rule document are decoupled in two separate aspects. Using multi-head self-attention to encode the graph and denote the length of the whole rule document as s, embedding dimension as d, we will get the following:

$$G_i = \mathrm{MHSA}(E, M_i),\ i \in \{l, c\}, \tag{6}$$

where $G_i \in \mathbb{R}^{s \times d}$ and E is the embedding result from PrLM. MHSA denotes the multi-head self-attention (Vaswani et al., 2017).

After enough interactions inside rule EDUs, we then fuse the information (Liu et al., 2020) of these two implicit discourse graphs-like items[2] above in a gated manner by considering both the original and graph encoding representation of rule document.

$$\begin{aligned} \tilde{E_1} &= \mathrm{ReLU}(\mathrm{FC}([E, G_l, E - G_l, E \odot G_l])), \\ \tilde{E_2} &= \mathrm{ReLU}(\mathrm{FC}([E, G_c, E - G_c, E \odot G_c])), \\ g &= \mathrm{Sigmoid}(\mathrm{FC}([\tilde{E_1}, \tilde{E_2}])), \\ C &= g \odot G_l + (1 - g) \odot G_c, \end{aligned} \tag{7}$$

where FC is the fully-connected layer and $C \in \mathbb{R}^{s \times d}$. We take the calculated result of the original `[RULE]` to stand for the updated rule EDUs from C, denoted as c_i.

3.3 Decoding Block

Interaction Layer. We use an interaction layer to attend to all available information so far to learn in a systematic way. A self-attention layer (Vaswani et al., 2017) is adopted here allowing all the rule EDUs and other elements to attend to each other. Let $[r_1, r_2, ...; u_q; u_s; h_1, h_2, ...]$ denote all the representations, r_i is the combined sentence-level representation of explicit and implicit discourse graph, u_q, u_s and h_i stand for the representation of user question, user scenario and dialog history respectively. After encoding, the output can be displayed as $[\tilde{r_1}, \tilde{r_2}, ...; \tilde{u_q}, \tilde{u_s}; \tilde{h_1}, \tilde{h}2...]$.

Decision Making. Similar to existing works (Zhong and Zettlemoyer, 2019; Gao et al., 2020a,b), we apply an entailment-driven approach for decision making. A linear transformation tracks the fulfillment state of each rule EDU among Entailment, Contradiction and Unmentioned. At last, the decision is made according to:

$$f_i = W_f \tilde{r_i} + b_f \in \mathbb{R}^3, \tag{8}$$

---

[2] Taking self-attention weights as edges connecting representations (as node), it can be seen as graph as well.

Table 1: Results on the blind held-out test set and the dev set of ShARC end-to-end task. Micro and Macro stand for Micro Accuracy and Macro Accuracy respectively.

where f_i is the score predicted for the three labels of the i-th condition. This prediction is trained via a cross entropy loss for multi-classification problems:

$$\mathcal{L}_{entail} = -\frac{1}{N}\sum_{i=1}^{N} \log \text{softmax}(f_i)_r, \qquad (9)$$

where r is the ground-truth state of fulfillment.

After obtaining the state of every rule, we are able to give a final decision towards whether it is *Yes*, *No*, *Inquire* or *Irrelevant* by attention.

$$\begin{aligned} \alpha_i &= w_\alpha^T[f_i;\tilde{r_i}] + b_\alpha \in \mathbb{R}^1, \\ \tilde{\alpha_i} &= \text{softmax}(\alpha)_i \in [0,1], \\ z &= W_z \sum_i \tilde{\alpha_i}[f_i;\tilde{r_i}] + b_z \in \mathbb{R}^4, \end{aligned} \qquad (10)$$

where α_i is the attention weight for the i-th decision and z has the score for all the four possible states. The corresponding training loss is:

$$\mathcal{L}_{decision} = -\log \text{softmax}(z)_l, \qquad (11)$$

The overall loss for decision making is:

$$\mathcal{L} = \mathcal{L}_{decision} + \lambda \mathcal{L}_{entail}. \qquad (12)$$

Qustion Generation. If the decision is made to be *Inquire*, the machine need to ask a follow-up question to further clarify. Question generation in this part is mainly based on the uncovered information in the rule document, and then that information will be rephrased into a question. We predict the position of an under-specified span within a rule document in a supervised way. Following Devlin et al. (2019), our model learns a start vector $w_s \in \mathbb{R}^d$ and end vector $w_e \in \mathbb{R}^d$ to indicate the start and end positions of the desired span:

$$span = \arg\min_{i,j,k}(w_s^T t_{k,i} + w_e^T t_{k,j}), \qquad (13)$$

where $t_{k,i}$ denote the i-th token in the k-th rule sentence. The ground-truth span labels are generated by calculating the edit-distance between the rule span and the follow-up questions. Intuitively, the shortest rule span with the minimum edit-distance is selected to be the under-specified span. Finally, we concatenate the rule document and the predicted span as an input sequence to finetune UniLM (Dong et al., 2019) and generate the follow-up question.

4 Experiments

4.1 Experimental Setup

Dataset. We conduct experiments on ShARC dataset, the current CMR benchmark[3] collected by Saeidi et al. (2018). It contains up to 948 dialog trees clawed from government websites. Those dialog trees are then flattened into 32,436 examples consisting of *utterance_id*, *tree_id*, *rule document*, *initial question*, *user scenario*, *dialog history*, *evidence* and the *decision*. It is worth noting that evidence is the information that we need to extract from user information and thus will not be given in the testing phase. The sizes of train, dev and test are 21,890, 2,270 and 8,276 respectively. We also showed the generalizability of our model on the Multi-Turn Dialogue Reasoning (MuTual) dataset (Cui et al., 2020), which has 8,678 multiple choice samples and is divided into 7,376, 651, 651 of train, dev and test sets respectively.

Evaluation. For the decision-making subtask, ShARC evaluates the Micro- and Macro- Acc. for the results of classification. If both the prediction and ground truth of decision is *Inquire*,

---

[3] Leaderboard can be found at website `https://sharc-data.github.io/leaderboard.html`

BLEU(Papineni et al., 2002) score (particularly BLEU1 and BLEU4) will be evaluated on the follow-up question generation subtask.

Implementation Details. For rule EDU relation prediction, we keep all the default parameters of the original discourse relation parser[4], with $F1$ score achieving 55. In the decision-making stage, we finetune an ELECTRA-based model. The dimension of hidden states is 1024 for both the encoder and decoder. The training process uses Adam (Kingma and Ba, 2015) for 5 epochs with learning rate set to 5e-5. We also use gradient clipping with a maximum gradient norm of 2, and a total batch size of 16. In the question generation stage, for the sake of consistency, we also use an ELECTRA-based model for span extraction. For UniLM, we finetune it with a batch size of 16, a learning rate of 2e-5 and beam size is set to 10 for inference. It takes 3-4 hours for training on a single TITAN RTX 2080Ti GPU (24GB memory).

4.2 Results

Table 1 shows the results of DGM and all the baseline models for the End-to-End task on the blind held-out test set of ShARC[5]. Evaluating results indicate that DGM outperforms the baselines in most of the metrics. In particular, DGM outperforms the previous state-of-the-art model DISCERN by 4.2% in Micro Acc. and 2.9% in Macro Acc.

To test the generality of DGM on other different PrLMs and to do a fair comparison with previous models, We alter the underlying PrLMs to other variants in DGM and the previous state-of-the-art model DISCERN respectively. The results on the dev set of ShARC are shown in Table 2. In the first place, DGM performs better than DISCERN on all the PrLMs, which indicates the all-round superiority of DGM. Additionally, results on ELECTRA is generally better than that of BERT and RoBERTa. This indicates that ELECTRA is an even better trained PrLM. By the aforementioned analysis, our DGM can generally perform well on widely-used PrLMs.

PrLMs	Micro Acc.		Macro Acc.	
	DISCERN	DGM	DISCERN	DGM
BERT$_{base}$	69.8	70.4	75.3	76.0
RoBERTa$_{base}$	74.9	75.8	79.8	80.2
ELECTRA$_{base}$	75.2	75.5	79.7	80.4
BERT$_{large}$	72.8	73.0	77.8	78.0
RoBERTa$_{large}$	76.1	76.6	80.6	81.0
ELECTRA$_{large}$	77.2	78.6	80.3	82.2

Table 2: Performance of DISCERN and DGM on different PrLMs on the dev set of ShARC.

In addition, Table 3 lists the class-wise classification accuracy of our model. Results demonstrate that our model performs quite satisfactorily for all classification subtasks, outperforming all other models in three of all four subtasks though a minor behind on the *Irrelevant* subtask. Compared to competent models, our model boosts the performance with a great gain to judge whether the user's requirements need further inquiry or are already fulfilled. It is worth noting that the *Inquire* subtask is the most fundamental one among all subtasks required by the concerned CMR. The superiority of our model for this core subtask shows that our DGM model indeed effectively captures the complicated interactions among all the concerned document rules and scenarios.

Models	Total	Yes	No	Inquire	Irrelevant
BERTQA	63.6	61.2	61.0	62.6	96.4
E^3	68.0	65.9	70.6	60.5	96.4
UrcaNet	65.9	63.3	68.4	58.9	95.7
EMT	73.2	70.5	73.2	70.8	98.6
DISCERN	75.2	71.9	75.8	73.3	**99.3**
DGM (ours)	**77.8**	**75.2**	**77.9**	**76.3**	97.8

Table 3: Class-wise decision prediction accuracy on the dev set of ShARC.

5 Analysis

5.1 Ablation Study

To investigate the impacts of different graphs, we conducted an ablation study on the decision-making subtask which is the vital part of our model, directly influencing the results afterward. Detailed results on the dev set of ShARC in Table 4 show that both the explicit and implicit discourse graph are indispensable as removing any one of them causes a performance drop (1-3 points) on both Macro Acc. and Micro Acc. Especially, these two metrics drop by a great margin as we remove the explicit discourse graph, which shows that explicit discourse relation reasoning is crucial in CMR.

---

[4] `https://github.com/shizhouxing/DialogueDiscourseParsing`

[5] As indicated in (Gao et al., 2020a,b), the question generation results normally suffer from randomness. As the focus of this task is the decision making task like previous studies.

Example	Structure Type	Discourse Relation	Decision
Snippet: Export products made from endangered animals: (special rules)$_0$ If the animal is classified as B, C or D$_1$ you do not need to do anything$_2$ **Scenario:** I do not have medicare for this person. **Question:** Can I export products made from this animal?	Simple		Yes × No Irrelevant Inquire ✓
Snippet: Who may receive a grant?$_0$ Contrary to what you might see online in the media$_1$ the federal government does not offer grants or free money to individuals$_2$ to start a business$_3$ or cover personal expenses$_4$ **Scenario:** I live in Norway with my wife and children. **Question:** Can I get a grant from federal government?	Disjunction		Yes No × Irrelevant Inquire ✓
Snippet: In order to qualify for this benefit program$_0$ homeowners and renters must have sustained damage B, C or D$_1$ and be located in a disaster declared county$_2$ **Scenario:** (empty) **Question:** Do I qualify for this loan?	Conjunction		Yes No Irrelevant × Inquire ✓
Snippet: Going abroad$_0$ If your trip is going to last longer than 8 or 12 weeks, contact the Tax Credit Office within a month$_1$ your tex credits will end unless$_2$ you get UK benifits or State Pension$_3$ and you live in another European country with a child$_4$ **Scenario:** (empty) **Question:** Will my tex credit end?	Complex		Yes No ✓ Irrelevant Inquire ×

Figure 4: Examples selected from the dev set of ShARC where DISCERN fails but our model succeeds.

Also, we can see that adding the special token `[RULE]` indeed conduce to the performance.

Models	Macro Acc.	Micro Acc.
DGM	82.2	78.6
w/o Explicit Discourse Graph	79.8	75.2
w/o Implicit Discourse Graph	81.3	76.7
w/o both	77.3	71.7
w/o [RULE]	81.6	77.9

Table 4: Ablation study of our model for decision making subtask on the dev set of ShARC.

5.2 User Scenario Interpretation

In DGM, by injecting the user scenario as the global node in the explicit discourse graph we intend to improve the interpretation ability of our model with respect to user scenarios. To test the effect of the proposed model on scenario interpretation, we create a subset based on the dev set consisting of 761 samples that have user scenarios and an empty dialog history. The results on the decision-making subtask in Table 5 shows that our model can greatly improve the interpretation of user scenarios by surpassing DISCERN 11.8% and 14.8% of Macro Acc. and Micro Acc. respectively. In particular, DGM outperforms DISCERN by a large margin in every class of decision.

Models	Macro	Micro	Yes	No	Irrelevant	Inquire
DISCERN	63.5	60.2	35.3	50.7	100.0	67.8
DGM	**75.3**	**75.0**	**58.3**	**62.8**	**100.0**	**79.1**

Table 5: Results for decision making over user scenario subset of the ShARC dev set.

Manually analyzing the predicted results also indicates that DGM is capable of various reasoning including numerical reasoning, commonsense reasoning and rule document paraphrasing. For example, for numerical reasoning, given a scenario *"I plan on being away for five months before returning"*, DGM is able to match that with *"your tax credits will stop if you expect to be away for one year or more"* in the rule document.

5.3 Rule Document Interpretation

To see how DGM interpret the rule document, we analyzed the predictions from DGM and DISCERN on the dev set of ShARC to see how our model fixes the erroneous cases made by DISCERN.

We selected four types of rule structures and the representative examples are shown in Figure 4. It can be seen that the discourse relation tagged for the rule document can well represent the real relation in the discourse. For example, in the third case, *"homeowners and renters must have sustained damage B, C or D"* is the continuation of *"in order to qualify for this benefit program"* and *"be located in a disaster declared county"* is the continuation of it. The discourse relation informs that *"be located in a disaster declared county"* and *"have sustained damage B, C or D"* are two conditions one must obey to be qualified. Generally, *Continuation* may indicate that two rules have some conjunctive relations while *Alternation* denotes a disjunctive relation. All the relations together characterize the complex rule relations and thus are vital in decision making. Statistics regarding relations can be found in Table 6. The contextualized information containing in the rule document learned by the implicit discourse graph also contributes to the overall performance as it digs the semantically rich representations of rule EDUs.

Relation Types	Train Set	Dev Set
Comment	28756	2374
Clarification_question	330	69
Elaboration	639	82
Acknowledgement	6242	815
Continuation	7317	1090

Conditional	1445	139
Question-answer_pair	1824	468
Alternation	896	323
Result	664	0
Correction	14	0
Contrast	16523	1595

Table 6: Statistics analysis of relation types of the train and dev on ShARC. "Comment", "Continuation", "Explanation" and "Contrast" constitutes the majority of the discourse relations.

5.4 Generalizability Evaluation

To verify DGM's generalizability and show that it can be smoothly applied to a broad type of QA tasks, We conducted experiments on a representative dialogue reasoning dataset MuTual. It is modified from Chinese high school English listening comprehension test data. It consists of 8860 annotated dialogues, namely, 7088 training samples, 886 developing samples and 886 testing samples. For each example, there is a dialogue history following by four candidate responses. Each candidate is relevant to the dialogue context but only one of them is logically correct. Our aim is to predict the correct answer given dialogue history and response candidates.

To apply DGM on MuTual, we first annotated the utterances of dialogue history of their discourse relations. Then pass the dialogue and the response candidates into a pre-trained language model to get the representation of each utterance. Armed with these representations and discourse relations, we are now able to construct the explicit discourse graph. Here, we set the global representation [CLS] (Devlin et al., 2019) of dialogue history as the global node. The implicit discourse graph can be constructed as Section 3.2 stated.

For the sake of computational efficiency, the maximum number of utterances is set to be 25. The concatenated context, response candidate in one sample is truncated or padded to be of length 256. We use ELECTRA as the PrLM and AdamW (Loshchilov and Hutter, 2019) as the optimizer for training. The batch size is 24 and the learning rate is 6e-6. We run a total of 3 epochs and select the model of the best results in the development set.

Table 7 displays the results on MuTual, which shows that DGM achieves a consistent improvement on the performance with respect to all the corresponding metrices.

Models	Dev Set			Test Set		
	R_4@1	R_4@2	MRR	R_4@1	R_4@2	MRR
ELECTRA	90.6	97.7	94.9	90.0	97.9	94.6
DGM	91.3	98.3	95.3	90.7	98.2	95.1

Table 7: Results on the dev and test set of MuTual dataset

6 Conclusions

In this paper, we presented a novel Dialogue Graph Modeling framework for Conversational Machine Reading. Our DGM consists of two complementary graphs which respectively capture both explicit and implicit interactions among multiple complicated elements in the challenging task, in which Explicit Discourse Graph is for extra knowledge learning with tagged EDU discourse relations while Implicit Discourse Graph helps with inside rule document understanding. Experiments on ShARC show the effectiveness by achieving a new state-of-the-art result. Our method may be smoothly applied to a broad type of QA tasks, such as our practice on the MuTual dataset that also achieves a consistent performance.

Acknowledgments

We would like to thank all the anonymous reviewers for their helpful comments and suggestions. Also thanks to Max Bartolo for evaluating our submitted models on the hidden test set.

Abstract

Indonesian language is heavily riddled with colloquialism whether in written or spoken forms. In this paper, we identify a class of Indonesian colloquial words that have undergone morphological transformations from their standard forms, categorize their word formations, and propose a benchmark dataset of Indonesian Colloquial Lexicons (IndoCollex) consisting of informal words on Twitter expertly annotated with their standard forms and their word formation types/tags. We evaluate several models for character-level transduction to perform morphological word normalization on this testbed to understand their failure cases and provide baselines for future work. As IndoCollex catalogues word formation phenomena that are also present in the non-standard text of other languages, it can also provide an attractive testbed for methods tailored for cross-lingual word normalization and non-standard word formation.

1 Introduction

Indonesian language is one of the most widely spoken languages in the world with around 200 million speakers. Despite its large number of speakers, in terms of NLP resources, Indonesian language is not very well represented (Joshi et al., 2020). Most of its data are in the form of unlabeled web and user generated contents in online platforms such as social media, which are noisy and riddled with colloquialism which poses difficulties for NLP systems (Baldwin et al., 2013a; Eisenstein, 2013a).

Traditionally, the majority of Indonesian colloquial or informal lexicons are borrowed words from foreign or local dialect words, and sometimes with phonetic and lexical modifications.[1] Increasingly however, Indonesian colloquial words are more commonly a morphological transformation[2] of their standard counterparts.[3] Despite these evolving lexicons, existing research on Indonesian word normalization has largely (1) relied on creating static informal dictionaries (Le et al., 2016), rendering normalization of unseen words impossible, and (2) for the specific task of sentiment analysis (Le et al., 2016) or machine translation (Guntara et al., 2020), with no direct implication to word normalization in general. Given the obvious utility of creating NLP systems that can normalize Indonesian informal data, we believe that the bottleneck is that there is no standard open testbed for researchers and developers of such system to test the effectiveness of their models to these colloquial words.

In this paper, we introduce IndoCollex, a new, realistic dataset aimed at testing normalization models to these phenomena. IndoCollex is a professionally annotated dataset, where each informal word is paired with its standard form and expertly annotated with its word formation type. The words are sampled from Twitter across different regions, therefore contain naturally occurring Indonesian colloquial words.

We benchmark character-level sequence-to-sequence transduction with LSTM (Deutsch et al., 2018; Cotterell et al., 2018) and Transformer (Vaswani et al., 2017) architectures, as well as a rule-based approach (Eskander et al., 2013; Moeljadi et al., 2019) on our data to understand their success and failure cases (§7.2, §7.3) and to provide baselines for future work. We also test methods for data augmentation in machine translation (back-translation), which to the best of our knowledge has never been applied to

---

[1] For example, *gue*, a common informal form of *aku* ('I', 'me'), is a word that originates from the Betawi dialect.

[2] We used the term morphological transformations broadly here to include word form changes at the respective interfaces of grammar (phonology, syntax, and semantics), following the definition by Trips (2017).

[3] For example, *laper*, a common informal form of *lapar* ('hungry'), is a phonetic change from its standard form.

August 1–6, 2021.

character-level morphological transformation, and observe that adding back-translated data to train transformer improves its performance for normalizing informal words. We also test models in the other direction: generating informal from formal words, which can be useful for generating possible lexical replacements to standard text (Belinkov and Bisk, 2018).

2 Related Work

With the advent of social media and other user generated contents on the web, non-standard text such as informal language, colloquialism and slang become more prevalent. Concurrently, the rise of technologies like unsupervised language modeling opened up a new avenue for low-resource languages which lack annotated data for supervision. These systems typically only require large amounts of unlabeled text to train (Lample and Conneau, 2019; Brown et al., 2020). However, even when NLP systems require only unlabeled data to train, the varying degrees of formalism between different sources of monolingual data pose domain adaption challenges to NLP systems which are trained on one source (e.g. Wikipedia) to transfer to another (e.g. social media) (Eisenstein, 2013b; Baldwin et al., 2013b; Belinkov and Bisk, 2018; Pei et al., 2019). Worse yet, for an overwhelming majority of lower resource languages, unstructured and unlabeled text on the Internet is often the sole source of data to train NLP systems (Joshi et al., 2020). Therefore, addressing the formalism discrepancy will augment the types of web texts which can be employed in language technologies, especially for languages such as Indonesian which are subject to a high degree of informalism as will be discussed.

While this motivates research on training systems that are robust to non-standard data (Michel and Neubig, 2018; Belinkov and Bisk, 2018; Tan et al., 2020b,a), one intuitive direction is to normalize colloquial language use. Most of the work on colloquial language normalization has been done at the sentence-level: for colloquial English (Han et al., 2013; Lourentzou et al., 2019), Spanish (Cerón-Guzmán and León-Guzmán, 2016), Italian (Weber and Zhekova, 2016), Vietnamese (Nguyen et al., 2015), and Indonesian (Barik et al., 2019; Wibowo et al., 2020). However, research on the linguistic phenomena of non-standard text (Mattiello, 2005), which argues that slang words exhibit extra-grammatical morphological properties (such as portmanteaus, clipping) that distinguish them from the standard form, justifies the need for word-level normalization.

Word-level normalization also has its merit because due to its much lower hypothesis space, models can be trained using significantly smaller amount of data (e.g., compare SIGMORPHON's 10k examples to WMT's 10^6 at high-resource setting). Further, from our manual analysis of the top-10k most frequent Indonesian informal words we collected from Twitter, we find that around 95% of these words do not require context to normalize. Additionally, previous works such as Kulkarni and Wang (2018) have suggested that creating computational models for this generation of informal words can give us insights into the generative process of word formation in non-standard language. This is important because studies into the generative processes of word formation in non-standard text can deepen our understanding of non-standard text. Moreover, they are potentially applicable to many languages since word formation patterns are shared across languages (Štekauer et al., 2012), e.g., portmanteaus (such as *brexit*) have been found not only in English but also in many other languages such as Indonesian (Dardjowidjojo, 1979), Modern Hebrew (Bat-El, 1996), and Spanish (Piñeros, 2004). Finally, the studies may have broader applications including development of rich conversational agents and tools like brand name generators and headlines (Özbal and Strapparava, 2012).

Previous work that qualitatively catalogues or creates computational models for informal word formations such as shortening has mostly been in English, using LSTMs (Gangal et al., 2017; Kulkarni and Wang, 2018) or finite state machines (Deri and Knight, 2015) to generate informal words given the standard forms and the type of word formation. Most of the dataset: formal-informal word pairs labeled with their word formation used to train these models are also in English. Other dictionaries of informal English words include SlangNet (Dhuliawala et al., 2016), SlangSD (Wu et al., 2018), and SLANGZY (Pei et al., 2019). There is also a dataset that contains pairs of formal-informal Indonesian words (Salsabila et al., 2018), but they are not annotated with word formation mechanisms. To the best of our knowledge, ours is the first dataset of formal-informal lexicon in a language other than English that is annotated with their word formation types.

3 Indonesian Colloquialism

3.1 Indonesian Colloquial Words

Language evolves over time due to the process of language learning across generations, contact with other languages, differences in social groups, and rapid casual usages (Liberman et al., 2003). Each of these factors exists to a high degree in Indonesia, resulting in the constant evolution of its language due to contacts with over 700 local languages (Simons and Fennig, 2017), socioeconomic and education inequalities that result in varying level of adoption of the standard Indonesian (Azzizah, 2015), and the rise of social media usages with widespread *celeb* culture (Suhardianto et al., 2019; Heryanto, 2008) that causes new words to be invented and spread rapidly.

We catalog the following word formation types that are common in colloquial Indonesian.

1. **Disemvoweling**: elimination of some or all the vowels, e.g: *jangan* to *jgn* ('no' or 'don't'). Disemvoweling does not correspond to any phonetic change,
2. **Shortening or Clipping**: syllabic shortening of the original word, e.g: *internet* to *inet*. Unlike disemvoweling, shortening does imply phonetic change,
3. **Space/dash removal**: shortened version of writing Indonesian plural form, e.g.: *teman-teman* to *temanteman* or *teman2* ('friends'),
4. **Phonetic (sound) alteration**: slight change both in sound and spelling in text, but the number of syllables stay the same, e.g: *pakai* to *pake* or *pakek* ('use'),
5. **Informal affixation**: modification, addition or removal of affixes, e.g: *mengajari* to *ngajarin* ('to teach'),
6. **Compounding and acronym**: syllabic and letter compounds of one or more words akin to acronyms, abbreviations, and portmanteau, e.g: *anak baru gede* to *abg* ('teen'), *budak cinta* to *bucin* (literally, 'being a slave to love'),
7. **Reverse**: letter reversal, or colloquially known as "Boso Walikan" (Hoogervorst, 2014), e.g: *malang* (the name of a city in Indonesia) to *ngalam*.
8. **Loan words**: borrowed words, often from local language or English, e.g: *bokap* ('dad' in Betawi)
9. **Jargon**: tagline, terms that have been made into a popular term, e.g: *meneketehe*, from *mana aku tahu* (a jargon for 'how should I know?').

Some of the above transformations are also found in the literature of other languages, such as English and Korean. In English, disemvoweling was common during the texting (SMS) era in order to write faster and to save on message lengths e.g., *c u l8r* ('see you later'). Informal affixation (*cryin*, *sweet-ass*), compounding and portmanteaus (*btw*, *sexting*), and phonetic alteration (*dis is da wae*) are also present. In Korean, some compounded or shortened version of *Konglish* is also widely used (Khan and Choi, 2016), e.g., *chimaek* from *chicken* and *maek* ('beer'). Any insight we obtain through evaluating models on our dataset may therefore be of interest to other languages that share similar colloquial transformations; insights that may be increasingly paramount due to the rising prevalance of non-standard text in many languages on the web (Kulkarni and Wang, 2018; Joshi et al., 2020) and the challenges they pose to NLP systems (Belinkov and Bisk, 2018; Pei et al., 2019).

Loan word transformations that come from other languages require multilingual dictionaries/embeddings to normalize while jargons often require background knowledge. Aside from these two, we follow the previous work and hypothesize that the word formations that fall in other categories are mostly morphological transformations that can be learned at character-level (Kulkarni and Wang, 2018; Gangal et al., 2017). In §4, we describe how we curate this colloquial transformation data.

3.2 Indonesian Colloquialism Analysis

In this section, we motivate the importance of research on Indonesian colloquialism by highlighting their prevalence in Indonesian web text. We indeed observe that in its daily use Indonesians use colloquial Indonesian to generate contents in the web with (1) vocabularies that are different from formal Indonesian and (2) at a higher rate than colloquial use in the English language.

To compare colloquial and formal Indonesian (from Twitter and Lazada product reviews[4] and from Kompas news articles respectively (Tala, 2003)), we compute these dataset perplexities as well as their out-of-vocabulary (OOV) rates with respect to an Indonesian formal lexicon constructed from tokenizing Indonesian Wikipedia articles. For a fair comparison, we sample 3685 sentences from

---

[4] www.kaggle.com/grikomsn/lazada-indonesian-reviews

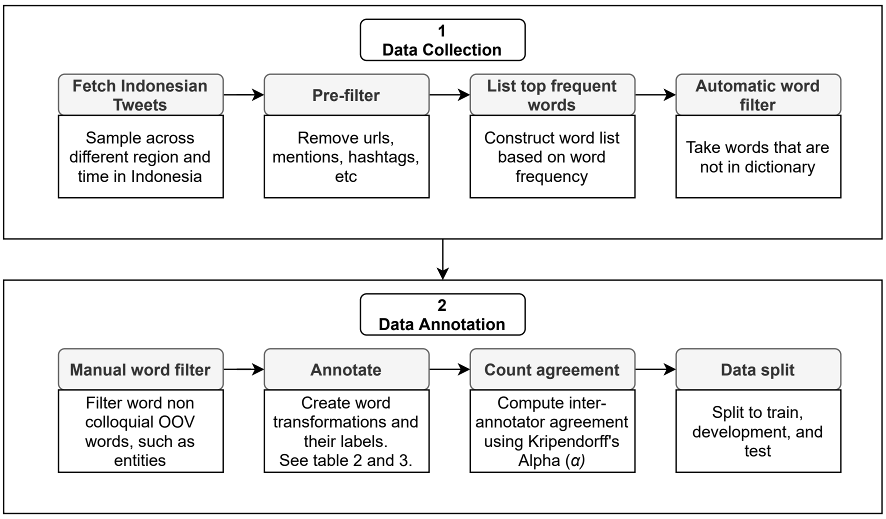

Figure 1: The data construction process composed of Data Collection and Data Annotation

each dataset based on the size of the smallest dataset. To compare to colloquial use in the English language, we also compare English tweets to an English formal lexicon constructed from English Wikipedia articles. We use Wikipedia to construct these lexicons to include named entities which are not typically present in traditional dictionaries.

Table 1 shows the OOV rate of the various datasets. Our OOV count excludes Twitter usernames, hashtags, mentions, URLs, dates, and numbers. To avoid rare words being captured as OOV, we also remove any token that only occurred once (shown as OOV-2) on the Table. We observe that the OOV rate of colloquial Indonesian is double the OOV rate of informal English. OOV of the formal Indonesian text (Kompas news) is low, as expected.

We use perplexity as a measure of impact of colloquialism beyond vocabulary usage and utilize a pre-trained Indonesian GPT-2 trained on Wikipedia[5] and Open AI's GPT-2[6] to calculate Indonesian and English data perplexities, respectively. Table 1 shows these perplexities.

Indonesian tweets have comparable perplexity as Lazada as they both use colloquial language. Both also have much higher perplexities than Kompas, implying that Indonesian LM finds that colloquial Indonesian is different than formal Indonesian. Similarly, English tweets have a higher perplexity compared to English Wikipedia (Radford et al., 2019). Notably, aside from Indonesian Twitter having around two times higher OOV rates: as high as 14.6% in OOV and 8.3% in OOV-2 than English Twitter, its perplexity too is significantly higher than English Twitter —suggesting that the non-standard word formation is a much more prominent issue when it comes to Indonesian, yet remains significantly under-researched.

Dataset	Lang.	OOV	OOV-2	Ppl
Twitter	ID	14.6%	8.3%	1617.0
Lazada review	ID	9.1%	7.0%	1824.3
Kompas news	ID	1.5%	1.1%	145.8
Wikipedia	ID	n/a	n/a	29.9
Twitter	EN	6.4%	4.5%	611.2
Wikipedia	EN	n/a	n/a	29.4

Table 1: OOV rates of Indonesian and English datasets

4 Data Collection and Annotation

Our dataset is constructed and manually annotated from a list of informal words obtained from Twitter. The data construction process is summarized in Figure 1. As an archipelago country, Indonesia is very diverse in local languages, which affects the way people use the Indonesian language. Hence, we sample 80 tweets per-day from March 2017 to May 2020, from each of the 34 provinces in Indonesia. We then select top 10k frequent tokens not appearing in our Wikipedia-based formal word dictionary and treat them as informal. Then we manually filter out from this list, OOV words that are not informal words such as product names or entities. Despite being sampled according to geolocation, we note that most of the informal words are more inclined to informal words commonly used in Jakarta. We suspect this is because Jakarta, being the center of Indonesian economy and pop culture (CITE), heavily influences the other regions through mainstream media. Further investigation on this aspect

---

[5] huggingface.co/cahya/gpt2-small-indonesian-522M

[6] huggingface.co/gpt2

is necessary and we leave this as a future work.

We assign four Indonesian native speakers[7], with formal education in linguistics and/or computational linguistics, to annotate each informal word with its standard form and label the pair with their word formation types according to our annotation codebook.[8] We annotate 9 different types of word formation mechanisms: disemvoweling, shortening, space/dash removal, phonetic (sound) alteration, affixation, compounding, reverse, loan word, and jargon. Since an informal word is often produced by stacking multiple transformations, we also annotate the transformation order, from the formal word to the informal. Some annotation examples are shown in Table 2. To simplify the transformation task, we assume single transformations and treat stacked transformations as a sequence of separate transformations. Words undergoing multiple transformations are broken down into different entries in our dataset. Ultimately, our dataset consists of parallel formal and informal Indonesian word pairs, each with its annotated word formation type from formal to informal. A sample of our dataset is shown in Table 3. Note that the same formal word with the same transformation may produce different informal words due to the open vocabulary of colloquial words.

Our dataset contains 3048 annotated word pairs[9] of which 2036 are those with morphological transformations (i.e., not loan words or jargons), which is comparable in size to other morphological transformation dataset such as the SIGMORPHON shared task (Cotterell et al., 2018). In comparison, Bengali, which is also a lower resource language comparable to Indonesian (Joshi et al., 2020), has 136 lemmas (and 4000 word forms) crowdsourced in the SIGMORPHON inflection dataset while our dataset has expertly annotated 1602 formal words (and 2036 informal variants).

In order to ensure the quality of our annotations, we sample 100 word pairs and compute Krippendorff's Alpha (α) (Hayes and Krippendorff, 2007) and Cohen's Kappa (κ) (Cohen, 1960) to measure agreement on word formation type annotations. The scores are $\alpha = 0.709$ $\kappa = 0.708$, showing that the annotators have substantial agreement on our dataset (Viera et al., 2005). We split the dataset into training, validation, and testing as in Table 4. Note that since reverse formation is quite rare, we augment the data and add additional reverse formation in the testing and validation sets.

In our experiments, we exclude loan word and jargon from the evaluation of character-level models, since these transformations are challenging, if not impossible to handle at the character-level alone without (1) additional resources such as multilingual dictionaries/embeddings and without (2) involving additional tasks such as translation.

5 Rule-Based Transformation Baseline

We believe that some formal to informal word formation mechanisms follow regular patterns. We manually define a rule-based system as one of our baselines (see Appendix). As we will demonstrate in the results section, there are several challenges entailed with a rule-based approach. Firstly, our rule-based transformation only works from formal to informal—as most of the colloquialism involves removing parts of the word, reverting from informal to formal Indonesian proves difficult for the rule-based system as it requires predicting the removed characters.

Secondly, the rule-based approach can not be universally applied. For example, in affixation, some Indonesian root words have sub-words similar to common morphological affixes in Indonesian such as *me-* or *-kan*. However, since these sub-words are part of the root words, they should not be removed/altered e.g., *membal* ('bouncy') cannot be transformed via informal affixation to *ngebal*, since *me-* in *membal* is part of the root word. Similarly, sound-alter transformation is applicable only to some words but not others e.g., *malam* ('night') can be altered to *malem*, but *galak* ('fierce') cannot be altered to *galek*. The rule of which words can be sound-altered seems arbitrary. In compounding, there is also no clear rule as to which abbreviation to use in different settings (e.g., *anak baru gede* is abbreviated to *ABG*, but *rapat kerja nasional* is abbreviated to *rakernas* instead of *RKN*). Lastly, as a single word may have multiple possible transformations that can apply, since rule-based system cannot rank these possible outputs, it randomly picks one of the candidates.

6 Character-Level Seq2Seq Models

Previous approaches for generating transformed words model the task as a character-level sequence-to-sequence (SEQ2SEQ) problem: the characters

[9] Full dataset: https://github.com/haryoa/indo-collex

Informal Word	Annotated Formal	Annotated Word Formation Type
kuy	ayo (let's go)	original → sound-alter → reverse **note:** ayo → *yuk* → *kuy*
gpp	tidak apa-apa (no problem)	original → shortening → disemvoweling **note:** tidak apa-apa → *gapapa* → *gpp*
ngeselin	mengesalkan (annoying)	original → affixation → sound-alter **note:** mengesalkan → ngesal*in* → nges*e*lin

Table 2: Examples of informal words annotated with their formal versions, alongside the transformation sequences.

Source	Target	Word Formation Tag
ayo (formal of "let's go")	yuk (informal of "let's go")	sound-alter
ayo (formal of "let's go")	yuks (informal of "let's go")	sound-alter
yuk (informal of "let's go")	kuy (informal of "let's go")	reverse
yuks (informal of "let's go")	skuy (informal of "let's go")	reverse
kemarin (formal of "yesterday")	kmrn (informal of "yesterday")	disemvoweling
nasi goreng (fried rice)	nasgor	compounding
membuka (formal of "opening")	ngebuka (informal of "opening")	affixation

Table 3: Example entries in our colloquial transformation dataset.

Word Formation Tag	Train	Valid	Test
sound-alter	489	21	35
shorten	363	41	43
disemvoweling	323	30	31
affixation	165	30	20
space/dash removal	157	26	21
acronym	155	23	16
reverse	5	15	27
Total	1657	186	193

Table 4: Formal (F)→Informal (I) data distribution.

from the root word and an encoding of the desired transformation type are given as input to a neural encoder, and the decoder is trained to produce the transformed word, one character at a time (Gangal et al., 2017; Deutsch et al., 2018; Cotterell et al., 2017). In reality however, transformation types are often implied, but not given. For example, an Indonesian speaker will be able to transform the formal *tolong* ('help') to *tlg* given examples that *jangan* ('don't') can be transformed to *jgn*, even without the transformation type i.e., disemvoweling being specified. Thus, we also experiment with these SEQ2SEQ models for generating informal words from formal (and vice versa) without inputting any word formation tag to see if the models can induce the desired transformation type based on morphologically similar words in the training examples. We also use these models trained to generate outputs without word formation input to generate back-translated data to augment our training (§7.1).

6.1 BiLSTM

The dominant model for character-level transduction that have been applied to many tasks such as morphological inflection (Cotterell et al., 2017), morphological derivation (Deutsch et al., 2018), and informal word formation (Gangal et al., 2017) adopts a character-level SEQ2SEQ model that learns to generate a target word from its original form given the desired transformation. These models typically use bi-directional LSTM with attention (Luong et al., 2015) to learn these transformations as orthographic functions. For the task of morphological derivation, the SOTA model (Deutsch et al., 2018) also proposes a dictionary constraint approach where the decoding process is restricted to output tokens listed in the dictionary, which improves the accuracy of their model.

We evaluate this SOTA character SEQ2SEQ that leverages dictionary constraint (BiLSTM+Dict), whose code is publicly available,[10] on our data. Following their approach, we train this model for 30 epochs with a batch-size of 5 using Adam optimizer with initial learning-rate of 0.005, an embedding size of 20, and a hidden state size of 40. For the dictionary constraint, we construct dictionaries of formal words from Indonesian Wikipedia (§3.2) and informal words we collected from Twitter (i.e., words we collected from Twitter that do not appear in our Wikipedia-based formal word dictionary §4).

6.2 Transformer

Given that more recently Transformer has been shown to outperform standard recurrent models on several character-level transduction tasks including morphological inflection and historical text normalization, grapheme-to-phoneme conversion, and transliteration (Wu et al., 2020); we evaluate character-based Transformer model (Vaswani et al., 2017) on our dataset. We conduct hyperparame-

---

[10] github.com/danieldeutsch/derivational-morphology

ter tuning on the size of the character embeddings, the number of layers, and the number of attention heads of the Transformer. For training, we use Adam with an initial learning rate of 0.005, a batch size of 128 (following (Wu et al., 2020)), and train for a maximum of 200 epochs, returning the model with the least validation loss.

7 Experiment and Results

We evaluate standard character-level transduction models on our dataset to assess its difficulty. Our goal is not to train SOTA models for word normalization but rather to test these models for such task on our data, and elucidate what features of the data make it difficult.

7.1 Experiment Settings

We train and evaluate the BiLSTM+Dict and Transformer models on our dataset. The models are trained and evaluated in both directions: formal↔informal (F↔I) Indonesian. However, as mentioned previously, we only explore formal→informal (F→I) for the rule-based model. We also train the SEQ2SEQ models with and without inputting the word formation tag. Each experiment took about 3 hours on a K80 GPU.

Aside from training the models to transform formal↔informal words, we also use the Transformer model to predict the word formation tag $t \in T$, where T is the set of word formation types in our dataset, that best applies given an informal word and its corresponding formal form (I→F) or vice versa (F→I) (i.e., Transformer$_{(I \to F) \to T}$ and Transformer$_{(F \to I) \to T}$).

We experiment with using backtranslation (Sennrich et al., 2016), which has been used to learn novel inflections in statistical machine translation (Bojar and Tamchyna, 2011), at the character-level to increase the training data for I→F. Using Transformer$_{F \to I}$ model that performs best on the validation set, we generate informal words from the words in our formal dictionary sorted by frequencies. We experiment with generating $M = kN$ additional word pairs, where $k = \{1, 2, 3\}$ and N is the number of word pairs in the original training data. We similarly augment training data for F→I by using the Transformer$_{I \to F}$ model that performs the best on the validation set to generate formal words from our informal word dictionary.

To ensure that the augmented data has similar transformation distribution as the original training data, we predict the word formation type that best applies to each generated word pair using the Transformer$_{(I \leftrightarrow F) \to T}$ model that performs best on validation. For each word formation type, we add rM generated pairs with such type to our training data based on its ratio r in the original training.

Each model's performance is measured by the top-*1* and top-*10* accuracy. Since formal→informal transformation is rather flexible, we also capture the BLEU score of the model's output. We report performances of the hyperparameter-tuned models that perform best on the validation set.

7.2 Results

Our experiment results are shown in Table 5. Generally, Transformer models outperform all other models. Specifying the target word formation type improves the performance of both models. Backtranslation is also shown to improve the performance of the Transformer. Transformer with added backtranslation and word formation tag yields the best test performance in both directions.

We also observe that in average the performance of the models are higher in the I→F direction than F→I. We observe similar trends when predicting word formation types given word pairs. The accuracy of the Transformer$_{(I \to F) \to T}$ model that predicts the type that applies given an informal word and its corresponding formal form is 81.4%; which is significantly higher than the 65.0% accuracy of the Transformer$_{(F \to I) \to T}$ model that predicts the type given a formal word and its corresponding informal form. This may point to the inherent ambiguity of generating informal words from the formal words. Due to the open-vocabulary of informal words, there are potentially many ways to transform a formal word into informal forms.

Surprisingly, rule-based transformation outperforms BiLSTM+Dict and several non-optimal Transformer configurations in terms of top-*1* accuracy. However, rule-based transformation does not perform well in terms of top-*10* accuracy. We observe that the rule-based transformation does not always manage to produce 10 transformation candidates, therefore missing out on the extra chances to correctly guess the output.

7.3 Discussion

In this section, we discuss failures and success cases of the best performing model (Transformer) on our dataset, elucidate what the model learns,

Model	Informal to Formal					Formal to Informal				
	Dev		Test			Dev		Test		
	Top1	BLEU	Top1	Top1(	BLEU	Top1	BLEU	Top1	Top1(	BLEU
Rule-Based	-	-	-	-	-	27.9	43.9	34.7	53.4	50.2
BiLSTM + Dict	23.5	53.0	30.5	58.8	57.9	18.8	47.3	22.8	56.1	47.7
BiLSTM + Dict + word-formation tag	25.7	54.8	30.5	56.3	53.2	30.6	60.8	30.1	62.5	54.4
Transformer	30.1	59.3	27.9	60.6	61.6	19.4	53.3	21.2	56.5	48.7
Transformer + word-formation tag	**33.9**	64.4	35.8	65.9	61.6	31.2	59.2	22.3	54.2	48.2
Transformer + BT	31.7	65.7	32.1	66.4	**63.7**	22.6	57.1	24.4	58.4	53.4
Transformer + BT + word-formation tag	33.3	**66.5**	**37.4**	**70.2**	62.1	**36.6**	**69.2**	**35.8**	**67.5**	**57.0**

Table 5: Experiment Result for Informal and Formal Colloquial transformation.

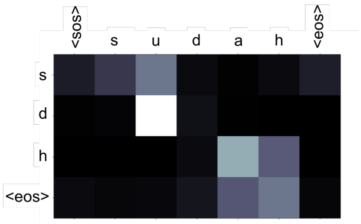

Figure 2: Attention matrix of *sudah* (F) → *sdh* (I) *without* word formation tag (column: source, row: target). The model learns to disemvowel implicitly by paying attention to the vowels and removing them.

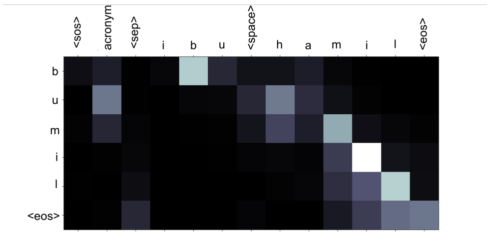

Figure 3: Attention matrix of *ibu hamil* F→I transformation *with* word formation tag (column: source, row: target). The model pays attention to the tag (acronym) while getting the prefix *bu-* from the first word and the suffix *-mil* from the second.

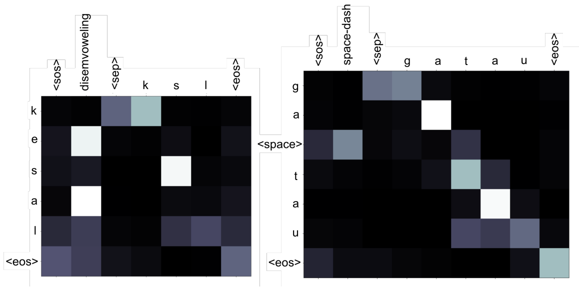

Figure 4: Attention matrix of *ksl* (I) → *kesal* (F) and *gatau* (I) → *ga tau* (F) *with* tag (column: source, row: target). The model learns to pay attention to the tag while regenerating the missing vowels and space.

and analyze features of the data that make it challenging for the model. As seen in Table 5, when the desired word formation is not given, the Transformer has worse performance when performing F→I transformation compared to I→F. This is because transforming from formal to informal has a higher level of ambiguity i.e., a word can be made informal by multiple possible word formations.

If the word formation type is not given, we observe that Transformer will learn to select the type implicitly. For example, it selects the disemvoweling mechanism implicitly as it pays attention to vowels in the word while removing them e.g., to correctly generate the informal *sdh* from the formal *sudah* (meaning, 'already') Figure 2). If the input consists of two words (separated by space), the model assumes the space/dash removal mechanism, paying attention to the characters before and after the space while removing the space e.g., given the word *ga tau* (meaning, 'don't know'), the model removes the space and correctly returns *gatau*.

However, the Transformer may select an incorrect transformation when the target word formation is not given e.g., the phrase *ibu hamil* ('pregnant mother') is often expressed as *bumil* (acronym). Without tag, the model performs a space/dash removal instead, and produced incorrect *ibuhamil*. Figure 3 shows how the model attends to the tag when it is given and applies the correct mechanism.

We observe that the model also attends to the tag when transforming the word in the reverse (I→F) direction e.g., the model pays attention to the tag while correctly generating the vowels of a disemvoweled words *ksl* to *kesal* ('annoyed') or the space between the compounded word *gatau* to *ga tau* (Figure 4).

In general, we observe that formal to informal transformation is challenging, since multiple valid informal words are possible even for a given word and word formation type. For example, *kamu* ('you') can be written informally as *km* or *kmu* both with the same disemvoweling transformation. Some word formation mechanisms are also ambiguous. For example, *budak cinta*'s acronym is *bucin* (using the *prefix* of the second word), whereas *ibu hamil*'s acronym is *bumil* (using the *suffix* of the second word). The acronym transformation seems to be applied on a case-by-case basis with no clear pattern. Reversing acronym to its original phrases is even more challenging (with or without tags) since it requires models to reconstruct the full phrase given minimum context e.g., reconstructing *anak layangan* ('tacky') from its acronym *alay*.

Another challenging transformation is affixation. Since *me-* and its different variants (*mem-*, *men-*, etc.) are common morphological prefixes in Indonesian, we observe that our best model, the Transformer, often puts *me-* in I→F affixation transformation, mistakenly transforming for example, *nyantai* ('to relax') into *menyantai* (expected: *bersantai*). This suggests that more training data may be needed to capture various affixation.

On the other hand, in sound alteration, we observe that Transformer successfully learns to sound-alter even when the word formation is not explicitly mentioned. For example, it learns to transform the informal *pake* ('to wear') to *pakai* (attending to the characters *e* when outputting *ai*), *kalo* ('if') to *kalau* (attending to the character *o* when outputting *au*), and *mauuu* ('want') to *mau* (attending to the characters *uuu* when outputting *u*).

8 Ethical Consideration

Normalizing informal Indonesian language might serve as a bridge to connect the generational gap in the use of the language, as the informal Indonesian language is more popular among the younger populace. Furthermore, it can potentially bridge linguistic differences across the Indonesian archipelago. Although we attempt to collect informal data from each province in Indonesia, the resulting informal dataset is still mostly Jakarta-centric, and further scraping and verification of the linguistic coverage is necessary for future work. Finally, as not every Indonesian speaks perfect standard Indonesian, having an NLP interface (such as chatbots) that can readily accept (process and understand via normalization) any kind of informality that might arise promotes inclusivity that all NLP research should strive for.

9 Conclusion and Future Work

We show that colloquial and formal Indonesian are vastly different in terms of OOV-rate and perplexity, which poses difficulty for NLP systems that are trained on formal corpora. This significant gap between train and test sets in terms of formalism may hinder progress in Indonesian NLP research. We propose a new benchmark dataset for Indonesian colloquial word normalization that contains formal-informal word pairs annotated with their word formation mechanisms. We test several dominant character-level transduction models as baselines on the dataset and observe that different word formation mechanisms pose different levels of difficulties to the models with transformation to informal forms being more challenging due to the higher degree of transformation variants. Through this dataset, we intend to provide a standard benchmark for Indonesian word normalization and foster further research on models, datasets and evaluation metrics tailored for this increasingly prevalent and important problem.

In the future, we are interested to use the context in which the words occur, either textual (e.g., sentences) or other modalities (e.g., images or memes), to improve word transformation (formal ↔ informal) by using the context as either implicit signal (Wijaya et al., 2017) or explicit signal for "translating" between the formal and informal word forms based on similarities between their sentence contexts (Feng et al., 2020; Reimers and Gurevych, 2020) or image contexts (Bergsma and Van Durme, 2011; Kiela et al., 2015; Hewitt et al., 2018; Khani et al., 2021). We are also interested to learn if simple clustering of contexts within which the words occur can help us learn the mapping between the formal and informal words similar to finding paraphrase matching (Wijaya and Gianfortoni, 2011). Lastly, we are interested in the use of text normalization to augment data for training informal text translation (Michel and Neubig, 2018; Jones and Wijaya, 2021) or for training other downstream applications such as framing identification (Card et al., 2015; Liu et al., 2019; Akyürek et al., 2020), which are typically trained on formal news text, on informal social media text.

Acknowledgments

We would like to thank the anonymous reviewers for their thoughtful comments. A Rule-based transformation

Our rule-based transformation can be described in Table 6.

Condition	Transformation	Example
Type: Affixation		
prefix meng- followed by a consonant	replace prefix to nge-	menghina - ngehina
prefix menc-	replace prefix to ny-	mencari - nyari
prefix mem- followed by a consonant	replace prefix to nge-	membuka - ngebuka
prefix men- followed by a consonant	replace prefix to nge-	menjitak ->ngejitak
prefix me- followed by l, q, r, w	replace prefix to nge-	melempar ->ngelempar
suffix -i	replace suffix to -in	pukuli ->pukulin
suffix -kan	replace suffix to -in	hidangkan ->hidangin
Type: Shorten		
prefix me- followed by ng	remove me-	mengegas ->ngegas
prefix me- followed by ny	remove me-	menyanyi ->nyanyi
prefix me- followed by m + vowel	remove me-	memukul ->mukul
prefix me- followed by n + vowel	remove me-	menendang ->nendang
prefix h-	remove h-	habis ->abis
identic duplicate words	replace word with 2	makan-makan ->makan2
Type: Sound-alteration		
last a	replace to e	malam - malem
last i	replace to e	kemarin ->kemaren
last ai	replace to e	sampai ->sampe
last au	replace to o	kalau-kalo
last ai	replace to ae	main - maen
last -nya	replace to -x	sepertinya - sepertix
last p	replace to b	mantap - mantab
last s	replace to z	habis - habiz
Compounding		
any pattern	select the first character	anak baru gede - abg
Second occurrence of cons. + vowel	All character before the pattern	butuh cinta - bucin
Second occurrence of cons. + vowel	All character up to the cons.	nasi goreng - nasgor
Disemvowelling		
any pattern	randomly remove vowels	kemarin - kmarin, kamu - km
Reverse		
any pattern	reverse the word	yuk - kuy

Abstract

Improving the robustness of neural machine translation models on variations of input sentences is an active area of research. In this paper, we propose a simple data augmentation approach by sampling virtual sentences from the vicinity distributions in higher-level representations, constructed either from individual training samples via adversarial learning or pairs of training samples through mixup. By simplifying and extending previous work that operates at the token level, our method can construct virtual training samples in a broader space and achieve improved translation accuracy compared to the previous state-of-the-art. In addition, we present a simple variation of the mixup strategy to better utilize the pseudo training samples created from back-translation, obtaining further improvement in performance.

1 Introduction

In recent years, neural machine translation (NMT) models (Sutskever et al., 2014; Bahdanau et al., 2014; Vaswani et al., 2017) have dramatically improved the quality of machine translation, especially with the introduction of the seminal Transformer architecture (Vaswani et al., 2017) that has become the de facto modeling choice. NMT training aims to learn a parameterized function that models the prediction of the translation in a target language given a source language sentence from labeled training data, which is often limited in volume especially for low-resource domains or languages. Similar to other fields in deep learning, model robustness is an area of concern for NMT as a minor change in the input sentence may result in a different or incorrect translation. In practice this can happen with spelling or grammar errors (Provilkov et al., 2019), speech recognition errors (Ruiz et al., 2019; Di Gangi et al., 2019), or even a sentence of the same meaning but with a slightly different use of words or expressions. Some studies (Belinkov and Bisk, 2017) have shown that the performance of NMT models can drop significantly when small perturbations are added to input sentences.

This problem can be attributed to overfitting as it is difficult to reliably model the translation distribution for the part of input space that has little or no training samples. There have been several attempts to address this problem by filling the space via data augmentation. One direction is to create new training samples by adding perturbations at the token level (Wang et al., 2018; Belinkov and Bisk, 2017; Sperber et al., 2017; Ebrahimi et al., 2018; Li et al., 2019; Cheng et al., 2018, 2019, 2020; Levy et al., 2019), through either token insertion, deletion, and substitution operations or introducing noises to token embedding vectors. Among these approaches, Cheng et al. (2019) demonstrated the effectiveness of incorporating adversarial training samples that are natural sentences, with their semantic relevance to the original sentence safeguarded by language modeling. Cheng et al. (2020) achieved further improvement by creating more diverse but virtual sentences by mixing up actual training samples or synthesized adversarial samples via interpolation of word embeddings, but again at the token level.

Inspired by the success of manifold mixup in computer vision (Verma et al., 2019) and the recent evidence of separable manifolds in deep language representations (Mamou et al., 2020), we propose to simplify and extend previous work on adversarial learning and mixup augmentation to operate in high-level hidden representations, and as such we name the method *manifold adversarial augmentation*. Specifically, we create adversarial representations on a randomly selected hidden layer to attack the NMT model by adding perturbations based on gradients at a random scale to

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3184–3189
August 1–6, 2021. ©2021 Association for Computational Linguistics

some randomly selected positions. Because the adversarial representations diverge slightly from the original representation but in many different ways, they can be viewed as many diverse sentences that are different in expression but have similar meanings. We also create virtual samples by mixing up the hidden representations of two randomly selected samples at a randomly selected hidden layer. Similarly, the mixup presentations can be viewed as many diverse sentences that fill the semantic space between the two original samples, which can help obtain smoother decision boundaries in the data space that is less populated. We further extend the mixup strategy to back-translation, another effective data augmentation method for machine translation, creating virtual samples to bridge the gap between pseudo samples and gold samples.

Experiments on the LDC Chinese-English and IWSLT English-French benchmark tasks demonstrate that our method can significantly improve the vanilla Transformer model by more than 4 and 3 BLEU respectively, averaged over multiple data sets for each task. Compared to the recent state-of-the-art AdvAug method in (Cheng et al., 2020), our method achieves an average improvement of 0.39 and 1.10 BLEU respectively. Further improvement can be achieved with the use of back-translation data.

2 Method

As our manifold adversarial augmentation method is closely related to the AdvAug method (Cheng et al., 2020), we start by highlighting, and also depicting in Figure 1, their similarities and differences.

AdvAug uses both adversarial learning and mixup augmentation at the token level. The adversarial samples are obtained by randomly replacing a small subset of input words (on either source or target side) with words adjacent in the direction of the gradient that can also fit in context based on language modeling. The generated adversaries tend to be natural sentences, however, the variation is limited as it cannot deal with word insertion, deletion, reordering, and more general variations in language expression. Their mixup operation creates virtual samples by interpolating the word embedding vectors of two randomly selected training samples or adversarial samples. While it can generate more training samples, it is hard to interpret the virtual samples as represention of natural sentences, limiting its potential in dealing with natural texts.

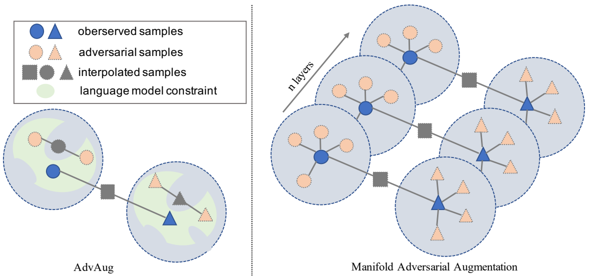

Figure 1: Comparison of the AdvAug method and our manifold adversarial augmentation method.

In contrast, our method operates on higher-level hidden represention for both adversarial learning and mixup augmentation, relying on multiple neural layers to extract semantic meanings, which makes it easier to perform arithmetic operations on semantics. Although we do not explicitly construct adversarial samples that are natural texts, we conjecture that our method has the potential of covering more variations that can occur naturally. We next describe the details of our approach.

2.1 Adversarial Learning

Let $\boldsymbol{x}$ be the input sequence to our model, which could be either a source language sentence or a target language text representing the translation history. We use $\boldsymbol{h}^{(j)}$ and $\boldsymbol{z}^{(\boldsymbol{k})}$ to denote the hidden representations at the j-th encoder layer and the history portion of the k-th decoder layer, respectively. $\texttt{Enc}_{>j}$ denotes the function composed of the encoder layers higher than j, and $\texttt{Dec}_{>k}$ the function composed of the decoder layers higher than k plus the output layer, which computes the generation distribution of output words[1]. We generate perturbation $\delta_{\boldsymbol{h}^{(j)}}$ to the encoder representations $\boldsymbol{h}^{(j)}$ as follows:

$$\delta_{\boldsymbol{h}^{(j)}} = \gamma * \boldsymbol{\eta} * \boldsymbol{g}^{(j)}$$

where $\boldsymbol{g}^{(j)}$ is the gradient with respect to the NMT training loss L_{nmt} back-propagated at $\boldsymbol{h}^{(j)}$, γ is a hyper-parameter controlling the maximum amount of perturbation, and $\boldsymbol{\eta} = [\eta_i \sim Beta(\alpha_{adv}, \beta_{adv}); 0 < i \leq |\boldsymbol{x}|]$ is a random variable providing more fine-gained control of the perturbation. By setting $\alpha_{adv} < 1$ and $\beta_{adv} < 1$, η_i

---

[1] Instead of performing manifold adversarial augmentation on a predetermined hidden layer, we choose to randomly select $j \in [0, K_{src}]$ and $k \in [0, K_{tgt}]$ among a range of encoder and decoder layers, allowing more variations. Appendix A.2 examines the effect of different K_{src} and K_{tgt} values on model performance.

can concentrate close to 0 or 1 and act like a gate independently controlling whether to add perturbation at a specific position, mimicking the random selection of positions for word replacement in AdvAug. Similarly, we generate perturbation $\delta_{\boldsymbol{z}^{(k)}}$ to $\boldsymbol{z}^{(k)}$ on the decoder side. The manifold adversarial learning loss L^m_{adv} is computed by:

$$\begin{aligned}\tilde{\boldsymbol{h}} &= \texttt{Enc}_{>j}(\boldsymbol{h}^{(j)} + \delta_{\boldsymbol{h}^{(j)}}) \\ L^m_{adv} &= \mathbb{E}[\texttt{KL}(\texttt{Dec}_{>k}(\tilde{\boldsymbol{h}}, \boldsymbol{z}^{(k)} + \delta_{\boldsymbol{z}^{(k)}}), \boldsymbol{\omega})]\end{aligned}$$

Here $\boldsymbol{\omega}$ represents the prediction distribution of NMT model on the original training sample, and we base the adversarial loss on KL-divergence instead of MLE, following the VAT work in (Miyato et al., 2018).

2.2 Mixup Augmentation

Verma et al. (2019) investigated manifold mixup augmentation as a way to leverage semantic interpolations at hidden representations as additional training signals for the image classification task. They demonstrated that it results in neural models with smoother decision boundaries at multiple layers, avoiding being overly confident in the space with little or no training samples, and can improve model performance and robustness. Inspired by this work, we attempt to extend the mixup augmentation method in AdvAug (Cheng et al., 2020) from word embeddings to hidden representations at higher layers for NMT training. Specifically, given two training samples, we first compute their hidden representations $\boldsymbol{h}^{(j)}$ and $\boldsymbol{h}'^{(j)}$ at the j-th encoder layer, hidden representations $\boldsymbol{z}^{(k)}$ and $\boldsymbol{z}'^{(k)}$ at the history portion of the k-th decoder layer, and their output distributions $\boldsymbol{\omega}$ and $\boldsymbol{\omega}'$. We then construct the hidden representations and the output distribution of the virtual mixup sample as follows:

$$\begin{aligned}\tilde{\boldsymbol{h}}^{(j)} &= m_\lambda(\boldsymbol{h}^{(j)}, \boldsymbol{h}'^{(j)}) \\ \tilde{\boldsymbol{z}}^{(k)} &= m_\lambda(\boldsymbol{z}^{(k)}, \boldsymbol{z}'^{(k)}) \\ \tilde{\boldsymbol{\omega}} &= m_\lambda(\boldsymbol{\omega}, \boldsymbol{\omega}')\end{aligned}$$

where $m_\lambda(\boldsymbol{x}, \boldsymbol{y}) = \lambda\boldsymbol{x} + (1-\lambda)\boldsymbol{y}$ denotes the interpolation of two vectors, with an interpolation weight $\lambda \sim Beta(\alpha_{mixup}, \beta_{mixup})$ randomly sampled from a Beta distribution for each pair of training samples. The manifold mixup augmentation loss L^m_{mixup} is computed by:

$$L^m_{mixup} = \mathbb{E}[\texttt{KL}(\texttt{Dec}_{>k}(\texttt{Enc}_{>j}(\tilde{\boldsymbol{h}}^{(j)}), \tilde{\boldsymbol{z}}^{(k)}), \tilde{\boldsymbol{\omega}})]$$

Finally, our manifold adversarial augmentation method optimizes on the combination of original NMT training loss, adversarial learning loss, and the mixup augmentation loss:

$$L = L_{nmt} + L^m_{adv} + L^m_{mixup}$$

2.3 Extention to Back-Translation

Back translation is an effective data augmentation method for machine translation. However, it is well known that pseudo training samples created from back translation have different characteristics from the gold training samples, due to factors such as domain mismatch and translation errors. To bridge this gap, we extend the manifold mixup augmentation strategy to create virtual training samples that are interpolated between a pseudo training sample and a gold training sample, again at hidden representations. We can adjust the parameters of the distribution $Beta(\alpha_{bt}, \beta_{bt})$ for generating the interpolation weight, biasing it toward the gold training sample to alleviate the aforementioned problems with back translation. Let $\tilde{\boldsymbol{h}}^{(j)}_{\boldsymbol{bt}}$, $\tilde{\boldsymbol{z}}^{(k)}_{\boldsymbol{bt}}$, and $\tilde{\boldsymbol{\omega}}_{\boldsymbol{bt}}$ be interpolation results, we define an additional training loss:

$$L^{m,bt}_{mixup} = \mathbb{E}[\texttt{KL}(\texttt{Dec}_{>k}(\texttt{Enc}_{>j}(\tilde{\boldsymbol{h}}^{(j)}_{\boldsymbol{bt}}), \tilde{\boldsymbol{z}}^{(k)}_{\boldsymbol{bt}}), \tilde{\boldsymbol{\omega}}_{\boldsymbol{bt}})]$$

3 Experiments

3.1 Setup

We conduct experiments on two language pairs: Chinese-English and English-French. For the Chinese-English translation task, we use the LDC corpus with 1.2M sentence pairs for training, NIST06 for validation, and NIST02, NIST03, NIST04, NIST05, NIST08 as the test sets. For the English-French translation task, we use the IWSLT 2016 corpus with 230k sentence pairs for training, test2012 for validation, and test2013 and test2014 as the test sets. All models are based on the Transformer architecture. Details of the data processing, model configuration, and training settings can be found in the appendix.

We compare with the following methods:

- The vanilla Transformer model (Vaswani et al., 2017).
- The virtual adversarial regularization method in (Sano et al., 2019), which adds a proportion of normalized gradient to the source and target word embeddings for adversarial training.

- The doubly adversarial inputs method in (Cheng et al., 2019), which performs adversarial learning with word substitutions in the source and target text based on language modeling and gradients at word embeddings.

- The AdvAug method in (Cheng et al., 2020), a state of the art adversarial learning method for NMT, also described in Section 2.

3.2 Main Results

Table 1 shows that our method is very competitive in comparison with other methods in the literature, achieving the overall best results. Compared to the vanilla Transformer, our method achieves more than 4 BLEU points of improvement on average on the Chinese-English task and more than 3 BLEU points of improvement on the English-French task. Compared to AdvAug, the previous state of the art, our method outperforms on 4 out of 6 test sets on the Chinese-English task, yielding up to 2.38 BLEU points of improvement on MT03 and an average improvement of 0.39 BLEU points over the 6 test sets. On the English-French task, our approach yields 1.55 and 0.65 BLEU points of improvement on the two test sets respectively.

METHOD	test13	test14

+back-translation	43.55	40.20
Our method	44.58	41.56
+back-translation	44.81	41.92
+back-translation, $L^{m,bt}_{mixup}$	45.46	42.13

Table 3: Back-translation results on the English-French task.

3.3 Ablation Study

Table 2 presents the ablation study results of different loss functions. In addition to two manifold adversarial augmentation loss functions described in Section 2, we also include their counterparts computed at the word embeddings for comparison. First, we always achieve better MT results with loss functions computed at the hidden represention than at the word embeddings, further validating our motivation that operating at higher hidden layer is superior. Second, we observe that adversarial learning and mixup augmentation are complementary to each other, with the combination of the two achieving the best performance.

3.4 Results with Back Translation

We conduct back-translation experiments on the English-French task as it has a smaller training set and can potentially benefit more from back translation. 25M French sentences from newscrawl07-11[2] are used as additional monolingual data, and are translated to English using a Transformer model trained with only the parallel training data. As shown in Table 3, both the Transformer baseline and our method can benefit from back-translation, although our method obtains a smaller improvement compared to the Transformer baseline as it has a significantly higher BLEU score to start with (actually higher than the Transformer baseline with back-translation). With the addition of our specially designed mixup loss $L_{mixup}^{m,bt}$ that biases toward the gold training samples in mixup augmentation, our method is able to achieve an extra gain of 0.65 and 0.21 BLEU improvement on the two test sets.

4 Conclusion

In this paper, we present a simple yet effective manifold adversarial augmentation method for NMT. By training on virtual samples constructed through adversarial learning and mixup augmentation at higher-level hidden representations, our method can train more robust NMT models with improved translation performance.

A Appendix

A.1 Experiment details

For the IWSLT English-French translation task, the training sets are preprocessed with BPE with 20k joint operations, and English and French share a vocabulary of 20k sub-words. For the NIST Chinese-English translation task, the training sets are preprocessed with BPE with 60k joint operations, and the vocabulary size is 60k and 30k for Chinese and English respectively.

We follow the network settings in the original Transformer work. The total numbers of the parameters of the model are 64757760 and 83247104 for French-English and Chinese-English translation tasks. The dropout ratio is 0.3. The model is optimized with Adam. We use inverse square root as the learning rate schedule, with the peak learning rate of 5e-4, warm-up steps of 4000. During decoding, the beam size is 4 and the length penalty is 0.6. We search hyper-parameters for producing adversarial examples according to BLEU [3] on the validation set. Finally, the maximum number of layers for manifold data augmentation at source side K_{src} and target side K_{tgt} are both set to 3. We let $\alpha_{adv} = 0.5$ and $\beta_{adv} = 0.5$ on the source side, and $\alpha_{adv} = 0.3$ and $\beta_{adv} = 0.7$ on the target side. When mixing training example pairs, the hyperparameter α_{mixup} and β_{mixup} are both set to 8 for the English-French translation task, and set to 0.2 for the Chinese-English translation task. When we mix parallel sentence with back-translated parallel sentence, we let $\alpha_{bt} = 8$ and $\beta_{bt} = 4$.

We use 1 V100 GPU for the IWSLT English-French translation task, and 4 V100 GPU for the NIST Chinese-English translation task. It takes about 24 hours and 72 hours for these two tasks respectively.

K_{src}	MT06	K_{tgt}	MT06
1	48.55	1	48.40
2	48.72	2	48.78
3	49.43	3	49.43
4	49.15	4	48.78
5	48.76	5	48.65
6	48.60	6	48.32

Table 4: Effect of K_{src} and K_{tgt} for manifold adversarial augmentation on NIST Chinese-English translation task

μ_1	μ_2	test13	test14
0	0	40.88	37.79
0	0.3	42.60	40.22
0	0.7	43.17	40.41
0	1	44.24	40.46
0.3	0	43.58	40.09
0.7	0	43.46	39.94
1	0	44.35	40.34
1	1	44.58	41.56

Table 5: Effect of different weights for losses on the IWSLT16 English-French translation task

A.2 Effect of K_{src} and K_{tgt} for manifold adversarial augmentation

Instead of performing manifold adversarial augmentation on a predetermined hidden layer, we choose to randomly select $j \in [0, K_{src}]$ and $k \in [0, K_{tgt}]$ among a range of encoder and decoder layers, allowing more variations. We study their effect on the validation set of the NIST Chinese-English translation task. We fix $K_{src} = 3$ (or $K_{tgt} = 3$), when change the value of K_{tgt} (or K_{src}). As shown in Table 4, large or small K_{src} and K_{tgt} will make the model performs worse down to about 1 BLEU.

A.3 Impact of different weights for losses

To further study the impact of different losses, we set the training loss of our model as $L = L_{nmt} + \mu_1 L^{(m)}_{adv} + \mu_2 L^{(m)}_{mixup}$, and compare the performance when we set different μ_1 and μ_2. We conduct experiments on the IWSLT English-French translation task. As shown in Table 5, too small μ_1 and μ_2 will make the model perform worse.

Learning to Bridge Metric Spaces: Few-shot Joint Learning of Intent Detection and Slot Filling

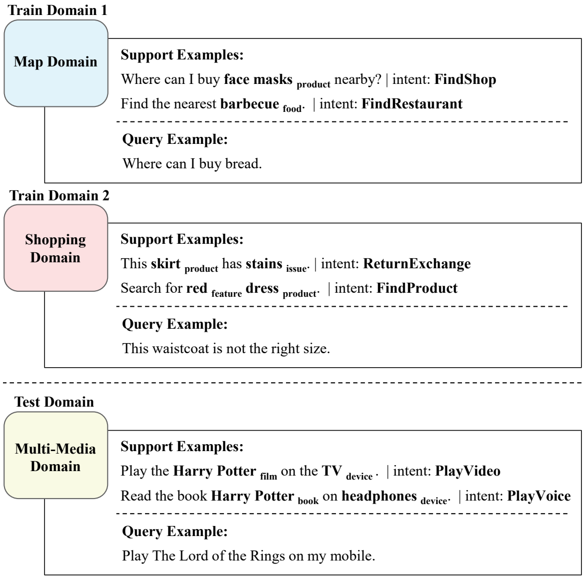
Yutai Hou*, Yongkui Lai*, Cheng Chen, Wanxiang Che†, Ting Liu
Research Center for Social Computing and Information Retrieval,
Harbin Institute of Technology
{ythou, yklai, cchen, car, tliu}@ir.hit.edu.cn

Abstract

In this paper, we investigate few-shot joint learning for dialogue language understanding. Most existing few-shot models learn a single task each time with only a few examples. However, dialogue language understanding contains two closely related tasks, i.e., intent detection and slot filling, and often benefits from jointly learning the two tasks. This calls for new few-shot learning techniques that are able to capture task relations from only a few examples and jointly learn multiple tasks. To achieve this, we propose a similarity-based few-shot learning scheme, named **Con**trastive **Pro**totype **M**erging network (**ConProm**), that learns to bridge metric spaces of intent and slot on data-rich domains, and then adapt the bridged metric space to specific few-shot domain. Experiments on two public datasets, Snips and FewJoint, show that our model significantly outperforms the strong baselines in one and five shots settings.

1 Introduction

Few-Shot Learning (FSL) that committed to learning new problems with only a few examples (Miller et al., 2000; Vinyals et al., 2016) is promising to break the data-shackles of current deep learning. Commonly, existing FSL methods learn a single few-shot task each time. But, real-world applications, such as dialogue language understanding, usually contain multiple closely related tasks (e.g., intent detection and slot filling) and often benefit from jointly learning these tasks (Worsham and Kalita, 2020; Chen et al., 2019; Qin et al., 2019; Goo et al., 2018). In few-shot scenarios, such requirements of joint learning present new challenges for FSL techniques to capture task relations from only a few examples and jointly learn multiple tasks.



Support Examples:
Where can I buy **face masks** $_{\text{product}}$ nearby? | intent: **FindShop**
Find the nearest **barbecue** $_{\text{food}}$. | intent: **FindRestaurant**

Query Example:
Where can I buy bread.

Support Examples:
This **skirt** $_{\text{product}}$ has **stains** $_{\text{issue}}$. | intent: **ReturnExchange**
Search for **red** $_{\text{feature}}$ **dress** $_{\text{product}}$. | intent: **FindProduct**

Query Example:
This waistcoat is not the right size.

Support Examples:
Play the **Harry Potter** $_{\text{film}}$ on the **TV** $_{\text{device}}$. | intent: **PlayVideo**
Read the book **Harry Potter** $_{\text{book}}$ on **headphones** $_{\text{device}}$. | intent: **PlayVoice**

Query Example:
Play The Lord of the Rings on my mobile.

Figure 1: Examples of the few-shot joint dialogue language understanding. On each domain, given a few labeled support examples, the model predicts the intent and slot labels for unseen query examples. Joint learning benefits from capturing the relation between intent and slot labels, but such relation is hard to learn from a few sparse examples and hard to transfer across different domains.

This paper explores the few-shot joint learning in dialogue language understanding as an early attempt for this issue. As shown in Figure 1, FSL models are usually first trained on source training domains, then evaluated on an unseen target test domain. Although joint learning can improve dialogue language understanding by utilizing the relation between intents and slots, e.g., "Harry Potter" is "film" in "PlayVideo" intent and "book" in "PlayVoice" intent, it faces serious challenges when engaging to FSL setting. Firstly, it is hard to learn generalized intent-slot relations from only a few support examples. Secondly, because the intent-slot relation differs in different domains, it is

---

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3190–3200
August 1–6, 2021.

hard to directly transfer the prior experience from source domains to target domains. For instance, the intent-slot relation, “PlayVideo”-“film”, has never appeared in source domains.

To tackle the aforementioned joint learning challenges in few-shot dialogue language understanding, we propose the **Prototype Merging**, which learns the intent-slot relation from data-rich training domains and adaptively captures and utilizes it to an unseen test domain. The intent-slot relation is learned with cross-attention between intent and slot class prototypes, which are the mean embeddings of the support examples belonging to the same classes. Such intent-slot relation adaptively connects the metric spaces of the two tasks.

Further, to jointly refine the intent and slot metric spaces bridged by Prototype Merging, we claim that related intents and slots, such as “PlayVideo” and “film”, should be closely distributed in the metric space, otherwise, well-separated. To achieve this, we propose **Contrastive Alignment Learning**, which exploits class prototype pairs of related intents and slots as positive samples and non-related pairs as negative samples. With these samples, it regularizes the FSL process with a margined contrastive loss.

Overall, we named the above novel few-shot joint learning framework as **Con**trastive **Pro**totype **M**erging network (**ConProm**), which connects intent detection and slot filling tasks by bridging the metric spaces of them. Two main components of it cooperate to accomplish this goal. As shown in Figure 2, Prototype Merging builds the connection between two metric spaces, and Contrastive Alignment Learning refine the bridged metric space by properly distributing prototypes.

Experiments on two public datasets show both Prototype Merging and Contrastive Aligning Objective significantly boost the few-shot joint learning effects and outperform strong baselines. In summary, our contribution is three-fold: (1) We investigate the few-shot joint dialogue language understanding problem, which is also an early attempt for few-shot joint learning problem. (2) We propose a novel Prototype Merging mechanism to build intent-slot connections adaptively. (3) We introduce a Contrastive Alignment Learning objective to jointly refines the metric spaces of intent detection and slot filling. For reproducibility, our code for this paper is publicly available at `https://github.com/AtmaHou/FewShotJoint`.

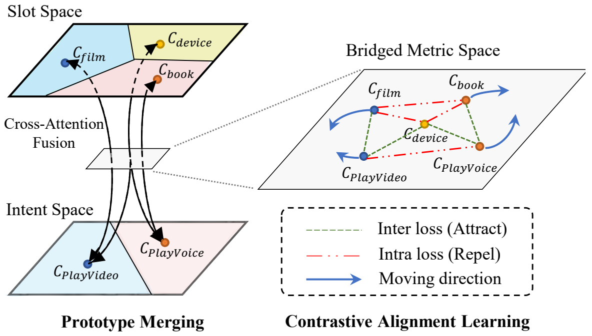

Figure 2: Illustration of two main components of the ConProm model: Prototype Merging and Contrastive Alignment Learning. C denotes prototypes. To ease understanding, we omit the repelling Inter loss in Bridged Metric Space, e.g, loss between C_{book} and $C_{\text{PlayVideo}}$.

2 Background

Before start, we introduce the background of dialogue language understanding and few-shot learning.

2.1 Dialogue Language Understanding

Dialogue language understanding contains two main components: intent detection and slot filling (Young et al., 2013). Intent detection is a sentence-level classification problem that classifies a user utterance into one of N intent categories.

Different from intent detection, slot filling aims to extract key entities within user utterances, which is often achieved by assigning slot tags to each token of a user utterance and is usually formulated as a sequence labeling problem. Given input utterance $\boldsymbol{x} = \langle x_1, x_2, \dots, x_n \rangle$ as a sequence of words, joint dialogue language understanding predicts the corresponding semantic frame $\boldsymbol{y} = (l, \boldsymbol{t})$, where l is the intent label and $\boldsymbol{t} = \langle t_1, t_2, \dots, t_n \rangle$ is the slot tags sequence of the utterance.

2.2 Few-shot Learning

Few-shot learning (FSL) extracts prior experience that allows quick adaption to new problems. Therefore, FSL models are usually first trained on a set of source domains, then evaluated on another set of unseen target domains. Figure 1 shows an example of the training and testing process of few-shot learning for dialogue language understanding.

A target domain only contains a few labeled examples, which is called support set $\mathcal{S} = \left\{(\boldsymbol{x}^{(i)}, \boldsymbol{y}^{(i)})\right\}_{i=1}^{|\mathcal{S}|}$. $\mathcal{S}$ includes K examples (K-shot) for each of N classes (N-way). Taking classification problem as an instance: given an input query example $\boldsymbol{x} = \langle x_1, x_2, \ldots, x_n \rangle$ and a K-shot support set $\mathcal{S}$ as references, we find the most appropriate class y^* of $\boldsymbol{x}$:

$$y^* = \arg\max_{y} \; p(y \mid \boldsymbol{x}, \mathcal{S}).$$

State-of-the-art few-shot learning is often similarity-based methods (Bao et al., 2020; Snell et al., 2017). These methods conquer the extreme lack of data by learning a general similarity metric space on data-rich source domains. Then on few-shot target domains, they classify a query example according to example-class similarity, where class representations are obtained from a few support examples.

Prototypical network (Snell et al., 2017) is one of the most classical similarity-based methods. It obtains the class representation as to the mean embedding of support examples belonging to the same class, so called **prototypes**:

$$C_i = \frac{1}{|\mathcal{S}_i|} \sum_{(\boldsymbol{x},y)\in\mathcal{S}_i} E(\boldsymbol{x}),$$

where $\mathcal{S}_i$ is the set of support examples of the ith class, and $E(\cdot)$ is the embedding function. The probability of $\boldsymbol{x}$ belongs to the ith class is then made as:

$$p(y_i \mid \boldsymbol{x}, S) = \frac{\exp\left(\textsc{Sim}(E(\boldsymbol{x}), C_i)\right)}{\sum_j \exp\left(\textsc{Sim}(E(\boldsymbol{x}), C_j)\right)},$$

where $\textsc{Sim}(\cdot,\cdot)$ is a vector similarity function.

3 Proposed Method

In this section, we introduce the proposed **Con**trastive **Pro**totype **M**erging network (ConProm). Firstly, we describe the few-shot intent detection and slot filling with Prototypical network (§3.1). Based on that, we present two key components of ConProm: the **Prototype Merging** mechanism that adaptively connects two metric spaces of intent and slot (§3.2) and the **Contrastive Alignment Learning** that jointly refines the metric space connected by Prototype Merging (§3.3).

3.1 Few-shot Intent Detection and Slot Filling

We build our few-shot intent detection and slot filling model based on the Prototypical Network described in Section 2.2. Given a query sentence $\boldsymbol{x}$ and a support set $\mathcal{S}$, we estimate the probability of $\boldsymbol{x}$ being associated with intent label l_i as:

$$\begin{aligned} &p(l_i \mid \boldsymbol{x}, \mathcal{S}) \\ &= \frac{\exp\left(\textsc{Sim}(E_{\text{intent}}(\boldsymbol{x}), C_{\text{intent}_i})\right)}{\sum_j \exp\left(\textsc{Sim}(E_{\text{intent}}(\boldsymbol{x}), C_{\text{intent}_j})\right)}, \end{aligned}$$

and estimates the probability of the kth token in $\boldsymbol{x}$ belonging to the ith slot class as:

$$\begin{aligned} &p(t_i \mid k, \boldsymbol{x}, \mathcal{S}) \\ &= \frac{\exp\left(\textsc{Sim}(E_{\text{slot}}(x_k), C_{\text{slot}_i})\right)}{\sum_j \exp\left(\textsc{Sim}(E_{\text{slot}}(x_k), C_{\text{slot}_j})\right)}, \end{aligned}$$

where C_{intent_i} and C_{slot_i} are prototypes derived with support examples. $E_{\text{intent}}(\cdot)$ and $E_{\text{slot}}(\cdot)$ are embedder functions for intent and slot respectively. We adopt BERT (Devlin et al., 2019) as the embedder, and the sentence embedding $E_{\text{intent}}(\boldsymbol{x})$ is calculated as the averaged embedding of its tokens. We use the dot-product similarity for function $\textsc{Sim}(\cdot,\cdot)$.

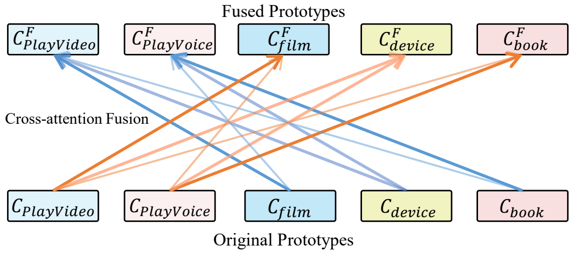

Figure 3: Illustration of cross-attention based information fusion in Prototype Merge. Thicker lines indicate higher cross-attention scores. For example, "PlayVideo" and "film" are more related, so the corresponding score is larger.

3.2 Prototype Merging

To achieve few-shot joint learning and capture the intent-slot relation with the similarity-based method described above, we need to bridge the metric spaces of intent detection and slot filling. However, as mentioned in the introduction, intent-slot relation differs in different domains, it is hard to transfer the bridged metric space learned from source domains to target domains.

To remedy this, we propose the **Prototype Merging** that can bridge metric spaces adaptively. As shown in Figure 3, Prototype Merging adaptively estimates intent-slot relevance with cross-attention between intent and slot, and then merges the intent and slot prototypes with attentive information fusion. Such an attentive fusion process enables both intent and slot prototype representations to reflect intent-slot relation and improves domain transferability.

On an unseen target domain, we estimate the intent-slot cross-attention scores from the support set with two methods: (1) use the statistic of co-occurrence of different intents and slots; (2) estimate the intent-slot relevance score using prototype representations.

Firstly, for the statistic-based attention-score, we estimate intent-slot attention scores A^{S} by counting the co-occurrence of different intents and slots, where $A^{\mathrm{S}}_{i,j}$ records the normalized number of co-occurrence times for the ith intent and the jth slot (normalized by row).

Secondly, for representation-based attention-score, we estimate the cross-attention scores with the Additive Attention (Bahdanau et al., 2015):[1]

$$A^{\mathrm{R}}_{i,j} = V^{\top}\tanh(WC_{\mathrm{intent}_i} + UC_{\mathrm{slot}_j}),$$

where A^{R} is the attention matrix, and $A^{\mathrm{R}}_{i,j}$ records the cross-attention score between the ith intent and the jth slot. U, V and W are parameters learned on source domains,which preserve the general experience of estimating relevance with representations. C_{intent_i} and C_{slot_j} are prototypes of ith intent and the jth slot respectively. We normalize A^{R} by row with softmax function.

We obtain the final cross-attention score matrix A by combining A^{S} and A^{R}.

$$A = \lambda A^{\mathrm{S}} + (1-\lambda)A^{\mathrm{R}},$$

where λ is the interpolation factor.

After obtaining the cross-attention scores, we represent each intent by fusing the information of related slot prototypes, where the attention scores are used as fusing weights. Similarly, we use intent prototypes to represent slots (See Figure 3). The fusion process is as follows:

$$C^{\mathrm{F}}_{\mathrm{intent}_i} = \sum_j A_{ij} \times C_{\mathrm{slot}_j},$$
$$C^{\mathrm{F}}_{\mathrm{slot}_j} = \sum_i A_{ij} \times C_{\mathrm{intent}_i},$$

where $C^{\mathrm{F}}_{\mathrm{intent}_i}$ and $C^{\mathrm{F}}_{\mathrm{slot}_j}$ are the fused prototypes of ith intent and the jth slot respectively.

At last, we obtain the representation of merged prototypes C' by combining the origin prototype C with the fused prototype C^{F}:

$$C'_{\mathrm{intent}} = \alpha \times C^{\mathrm{F}}_{\mathrm{intent}} + (1-\alpha) \times C_{\mathrm{intent}},$$
$$C'_{\mathrm{slot}} = \alpha \times C^{\mathrm{F}}_{\mathrm{slot}} + (1-\alpha) \times C_{\mathrm{slot}},$$

where the α is a hyper-parameter that controls the importance of intent-slot relation.

3.3 Contrastive Alignment Learning

Similarity-based few-shot learning relies heavily on a good metric space, where different classes should be well separated from each other (Hou et al., 2020a; Yoon et al., 2019). In joint-learning scenarios, there are further requests to connect metric spaces of joint learned tasks and jointly optimize these metric spaces.

In response to the above requests, we argue that the distribution of prototypes of dialogue language understanding should fit these intuitions: (1) different intent prototypes should be far away and the same as slot prototypes (*Intra-Contrastive*); (2) the slot prototypes should close to the related intent prototypes and should be far away from the unrelated intent prototypes (*Inter-Contrastive*).[2] To achieve these, we introduce a **Margined Contrastive Loss** to force the model to learn the separation and alignment of intent and slot prototypes.

Firstly, to encourage separation of prototypes from the same task, we regularize the learning of intent and slot prototypes with *Intra-Contrastive* loss $\mathcal{L}_{\mathrm{Intra}} = \frac{1}{2}(\mathcal{L}_{\mathrm{Intra-intent}} + \mathcal{L}_{\mathrm{Intra-slot}})$, where both the $\mathcal{L}_{\mathrm{Intra-intent}}$ and $\mathcal{L}_{\mathrm{Intra-slot}}$ are calculated as:

$$\mathcal{L}_{\mathrm{Intra}} = \frac{1}{N^2}\sum_i\sum_j \max(0, m - \|C_i - C_j\|)^2,$$

where m is the margin value and N is the number of prototypes. The margin m is important since it can protect metric space from excessive dispersion.

Next, we learn the alignment (separation) between intent prototypes and slot prototypes with *Inter-Contrastive* loss $\mathcal{L}_{\mathrm{Inter}}$:

$$\mathcal{L}^{\mathcal{R}}_i = \frac{1}{2|\mathcal{R}_i|}\sum_{j\in\mathcal{R}_i}(\|C_{\mathrm{intent}_i} - C_{\mathrm{slot}_j}\|^2),$$
$$\mathcal{L}^{\mathcal{U}}_i = \frac{1}{2|\mathcal{U}_i|}\sum_{k\in\mathcal{U}_i}\max(0, m - \|C_{\mathrm{intent}_i} - C_{\mathrm{slot}_k}\|)^2,$$
$$\mathcal{L}_{\mathrm{Inter}} = \sum_i^{N_I}(\mathcal{L}^{\mathrm{R}}_i + \mathcal{L}^{\mathrm{U}}_i),$$

---

[1] We adopt additive attention because we find it outperforms common product-based attention in our setting. This is mainly due to that additive attention interferes less with product-based similarity calculations.

[2] A slot is related to an intent means that they used to co-occur in the same semantic frame.

where $\mathcal{R}_i$ is the set of slots related to the ith intent and $\mathcal{U}_i$ is the set of slots that are not related to the ith intent. N_I is the number of intents. Here, we simply obtain the relatedness with the co-occurrence matrix M^{S} in Section 3.2.

Finally, the Margin Contrastive Loss is calculated as:

$$\mathcal{L}_{\text{Contrastive}} = \mathcal{L}_{\text{Inter}} + \mathcal{L}_{\text{Intra}}$$

3.4 Learning Objective

In dialogue language understanding task, we joint learn the intent detection task and slot filling by optimizing both losses at the same time. Specifically, we use CrossEntropy (CE) to calculate the loss for intent detection and slot filling. Combining with the loss of Contrastive Alignment Learning, we train the entire model with the following objective function:

$$\mathcal{L}_{all} = \text{CE}_{\text{intent}} + \text{CE}_{\text{slot}} + \mathcal{L}_{\text{Contrastive}}$$

4 Experiments

We evaluate our method on the dialogue language understanding task of 1-shot/5-shot setting, which transfers knowledge from source domains (training) to an unseen target domain (testing) containing only 1-shot/5-shot support set.

4.1 Settings

Dataset We conduct experiments on two public datasets: Snips (Coucke et al., 2018) and FewJoint (Hou et al., 2020c). Snips is a widely-used dataset for dialogue language understanding, containing seven single-intent domains together with 53 slots. The other dataset FewJoint is joint dialogue language understanding used in the few-shot learning contest of SMP2020-ECDT Task-1.[3] It contains 59 multi-intent domains, 143 different intents, and 205 different slots.

In the few-shot learning setting, we train models on several source domains and test them on unseen target few-shot domains. For Snips, we follow Krone et al. (2020a) and combine single-intent domain into multi-intent domain to achieve the classification of intents. After that, we split the Snips dataset into 3 parts: the training domain with 3 intents, the developing domain with 2 intents and the testing domain with 2 intents. FewJoint is already a few-shot learning benchmark. Therefore, we follow the original data split and there are 45 domains for training, 5 domains for developing and 9 domains for testing.

Few-shot Dataset Construction To simulate the few-shot learning situation, we follow previous few-shot learning works (Vinyals et al., 2016; Krone et al., 2020a; Finn et al., 2017) and construct the dataset into a few-shot episode style, where the model is trained and evaluated with a series of few-shot episodes. Each episode contains a support set and query set. However, different from the single-task problem, joint-learning examples are associated with multiple labels. Therefore, we cannot guarantee that each label appears K times while sampling examples for the K-shot support set. To remedy this, we build support sets with the Mini-Including Algorithm (Hou et al., 2020a), which is intended for such situations. It constructs support set generally following two criteria: (1) All labels appear at least K times in support set. (2) At least one label will appear less than K times in the support set if any support example is removed from the support set. For Snips, we construct 200 few-shot episodes for training, 50 for developing, and 50 for testing. We set the query set size as 16 for training and developing, 100 for testing. For FewJoint, we use the few-shot episodes provided by the original dataset.

Evaluation We adopt three metrics for evaluation: Intent Accuracy, Slot F1-score, Joint Accuracy.[4] For joint dialogue language understanding, Joint Accuracy is the most important metric among all three metrics (Hou et al., 2020c). It evaluates the sentence level accuracy, which considers one sentence is correct only when all its slots and intents are correct.

To conduct a robust evaluation under few-shot setting, we validate the models on multiple few-shot episodes (i.e., support-query set pairs) from different domains and take the average score as final results. To control the non-deterministic neural network training (Reimers and Gurevych, 2017), we report the average score of 5 random seeds for all results.

4.2 Baselines

We compare our model with two kinds of strong baseline: fine-tune based transfer learning methods

Table 2: Scores on 5-shot dialogue language understanding task on Snips dataset and FewJoint dataset.

(JointTransfer, Meta-JOSFIN) and similarity-based FSL methods (SepProto, JointProto, LD-Proto).

JointTransfer is a domain transfer model based on the JointBERT (Chen et al., 2019). It consists of a shared BERT embedder with intent detection and slot filling layers on the top. We pretrain it on source domains and finetune it on target domain support sets.

Meta-JOSFIN (Bhathiya and Thayasivam, 2020) is a meta-learning model based on the MAML (Finn et al., 2017). The meta-learner model here is a BERT-based joint dialogue language understanding model similar to **JointTransfer**. It learns initial parameters that can fast adapt to the target domain after only a few updates.

SepProto is a prototypical-based dialogue language understanding model with BERT embedding, that learns intent detection and slot filling separately. During the experiment, it is pre-trained on source domains and then directly applies to target domains without fine-tuning.

JointProto (Krone et al., 2020a) is all the same as SepProto except that it jointly learns the intent and slot tasks by sharing the BERT encoder.

LD-Proto is also a prototypical model similar to **JointProto**. The only difference is that it is enhanced by the logits-dependency tricks (Goo et al., 2018), where joint learning is achieved by depending on the intent and slot prediction on the logits of the accompanying task.

Implements For both ours and baseline models, we determine the hyperparameters on the development set. We use ADAM (Kingma and Ba, 2015) for training and set batch size as 4 and learning rate as 10^{-5}. We adopt embedding tricks of Pairs-Wise Embedding (Gao et al., 2019; Hou et al., 2020a) and Gradual Unfreezing (Howard and Ruder, 2018). The λ and α in Section 3.2 are both set as 0.5. We implement both our and baseline models with the few-shot platform MetaDialog.[5] Besides, to use the information in target domains and make a fair comparison with fine-tuning baselines, we explore the performance of the similarity-based model under fine-tuning setting (+FT) and enhance the model with a fine-tune process similar to Meta-JOSFIN. In addition, following the suggestions of Hou et al. (2020a), we investigate adding Transition Rules (+TR) between slot tags, which bans illegal slot prediction, such as "I" tag after "O" tag.

4.3 Main Results

In this section, we present the evaluation of the proposed method on both 1-shot and 5-shot dialogue understanding setting.

Result of 1-shot setting As shown in Table 1, our method (ConProm) achieves the best performance on Joint Accuracy, which is the most important metric. Among all metrics, ConProm only lags a bit than LD-Proto on intent accuracy. We address this to the fact that there are many slots shared by different intent, and representing an intent with slots may unavoidably introduce noise from other intents. Considering the huge improvements on Slot and Joint performance over LD-Proto, we argue that the limited loss is a worthy compromise here. Since similarity-based models predict slot tags independently for each token, they tend to predict illegal tags. We employ a simple transition rule (+TR) to remedy such defects and further improves the performance. For fairness, we also enhance LD-Proto with TR trick and our model still outperforms the enhanced baseline.

For those non-finetuned methods, ConProm outperforms LD-Proto by Joint Accuracy scores of 11.05 on Snips and 2.62 on FewJoint, which show that our model can better capture the relation between intent and slot. Our improvements on Snips are higher than those on FewJoint, which is mainly because that there is clearer intent-slot dependency in Snips. The performance of JointProto is even lower than SepProto, which demonstrates that few-shot joint learning is not a trivial issue as simply sharing the embeddings

Setting	Snips		FewJoint	
	1-shot	5-shot	1-shot	5-shot
Ours	21.72	32.20	16.32	24.18
- PM	-1.90	-2.63	-4.90	-8.39
- CAL	-5.19	-12.73	-1.78	-3.78

Table 3: Ablation study over two main components of proposed framework: Prototype Merge (PM) and Contrastive Alignment Learning (CAL). The score is Joint Accuracy.

When finetuning brings significant improvements for all methods, our model (ConProm+FT) still achieves the best performance. Interestingly, we observe that finetuning often hurts the intent prediction. This shows that finetuning brings limited gains on sentence-level domain knowledge but leads to overfitting.

Result of 5-shot setting Table 2 shows the 5-shot results. The results are consistent with 1-shot setting in general trending and our methods achieve the best performance. While more learning shots improve the performance for all methods, the superiority of our best performed baseline is further strengthened. This shows that the model can better exploit the richer intent-slot relations hidden in 5-shot support sets.

4.4 Analysis

Ablation Test To inspect how each component of the proposed model contributes to the final performance, we conduct ablation analysis. As shown in Table 3, we independently removing two main components: Prototype Merge (PM) and Contrastive Alignment Learning (CAL).

When PM is removed, the intent and slot prototypes are represented only with corresponding support examples, and Joint Accuracy drops are witnessed. There is more loss on FewJoint. Because there are much more slots shared by different intents in FewJoint, and the attention mechanism of PM is important for identifying relatedness between intents and slots.

For our model without CAL, we train the model with only cross entropy loss and get lower scores on all settings. There are more performance drops on Snips. This is mainly because that there much clearer intent-slot relation in Snips, which can be easily handled by CAL.

In terms of contribution, there are opposite performance for CAL and PM on two dataset, which shows that PM and CAL complement each other and reach a balance for various situations.

Table 4: Analysis for sentence level slot accuracy.

Visual Analysis of Prototype Distribution To get further an understanding of the model effects on bridging the metric spaces of intent and slot, we visualize the prototype distributions in the metric space. As shown in Figure 4, it is exciting to see that our model successfully refine the prototype distribution by aligning the slots to related intent and making prototypes properly well-separated.

Sentence level slot accuracy analysis There is some confusion in Table 1 and Table 2 that there are huge performance differences of Joint Accuracy score when Intent Accuracy scores and Slot F1 scores are similar. We inspect this issue by evaluating the Sentence Level Slot Accuracy, which considers a sentence to be correct when all slots are correct. As shown in Table 4, there is a huge gap in the slot accuracy score between LD-Proto and ConProm, which explains the gap in Joint score.

5 Related Work

Few-shot learning is one of the most important direction for machine learning area (Fei-Fei, 2006; Fink, 2004) and often achieved by similarity-based method (Vinyals et al., 2016) and fine-tuning based method (Finn et al., 2017). FSL in natural language processing has been explored for various tasks, including text classification (Sun et al., 2019; Geng et al., 2019; Yan et al., 2018; Yu et al., 2018), entity relation classification (Lv et al., 2019; Gao et al., 2020; Ye and Ling, 2019), sequence labeling (Luo et al., 2018; Hou et al., 2018; Shah et al., 2019; Hou et al., 2020a; Liu et al., 2020).

As the important part of a dialog system, dialogue language understanding attract a lot of attention in few-shot scenario. Dopierre et al. (2020); Vlasov et al. (2018); Xia et al. (2018) explored few-shot intent detection technique. Luo et al. (2018) and Hou et al. (2020a) investigated few-shot slot tagging by using prototypical network. Hou et al. (2020b) explored few-shot multi-label intent detection with an adaptive logit adapting threshold. But all of these works focus on a single task.

Despite a lot of works on joint dialogue understanding (Goo et al., 2018; Li et al., 2018; Zhang et al., 2019; Qin et al., 2019; Wang et al., 2018; E et al., 2019; Wu et al., 2020; Gangadharaiah and Narayanaswamy, 2019; Liu et al., 2019; Qin et al., 2020), few-shot joint dialogue understanding is less investigated. Krone et al. (2020b) and Bhathiya and Thayasivam (2020) make the earliest attempts by directly adopt general and classic few-shot learning methods such as MAML and prototypical network. These methods achieve joint learning by sharing the embedding between intent detection and slot filling task, which model the relation between intent and slot task implicitly. By contrast, we explicitly model the interaction between intent and slot with attentive information fusion and constrastive loss. Experiment results also demonstrate the superiority of our method on this task.

6 Conclusion

In this paper, we propose a similarity-based few-shot joint learning framework, ConProm, for dialogue understanding. To adaptively model the interaction between intents and slots, we propose the Prototype Merging that bridges the intent metric and slot metric spaces with cross-attention between intent and slot. To learn better bridged metric space for intent and slot, we propose the Contrastive Alignment Learning to align related cross-task labels in metric space and force unrelated labels properly separated. Experiment results validate that both Prototype Merging and Contrastive Alignment Learning can improve performance.

Abstract

Sequences are typically decoded in a left-to-right fashion, requiring as many decoding steps as there are tokens in the sequence. Recently, several works have proposed non-autoregressive decoders that are sub-linear, allowing to decode a sequence using fewer decoding steps than the length of the sequence, and thus substantially speed up inference. In contrast, non-autoregressive decoding of trees is less well-analysed, even though trees are used in important applications like semantic parsing and code generation. In this work, we present a novel general-purpose partially autoregressive tree decoder that uses tree-based insertion operations to generate trees in sub-linear time. We evaluate our approach on semantic parsing and compare it against strong baselines, including an insertion-based sequence decoder. The results demonstrate that the partially autoregressive tree decoder reaches competitive accuracies while clearly reducing the number of decoding steps.

1 Introduction

Sequence generation is usually based on a left-to-right autoregressive decoder that decomposes the probability of the entire sequence y conditioned on x (x can be empty) as the product $p(y|x) = \prod_{i=0}^{N} p(y_i|y_{<i}, x)$. At each decoding step, the decoder model predicts the next token y_i based on the previously generated outputs $y_{<i}$ and the input x. This approach to decoding sequences is linear in sequence length: the number of decoding steps necessary to produce the sequence is equal to the length of the sequence. However, recently, several works have proposed non-autoregressive decoders that are sub-linear. This allows to decode a sequence using fewer decoding steps than the length of the sequence and can thus greatly speed up inference, especially for longer sequences (Stern et al., 2019; Ma et al., 2019; Ghazvininejad et al., 2019; Gu et al., 2017; Kasai et al., 2020). In particular, the Insertion Transformer of Stern et al. (2019) uses insertion operations to iteratively expand the sequence, achieving a best-case number of $\mathcal{O}(\log_2 N)$ decoding steps.

In this work, we extend insertion-based decoding of sequences to insertion-based decoding of trees. Insertion-based sequence decoder can also be applied to decoding trees (Zhu et al., 2020). However, this requires linearizing trees into sequences, and requires the explicit decoding of subtree termination tokens (e.g. closing parentheses ")"). This results in larger structures, which for the Insertion Transformer increases the minimum necessary number of decoding steps and increases the computational requirements per step. In contrast, the insertion-based tree decoder that we propose here does not need to explicitly decode structure tokens. Moreover, it can achieve a best-case complexity *below* $\mathcal{O}(\log_2 N)$[1] in terms of the number of decoding steps and guarantees that all intermediate outputs are valid trees. To the best of our knowledge, no existing research focuses on insertion-based non-autoregressive decoding of trees so far.

We evaluate the proposed decoder for semantic parsing on the OVERNIGHT (Wang et al., 2015) dataset. Semantic parsing is the task of converting natural language expressions into a formal representation of its meaning. An important application of semantic parsing is question answering from structured data sources. In such use cases, the input to the semantic parser is a natural language question and the expected output is a query, which can be written in a query language (e.g. SQL or SPARQL). Since these queries can often be represented as trees (e.g. abstract syntax tree), semantic parsing is a particularly interesting task for the evaluation of the presented decoding approach.

---

[1] The exact best possible speed-up heavily depends on the data.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3201–3213
August 1–6, 2021.

To summarize, the contributions of this work are:

- a transformer-based decoding algorithm that uses insertion operations specifically tailored for decoding trees,
- a novel transformer architecture that uses novel tree-based relative positions,
- and an evaluation of the proposed algorithm and model on the well-known OVERNIGHT dataset, and a comparison against a strong non-autoregressive baseline.

2 Insertion Transformer

Below, we give a very brief overview of the Insertion Transformer, which we use here as a baseline. Due to space constraints, we refer interested readers to the work of Stern et al. (2019) for a more elaborate description of their model and training procedure.

Decoding approach. Rather than decoding autoregressively left-to-right (LTR), the insertion transformer decodes sequences by using insertion operations. For example, consider the sequence "*A B C D E F G*". LTR decoding would require at least seven decoding steps, producing some left-aligned subsequence at every step (e.g. "A B C D" at the fourth step). In contrast, decoding using insertions allows to decode the same sequence using just three steps. Starting from the initial empty state " ", we first decode (1) "***D***", then (2) "***B D F***" and finally (3) "***A B C D E F G***", where the bold faced tokens are the ones inserted in each step, respectively.

Model. The model we use in our experiments uses BERT (Devlin et al., 2019) as the encoder and a standard transformer (Vaswani et al., 2017) with learned absolute position vectors as the decoder. In contrast to the vanilla transformer decoder however, the causal attention mask is not used. After encoding a subsequence using the transformer, the output layer concatenates the representations of two neighbouring tokens to build a representation for the insertion slot between the tokens. We normalize the probabilities per slot.

Training. Given training data consisting of pairs of input and output sequences (x, y), at every epoch, the training algorithm samples a subsequence $\hat{y}$ for every output sequence y. First, a length for the subsequence is drawn from a uniform distribution on $[0, |y|]$. Then, a subsequence $\hat{y}$ of the given length is randomly drawn from y. For example, for the sequence "A B C D E F G" and a randomly drawn length of 3, a sampled subsequence of length 3 could be "B D E".

The Insertion Transformer is then trained by optimizing a loss of the following form:

$$-\sum_{l}\sum_{i=i_l}^{j_l} w_{i,l} \log p(y_i, l|x, \hat{y}) \ , \qquad (1)$$

where i_l and j_l are the beginning and end positions of the subsequence to be decoded in slot l. Two variants of this loss function are proposed that differ in the strategy of assigning the weights $w_{i,l}$ to the different tokens and which are referred to as *uniform* and *binary*, respectively. In the uniform case, for a given l the weights $w_{i,l}$, $i = i_l, \ldots, j_l$ are equal and sum up to one. In the binary case, a larger weight is assigned to tokens closer to the center of slot l:

$$w_{i,l} = \frac{e^{-d_l(i)/\tau}}{\sum_{i'=i_l}^{j_l} e^{-d_l(i')/\tau}} \ , \qquad (2)$$

where $d_l(i)$ is the distance between token i and the center of the span to be decoded in slot l, and τ is the *temperature*.

3 Tree-based Insertion Transformer

In this section, we propose a novel transformer-based method for non-autoregressive decoding of trees. The proposed method consists of (1) a novel transformer architecture, and (2) a novel insertion-based decoding procedure.

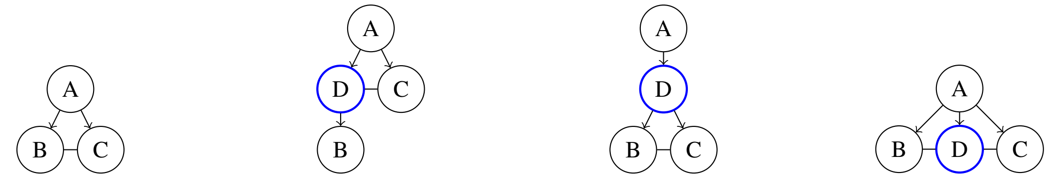
3.1 Decoding

The proposed decoding algorithm is similar to the one proposed by Stern et al. (2019) in that it uses insertion operations to expand the decoded structure. However, instead of using the implicitly defined insertion slots between two neighbouring tokens in a sequence, here, insertion slots are used that are placed between neighbouring nodes in the graph representing the tree.

As an example, consider the tree *(A B C)*[2], shown in Fig. 1a. For sequence-based insertion decoding, we would take the linearization *(· A · B · C ·)*, where four insertion slots are explicitly denoted by "·". The linearized representation clearly has some disadvantages. For example, performing some insertions at some slots can destroy the tree structure,

---

[2] Trees are given in a Lisp-like notation in this work.



(a) Simple tree

(b) Inserting D at the ancestral slot of B.

(c) Inserting D at the descendant slot of A.

(d) Inserting D at sibling slot between B and C.

Figure 1: Examples of insertions at different insertion slots.

e.g. inserting ")" between B and C yields *(A B) C)*, which is not a valid tree. Also, as mentioned before,

In this work, we propose a tree-based insertion decoding algorithm that defines insertion slots on edges between siblings, as well as on edges between parents and children. Following this approach, the example tree can be described by the following linearization with explicit insertion slots:

$$(\wedge A \vee \mid - \wedge B \vee - \wedge C \vee -) \quad ,$$

where we use three types of insertion slots: (1) ancestor insertion slots denoted by $\wedge$, (2) descendant insertion slots denoted by $\vee$, and (3) sibling insertion slots denoted by –, as described in more detail in the following. Note that the parentheses and the pipe symbol "|" are ignored by the model (when relative positioning is used) and is used mostly for notational and programming convenience. The pipe symbol separates the root portion of the "slotted" subtree string.

Ancestor insertion: If node D is used for the ancestor insertion slot $\wedge$ of B, which corresponds to the red slot in

$$(\wedge A \vee \mid - \wedge B \vee - \wedge C \vee -) \quad ,$$

we obtain the tree *(A (D B) C)* (see Fig. 1b). In other words, D replaces B and the entire subtree B is attached as a child of D.

Descendant insertion: If node D is used with a descendant insertion slot $\vee$ of A, which corresponds to the red slot in

$$(\wedge A \vee \mid - \wedge B \vee - \wedge C \vee -) \quad ,$$

then the child subtrees of A are moved to node D and the entire subtree D (that now contains the children of A) is attached to A to yield the tree *(A (D B C))*, which is depicted in Fig. 1c.

Sibling insertion: If node D is used with a sibling insertion slot "–" between B and C, which corresponds to the red slot in

$$(\wedge A \vee \mid - \wedge B \vee - \wedge C \vee -) \quad ,$$

then D is inserted as a child of A between B and C to yield the tree *(A B D C)* (see Fig. 1d).

These insertion actions can be used to decode any tree starting from a tree containing only a root node *(ROOT)*. Note that every decoding step is guaranteed to yield a valid tree, unlike in the sequence-based insertion decoder.

3.1.1 Decoder operation

In every step, the decoder takes the previous intermediate tree y_{t-1} (where y_0 = *(ROOT)*) and applies one or more insertion operations to expand the tree to the next intermediate tree y_t. To predict which insertion operations to execute at every available slot, the model described in the following sections encodes the *entire* input tree y_{t-1}. The prediction is then based on this encoding. This procedure is similar to the approach used by Stern et al. (2019). While more efficient methods that re-use computations are possible, we leave an investigation of those for future work. The decoding process is terminated when all slots predict a slot closing actions indicating that no more nodes should be inserted, and thus $y_t = y_{t-1}$.

3.2 Model

We propose a novel architecture that takes advantage of the fact that the intermediate structures generated in all steps of the decoding algorithm are trees. While the encoder stays the same (i.e. BERT), the decoder of our model relies on a transformer-based tagger with tree-based relative positions and a special attention mask. The tree-based relative positions allow us to ignore structure tokens.

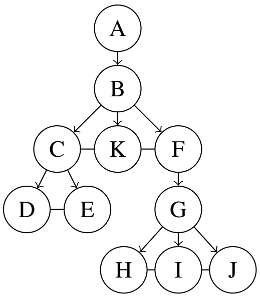


Figure 2: An example of a tree.

3.2.1 Computing Relative Positions in Trees

The proposed architecture uses **tree-based relative positioning** instead of absolute positional embeddings. The relative position is described by the **movements in the tree** that the path from node u to node v defines. For example, in the tree *(A (B (C D E) K (F (G H I J))))* depicted in Fig. 2, the relative position of node D to node I is given by "1↑ 2→ 2↓". This describes the following movement in the tree: starting in D go up one hop to reach parent C (1↑), then move right among the siblings two hops to reach F (2→), and finally move down two hops to reach I (2↓). The scheme is *insensitive to the order of children*, e.g., the relative position from B to K is "1↓", the same as for (B, C) and (B, F). To distinguish these cases, we propose to instead use **special relative position relations** "child_X" and "child_X_of" between parent and child nodes (where X denotes the position of the child among all children of its parent, e.g., X is 1 for node K). While this should improve local modeling of parent-child relations, it still does not add sufficient information to other paths, e.g., the relative positions for (D, H) and (D, J) are identical to that for (D, I)[3].

3.2.2 Using Relative Positions in the Model

With e_{ij} denoting the unnormalized attention scores, x_i the vector corresponding to element i in the input sequence and a^K_{ij} and a^V_{ij} the key (K) and value (V) vector representations of the relative position between the input elements at position i and position j, the following equations describe how the relative position vectors are used in the attention mechanism:

$$e_{ij} = \left(x_i W^Q (x_j W^K)^T + x_i W^Q (a^K_{ij})^T\right) / \sqrt{d_z}$$
$$z_i = \textstyle\sum_{j=1}^{n} \alpha_{ij} (x_j W^V) + \alpha_{ij} a^V_{ij} \ .$$

This approach to incorporate relative positions is similar to that of Shaw et al. (2018) but differs in the computation of a^K_{ij}'s and a^V_{ij}'s. A naive implementation would create an independent position embedding for every possible combination of the elements of a movement pattern. For an efficient implementation that is both faster and has fewer parameters, we separately consider the three parts of a movement pattern, embed them separately and add their embeddings:

$$a^K_{ij} = a^{K,\uparrow}_{ij} E^{K,\uparrow} + a^{K,\leftrightarrow}_{ij} E^{K,\leftrightarrow} + a^{K,\downarrow}_{ij} E^{K,\downarrow} \ , \quad (3)$$

where $a^{K,\downarrow}_{ij}$, $a^{K,\uparrow}_{ij}$, and $a^{K,\leftrightarrow}_{ij}$ are one-hot vectors representing the components of the movement pattern, and $E^{K,\downarrow}$, $E^{K,\uparrow}$, and $E^{K,\leftrightarrow}$ are their corresponding embedding lookup matrices.

In case the relative position is not a movement pattern, as is the case for parent-child relations, we simply look up a single embedding vector. We also use relative positions *from* insertion slot positions to some of the node positions: (1) ancestor (∧) and descendant (∨) slots use the "ancestors" and "descendant" relations, respectively, and (2) the sibling slots (–) use the "left_sibling" and "right_sibling" as well as a "parent" relation. Since insertion slot positions are not attended *to* (they are not used as keys in attention), we do not need relative positions *to* slot positions.

3.2.3 Attention Mask

We use a custom attention mask pattern that prevents real query tokens from attending to structural tokens and insertion slots. Since we do insertion-based decoding, we don't use a causal attention mask. However, since structural information is already described by the relative positions (see above), we do not need to process the structure-describing tokens, such as parentheses. Thus, these tokens are masked both as keys and as queries and do not participate in the decoding process at all. Additionally, we use a special mask for the insertion slots (defined above) such that (1) other tokens can not attend *to* the slot tokens and (2) the slot tokens can *only* attend to their immediate neighbours.

3.3 Decoder Training

The decoder learns to imitate optimal trajectories (Section 3.3.1). Let a tree y be the target output

---

[3] We leave the investigation of better relative position encoding for trees for future work since it is non-trivial to retain constant time complexity of the transformer and have a fully expressive position encoding.

for the current input x. For training the decoder, a **sampling function** (described in Section 3.3.2) is applied to select a partial tree[4] y' from y. A **supervision function** (see Section 3.3.3) is then used that determines the output distribution for every slot, which serves as target in the training of the insertion model. This procedure is detailed in the following.

3.3.1 Optimal Trajectories

The insertion operations described earlier in Section 3.1 can be used to describe a set of actions that transform one partial tree into another. Given an output tree y and the initial tree y_0 that contains a single root node, i.e., y_0 = *(ROOT)*, a *trajectory* from y_0 to y can be defined as a sequence of in total T partial trees (states) $y_0, \dots, y_T$ and corresponding actions $a_0, \dots a_T$, such that, when the actions are applied in succession on y_0, they produce $y = y_T$. Each step thus corresponds to the application of an action a_t to the current partial tree y_t resulting in a new partial tree y_{t+1}, i.e. $y_{t+1} = \mathrm{step}(a_t, y_t)$. Each action a_t is a set of atomic actions that insert a node at one of the insertion slots, which can be either ancestor, descendant, or sibling insertion slots. The atomic actions are described as tuples (k, w), where k is the slot in y_t where a node with label w will be inserted when the action is executed. Note that the type of insertion is characterized by the type of insertion slot.

While many trajectories exists that successfully reach y from y_0, we are interested in *optimal trajectories*, which are trajectories that minimize the number of decoding steps T that need to be performed.

Computing Optimal Trajectories: To practically compute trajectories where we try to minimize the number of steps taken, we rely on the fact that first decoding the most central nodes of a slot's subgraphs enables greater parallelization. For a given tree y_t at decoding step t that is a partial tree of the original tree y, we (1) align y_t and y and determine which nodes are allowed to be inserted in every slot in y_t and (2) compute which of these nodes is the best in order to minimize the number of decoding steps.

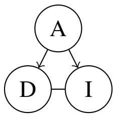

Figure 3: A partial tree of the tree in Fig. 2.

Computing allowed insertions: Given a partial tree y_t (e.g. Fig. 3) aligned with the original tree y (e.g. Fig. 2), we first compute the set of allowed insertions C_k for every slot k.

For an **ancestor insertion slot** ($\wedge$) in y_t associated with some node n, C_k corresponds to the nodes from y on the path from n up to the *lowest used ancestor* of n. The lowest used ancestor $\mathrm{lua}(n)$ of a node n from the partial tree y_t is the lowest[5] node in the original tree y that is an ancestor of n as well as *any* other node from y_t. That is, for node I in the example tree in Fig. 2, the lowest used ancestor of node I is the node B: $\mathrm{lua}(I) = B$ and the set of allowed nodes for I's ancestor slot is $\{F, G\}$.

For a **descendant insertion slot** ($\vee$), the set of allowed nodes C_k is the set of all descendants of n in y , if n doesn't have children in the partial tree y_t. Otherwise, it's the set of all of its children in y_t that are also an ancestor for *all* the children of n in the partial tree y_t.

Finally, for a **sibling insertion slot** (–), to find the set of allowed nodes, we first find the lowest common ancestor in the original tree y of the slot's left node l and right node r. The lowest common ancestor $\mathrm{lca}(n, n')$ of two nodes n and n' in a tree is the lowest node that is an ancestor of both n and n'. We first determine the set C of children of $\mathrm{lca}(l, r)$ that are between the children of $\mathrm{lca}(l, r)$ and that are also the ancestors of nodes l or r. The set of allowed nodes C_k for this slot is then the set C as well as all their descendants in y. In the example, the sibling insertion slot between D and I should accept only the node K since $\mathrm{lca}(D, I)$ is B and K is the only node between C and F, which are the ancestors of D and I, respectively, that are also children of $\mathrm{lca}(D, I)$. [6]

Computing best insertions: Now, for each insertion slot k in y_t, we are given the set C_k of nodes allowed to be inserted. The node $n \in C_k$

---

[4] Note that what we refer to as a partial tree is not the same as a subtree. A subtree retains all the descendants starting from a certain parent node. In contrast, we refer with partial tree to any tree consisting of nodes that can also be found in the original tree, and which can be extended to the full tree y by means of the defined insertion operations.

[5] Lowest and highest refer to tree depth, i.e., the root node is the highest node in the tree.

[6] Note that inserting E between D and I will lead to a tree from which we can't recover the original tree since D, E and I now assume the same parent and there is no action defined to separate them under different parents.

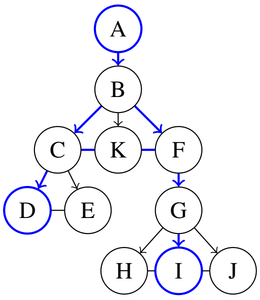

Figure 4: The tree from Fig. 2 and the nodes and edges covered by the partial tree from Fig. 3. Nodes with the same labels in Figures 2 and 3 are aligned.

to be inserted in slot k in order to minimize the number of decoding steps is the most central node in C_k.

The centrality of a node is computed over the subgraph G_k of the original tree y that contains the nodes in C_k, as well as their descendants that are not separated by the partial tree. The *closeness centrality* is used:

$$H_{G_k}(n) = \frac{1}{\sum_{n' \in G_k} d(n, n')} \quad , \tag{4}$$

where $d(n, n')$ is the distance between nodes n and n' in the original tree, which is the minimum number of steps necessary to reach n from n'.

The node picked to be inserted into some slot k is then the one with highest centrality for the slot.

Computing best actions: The best action for a certain partial tree y_t of y then consists of the insertions that are the best for every of its insertion slots. If C_k is empty for some insertion slot, a dummy insertion operation is used that does not insert anything.

3.3.2 Partial Tree Sampling

Rather than sampling all possible partial trees, which would be equivalent to the method described by Stern et al. (2019), we use a different method that samples only from the most optimal trajectory. The partial trees that are used for training are only those that occur on one of the optimal trajectories. For efficiency reasons, we precompute a certain number (5 in our experiments) of trajectories, where we randomly sample when ties occur in the centrality measure, and reuse these trajectories throughout training.[7] Sampling more than one trajectory could reduce the exposure bias.

3.3.3 Supervising Partial Trees

To produce the target distribution for a slot k, we take the nodes $n \in C_k$ computed as valid insertions, as well as their centralities. Then, we rank the nodes in C_k by centrality scores, where the most central node is the highest-ranked one, receiving rank value 0. Ties in centrality are broken by favouring nodes that are lower in the tree y and further ties are broken alphabetically (based on node label). The target distribution for a slot k is then computed using a softmax:

$$p_k(n) = \frac{e^{-\mathrm{rank}_k(n)/\tau}}{\sum_{n' \in C_k} e^{-\mathrm{rank}_k(n')/\tau}} \quad , \tag{5}$$

where τ is a temperature hyperparameter. $p_k(n)$ is zero if n is not in C_k and $\mathrm{rank}_k(n)$ is rank value given to node n.

For each slot k the model outputs a predictive distribution $\pi_k(n)$. Given the target distributions for all slots the training loss is the sum of the Kullback-Leibler (KL) divergences between the target and predictive distributions for all slots:

$$-\sum_k \sum_{n \in \mathcal{G}} p_k(n) \log \frac{\pi_k(n)}{p_k(n)} \quad , \tag{6}$$

where $\mathcal{G}$ denotes the set of all possible node labels.

4 Experiments[8]

We run experiments on the OVERNIGHT (Wang et al., 2015) dataset and report the results in Tables 1 and 2. A description of the dataset and its statistics are provided in Appendix A.

Evaluation: The metric reported is logical form accuracy, which we compute by (1) taking the predictions of the models, (2) balancing parentheses on the left and on the right and (3) computing whether the trees are the same.[9]

Data preprocessing: We notice that many examples in the Overnight dataset contain nested filters. This fact was ignored during training and evaluation of some models in previous work (Damonte

---

[7] Note that only one of the partial trees y_t of some example is used in a single epoch.

[8] The code is provided at `https://github.com/lukovnikov/parseq/tree/crforen/parseq/scripts_insert`

[9] The trees are considered the same if every node's children occur in both trees in the same order, if the node's children should be ordered (for example argmax expressions) and if every node's children occur in both trees in *any* order for nodes of which the children should not be ordered (for example SW:concat and a collection of filter conditions).

et al., 2019; Xu et al., 2020). During evaluation, an example was considered wrong if the filters were decoded in a different nesting order. For this reason, we use slightly simplified logical forms for the Overnight dataset that remove nesting between filters (see also Appendix B). Evaluation with these logical forms better reflects the true meaning of the queries. See Appendix C for an example.

For the sequence-based decoder, we found that it is necessary to use **numbered tokens** to to successfully train the model. We simply replace every token "X" by a token "X_d", where d specifies how many tokens "X" have been observed before and including the current token "X". For example, this would transform "(A (B C) (B D))" into "$(_1$ A_1 $(_2$ B_1 C_1 $)_1$ $(_3$ B_2 D_1 $)_2$ $)_3$". This ensures that every token in the sequence is unique. We use numbered tokens in all the experiments, both for the sequence-based as well as the tree-based decoders. We leave a deeper investigation of the effect of numbering tokens for future work.

Baselines: We considered the following models as baselines in our experiments: (1) BERT with a transformer decoder (BERT+Transformer), (2) a re-implemented insertion transformer (Seq-Insert) in both binary and uniform supervision settings (BERT is used for encoding the input), and (3) BERT with a regular tree-based decoder similar to the one proposed by Dong and Lapata (2016) (BERT+TreeGRU; see also Appendix E). Note that both (1) and (3) are essentially left-to-right decoders and can't decode in parallel. Even though they are not directly comparable, we also include the results reported by Chen et al. (2018a). Rather than decoding logical forms (i.e. Lisp-style expressions), they decode an intermediate representation called a query graph using special graph generation actions (e.g. add variable node, add edge). Moreover, the evaluation is based on execution accuracy instead of logical form accuracy (Xu et al., 2020)

Training details: We train all models using Adam (Kingma and Ba, 2014), varying the initial learning rate within $\{0.0001, 0.00005, 0.00001\}$ and experimenting with dropout rates out of $\{0.0, 0.1, 0.2, 0.4\}$. We also experimented with values from $\{1.0, 0.1\}$ for the temperature τ. The validation set for each domain was constructed by taking a random 20% subset of the training examples. This validation set was used for early stopping. We randomly searched the hyperparameter space and took the best performing parameters based on its validation performance on the *publications* domain. These hyperparameters[10] were used for training the models on the other domains. We train each model three times on every domain independently (with the same seed values shared over domains and settings) and also report the average over the domains. For all our experiments, we use a 12-layer BERT model from Huggingface (Wolf et al., 2020) as the encoder and use a transformer with 6 layers, 12 heads, and 768 dimension for the decoder.

4.1 Results

Table 1 shows the results on all domains of the Overnight dataset. Table 2 shows the results on four Overnight domains, and indicates the accuracy and speed-up measured in terms of the number of decoding steps compared to the BERT+Transformer left-to-right baseline.

Baseline equivalence: First, we establish that the results of our left-to-right baseline are on par with previous reported numbers in similar settings. This is shown in the middle part of Table 1, where our "BERT+Transformer" beats Xu et al. (2020)'s BERT+LSTM baseline by a small margin.

Sequence-based insertion baseline results: In the bottom part of Table 1, we report numbers for the slightly simplified logical forms. The performance of the parallel sequence insertion decoder with binary supervision is on par with that of our left-to-right baseline. The uniform variant performs slightly worse. Concerning the speed-up obtained, Table 2 shows that the binary supervision is (more than ×2) more effective than uniform supervision. However, even the binary supervised version lags behind the theoretically best possible speed-up ("Seq-Insert Th.B.").

Tree-based insertion results: The tree-based insertion decoding procedure described in Section 3.1 enables a decoding complexity that is lower than the theoretically best $\mathcal{O}(log_2(N))$ of the sequence-based insertion decoder. However, the theoretically best possible speed-up for tree insertion decoding heavily depends on the tree structure. We report this number ("Tree-Insert Th.B.") for the different domains in Table 2. The theoretically best possible speedup of the tree-based insertion decoder is

Table 1: Results on the test set of the different domains of the Overnight dataset. Top part: denotation accuracy. Middle part: logical form accuracy on original trees. Bottom part: logical form accuracy on simplified trees. In the last column, we report the average accuracy over the domains as well as the average (over domains) of standard deviations of accuracies for every domain over different seeds.

slightly higher than that of the sequence-based insertion decoder: an average of 0.48 decoding steps can be gained, which corresponds to a potential reduction of decoding steps of ×1.08 on average. However, one needs to investigate how close an actual tree-based insertion decoder can get to the theoretically best number in practice.

The bottom part of Table 2 reports the results for the tree-based insertion decoder. Our insertion-based tree decoder achieves **competitive accuracy** to both the left-to-right baseline as well as the sequence insertion decoder, while requiring **fewer decoding steps** than the strong sequence insertion baseline: an average of 0.7 decoding steps is gained, which corresponds to an average of a ×1.11 reduction in the number of decoding steps.

Ablation study: In Table 3, we assess the effects of some design choices and hyperparameters. Decreasing the number of trajectories used during training from 5 to 1 results in a significant decrease in accuracy. The chosen temperature τ also affects training. When τ is set to a high value, the target distribution becomes more uniform, which allows the model to use insertions that are not covered by the trained trajectories making it more likely to fail due to exposure bias, which is reflected in the poor result for $\tau = 10$. Using absolute instead of relative position information leads only to a slight decrease in accuracy. Note that using just absolute positioning requires to process the structure tokens because the structure information contained in relative positions is not being used. The child relations (§3.2.2) appear to not have any significant effect.

5 Discussion

To obtain an efficient decoder other considerations next to the number of decoding steps must be taken into account. The actual execution speed and computational load also heavily depend on (1) the size of processed data and (2) efficiency of implementation. In the proposed tree decoder, the *effective* size of model inputs is *smaller* than for the sequence insertion decoder since it does not need parentheses. Thus, when implemented efficiently, it requires less computation and less memory, which is attractive given the quadratic memory complexity of the transformer's attention.

Another point worth noting is that the best possible speed-up of the proposed insertion-based tree decoder heavily depends on the data. However, considering that the proposed model has between two and three insertion slots per token, and the sequence insertion decoder only one, our method can expand trees much faster.

A limitation of the proposed insertion-based tree decoder is that it, like the Insertion Transformer, is unable to recover from mistakes made during decoding. In contrast, the Levenshtein transformer (Gu et al., 2019b) also defines deletion operations and can thus recover from erroneous predictions. Extending the insertion-based tree decoder to also delete part of the trees is an interesting direction for future work. While we simply sample from a number of optimal trajectories, a more general decoder that allows for deletion would have to be trained using dynamic oracles (Goldberg and Nivre, 2012; Ross et al., 2011; Vlachos and Clark, 2014) or reinforcement learning. This is likely to

6 Related Work

To the best of our knowledge, to this date, only two other works have investigated non-autoregressive methods for trees and semantic parsing. The work of Rubin and Berant (2020) proposes a bottom-up tree decoder, however, their decoder is limited to being linear in depth and thus less parallelizable for deeper and narrower trees. In contrast, the Insertion Transformer can be sub-linear both in depth and breadth. Zhu et al. (2020) apply the Insertion Transformer to semantic parsing, albeit on SNIPS (Coucke et al., 2018), ATIS (Price, 1990) and TOP (Gupta et al., 2018) datasets and focuses on cross-lingual performance.

Only a few transformer architectures specialized for trees have been proposed to date. The work of Shiv and Quirk (2019) proposes a new positional encoding to improve tree representation using transformers. The work of Anonymous (2020), similarly to ours, investigates relative positioning for transformers operating on trees. Other architectures to encode trees exist as well, such as the TreeLSTM (Tai et al., 2015), however, a transformer-based model enjoys greater parallelism and direct modeling of long-range dependencies.

Several methods have recently been proposed for non-autoregressive decoding and insertion-based decoding. Stern et al. (2019), Gu et al. (2019a) and Gu et al. (2019b) experiment with insertion-based decoding where Gu et al. (2019b) also support deletion operations. Ma et al. (2019), on the other hand, develop a non-autoregressive sequence generation model using normalizing flows (Rezende and Mohamed, 2015). Some other examples of non-autoregressive decoding for NMT are (Ghazvininejad et al., 2019; Gu et al., 2017; Kasai et al., 2020).

Various works have recently explored the use of neural networks for semantic parsing. Dong and Lapata (2016) explore both sequence-based as well as tree-structured decoding. Alvarez-Melis and Jaakkola (2017) propose an improved tree decoder that uses additional classifiers to perform structure prediction rather than using structure tokens. Chen et al. (2018c) propose a binary tree generator for code translation.

7 Conclusion

In this work, we presented a novel neural network based method for non-autoregressive decoding of trees. We define insertion operations used in the step-wise decoding process that guarantee that intermediate structures are trees. This results in a reduction of the number of decoding steps and allows to exploit tree structure. Experiments on semantic parsing show competitive accuracy and a significantly decreased number of decoding steps, compared to strong autoregressive and non-autoregressive baselines.

Acknowledgments

We thank the reviewers for their helpful comments and suggestions. We also thank Prof. Dr. Jens Lehmann, Priyansh Trivedi, and Gaurav Maheshwari for their comments and help with this work.

A Dataset Description and Statistics

The OVERNIGHT dataset consists of pairs of natural language questions and corresponding formal language queries from 8 distinct domains, such as "publications" and "restaurants". The dataset was generated as follows: (1) first, a grammar was defined, which consists of a general part applicable for any domain, and a domain-specific part that specifies a *seed lexicon* mapping between predicates and NL. Then, (2) a number of examples was generated, which at this point consist of (i) a canonical utterance and (ii) a formal query. Finally, (3) the canonical utterances are paraphrased by Amazon Mechanical Turk workers to generate more natural examples. See Appendix C for an example question-query pair from the data set.

See Table 4 for dataset statistics.

Domain	#Train	#Test	Avg. tree size	Avg. tree depth	Avg. seq. length
cal.	669	168	17.5	5.7	39.1
blo.	1596	399	18.8	5.8	42.1
hou.	752	189	17.3	5.6	38.8
res.	1325	332	16.3	5.4	37.1
pub.	640	161	18.3	5.8	41.1
rec.	864	216	16.1	5.7	36.3
soc.	3535	884	25.3	8.7	57.3
bas.	1561	391	19.8	8.2	45.1

Table 4: Statistics for the OVERNIGHT dataset after simplification.

B Preprocessing

This simplified version is obtained by (1) merging the "call" node with the function of the call (e.g. replacing *(call SW:someFunction ...)* with *(call-SW:someFunction ...))* and (2) merging nested filters into a multi-conditional expression where the order of conditions doesn't matter. Note that these simplifications are easily reversible. During training, we sort the different parts of a multi-conditional filter expression alphabetically and during evaluation, we consider the different conditions as unordered and accept them in any decoded order. We use this simplified version for all further experiments.

C An example from the Overnight dataset

An actual example from the "publications" domain from the OVERNIGHT dataset is the following.

The natural language question is:

"*find an article published in 2004*".

The formal query corresponding to this question is (after preprocessing):

Listing 1: Example query

```
(call_SW_listValue
  (filter
    (call_SW_getProperty
      (call_SW_singleton
        (en.article ))
      (string
        (!type )))
    (condition
      (string
        (publication_date ))
      (string
        (= ))
      (date
        (2004 )
        (−1 )
        (−1 )))))
```

D An example of insertion-based decoding for a real example.

Consider the example in Appendix C. This example can be decoded in 5 steps using tree-based insertion actions as elaborated in the following. Note that multiple insertion action sequences would work with the same number of steps.

Listing 2: Example query

```
1.    (filter)
```

Listing 3: Example query

```
2. (call_SW_listValue
     (filter
         (string)))
```

Listing 4: Example query

```
3. (call_SW_listValue
     (filter
         (call_SW_singleton)
       (condition
         (string)
```

```
(string
  (= ))
(date))))
```

Listing 5: Example query

4.
```
(call_SW_listValue
  (filter
    (call_SW_getProperty
      (call_SW_singleton
        (en.article ))
      (string))
    (condition
      (string
        (publication_date ))
      (string
        (= ))
      (date
        (−1 )))))
```

5. Same as original tree in Appendix C.

E TreeGRU

We implement the tree-based left-to-right baseline decoder similarly to Dong and Lapata (2016). However, in our implementation, we use depth-first instead of breadth-first decoding. We achieve similar conditioning in the different decoding steps by manipulating which of the previous states are used as the previous sibling state and the parent state. If the previously decoded token was an opening parenthesis "(", then the parent state correspond to the state of the GRU after producing the opening parenthesis (this is the previous state), the previous sibling state is set equal to the parent state. Following Dong and Lapata (2016), we use the parent state explicitly as part of the GRU input in every step. When a closing parenthesis ")" is decoded, the parent of the previous parent state is used as the parent state, the state accumulated from the closed subtree is discarded, and the previous parent state becomes the previous sibling state. Thus, we make sure that similarly to Dong and Lapata (2016)'s breadth-first decoding, the different branches aren't directly conditioned on each other through decoder states.

Is the Lottery Fair? Evaluating Winning Tickets Across Demographics

Victor Petrén Bach Hansen,[1 2] **Anders Søgaard**[1]

{victor.petren,soegaard}@di.ku.dk

Abstract

Recent studies have suggested that weight pruning, e.g. using lottery ticket extraction techniques (Frankle and Carbin, 2018), comes at the risk of compromising the group fairness of machine learning models (Paganini, 2020; Hooker et al., 2020), but to the best of our knowledge, no one has empirically evaluated this hypothesis at scale in the context of natural language processing. We present experiments with two text classification datasets annotated with demographic information: the Trustpilot Corpus (sentiment) and CivilComments (toxicity). We evaluate the fairness of lottery ticket extraction through layer-wise and global weight pruning across three languages and two tasks. Our results suggest that there is a small increase in group disparity, which is most pronounced at high pruning rates and correlates with instability. The fairness of models trained with distributionally robust optimization objectives is sometimes less sensitive to pruning, but results are not consistent. The code for our experiments is available at `https://github.com/vpetren/fairness_lottery`.

1 Introduction

Heavily pruning deep neural network models is a way of reducing inference cost for resource-constrained environments, but does weight-pruning of deep neural networks increase their unfairness? Several recent papers suggest this (Paganini, 2020; Hooker et al., 2020), based on experiments from face and digit recognition, but does this also hold for natural language processing (NLP) models? Systematic biases may easily be exacerbated by pruning interventions in high-dimensional problems because of feature swamping effects (Sutton et al., 2006). Overparameterized deep neural networks generalize well, in part because they can hedge their bets and rely on multitudes of weak evidence rather than the most prominent independent variables. Sparse models do not have that luxury and are therefore more sensitive to shifts (Globerson and Roweis, 2006; Søgaard, 2013).

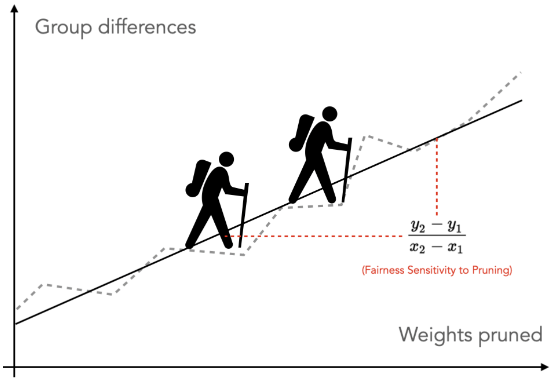

Figure 1: Fairness Sensitivity to Pruning (FSP): the gradient of the linear fit of (the logarithm of) the pruning ratio to min-max group-level disparity. We use this to quantify the sensitivity of Rawlsian min-max fairness to weight pruning across architectures, pruning strategies and datasets.

We introduce a *fairness sensitivity to pruning* metric that measures how Rawlsian min-max fairness across demographic groups changes with weight pruning. We estimate this sensitivity by taking the gradient of the linear fit of the logarithm of the pruning ratio to min-max group-level disparity. We show that across four datasets, fairness sensitivity to pruning is similar for layer-wise and global pruning strategies (Frankle and Carbin, 2018), as well as for text classifiers based on feed-forward and recurrent neural networks. Subsequently, we consider the impact of a popular robust optimization strategy designed to improve the fairness of classification models (Hashimoto et al., 2018; Sagawa et al., 2020b), on the fairness sensitivity of feed-forward networks.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3214–3224

Contributions We are, to the best of our knowledge, the first to study the impact of weight pruning on fairness in NLP at scale. We introduce a *fairness sensitivity to pruning* (FSP) metric that measures how Rawlsian min-max fairness across demographic groups decreases with weight pruning. We evaluate FSP across two architectures, two pruning strategies and two datasets, including multilingual sentiment classification and English toxicity classification. Our results suggest that pruning increases group-level performance disparities, but mostly at high pruning rates and with some variance across architectures and pruning strategies. Group-level disparities seem to be in part a result of the instability of weight pruning. We compare FSP between our baseline empirical risk models and robust models induced with Distributional Robust Optimization (DRO) (Hashimoto et al., 2018; Sagawa et al., 2020b). Our results show that weight pruning in combination with DRO can *sometimes* (8/16 cases here) be used to induce fairer, sparse classifiers, but the effect is not significant ($p \sim 0.18$) across our experiments.

2 Related Work

Pruning neural networks The literature on pruning neural networks is decades old (Mozer and Smolensky, 1989; Cun et al., 1990; Hassibi and Stork, 1993), but has recently seen a resurgence with the all-encompassing success of neural networks and the need for small and fast on-device model inference (Han et al., 2015; Sze et al., 2017; Frankle and Carbin, 2018; Frankle et al., 2019). In NLP, specifically, pruning methods have been applied to recurrent neural networks (Desai et al., 2019; Yu et al., 2020), as well as transformers (Gordon et al., 2020; Brix et al., 2020; Prasanna et al., 2020; Chen et al., 2020; Sanh et al., 2020).

Fairness in pruned models Measuring fairness in pruned models is an unexplored area. However, Paganini (2020) evaluates the fairness, i.e., the difference between the best- and worst-case groups, of lottery ticket-style weight pruning for digit recognition problems: Specifically, they retrain models for a fixed number of iterations using global unstructured pruning. In addition, they present a meta-regression study suggesting that underrepresented and more complex classes are most severely affected by pruning procedures. See Hooker et al. (2020) for related work and similar results in face recognition.[1]

Improving fairness Fairness of overparameterized models can be improved by distributionally robust optimization (DRO) (Hashimoto et al., 2018; Levy et al., 2020), or to some extent by simpler post-hoc correction methods such as classifier retraining or group-specific classification thresholds (Menon et al., 2021). DRO minimizes the worst-case expected loss over an uncertainty set of distributions. The uncertainty set represents the distributions we want our model to perform well on. In Sagawa et al. (2020a), the uncertainty set is all possible mixtures of a known set of groups, a variant referred to as Group DRO. Sagawa et al. (2020b) find that subsampling the majority groups can be a way for overparameterized models to achieve both low minority test error as well as low average test error.

3 Pruning methodology

We extract winning lottery tickets from our network according to the iterative procedure outlined in Frankle and Carbin (2018): Given a model $f(x;\theta)$ with initial network parameters θ_0 and mask m_0, for each pruning iteration i, we start by initializing a model $f(x;\theta)$ with initial parameter θ_0 and train it for N epochs, resulting in $f(x;\theta_N)$. After training, we prune a fixed fraction $p \in [0,1]$ from the remaining parameters in θ_N to obtain the mask m_i. The pruned weights are chosen using the L_1 norm, meaning the neurons with the lowest magnitude are masked out. Pruning can either be done w.r.t. individual layers or all of them combined, also referred to as *layer-wise* and *global* pruning. m_i is then carried over to the subsequent pruning iteration $i+1$ with the model $f(x, m_i \odot \theta_0)$ and retrained once again. At iteration i, the fraction of weights pruned is therefore $1-(1-p)^i$.

4 Experiments

4.1 Data

Datasets We examine fairness among heavily pruned models using two text classification datasets: i) The multilingual **Trustpilot** Corpus

---

[1] Bartoldson et al. (2020) arguably present results from object recognition that show the opposite trend: Generalization increases with (layer-wise) pruning. This seems to be a side effect of overparameterization; interestingly, we see the opposite trend for feed-forward networks and layer-wise pruning.

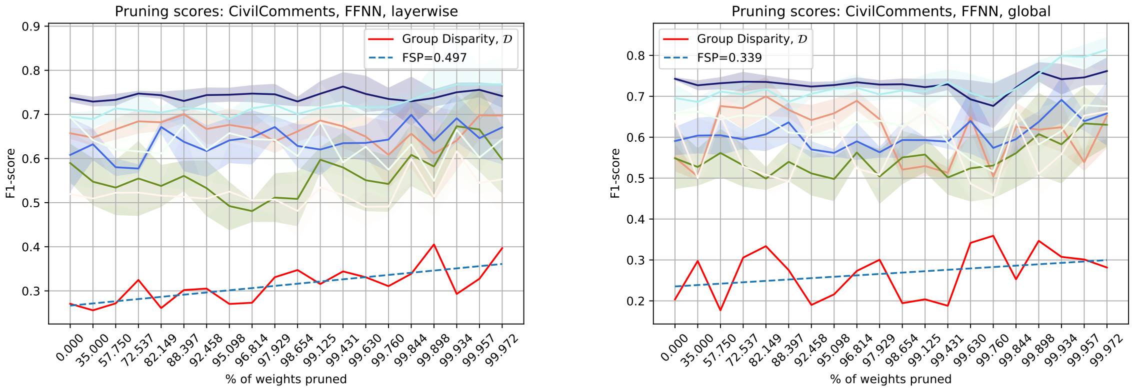

Figure 2: Macro-averaged performance of our feed-forward networks as a function of pruning ratio. Fairness Sensitivity to Pruning (FSP) correspond to the gradient of the linear fit to the min-max differences across individual runs. Results are for CIVILCOMMENTS. The hard line represents the average demographic score over 5 individual runs and the shaded area represents the standard deviation. See the Appendix for similar plots for the Trustpilot Corpus.

(Hovy et al., 2015),[2] which contains user reviews from the Trustpilot website of various companies and services in five different countries (Germany, Denmark, France, United Kingdom and United States). The reviews are based on a one to five star rating scale and some are accompanied by demographic attributes about the author, such as gender, age and location. 2) The **CivilComments** dataset (Borkan et al., 2019),[3] which contains comments annotated for toxicity, for the purpose of hate speech detection. A subset of the comments are also annotated for the protected attributes they address, including gender, race, and religion.

Preprocessing For the Trustpilot Corpus, we divide the data into demographics based on a combination of *gender* (male/female), *age* (young/old) and *location* (NUTS regions). For age, young is defined as being 35 or less. We exclude the French and American parts of the datasets as they do not have properly annotated NUTS regions. For UK and Germany, we use NUTS-1 regions, and for Denmark, where more data is available, we use NUTS-2 regions. We convert the 5-star ratings to binary sentiment labels, grouping 4 and 5 stars as positive, and 1 and 2 as negative. Neutral reviews (three stars) are discarded.[4] Likewise for CivilComments, we threshold comments with a toxicity rating > 0.5 as toxic, and otherwise label them as a non-toxic. This is similar to the binarization performed in Koh et al. (2020). Comments can for each demographic sub-attribute contain multiple partial values (e.g. $asian = 0.3$, $black = 0.4$ for the *race* attribute), so for each annotated attribute we assign it the sub-attribute with the largest value. In our experiments we consider demographics based on combinations of the *race* and *gender* attributes. For each language and dataset we randomly sample 100, 200 or 500 of each demographic as test sets, based on the the amount of annotated datapoints in the dataset, and use a 80-20 split of the remaining data for training and validation. If a demographic contains less than the specified number of datapoints, we disregard it. Due to high class imbalance, the majority class for our train-val data is downsampled to match the minority class. Table 1 shows the statistics for the respective datasets we train and evaluate on.

Dataset	Train	Val	N	S
Trustpilot-DK	222229	55557	20	500
Trustpilot-DE	26146	6536	42	100
Trustpilot-UK	127965	31991	50	200
CivilComments	357602	89400	7	100

Table 1: Detailed dataset statistics. N refers to the number of discrete demographics in the dataset and S is the size of each demographic test set.

4.2 Models

We consider simple **FFNN** (Rumelhart et al., 1986) and **LSTM** (Hochreiter and Schmidhuber, 1997)

---

[2] https://bitbucket.org/lowlands/release/src/master/WWW2015/data/

[3] https://www.kaggle.com/c/jigsaw-unintended-bias-in-toxicity-classification/data

[4] This binarization scheme is standard; see, e.g., Gupta et al. (2020) and Desai et al. (2019)

FFNN

Dataset	E_{dim}	h_{dim}	B	N
Trustpilot-DK	128	256	15	32
Trustpilot-DE	128	256	15	8
Trustpilot-UK	128	256	15	16
CivilComments	128	256	15	32

LSTM

Dataset	E_{dim}	h_{dim}	B	N
Trustpilot-DK	128	256	10	64
Trustpilot-DE	128	256	15	16
Trustpilot-UK	128	256	10	32
CivilComments	128	256	10	64

Table 2: FFNN and LSTM hyperparameters. E_{dim} is embedding layer size, h_{dim} is hidden layer size, B is batch size and N is number of epochs. Both the layer-wise and global pruning structures use the same set of hyperparameters.

neural networks for text classification.

FFNN The FFNN consists of the following: The embedding layer, which maps every token id in the text to a fixed size vector as a bag-of-embeddings and sums them together, resulting in a single representation $e \in \mathbb{R}^{|}E_{dim}|$, followed by 3 fully connected layers of size $\mathbb{R}^{|E_{dim} \times h|}$, $\mathbb{R}^{|h \times h|}$ and $\mathbb{R}^{|h \times 2|}$ respectively. We use the hyperbolic tangent activation between layers and each linear layer is initialized using He initialization (He et al., 2015).

LSTM The LSTM network is a 2-layer bidirectional LSTM (Hochreiter and Schmidhuber, 1997) which encodes our input text, followed by a fully connected layer for classification. The weights are initialized using $\mathcal{U}(-\sqrt{k}, \sqrt{k})$ where $k = \frac{1}{hidden\_size}$ and the final fully connected layer uses He initialization. See all model hyperparameters used in Table 2.

Both the FFNN and LSTM models are trained using the Adam optimizer (Kingma and Ba, 2017) with a learning rate of $1e-3$ and a weight decay of $1e-4$.

Distributionally Robust Optimization Loss Additionally, we also train our models with DRO loss (Levy et al., 2020). We use the implementation provided by Levy et al. (2020) [5]. For our experiments, a χ^2 uncertainty set of size 1 is used.

For all of our experiments, we extract our winning tickets over 20 pruning iterations and use a pruning rate of $p = 0.35$. We run a total of 5 independent runs for each model-dataset combination.

		Trustpilot			CC	Avg
		da	de	en	en	
FFNN	lw	-0.183	0.281	-0.230	0.497	0.091
	gl	0.227	1.375	1.054	0.339	0.749
FFNN-DRO	lw	-0.044	0.321	0.143	0.089	0.127
	gl	0.351	0.875	-0.040	0.368	0.388
LSTM	lw	0.221	0.411	0.206	0.823	0.415
	gl	1.099	0.198	0.352	0.252	0.475
LSTM-DRO	lw	0.263	-0.282	-0.082	1.335	0.309
	gl	0.262	-0.609	0.544	0.006	0.051

Table 3: FSP values across architectures, layer-wise (lw) and global (gl) pruning, and the four datasets. Our main observation is that FSP values are almost consistently positive, and slightly higher for global pruning. DRO does not consistently reduce FSP; we highlight cases where it does.

4.3 Measuring group disparity

At each pruning step we measure the group disparity $\mathcal{D}$, from a set of demographics D, between repeated runs R, by computing the maximum difference of F_1 scores as follows:[6]

$$\mathcal{D} = \max_{d_m \in D} \max_{d_{n \neq m} \in D} \max_{r_i \in R} \max_{r_{j \neq i} \in R} |F_{1_{r_i d_m}} - F_{1_{r_j d_n}}| \tag{1}$$

Intuitively, this corresponds to the difference between the highest scoring run for the highest scoring demographic and the lowest counterpart. We compute FSP by taking the gradient of the linear fit of $\mathcal{D}$ over a P pruning steps multiplied by 100.

5 Results

Main experiments Our first set of results evaluate FSP across architectures, datasets, and pruning techniques. In 14/16 combinations of FFNN and LSTM neural networks, the Trustpilot Corpus and CivilComments, layer-wise and global pruning, we see positive FSP values. In other words, weight pruning leads to higher group-level performance disparities, i.e., less fairness. Comparing layer-wise and global pruning, we note that group disparity is generally higher for global pruning. In Figure 2, we present two plots - for layer-wise and global pruning of a feed-forward network trained on CivilComments. The remaining plots are presented in the Appendix. The FSP values are listed in Table 3. FFNNs exhibit very high FSP values

---

[5] `https://github.com/daniellevy/fast-dro/`

[6] Maximum discrepancy has also been used as a measure of fairness in Calmon et al. (2017); Alabi et al. (2018). See Williamson and Menon (2019) for discussion.

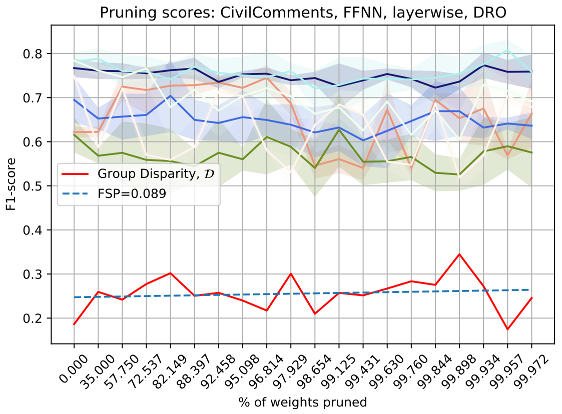

Figure 3: FSP for Distributional Robust Optimization

with global pruning, but while global pruning increases unfairness, layer-wise pruning does not. For LSTMs, the effects of the two pruning strategies are similar: Both lead to moderate increases in group disparities.[7] In a couple of instances we witnessed model degeneration due to heavy pruning resulting in single-class prediction before 20 pruning iterations. The plots and FSP values exclude these datapoints as they are not relevant for our analysis.

Distributionally Robust Optimization We ran comparable experiments using DRO loss (Hashimoto et al., 2018) to see whether the adverse effects of weight pruning on min-max fairness could be reduced by training with a more robust objective. This seems to hold true in some instances. We present a single plot for DRO in Figure 3, for feed-forward networks, layer-wise pruning on CivilComments; see the Appendix for more plots. Comparing with Figure 2 (left) the FSP metric is considerably lower than for baseline empirical risk minimization (0.089 vs. 0.497) while maintaining equal, or even better, performance at high pruning rates; but note from the red numbers in Table 3, that we only see this type of reduction in FSP in 3/8 cases for FFNNs, but DRO does reduce the average FSP for global pruning. In 5/8 cases for the LSTM, however, DRO does improves fairness, reducing the average FSP with both layer-wise and global pruning.

6 Conclusion

In this work, we take a first step in examining group disparity among heavily pruned models, using lottery ticket extraction, in NLP. We measure group disparity, using *fairness sensitivity to pruning*, on the Trustpilot Corpus, a sentiment classification dataset covering 3 languages, as well as CivilComments, a toxicity classification dataset, for both feed-forward and recurrent neural networks. We find that models subject to heavy pruning are more susceptible to higher levels of group disparity, but that this effect can to some degree be mitigated using distributionally robust optimization objectives.

[7] While fairness correlates with stability, the difference between FFNNs and LSTMs is not explained by stability differences (see plots in the Appendix), but should probably be attributed to the general performance differences between FFNNs and LSTMs, as well as relative overparameterization in FFNNs (see Footnote 1).

SSMix: Saliency-Based Span Mixup for Text Classification

Soyoung Yoon[1,2*†] **Gyuwan Kim**[1*] **Kyumin Park**[2]

`{soyoungyoon,pkm9403}@kaist.ac.kr, gyuwan.kim@navercorp.com`

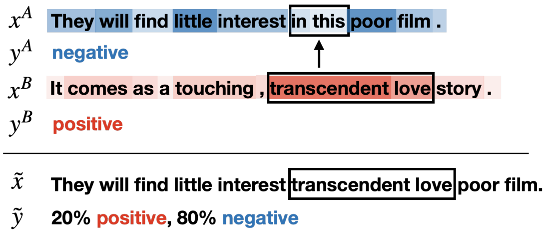
Abstract

Data augmentation with mixup has shown to be effective on various computer vision tasks. Despite its great success, there has been a hurdle to apply mixup to NLP tasks since text consists of discrete tokens with variable length. In this work, we propose *SSMix*, a novel mixup method where the operation is performed on input text rather than on hidden vectors like previous approaches. *SSMix* synthesizes a sentence while preserving the locality of two original texts by span-based mixing and keeping more tokens related to the prediction relying on saliency information. With extensive experiments, we empirically validate that our method outperforms hidden-level mixup methods on a wide range of text classification benchmarks, including textual entailment, sentiment classification, and question-type classification. Our code is available at https://github.com/clovaai/ssmix.

1 Introduction

Data augmentation gains popularity in natural language processing (NLP) (Feng et al., 2021) due to the expensive cost of data collection. Some of them are based on simple rules (Wei and Zou, 2019) and models (Edunov et al., 2018; Ng et al., 2020) to generate similar text. Augmented samples are trained jointly with original samples by a standard way or advanced training methods (Zhu et al., 2019; Park et al., 2021). On the other hand, mixup (Zhang et al., 2018) interpolates input texts and labels for the augmentation.

Training with mixup and its variants become a popular regularization method in computer vision to improve the generalization of neural networks. Mixup approaches are categorized into input-level mixup (Yun et al., 2019; Kim et al., 2020; Walawalkar et al., 2020; Uddin et al., 2021) and hidden-level mixup (Verma et al., 2019) depending on the location of the mix operation. Input-level mixup is a more prevalent approach than hidden-level mixup because of its simplicity and the ability to capture locality, leading to better accuracy.



x^A They will find little interest in this poor film .
y^A negative
x^B It comes as a touching , transcendent love story .
y^B positive
$\tilde{x}$ They will find little interest transcendent love poor film.
$\tilde{y}$ 20% positive, 80% negative

Figure 1: Illustration of *SSMix*. Two data samples x^A and x^B are labeled negative and positive respectively for sentiment classification task. For each token, saliency maps are visualized where darker concentration of colors mean higher contribution to corresponding label. We select the least salient span from x^A and replace it with the most salient span from x^B. The output results in $\tilde{x} = mixup(x^A, x^B)$. We also assign $\tilde{y}$ by the mixup ratio λ. In this example, λ is set to 0.2 as the span length is 2 out of 10.

Applying mixup in NLP is more challenging than in computer vision because of the discrete nature of text data and variable sequence lengths. Therefore, most previous attempts on mixup for texts (Guo et al., 2019; Chen et al., 2020) apply mixup on hidden vectors like embeddings or intermediate representations. However, input-level mixup might have an advantage over hidden-level mixup with a similar intuition from computer vision. This motivation encourages us to examine input-level mixup approaches for text data.

In this work, we propose *SSMix* (Fig 1), a novel input-level spanwise mixup method considering the saliency of spans. First, we conduct a mixup by replacing a span of contiguous tokens with a span in another text, which is inspired from CutMix

---

[*] Equal contribution.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3225–3234
August 1–6, 2021.

(Yun et al., 2019), to preserves the locality of two source texts in the mixed text. Second, we select a span to be replaced and to replace based on saliency information to make the mixed text contain tokens more related to output prediction, which may be semantically important. Our input-level method is different from hidden level mixup methods in that while current hidden level mixup methods linear interpolate original hidden vectors, our method mix tokens on the input level, resulting in a *nonlinear* output. Also, we utilize saliency values to select span from each sentence and discretely define the length of span and mixup ratio, which is outside the hidden level.

SSMix has empirically proven effective through extensive experiments on a wide range of text classification benchmarks. Especially, we prove that input-level mixup methods generally outperform hidden-level methods. We also show the importance of using saliency information and restricting token selection in span-level when conducting our method via ablation study.

2 *SSMix*

We propose *SSMix* to synthesize a new text $\tilde{x}$ by replacing a span x_S^A from one text x^A into another span x_S^B from another text x^B based on saliency information. Also, we have to set a new label $\tilde{y}$ for $\tilde{x}$ using y^A and y^B which are one-hot labels corresponding to x^A and x^B, respectively. Consequently, we can additionally use this generated virtual sample $(\tilde{x}, \tilde{y})$ for training.

Saliency Saliency measures how each portion of data (in this case, tokens) affects the final prediction. Gradient-based methods (Simonyan et al., 2013; Li et al., 2016) are widely used for the saliency computation. We compute the gradient of classification loss $\mathcal{L}$ with respect to input embedding e, and use its magnitude as the saliency: i.e., $s = \|\partial\mathcal{L}/\partial e\|_2$. We apply the L2 norm to obtain the magnitude of a gradient vector, which becomes a saliency of each token similar to PuzzleMix (Kim et al., 2020).

Mixing text Text data x^A and x^B are discrete token sequences. Using saliency scores as explained earlier, we can find the least salient span in x^A with a length l_A as x_S^A and the most salient span in x^A with a length l_B as x_S^B. We set $l_A = l_B = max(min([\lambda_0|x^A|], |x^B|), 1)$ given a prior mixup ratio λ_0. Then, final $\tilde{x}$ becomes the concatenation of $(x_L^A; x_S^B; x_R^A)$ where x_L^A and x_R^A are tokens located to the left and the right side of x_S^A respectively in the original text x^A.

Algorithm 1 Mixup loss calculation

```
procedure SSMix_Loss($x^A, x^B, y^A, y^B, \lambda$)
    $\tilde{x} \leftarrow SSMix(x^A, x^B)$
    $logit \leftarrow model(\tilde{x})$
    $loss^A \leftarrow CrossEntropy(logit, y^A)$
    $loss^B \leftarrow CrossEntropy(logit, y^B)$
    $total\_loss \leftarrow loss^A * \lambda + loss^B * (1 - \lambda)$
return $total\_loss$
end procedure
```

Same span length We set the length of the original (l_A) and replaced (l_B) span to be the same, since allowing different length of spans would result in redundant and ambiguous mixup variations. Also, calculating the mixup ratio between different span length would be too complex. This same-size replacement strategy is also adopted in (Yun et al., 2019) and (Uddin et al., 2021). In situations where span length is the same, our method maximizes the effect of saliency. Since *SSMix* doesn't restrict the position of tokens, we can pick the *most* salient span and replace it with *least* salient span on the other text.

Mixing label We set mixup ratio λ for label as $\lambda = |x_S^B|/|\tilde{x}|$. Since λ is recalculated by counting the number of tokens in the span, it may differ from λ_0. We set the label of $\tilde{x}$ to $\tilde{y} = (1 - \lambda)y^A + \lambda y^B$. Algorithm 1 shows how we utilize the original sample pairs to compute the mixup loss for augmented samples. We calculate the cross-entropy loss of the augmented output logit with respect to the original target label of each sample and combine them by weighted sum, which is similar to the original implementation of (Zhang et al., 2018).[1] Therefore, applying *SSMix* is independent of the total number of labels of the classification dataset. On any dataset, output label ratio is calculated by linear combination of *two* original labels.

Paired sentence tasks For tasks requiring a pair of texts as an input such as textual entailment and similarity classification, we conduct mixup in a pairwise manner and calculate the mixup ratio by aggregating token counts in each mixup result. Denoting $x^A = (p^A, q^A)$, $x^B = (p^B, q^B)$, and

TREC-fine	Classification	47	5.5k / 500
ANLI	NLI	3	162.8k / 3.2k / 3.2k

Table 1: Dataset name, task, number of total labels, and dataset size of datasets we used as benchmark. Task column describes the objective of each dataset. ANLI dataset shows aggregated dataset statistics among different rounds. GLUE tasks report the size as (train / validation) format, TREC reports (train / test) and ANLI reports (train / validation / test).

$\tilde{x} = (\tilde{p}, \tilde{q})$, we define mixup of paired sentence data as $\tilde{x} = (mixup(p^A, p^B), mixup(q^A, q^B))$. Here, we set the mixup ratio on paired sentence tasks as $\lambda = (|p_S| + |q_S|)/(|\tilde{p}| + |\tilde{q}|)$, where p_S and q_S are replacing spans of independent mixup operations. Illustation is available in Appendix B.3.

3 Experimental Setup

3.1 Dataset

As listed in table 1, to evaluate the effectiveness of *SSMix*, we perform experiments on various text classfication benchmarks: six datasets in GLUE benchmark (Wang et al., 2018), TREC (Li and Roth, 2002; Hovy et al., 2001), and ANLI (Nie et al., 2020). Two of them are single sentence classification tasks, and six of them are sentence pair classification tasks. All datasets are extracted from HuggingFace datasets library.[2]

For GLUE, we use SST-2 (Socher et al., 2013), MNLI (Williams et al., 2018), QNLI (Rajpurkar et al., 2016), RTE (Bentivogli et al., 2009), MRPC (Dolan and Brockett, 2005), and QQP[3]. Among GLUE, we leave out datasets that were not evaluated by accuracy, along with WNLI, because the size is too small to show any general trend of effectiveness.

TREC is a commonly used dataset to evaluate mixup methods in sentence classification (Guo et al., 2019; Thulasidasan et al., 2019). We use two different versions of TREC (coarse, fine) that have different levels of label number to test the dependency of mixup effectiveness on the number of class labels. In addition, we use ANLI to see how mixup can help to improve model robustness. For training ANLI, we concatenate all training data from different rounds and use them to train the model.

3.2 Baseline

We compare *SSMix* with three baselines: (1) standard training without mixup, (2) EmbedMix, and (3) TMix. EmbedMix apply mixup on the embedding layer, which is similar to the wordMixup in Guo et al. (2019) except their experiments are performed with LSTM or CNN architecture. TMix, borrowed from Chen et al. (2020), interpolates hidden states of two different inputs at a particular encoder layer and forward the combined hidden states to the remaining layers. For EmbedMix and TMix, we follow the best settings stated in the original papers: mixup ratio is set by $\lambda' \sim Beta(\alpha, \alpha)$, $\lambda = max(\lambda', 1 - \lambda')$ with $\alpha = 0.2$. During the training with TMix, we randomly sample the mixup layer from $[7, 9, 12]$.

3.3 Ablation study

To investigate how much (1) considering saliency and (2) restricting mixup operation on the span-level individually benefit our proposed method, we conduct an ablation study. We implement *SSMix* without considering saliency information (*SSMix* - saliency) where the spans are randomly selected, and additionally without the span-level restriction (*SSMix* - saliency - span). For *SSMix* - saliency - span, we randomly sample tokens from x^B, which need not be a contiguous span and are conducted on a per-token basis. Then, we replace tokens accordingly with the position of the token be preserved, meaning that the second token from x^A is replaced with the second token from x^B, and so on. For all ablation studies, the lambda values were set to 0.1 to compare methods with the same setting as *SSMix*. Detailed implementation and illustration of ablation methods and comparison with simple word dropout methods are described in Appendix B.

3.4 Training Details

Among the entire experiment, we use sequence classification task with the pre-trained BERT-base model having 110M parameters from Hugging-

---

[2] https://github.com/huggingface/datasets

[3] https://www.quora.com/First-Quora-Dataset-Release-Question-Pairs

Face Transformers library.[4] We perform all experiments with five different seeds (0 to 4) on a single NVIDIA P40 GPU and report the average score. We set a maximum sequence length of 128, batch size of 32, with AdamW optimizer with eps of 1e-8 and weight decay of 1e-4. We use a linear scheduler with a warmup for 10% of the total training step. We update the best checkpoint by measuring validation accuracy on every 500 steps. For datasets that have less than 500 steps per epoch, we update and validate every epoch.

Considering our objective of enhancing performance through mixup, we conduct training in two steps. We first train without mixup with a learning rate of 5e-5 for three epochs, and then train with mixup starting from previous training's best checkpoint, with a learning rate of 1e-5 for five epochs. This two-step training, which also utilized by Zhang et al. (2018), speeds up the model convergence. We report the best accuracy among both training with and without mixup. For the ANLI task, we select the best checkpoint for training without mixup separately for each round, then conduct training with mixup and report the best accuracy of each round's evaluation dataset.

For each iteration, we split the batch into two smaller batches with the same size, A and B. Since mixup operation in *SSMix* is not symmetric, we conduct mixup back-and-forth so that mixup performance is evaluated regardless of the data position in batch. To prevent the training data distribution getting too far from the original data distribution, we train with and without mixup together as He et al. (2019). As a result, we forward each step with average loss from A, B, $mixup(A, B)$, and $mixup(B, A)$.

We leave out tokens specific to transformer architecture (e.g., $[CLS]$, $[SEP]$) when conducting a mixup to preserve special signs. As stated by Zhang et al. (2018), giving too high values for mixup ratio may lead to underfitting, while giving λ close to 0 leads to the same effect of giving non-augmented original data. From our experiments, we found out that augmentation with prior ratio $\lambda_0 = 0.1$ is the optimal hyperparameter.

In terms of computation time, *SSMix* takes about twice the training time compared with other mixup methods since we need an additional forward and backward step to compute the saliency of tokens. Among hidden-level mixup methods, TMix takes a slightly longer time to train than EmbedMix.

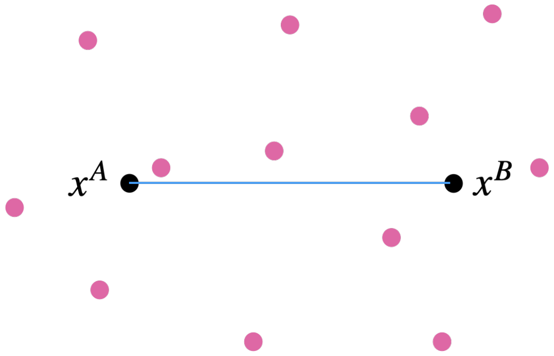

Figure 2: Visualization of original data and synthesized data by hidden-level mixup (EmbedMix or TMix) and *SSMix* in the hidden space. Black dots indicate the original data, x^A and x^B. For hidden-level mixup, synthetic data ($\tilde{x}$) are created only along the line (blue) connecting two points, since it is a linear combination within the hidden space. However, *SSMix* explore larger synthetic sample space for $\tilde{x}$, since it consists of a discrete combination within the *input* space. Synthetic data for *SSMix* are illustrated in pink dots.

4 Results and Discussion

Table 2 illustrates our results. We investigate the effectiveness of *SSMix* compared with hidden layer mixup methods on the aspect of dataset size, number of class labels, and paired sentence tasks.

Dataset size Compared with hidden-level mixup methods, *SSMix* fully demonstrate its effectiveness on datasets having a sufficient amount of data. Since *SSMix* is a discrete combination rather than a linear combination of two data samples, it creates data samples on a synthetic space in a larger range than hidden-level mixup (Fig. 2). We hypothesize that a large amount of data help better representation in synthetic space.

The number of class labels *SSMix* is especially effective for multiple class label datasets (TREC, ANLI, MNLI, QNLI). Accordingly, the accuracy gain of *SSMix* from the training without mixup is much higher on TREC-fine (47 labels) than TREC-coarse (6 labels), with +3.56 and +0.52, respectively. We hypothesize that this result originates from the mixup characteristic that benefits more from cross-label mixup than mixup with the same label, as stated at Zhang et al. (2018).[5] Since datasets with multiple total class labels increase the

---

[4] https://github.com/huggingface/transformers

[5] Zhang et al. (2018) states that mixing random pairs from all classes (per-batch basis) has the strongest regularization effect compared with mixup by per-class (same class) basis.

possibility of being selected cross-label in a random sampling of mixup sources, we assert mixup performance increases in such datasets.

Paired sentence tasks *SSMix* have a competitive advantage on paired sentence tasks, such as textual entailment or similarity classification. We suspect this accuracy gain originates from consideration of individual tokens. Existing methods (hidden-level mixup) apply mixup on the hidden layer, without consideration of special tokens, i.e., $[SEP]$, $[CLS]$. These methods may lose information about the start of the sentence or appropriate separation of pair of sentences. In contrast, *SSMix* can consider the individual token property when applying mixup. Here, our mixup strategy on paired data (Section 2) preserves the property of $[SEP]$, which is not guaranteed by hidden mixup.

Ablation Study The results of *SSMix* and its variants demonstrate that the performance improves as we add span constraint and saliency information. Adding span constraint in the mixup operation benefit from better localizable ability, and most salient spans have more relationship to corresponding labels while discarding least salient spans have a higher probability that those spans are not semantically important with respect to the original labels. Among those two, introducing saliency information contributes to accuracy relatively more than the span constraint.

5 Conclusion

We present *SSMix*, a novel and simple input-level mixup method for text data that improves regularization ability leading to better performance in text classification. *SSMix* preserves the locality of mixing texts by replacing in span-level and keep most discriminative tokens in the mixed text using saliency score. Throughout the experiment, we show that our method improves performance in various types of text classification tasks. For future work, we plan to apply *SSMix* on a broader range of tasks, including generation or different scenarios like semi-supervised learning.

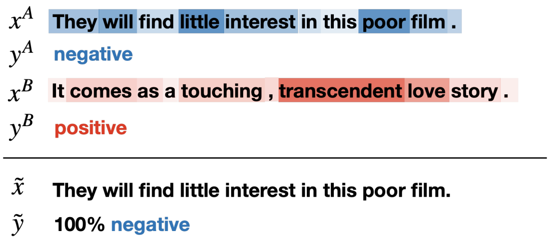
We also report accuracy variance among the five seeds for each experiment (Table. A.1).

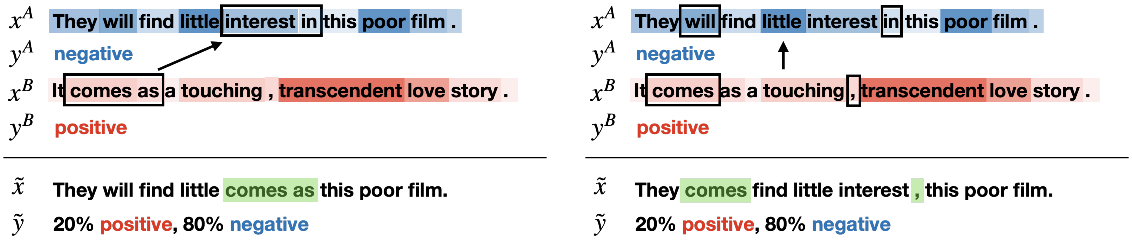
B Ablation

Fig. 3 and Fig. 4 shows the illustration of different variants of *SSMix* and random UNK replacement with $\lambda = 0.2$. Fig. 5 shows the illustration of getting the augmented output with lambda calculation by *SSMix* for paired sentence tasks. The saliency maps are visualized where darker concentration of colors mean higher contribution to corresponding label.

B.1 Variants of *SSMix*



(a) Normal training without mixup



(b) *SSMix* - saliency (c) *SSMix* - saliency - span

Figure 3: Illustration of normal training and variants of *SSMix*

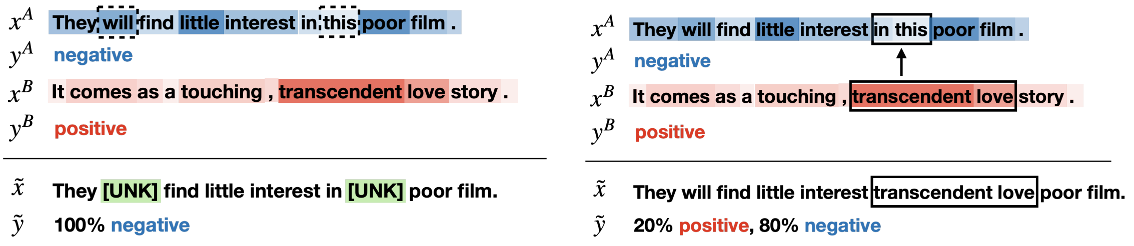
Here, we describe in detail how we implement *SSMix* without saliency (Figure. 3 (b)) and *SSMix* without saliency and span restriction (Figure. 3 (c)).

Model	GLUE						TREC		ANLI		
	SST-2	QQP	MNLI	QNLI	RTE	MRPC	coarse	fine	R1	R2	R3
No mixup	92.96	91.32	84.27	91.28	65.56	86.37	97.08	86.68	56.40 57.16	47.10 47.36	47.62 48.00
Random UNK replacement	93.10	91.33	84.46	91.45	66.86	**86.62**	97.44	89.24	56.98 57.26	47.86 **48.36**	**47.98** **48.32**
SSMix	93.10	**91.43**	**84.54**	**91.54**	**67.22**	86.57	**97.60**	**90.24**	**57.26** **57.34**	**48.36** 48.06	47.78 48.00
SSMix - saliency	93.12	91.32	84.48	91.29	67.00	86.42	97.44	89.56	57.04 57.16	48.22 47.94	47.95 48.07
SSMix - saliency - span	**93.14**	91.32	84.54	91.45	66.93	86.37	97.40	89.20	56.74 57.20	47.52 47.90	47.77 48.00

Table B.1: Accuracy (%) comparison with simple data augmentation method(random UNK replacement) and input mixup methods. The results are average of five runs with different seeds. Results show that our input level mixup methods are generally competitive with simple word dropout methods.

At normal training, only two real data samples (x^A and x^B) are used to train the model. For Figure. 3 (b), we *randomly* select each span from x^A and x^B. Then, we replace x^B to x^A to make a new data $\tilde{x}$. For Figure. 3 (c), input level mixup is conducted on a per-token basis. After calculaton of l given the prior mixup ratio, we randomly sample tokens from x^A. The tokens need not be a contiguous span. Then, we replace tokens accordingly with the position of the token be preserved, meaning that the second token from x^A is replaced with second token from x^B, the sixth token from x^A is replaced with sixth token from x^B (by the illustration example), and so on.

B.2 Comparison with other simple augmentation methods



(a) Random `[UNK]` replacement (b) *SSMix*

Figure 4: Comparison of our methods with word dropout

We also compare *SSMix* with simple word dropout methods, which may seem similar in the perspective that they create noisy sentences. The difference is whether label mixup is performed. Illustration of the implementation of random [UNK] replacement is available at Fig. 4. Random UNK replacement is similar to word dropout. We don't use x^B when making synthetic samples ($l = 0$). Instead, we randomly sample a set of tokens from x^A and replace each token in that span with [UNK]. The process is similar to Figure. 3 (c), except that the selected tokens at x^A are replaced into [UNK]. Another difference is that the output label ($\tilde{y}$) completely follow the origin (y^A) and no label mixup is performed. The illustration is available at 3.

We evaluate the random [UNK] replacement method on all dataset with *SSMix* and variants of *SSMix* at ablation study. By the experiment results at Table B.1, we show that input level mixup methods generally outperform simple regularization methods. This means that datasets synthesized from *SSMix* and the according target vectors have more gain on the generalization ability than word dropout.

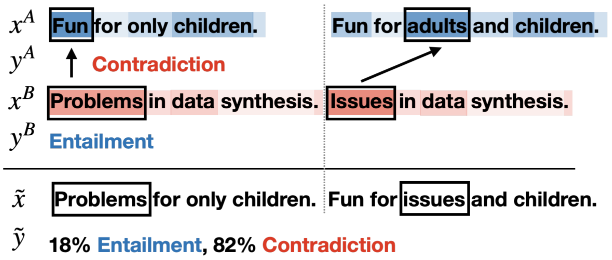


Figure 5: Illustration of applying SSMix to make $\tilde{x}$ for paired sentence, in particular NLI tasks, which classifies whether the relation of sentence pairs is entailment, neutral, or contradiction. Mixup is conducted individually, sentence by sentence.

B.3 Illustration of SSMix on paired sentence tasks

Fig. 5 shows the illustration of example for paired sentence. Here, "Fun for only children." and "Fun for adults and children." correspond to p^A and q^A, "Problems in data synthesis." and "Issues in data synthesis." correspond to p^B and q^B, and "Problems for only children.", "Fun for issues and children." correspond to p and q, respectively. λ is calculated as : $\lambda = (|p_S| + |q_S|)/(|\tilde{p}| + |\tilde{q}|) = (1+1)/(5+6) = 2/11 \approx 0.18$.

Detecting Bot-Generated Text by Characterizing Linguistic Accommodation in Human-Bot Interactions

Paras Bhatt and **Anthony Rios**
Department of Information Systems and Cyber Security
University of Texas at San Antonio
`{Paras.Bhatt, Anthony.Rios}@utsa.edu`

Abstract

Language generation models' democratization benefits many domains, from answering health-related questions to enhancing education by providing AI-driven tutoring services. However, language generation models' democratization also makes it easier to generate human-like text at-scale for nefarious activities, from spreading misinformation to targeting specific groups with hate speech. Thus, it is essential to understand how people interact with bots and develop methods to detect bot-generated text. This paper shows that bot-generated text detection methods are more robust across datasets and models if we use information about how people respond to it rather than using the bot's text directly. We also analyze linguistic alignment, providing insight into differences between human-human and human-bot conversations.

1 Introduction

Bots are useful in a wide variety of applications areas including business (Kaczorowska-Spychalska, 2019), education (Kerlyl et al., 2006), and health (Yadav et al., 2019; Liednikova et al., 2020). For instance, Yadav et al. (2019) studied the use of chatbots as a drop-in first-point-of-contact for women in India seeking breastfeeding information. Similarly, researchers have studied bots to answer COVID-19-related questions (Oniani and Wang, 2020) and screen individuals for risks of contracting the virus (Martin et al., 2020). Overall, the wide availability of software packages, tools, and pre-trained models has democratized the creation of bots.

Even with the increasing interest in bots for social good (e.g., COVID-related chatbots), there is still a concern regarding their abuse to spread misinformation, be used for targeted discrimination, deceive users, and perform fraud (Daniel et al., 2019). Given the potential good and harm bots can create, it is essential to study how the bots *should* act and how people *do* interact with such bots for specific applications.

Automatically identifying bots online is well studied (Garcia-Silva et al., 2019; Herzig et al., 2019; Kosmajac and Keselj, 2019; Ippolito et al., 2020; Jawahar et al., 2020). Bot detection methods rely on two forms of information (Orabi et al., 2020): behavior and content. Behavior relates to measuring how often bots post, the time posts are created, and conversational network structures (Beskow and Carley, 2018). Content involves using the bot's text directly. Focusing on text suffers from generalization issues, making it challenging to detect bots that discuss different topics or operate in different domains. Likewise, behavioral approaches assume that bots will behave differently than people at a superficial level, such as posting more often than humans. Even in the network analysis of conversation structures (Beskow and Carley, 2018), many of the human-bot interactions on social media are not human-like interactions. For instance, it is understandable that humans will interact with a bot that converts pounds to kilograms differently than other humans. Given bots' current use-cases ranging from counselors to healthcare information providers, it is vital to understand how humans and bots interact beyond trivial applications.

Before looking at how humans interact with bots, it is essential to understand how humans interact. This paper focuses on Communication Accommodation Theory (CAT) and general language use to analyze interactions. CAT is used to study language use in various domains to understand human behavior (Giles et al., 1973; Tausczik and Pennebaker, 2010). More specifically, we study linguistic accommodation—where speakers come to talk more (or less) similarly as they interact—

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3235–3247
August 1–6, 2021.

which has been analyzed in mental health support on Reddit, showing a positive link with informational and emotional support (Sharma and De Choudhury, 2018). The alignment of two people in terms of linguistic style has positively predicted successful outcomes of negotiations (Taylor and Thomas, 2008), and doctors are recommended to accommodate perspective to improve patient care (Kline and Ceropski, 1984; Wood, 2019). The way people use and accommodate pronouns can indicate power, where high-status individuals use "I" less and "you/we" words more than low-status individuals (Kacewicz et al., 2014).

Linguistic accommodation in human-bot interactions has been studied in system design, showcasing that there is a strong link between user experience and language style of the system (Chaves et al., 2019; Chaves, 2020; Thomas et al., 2020). Recent research has also shown a link between language style in chatbots and user engagement for e-commerce (Elsholz et al., 2019). Our focus is to understand real long open-domain human-bot interactions better. Our study can also influence how bots are detected on social media and provide a better understanding of how human-human interactions differ from human-bot interactions is essential for bot development. For instance, when should bots accommodate towards the user? Can we tell how well a system performs for a specific task based on whether the user accommodates the bot? If human-bot conversations are linguistically different than human-human interactions, research from human-human studies may not generalize to human-bot interactions.

Toward addressing the potential societal impacts of open-domain bots, this paper addresses the following research questions (RQs) in the context of bot Detection:

RQ1. How do humans and bots align in human-bot interactions?

RQ2. How does the alignment in human-bot interactions compare to the alignment in human-human interactions?

RQ3. Are differences in alignment between human-human and human-bot interactions similar across domains and language generation learning methods?

Overall, we analyze whether human users' language changes stylistically with bots as compared to human-human conversations. Furthermore, we show that small differences in language style provides robust information, compared to the bots' language patterns, to accurately detect bots.

2 Related Work

Bot Detection. Detecting bots in the wild is a widely studied problem (Garcia-Silva et al., 2019; Herzig et al., 2019; Kosmajac and Keselj, 2019; Ippolito et al., 2020; Jawahar et al., 2020). bot detection methods rely on two forms of information (Orabi et al., 2020): Content and Behavior. Garcia-Silva et al. (2019) studied how pretrained language models perform for the task of bot detection. Kosmajac and Keselj (2019) developed "language-independent" stylistic features that measure language diversity to detect bots. Knauth (2019) empirically explored content and behavioral features for bot detection. Beskow and Carley (2018) analyzed human-bot interactions by developing methods to detect bots using network analysis of conversation structures. Much of the prior work has focused on detecting bots "in the wild.“ Thus, many of the interactions between bots and humans are superficial (e.g., receiving movie quotes from a bot). This paper differs from prior work in two ways. First, rather than using content from the bot or general behavioral information (e.g., post frequency), we try to detect bots by analyzing how humans respond to them (compared to human-human interactions). Second, rather than exploring bots in the wild, we explore two types of datasets: one where researchers instruct participants to interact with bots and humans in the same way, and another dataset where researchers instruct participants to converse with a bot.

Analyzing Human-Human Conversations. Linguistic alignment is known to interact with a wide array of social factors. For instance, the level of alignment of people's linguistic style in a conversation has been claimed to be affected by their relative social power (Gnisci, 2005; Xu et al., 2018; Danescu-Niculescu-Mizil et al., 2011). Cooperative decision-making tasks are positively related to the participants' linguistic convergence (Fusaroli et al., 2012; Kacewicz et al., 2014). Recently, Sharma and De Choudhury (2018) analyzed mental health support forums on Reddit, showing that linguistic accommodation is positively linked with informational and emotional support. Similarly, Taylor and Thomas (2008) analyzed negotiation outcomes and linguistic alignment, showing that alignment positively predicted successful negotiation outcomes. There is also the support of linguistic alignment by doctors to enhance patient care by improving trust and adherence to a treatment plan (Kline and Ceropski, 1984; Wood, 2019). Alignment is a powerful tool that can be used to improve understanding, trust, and potentially patient outcomes. Therefore, understanding *when* and *how* people should align with each other is an important area of research. Furthermore, it is essential to draw a line between engaging with a culture and language style and appropriating it, thereby potentially causing harm rather than building rapport with the partners in a conversation.

With the goal of understanding human-human interactions, there has also been progress in linguistic alignment measurement techniques (Niederhoffer and Pennebaker, 2002; Danescu-Niculescu-Mizil et al., 2011; Jones et al., 2014; Wang et al., 2014; Doyle and Frank, 2016; Shin and Doyle, 2018). Danescu-Niculescu-Mizil et al. (2011) presented an easy-to-compute expression that measures the increase in the conditional probability given that a conversational partner has used it. An issue with the method proposed by Danescu-Niculescu-Mizil et al. (2011) is that it assumes messages between two people have similar length. To overcome this limitation, Doyle and Frank (2016) introduced the Word-Based Hierarchical Alignment Model (WHAM), a hierarchical graphical model where the parameters are learned using Bayesian inference. Another method called the Simplified Word-Based Alignment Model (SWAM) was recently proposed by Shin and Doyle (2018). SWAM attempts to compare alignment between different groups when the alignment scores are assumed to differ substantially. Unfortunately, SWAM only estimates group-level alignment, not conversation-level between two specific users/bots. Linguistic alignment has also been shown to be predictive of specific tasks. In this paper, we use the method proposed by Danescu-Niculescu-Mizil et al. (2011) to estimate linguistic alignment. For instance, Niven and Kao (2019) use alignment features to predict discourse acts.

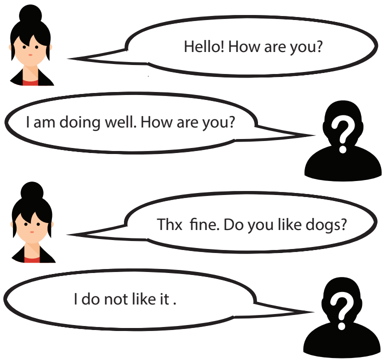

Figure 1: This figure depicts an potential conversation between a known human user and an unknown user. The unknown user may be a human or a bot.

Analyzing Human-Bot Conversations. Research studying the interaction between bots and humans has been explored from a wide array of perspectives. For example, systems that use emotionally expressive interjections ("wow", "ahem") in their text to speech responses can significantly improve the user experience (Cohn et al., 2019). Given the popularity of bots in application areas from business (Kaczorowska-Spychalska, 2019) to healthcare (Pieraccini et al., 2009), it is also important to understand how language generation style and alignment impacts their intended use. There has been a recent interest in analyzing accommodation and similar concepts in human-bot interactions. For instance, Ahn et al. (2020) show that humans will match *code-switching* patterns introduced by a chat system. Moreover, users tend to have positive reactions towards systems that code-switch. Ma and Lalor (2020) measure *lexical entrainment* between a specific Reddit bot and users. They find that sentiment of bot has a positive effect on the sentiment of the humans response. Furthermore, Ma and Lalor (2020) show that human responses tend to overlap with the bots original post. Compared to prior work studying accommodation-related aspects of human-bot interactions, this paper differs in two ways. First, just analyzing linguistic alignment, we ground our study of human-bot interactions in the real-world task of bot detection. Second, we analyze cross-domain generalization of accommodation patterns in human-bot interactions, where cross-domain includes types of bots (e.g., retrieval and transformer-based models), data collection procedures (e.g., sampling bias), and conversation topics.

3 Datasets

An overview of the task we introduce in this paper is shown in Figure 1. We formulate a bot de-

Dataset Name	# D	# u	Avg. u	Avg. W
ConvAI2 Data				
INTERMEDIATE	291	4317	14.83	6.66
TOLOKERS	3127	39155	12.52	7.05
VOLUNTEER	1111	14623	13.16	6.60
PERSONA-CHAT	18878	278478	14.75	1.85
Control Data				
IRIS	163	5687	34.89	5.46
TICKTOCK	206	5462	26.51	7.07
DailyDialog	13118	102980	7.85	13.08

Table 1: Summary of each dataset, including the number of dialogues (# D), average number of utterances per dialogue (Avg. u), average number of words per utterance (Avg. W) and total number of utterances (U)

tection task between two entities, either a human and bot or a human and human. We assume that one entity is always human, and the other entity is unknown—either a human or a bot. Formally, let $D = [u_1^h, u_2^o, \ldots, u_{N-1}^h, u_N^o]$ represents a sequence of utterances, where u_i^h represents the *i*-th utterance in a conversation and that it was made by a human h. Likewise, u_i^o represents an unknown entity's utterance (human or bot). N is the total number of utterances in the conversation. Our goal is to develop a classifier $f(D)$ that maps to a class in the set $T = \{\text{human-human}, \text{human-bot}\}$, where the human-bot means a bot is a part of the conversation. We formulate two bot detection datasets for this task consisting of three known bot datasets: ConvAI2, WOCHAT, and DailyDialog. The basic statistics of each dataset are shown in Table 1. WOCHAT and DailyDialog are used to form a Control dataset. We describe each dataset below:

ConvAI2. We use four datasets from the Second Conversational Intelligence Challenge (ConvAI2). The motivation behind the ConvAI2 challenge was to develop new approaches towards open-domain chatbots (Zhang et al., 2018; Dinan et al., 2019). Overall, we use two types of ConvAI2 datasets: training datasets containing human-human interactions and evaluation phase datasets containing human-bot interactions. First, we use the PERSONA-CHAT dataset, a collection of human-human interactions where researchers instructed Mechanical Turk users to converse with one another, assuming specific personas (i.e., profile descriptions). The ConvAI2 competition used automatic (e.g., Perplexity) and human evaluation procedures. The human evaluation procedures involve either paid workers or volunteers that interact with models built using PERSONA-CHAT, after which the volunteers/workers are asked to rate their interactions. Moreover, the human evaluator is instructed to interact with the bots in the same way as the Mechanical Turk users who participated in creating the PERSONA-CHAT dataset.

We use three "evaluation-phase" datasets [1]: TOLOKERS, VOLUNTEERS, and INTERMEDIATE. The TOLOKERS used solicited workers to chat with the models, similar to the PERSONA-CHAT's Mechanical Turk setup. Specifically, TOLOKERS consists of data collected during DeepHack.Chat [2] hackathon via paid workers using the Yandex.Toloka service. The INTERMEDIATE dataset consists of more dialogues by the bots from DeepHack.Chat, but the interactions come from volunteers. Finally, the VOLUNTEER dataset was collected during the final "wild evaluation" round of the ConvAI2 competition. Human-bot interactions were collected from volunteers through the Facebook Messenger and Telegram APIs.

Control Dataset. One of the research questions we explore in this paper is related to out-of-domain performance. Specifically, can we detect bots based on human response when data were collected under different settings and where the conversation topics differ? To address the out-of-domain research question, we use two additional datasets collected in the The Workshop on Chatbots and Conversational Agent Technologies (WOCHAT) (Kong-Vega et al., 2019). As part of a shared task, the workshop makes several bots available, has participants contribute new bots, and participants interact with the bots providing utterance-level feedback regarding their performance. We use two human-bot interaction datasets released by the organizers: IRIS and the TickTock dataset. [3] both IRIS (Banchs and Li, 2012) and TickTock (Yu et al., 2015) are retrieval-based bot variants that were "trained" on different datasets. Unlike the ConvAI2 task, humans are not instructed to converse with the bots as if they are another human. Thus, sometimes humans will ask things such as, "Are you a Robot?". This point

---

[1] `http://convai.io/data/`

[2] `http://deephack.me/chat`

[3] `http://workshop.colips.org/wochat/data/index.html`

provides a unique aspect that increases cross-data differences.

Unfortunately, human-human conversations were not released from the WOCHAT shared task. The focus was annotating human-bot interactions. Thus, we need to augment WOCHAT with real human-human conversations. Our study uses the DailyDialog dataset as our source of human-human interactions (Li et al., 2017). Unlike the ConvAI2-related data, DailyDialog consists of conversations between English learners practicing everyday English dialog in daily life.

Data Processing. We split the data into three groups: Unpaid (U), Paid (P), and Control (C). The U dataset consists of PERSONA-CHAT, INTERMEDIATE, and VOLUNTEER ConvAI2 datasets. The P dataset consists of PERSONA-CHAT and TOLOKERS—the name Paid comes from the fact that the TOLOKERS were paid as part of a crowdsourcing task. We split this group from the others in case this affects conversation behavior. The C dataset consists of IRIS, TICK-TOCK, and DailyDialog. Each dataset is divided into 70%, 10%, and 20% training, validation, and test splits, respectively. It is important to note that the same PERSONA-CHAT training, validation, and test examples are used in both the U and P datasets.

4 Method

To detect human-bot conversations, we explore two types of features below: Content and Stylistic features.

4.1 Content Features

We define content information as features describing "*what*" humans and bots say in their interactions. Specifically, we describe two sets of content features: bag-of-words and embeddings.

Bag-of-words. As a simple baseline, we use TF-IDF-weighted unigrams from a dialog to detect whether a bot is part of the conversation. We explore three settings for the TF-IDF features: human-only, unknown-only, and human-unknown. The *unknown* user in the conversation can be either a bot or a human. Thus, in the human-Only setting, only the human's unigrams from each dialogue $D_h = [u_1^h, u_3^h, \ldots, u_{N-1}^h]$ are used to detect human-bot interactions. The unknown-only setting uses only the unknown user's unigrams from each dialogue $D_o = [u_2^o, u_4^o, \ldots, u_N^o]$, and the human-unknown setting uses both the human's and unknown user's unigrams from each dialogue $D = [u_1^h, u_2^o, \ldots, u_{N-1}^h, u_N^o]$.

Embedding Features. We encoded each dialogue D using BERT (Devlin et al., 2019)[4] by feeding the first 510 WordPieces and then averaging the word representations extracted from the second-to-last layer. We explore three variants, human-Only, Unknown-Only, and human-Unknown. Depending on the variant, the exact WordPieces passed to BERT change. For instance, in the human-Only setting, the first 510 WordPieces made by the human from a concatenation of all of the humans utterances $D_h = [u_1^h, u_3^h, \ldots, u_{N-1}^h]$ are passed to BERT. Similarly, all of the unknown user's utterances are used for the unknown-only variant to obtain $D_o = [u_2^o, u_4^o, \ldots, u_N^o]$. In the human-unknown setting, all human and unknown utterances are concatenated in $D = [u_1^h, u_2^o, \ldots, u_{N-1}^h, u_N^o]$ before generating features with BERT.

4.2 Stylistic Features

The stylistic features encode "*how*" humans and bots speak in their interactions. We use two sets of stylistic features: Linguistic Inquiry and Word Count (LIWC) (Pennebaker et al., 2015) and linguistic accommodation (Danescu-Niculescu-Mizil et al., 2011).

LIWC. We experiment with the psychologically validated word categories (e.g., positive emotion, cognitive, and social processes) in LIWC as features. These lexicons might reveal more about a writer's thought processes, emotional states, and intentions. For LIWC features, we use the same word categories described in the Linguistic Accommodation Section below to train our LIWC-based classifier. Specifically, we use LIWC to process each utterance. Next, each utterance's LIWC scores are averaged together to form a dialogue-specific feature vector. We experiment with LIWC features variants: human-only, unknown-only, and human-unknown. Each setting averages the LIWC scores across a different set of utterances, similar to the bag-of-words and embedding features.

Linguistic Accommodation. We use the method

---

[4] We use the bert-base-uncased pre-trained model available in the HuggingFace package (Wolf et al., 2019).

proposed by Danescu-Niculescu-Mizil et al. (2011) to analyze linguistic alignment. It includes two primary group-level and conversation-level measures: baseline word usage and alignment. The group-level baseline word use corresponds to the rate at which a person uses a given *word category* when it has not been used previously in a conversation. The group-level alignment score reflects the proportionate increase—compared to the baseline score—in the likelihood of the word being used when it has been used previously in the conversation. Similarly, the conversation-level metrics measure accommodation and usage between a human and Unknown (bot or human) user in the each dialogue D_i. We measure the probability of seeing a word category (e.g., LIWC categories) w_c given w_c appeared in the previous utterance $P(w_c \in u_i^o | w_c \in u_{i-1}^h)$[5] and the baseline probability of seeing w_c in the conversation $P(w_c \in u_i^o)$. Next, the accommodation score is calculated by taking the difference between both probabilities, $acc(c) = P(w_c \in u_i^o | w_c \in u_{i-1}^h) - P(w_c \in u_i^o)$. These empirical probabilities are at the conversation level (i.e., measuring how two specific users align). To obtain the group-level estimates, we simply average the accommodation scores $acc(c)$ over all conversations D_i for each word category. We use the following 17 LIWC categories (Pennebaker et al., 2015): i, you, we, they, social, cogproc, posemo, negemo, article, prep, certain, conj, discrep, negate, pronoun, quant, and tentat. We experiment with two main settings as described for the previous methods: Human-Only, Unknown-Only. The Human-Only setting consists of just using the known human's alignment scores in each conversation and vice-versa for the Unknown-Only setting.

Model Training Details. For the content feature sets, we train a Logistic Regression classifier from the Scikit-Learn package (Pedregosa et al., 2011). Using the validation split for each dataset, we grid-search over the C-values {.0001, .001, .01, .1, 1., 10.}, the logistic regression class weight parameters {None, balanced}, and normalization procedures {standardize, unit normalize, None}. For the Stylistic features, we train a Random Forest classifier from the Scikit-Learn package. Again, using the validation split, we grid-search over the class weight parameters {None, balanced, balanced_subsample}, criterion measures {gini, entropy}, max features {sqrt, log2, None}, and bootstrap parameters {True, False}. For all experiments using the Random Forest classifier, we set n_estimators to 1000.

Table 2: Source → Source Macro F1 Results for Bot Detection

5 Results

In this section, we report two sets of results. First, in Subsection 5.1 we present the performance of the bot detection models we explain in Section 4. Beyond the methods described in Section 4, we also compare three baselines: Most Frequent, Most Infrequent, and Stratified. The Most Frequent baseline predicts the most frequent class for every example (i.e., human-human). The Most Infrequent baseline predicts the most infrequent class (i.e., human-bot) and the Stratified baseline makes random prediction proportional to each class's frequency. Second, in Subsection 5.2, we present a fine-grained analysis of the linguistic accommodation results on the ConvAI2 datasets. For all results, we report the Macro F1 (average F1 for the human-human and human-bot conversation classes).

5.1 Bot Detection Experiments

The source dataset results are reported in Table 2. Overall, we find that content features are the most

Table 3: This table reports the cross-dataset Macro F1 score for detecting human-bot conversations for three datasets: Unpaid (U), Paid (P), and Control (C). The largest Macro F1 score in each column is in **bold**.

predictive for bot detection, when training and testing on the same train-test splits from the same dataset. Furthermore, we find that the BERT-based models are able to outperform the Bag-of-Words models on average. For instance, the Human Bag-of-Words model on dataset C obtains an F1 of .939. Yet, the Human BERT model obtains an F1 of .987. Likewise, for the stylistic features, we find that simply using LIWC works better than using the accommodation features alone for dataset C. However, combining both Accommodation and LIWC features from both the Human and the Bot is better than using either feature set individually with an F1 of .729.

The cross-dataset bot detection results are presented in Table 3. Specifically, the scores are from experiments where we train on a source dataset and evaluate each model on a target dataset's test split (i.e., source → target). Overall, we make three major findings. First, for both Content and Stylistic features, we find that analyzing the known human's language in each conversation is more informative than analyzing the bot's content. For instance, the average (AVG) score for human bag-of-words is .541, while the bot bag-of-words model AVG result is nearly 4% lower (.499). We have similar findings between human LIWC (.502) and bot LIWC (.478). We find that combining both bot and human LIWC improves the AVG performance of the human-only LIWC model with an F1 of 0.528. Second, while the BERT-based model performs better when applied to data from the same datasets in Table 2 (e.g., U → U) in many settings, when the test dataset changes substantially (e.g., U → C), the generalization performance of BERT drops compared to using bag-of-words. This result is potentially caused by overfitting to random source-specific characteristics. Third, we find that Accommodation features outperform all other individual feature sets with an AVG bot-detection Macro F1 of .584, with the exception of using both the human's and bot's accommodation features which has a Macro F1 of .637. Interestingly, human accommodation information (.584) is more predictive than the bot's text (.462). Intuitively, the type of responses generated by a bot can differ substantially depending on the bot's training data (e.g., ConvAI2 vs. DailyDialog) and model (e.g., transformer vs. retrieval-based models). Hence, the human's responses are more consistent with regard to alignment. The best combination overall is the combination of the human's LIWC features with the human's accommodation features achieving a Macro F1 of .660. Yet, with the bot (Unknown) feature combination, the performance drops from .768 with Unknown LIWC to .674 after combining accommodation features.

In Table 4, we analyze the Random Forest's importance scores for the best model (trained on dataset P's human responses) features using the model that combines human LIWC and accommo-

dation features. The most informative feature is pronoun accommodation. See Section 6 for more details. Other informative features include the human's use of social, quant (quantitative), and tentative words.

5.2 Accommodation Analysis

In this section, we analyze the group-level (averaged) accommodation scores for the INTERMEDIATE and TickTock datasets. Again, note that the group-level scores are dataset averages for each group (human and bot), the conversation-level estimates can vary from the group scores. The accommodation analysis is displayed in Figure 2. The bot results (Figures 2d and 2b) indicate how the bot responds to a human, and the human scores (Figures 2c and 2a) represent how a human responds to a bot. We report all LIWC categories, including Pronoun usage (e.g., pronoun, I, you, we, and they) and Rhetorical words (e.g., social, cogproc, posemo, and negemo) results. Find the analysis for all of the datasets in the Supplementary Material.

Overall, some indicators are robust across datasets, whereas others can vary. For instance, for the general pronoun category, we find that human generally accommodate less towards bots than bots accommodate towards them. The pronoun accommodation pattern for pronouns is robust across both datasets. Similarly, for both datasets, humans accomodate more often than bots for social words. Yet, for negative emotion words (negemo), we find that Bot's accommodate less than humans in the TickTock dataset, yet they accommodate more in the INTERMEDIATE dataset. In contrast, in the ConvAI2 and DailyDialog datasets, human accommodation is the same *on average* when two humans participate in a conversation together (not shown in the Figures).

6 Discussion

Why is humans' accommodation such a powerful predictor that they are in a conversation with a bot—even when they are supposedly treating the conversation the same as a human-human interaction? Overall, we found two major reasons to explain the model's high performance. First, modern bots from the transformer to retrieval-based models generate bad responses. For instance, in the conversation below from the VOLUNTEER dataset, the human and bot have already had a conversation about hair color:

```
Bot:   What is your hair color?
Human: I said its black....
Bot:   I know the feeling.
Human: What?
```

From the example, we can see that the bot is asking about hair color, which was already discussed, then the bot responds with a nonsensical output, "I know the feeling." Thus, we see that the final human response does not accommodate with with"I" nor any first singular pronoun. The lower alignment score for humans (compared to bots) for the word category I in Figure 2 supports this finding. Furthermore, from Table 4, we know that accommodation in terms of pronoun usage is highly predictive of a human-bot conversation. Similar posts can be found in all datasets where bad outputs can explain why humans align differently concerning "I" in bot-human interactions than human-human interactions. This finding is interesting because it is similar to the findings in human-human interactions where alignment is positively correlated with understanding in cooperative decision-making tasks (Fusaroli et al., 2012; Kacewicz et al., 2014). If humans don't understand the conversation, they align less, at least with regards to pronoun usage in our case. The next example from the VOLUNTEER dataset is a better, more coherent conversation:

```
Human: What is your Hobby?
Bot:   I love music! I love Taylor Swift
Human: Me too. And what about Iggy Pop?
```

We can see that the final human response aligns with the first person singular word "me" to the bot's use of "I". A potential use that warrants future work in the area of bots evaluation involves using accommodation information as an additional evaluation metric in human evaluation studies if certain types of accommodation correlate with bad system responses. If human ratings of bot performance are noisy, the use of accomodation information can provide insight into how well a bot performs, if a human interacts with it differently than they do in human-human conversations.

The second reason for the significant predictive performance can be seen in adversarial conversations between the human and bot. Specifically, in instances where the human is trying to trick the bot or simply trying to ask questions, bot-human alignment can differ from human-human conversations. The example below from the TickTock dataset

```
Human: Are you a robot?
Bot:   No.
Human: Where are you from?
```

shows repeated "*You*" usage by the user, repeatedly asking multiple questions. Again, differences in pronoun usage can reflect adversarial users. Again, in terms of bot evaluation, if a human is acting adversarially, and it is possible to differentiate adversarial interactions from the human not understanding, this can provide insight into . More examples can be found in the Supplementary Material.

7 Conclusion

This study has is an exploration of the levels of linguistic alignment in human-bot conversations and presents evidence about how bot-human interactions are different than human-human conversations. This work's insights have implications for future bot detection methodologies. How humans and bots come together and converse manifested by their level of agreement and disagreement is a first step towards understanding human interactions with general conversational agents. Furthermore, as future work, we will explore the use of linguistic alignment to improve bot evaluation frameworks involving human-bot interactions. Moreover, we will also explore methods of controlling the accommodation level of bots themselves. Given the implicit social implications of certain types of accommodation, controlling it can help important tasks (e.g., counseling or customer service-related bots).

A Expanded Alignment Analysis

The complete group-level alignment scores for the IRIS and Tolokers datasets can be found in Figures 3a, 3b, 3c, and 3d.

B Example Conversations

Here we present examples of conversations between humans and bots that are representative of good conversational structure in terms of alignment between the two parties such as the usage of pronoun "*I*" in the first example.

```
Bot:   I love iphone!
       i just bought new iphone!
Human: Thats good for you  i m not
       very into new tech
```

```
Human: I am fine. I like hip hop.
       What about you?
Bot:   I like r b and pop
       are you 100 years old?
Human: What? No. You are rude
```

```
Human: Do you have dogs?
Bot:   Yes  i have two dogs  and a cat.
Human: Cool  I love dogs.
       But i have siblings instead...
Bot:   I have two brothers and
       a sister  and a sister.
```

Here conversations between humans and bots involve irregular pronoun usage that are representative of a break in the conversational pattern and little or no alignment between the two parties such as the usage of pronouns "*You*" and resultant use of "*I*" reply in the first example.

```
Human: See you then!
Bot:   I m not going to see you.
```

```
Bot:   I am 24 and I have a dog named
       her name is named name
Human: Really her name is name?
Bot:   She is a good name.
```

```
Human: who is obama
Bot:   i partially have interest in that
Human: can you tell me more about obama
Bot:   i hate pigs i live a farm
```

These conversations signify a complete breakdown of conversational structure with respect to alignment, as there is none. The chats seem haphazard and vague with either the bot or the human replying in an ambiguous manner.

```
User:   Good afternoon
System: Well  you know  I'm not sure.
        What do you think about movies
User:   That didn't make any sense
```

```
User:   hi again
System: Of course. Any thoughts?
User:   no
```

```
User:   Hello
System: Do not argue with an idiot.
        He will drag you down to his
        level and beat you with
        experience.
User:   Um  Okay  that was random
```

Abstract

Pre-trained contextualized language models (PrLMs) have led to strong performance gains in downstream natural language understanding tasks. However, PrLMs can still be easily fooled by adversarial word substitution, which is one of the most challenging textual adversarial attack methods. Existing defence approaches suffer from notable performance loss and complexities. Thus, this paper presents a compact and performance-preserved framework, **A**nomaly **D**etection with **F**requency-**A**ware **R**andomization (ADFAR). In detail, we design an auxiliary anomaly detection classifier and adopt a multi-task learning procedure, by which PrLMs are able to distinguish adversarial input samples. Then, in order to defend adversarial word substitution, a frequency-aware randomization process is applied to those recognized adversarial input samples. Empirical results show that ADFAR significantly outperforms those newly proposed defense methods over various tasks with much higher inference speed. Remarkably, ADFAR does not impair the overall performance of PrLMs. The code is available at https://github.com/LilyNLP/ADFAR.

1 Introduction

Deep neural networks (DNNs) have achieved remarkable success in various areas. However, previous works show that DNNs are vulnerable to adversarial samples (Goodfellow et al., 2015; Kurakin et al., 2017; Wang et al., 2021), which are inputs with small, intentional modifications that cause the model to make false predictions. Pre-trained language models (PrLMs) (Devlin et al., 2019; Liu et al., 2019; Clark et al., 2020; Zhang et al., 2020, 2019) are widely adopted as an essential component for various NLP systems. However, as DNN-based models, PrLMs can still be easily fooled by textual adversarial samples (Wallace et al., 2019; Jin et al., 2019; Nie et al., 2020; Zang et al., 2020). Such vulnerability of PrLMs keeps raising potential security concerns, therefore researches on defense techniques to help PrLMs against textual adversarial samples are imperatively needed.

Different kinds of textual attack methods have been proposed, ranging from character-level word misspelling (Gao et al., 2018), word-level substitution (Alzantot et al., 2018; Ebrahimi et al., 2018; Ren et al., 2019; Jin et al., 2019; Zang et al., 2020; Li et al., 2020; Garg and Ramakrishnan, 2020), phrase-level insertion and removal (Liang et al., 2018), to sentence-level paraphrasing (Ribeiro et al., 2018; Iyyer et al., 2018). Thanks to the discrete nature of natural language, attack approaches that result in illegal or unnatural sentences can be easily detected and restored by spelling correction and grammar error correction (Islam and Inkpen, 2009; Sakaguchi et al., 2017; Pruthi et al., 2019). However, attack approaches based on adversarial word substitution can produce high-quality and efficient adversarial samples which are still hard to be detected by existing methods. Thus, the adversarial word substitution keeps posing a larger and more profound challenge for the robustness of PrLMs. Therefore, this paper is devoted to overcome the challenge posed by adversarial word substitution.

Several approaches are already proposed to mitigate issues posed by adversarial word substitution (Zhou et al., 2019; Jia et al., 2019; Huang et al., 2019; Cohen et al., 2019; Ye et al., 2020; Si et al., 2021). Although these defense methods manage to alleviate the negative impact of adversarial word

substitution, they sometimes reduce the prediction accuracy for non-adversarial samples to a notable extent. Given the uncertainty of the existence of attack in real application, it is impractical to sacrifice the original prediction accuracy for the purpose of defense. Moreover, previous defense methods either have strong limitations over the attack space to certify the robustness, or require enormous computation resources during training and inference. Thus, it is imperatively important to find an efficient performance-preserved defense method.

For such purpose, we present a compact and performance-preserved framework, **A**nomaly **D**etection with **F**requency-**A**ware **R**andomization (ADFAR), to help PrLMs defend against adversarial word substitution without performance sacrifice. Xie et al. (2018) show that introducing randomization at inference can effectively defend adversarial attacks. Moreover, (Mozes et al., 2020) indicate that the usual case for adversarial samples is replacing words with their less frequent synonyms, while PrLMs are more robust to frequent words. Therefore, we propose a frequency-aware randomization process to help PrLMs defend against adversarial word substitution.

However, simply applying a randomization process to all input sentences would reduce the prediction accuracy for non-adversarial samples. In order to preserve the overall performance, we add an auxiliary anomaly detector on top of PrLMs and adopt a multi-task learning procedure, by which PrLMs are able to determine whether each input sentence is adversarial or not, and not introduce extra model. Then, only those adversarial input sentences will undergo the randomization procedure, while the prediction process for non-adversarial input sentences remains the same.

Empirical results show that as a more efficient method, ADFAR significantly outperforms previous defense methods (Ye et al., 2020; Zhou et al., 2019) over various tasks, and preserves the prediction accuracy for non-adversarial sentences. Comprehensive ablation studies and analysis further prove the efficiency of our proposed method, and indicate that the adversarial samples generated by current heuristic word substitution strategy can be easily detected by the proposed auxiliary anomaly detector.

2 Related Work

2.1 Adversarial Word Substitution

Adversarial word substitution (AWS) is one of the most efficient approaches to attack advanced neural models like PrLMs. In AWS, an attacker deliberately replaces certain words by their synonyms to mislead the prediction of the target model. At the same time, a high-quality adversarial sample should maintain grammatical correctness and semantic consistency. In order to craft efficient and high-quality adversarial samples, an attacker should first determine the vulnerable tokens to be perturbed, and then choose suitable synonyms to replace them.

Current AWS models (Alzantot et al., 2018; Ebrahimi et al., 2018; Ren et al., 2019; Jin et al., 2019; Li et al., 2020; Garg and Ramakrishnan, 2020) adopt heuristic algorithms to locate vulnerable tokens in sentences. To illustrate, for a given sample and a target model, the attacker iteratively masks the tokens and checks the output of the model. The tokens which have significant influence on the final output logits are regarded as vulnerable.

Previous works leverage word embeddings such as GloVe (Pennington et al., 2014) and counter-fitted vectors (Mrkšić et al., 2016) to search the suitable synonym set of a given token. Li et al. (2020); Garg and Ramakrishnan (2020) uses BERT (Devlin et al., 2019) to generate perturbation for better semantic consistency and language fluency.

2.2 Defense against AWS

For general attack approaches, adversarial training (Goodfellow et al., 2015; Jiang et al., 2020) is widely adopted to mitigate adversarial effect, but (Alzantot et al., 2018; Jin et al., 2019) shows that this method is still vulnerable to AWS. This is because AWS models leverage dynamic algorithms to attack the target model, while adversarial training only involves a static training set.

Methods proposed by Jia et al. (2019); Huang et al. (2019) are proved effective for defence against AWS, but they still have several limitations. In these methods, Interval Bound Propagation (IBP) (Dvijotham et al., 2018), an approach to consider the worst-case perturbation theoretically, is leveraged to certify the robustness of models. However, IBP-based methods can only achieve the certified robustness under a strong limitation over the attack space. Furthermore, they are difficult to adapt to PrLMs for their strong reliance on the assumption

of model architecture.

Two effective and actionable methods (DISP (Zhou et al., 2019) and SAFER Ye et al. (2020)) are proposed to overcome the challenge posed by AWS, and therefore adopted as the baselines for this paper. DISP (Zhou et al., 2019) is a framework based on perturbation discrimination to block adversarial attack. In detail, when facing adversarial inputs, DISP leverages two auxiliary PrLMs: one to detect perturbed tokens in the sentence, and another to restore the abnormal tokens to original ones. Inspired by randomized smoothing (Cohen et al., 2019), Ye et al. (2020) proposes SAFER, a novel framework that guarantees the robustness by smoothing the classifier with synonym word substitution. To illustrate, based on random word substitution, SAFER smooths the classifier by averaging its outputs of a set of randomly perturbed inputs. SAFER outperforms IBP-based approaches and can be easily applied to PrLMs.

2.3 Randomization

In recent years, randomization has been used as a defense measure for deep learning in computer vision (Xie et al., 2018). Nevertheless, direct extensions of these measures to defend against textual adversarial samples are not achievable, since the text inputs are discrete rather than continuous. Ye et al. (2020) indicates the possibility of extending the application of the randomization approach to NLP by randomly replacing the words in sentences with their synonyms.

3 Method

3.1 Frequency-aware Randomization

Since heuristic attack methods attack a model by substituting each word iteratively until it successfully alters the model's output, it is normally difficult for static strategies to defense such kind of dynamic process. Rather, dynamic strategies, such as randomization, can better cope with the problem. It is also observed that replacing words with their more frequent alternatives can better mitigate the adversarial effect and preserve the original performance. Therefore, a frequency-aware randomization strategy is designed to perplex AWS strategy.

Figure 1 shows several examples of the frequency-aware randomization. The proposed approach for the frequency-aware randomization is shown in Algorithm 1, and consists of three steps. Firstly, rare words with lower frequencies and a number of random words are selected as substitution candidates. Secondly, we choose synonyms with the closest meanings and the highest frequencies to form a synonym set for each candidate word. Thirdly, each candidate word is replaced with a random synonym within its own synonym set. To quantify the semantic similarity between two words, we represent words with embeddings from (Mrkšić et al., 2016), which is specially designed for synonyms identification. The semantic similarity of two words are evaluated by cosine similarity of their embeddings. To determine the frequency of a word, we use a frequency dictionary provided by FrequencyWords Repository[*].

3.2 Anomaly Detection

Applying the frequency-aware randomization process to every input can still reduce the prediction accuracy for normal samples. In order to overcome this issue, we add an auxiliary anomaly detection head to PrLMs and adopt a multi-task learning procedure, by which PrLMs are able to classify the input text and distinguish the adversarial samples at the same time, and not introduce extra model. In inference, the frequency-aware randomization only applied to the samples that are detected as adversarial. In this way, the reduction of accuracy is largely avoided, since non-adversarial samples are not affected.

Zhou et al. (2019) also elaborates the idea of perturbation discrimination to block attack. However, their method detects anomaly on token-level and requires two resource-consuming PrLMs for detection and correction, while ours detects anomaly on sentence-level and requires no extra models. Com-

Algorithm 1 Frequency-aware Randomization

```
Input: Sentence $X = \{w_1, w_2, ..., w_n\}$, word embeddings $Emb$ over the vocabulary $Vocab$
Output: Randomized sentence $X_{rand}$
Initialization: $X_{rand} \leftarrow X$
Create a set $W_{rare}$ of all rare words with frequencies less than $f_{thres}$, denote $n_{rare} = |W_{rare}|$.
Create a set $W_{rand}$ by randomly selecting $n * r - n_{rare}$ words $w_j \notin W_{rare}$, where $r$ is the pre-defined ratio of substitution.
Create the substitution candidates set, $W_{sub} \leftarrow W_{rare} + W_{rand}$, and $|W_{sub}| = n * r$.
Filter out the stop words in $W_{sub}$.
for each word $w_i$ in $W_{sub}$ do
    Create a set $S$ by extracting the top $n_s$ synonyms using $CosSim(Emb_{w_i}, Emb_{w_{word}})$ for each word in $Vocab$.
    Create a set $S_{freq}$ by selecting the top $n_f$ frequent synonyms from $S$.
    Randomly choose one word $w_s$ from $S$.
    $X_{rand} \leftarrow$ Replace $w_i$ with $w_s$ in $X_{rand}$.
end for
```

pared to Zhou et al. (2019), our method is two times faster in inference speed and can achieve better accuracy for sentence-level anomaly detection.

3.3 Framework

In this section, we elaborate the framework of ADFAR in both training and inference.

3.3.1 Training

Figure 2 shows the framework of ADFAR in training. We extend the baseline PrLMs by three major modifications: 1) the construction of training data, 2) the auxiliary anomaly detector and 3) the training objective, which will be introduced in this section.

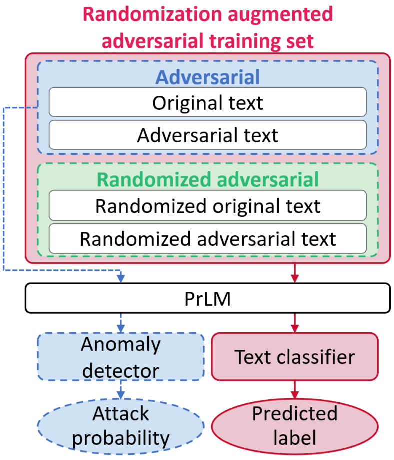

Figure 2: Framework of ADFAR in training.

Construction of Training Data As shown in Figure 2, we combine the idea of both adversarial training and data augmentation (Wei and Zou, 2019) to construct our randomization augmented adversarial training data. Firstly, we use a heuristic AWS model (e.g. TextFooler) to generate adversarial samples based on the original training set. Following the common practice of adversarial training, we then combine the adversarial samples with the original ones to form an adversarial training set. Secondly, in order to let PrLMs better cope with randomized samples in inference, we apply the frequency-aware randomization on the adversarial training set to generate a randomized adversarial training set. Lastly, the adversarial training set and the randomized adversarial training set are combined to form a randomization augmented adversarial training set.

Auxiliary Anomaly Detector In addition to the original text classifier, we add an auxiliary anomaly detector to the PrLMs to distinguish adversarial samples. For an input sentence, the PrLMs captures the contextual information for each token by self-attention and generates a sequence of contextualized embeddings $\{h_0, \ldots h_m\}$. For text classification task, $h_0 \in R^H$ is used as the aggregate sequence representation. The original text classifier leverages h_0 to predict the probability that X is labeled as class $\hat{y_c}$ by a logistic regression with softmax:

$$
\begin{aligned}
y_c &= Prob(\hat{y_c}|x), \\
&= \mathrm{softmax}(W_c(dropout(h_0)) + b_c),
\end{aligned}
$$

For the anomaly detector, the probability that X is labeled as class $\hat{y_d}$ (if X is attacked, $\hat{y_d} = 1$; if X is normal, $\hat{y_d} = 0$) is predicted by a logistic regression with softmax:

$$
\begin{aligned}
y_d &= Prob(\hat{y_d}|x), \\
&= \mathrm{softmax}(W_d(dropout(h_0)) + b_d),
\end{aligned}
$$

As shown in Figure 2, the original text classifier is trained on the randomization augmented adversarial training set, whereas the anomaly detector is only trained on the adversarial training set.

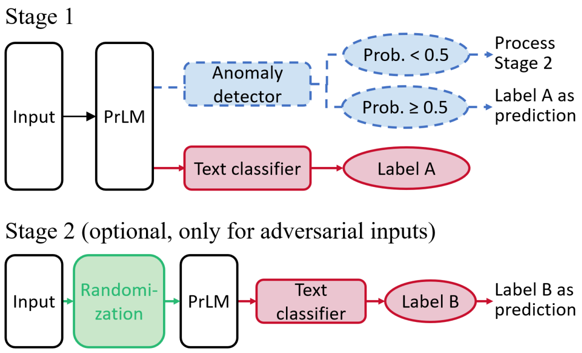

Figure 3: Framework of ADFAR in inference.

Training Objective We adopt a multi-task learning framework, by which PrLM is trained to classify the input text and distinguish the adversarial samples at the same time. We design two parallel training objectives in the form of minimizing cross-entropy loss: $loss_c$ for text classification and $loss_d$ for anomaly detection. The total loss function is defined as their sum:

$$loss_c = -[y_c * \log(\hat{y_c}) + (1 - y_c) * \log(1 - \hat{y_c})]$$
$$loss_d = -[y_d * \log(\hat{y_d}) + (1 - y_d) * \log(1 - \hat{y_d})]$$
$$Loss = loss_c + loss_d$$

3.3.2 Inference

Figure 3 shows the framework of ADFAR in inference. Firstly, the anomaly detector predicts whether an input sample is adversarial. If the input sample is determined as non-adversarial, the output of the text classifier (Label A) is directly used as its final prediction. If the input sample is determined as adversarial, the frequency-aware randomization process is applied to the original input sample. Then, the randomized sample is sent to the PrLM again, and the second output of the text classifier (Label B) is used as its final prediction.

4 Experimental Implementation

4.1 Tasks and Datasets

Experiments are conducted on two major NLP tasks: text classification and natural language inference. The dataset statistics are displayed in Table 1. We evaluate the performance of models on the non-adversarial test samples as the original accuracy. Then we measure the after-attack accuracy of models when facing AWS. By comparing these two accuracy scores, we can evaluate how robust the model is.

Task	Dataset	Train	Test	Avg Len
Classification	MR	9K	1K	20
	SST2	67K	1.8K	20
	IMDB	25K	25K	215
Entailment	MNLI	433K	10K	11

Table 1: Dataset statistics.

Text Classification We use three text classification datasets with average text lengths from 20 to 215 words, ranging from phrase-level to document-level tasks. **SST2** (Socher et al., 2013): phrase-level binary sentiment classification using fine-grained sentiment labels on movie reviews. **MR** (Pang and Lee, 2005): sentence-level binary sentiment classification on movie reviews. We take 90% of the data as training set and 10% of the data as test set as (Jin et al., 2019). **IMDB** (Maas et al., 2011): document-level binary sentiment classification on movie reviews.

Natural Language Inference NLI aims at determining the relationship between a pair of sentences based on semantic meanings. We use Multi-Genre Natural Language Inference (**MNLI**) (Nangia et al., 2017), a widely adopted NLI benchmark with coverage of transcribed speech, popular fiction, and government reports.

4.2 Attack Model and Baselines

We use TextFooler[†](Jin et al., 2019) as the major attack model for AWS. Moreover, we implement (Ren et al., 2019) and GENETIC (Alzantot et al., 2018) based on the TextAttack (Morris et al., 2020) code base to further verify the efficiency of our proposed method.

We compare ADFAR with DISP (Zhou et al., 2019) and SAFER (Ye et al., 2020). The implementation of DISP is based on the repository offered by Zhou et al. (2019). For SAFER, we also leverage the code proposed by Ye et al. (2020). Necessary modifications are made to evaluate these methods' performance under heuristic attack models.

4.3 Experimental Setup

The implementation of PrLMs is based on PyTorch[‡]. We leverage, BERT$_{\text{BASE}}$ (Devlin et al., 2019), RoBERTa$_{\text{BASE}}$ (Liu et al., 2019) and ELECTRA$_{\text{BASE}}$ (Clark et al., 2020) as baseline

Table 2: The performance of ADFAR and other defense frameworks using BERT$_{\text{BASE}}$ as PrLM and TextFooler as attack model. Orig. Acc. is the prediction accuracy of normal samples and Adv. Acc. is the after-attack accuracy of models when facing AWS. The results are based on the average of five runs.

PrLMs. We use AdamW (Loshchilov and Hutter, 2018) as our optimizer with a learning rate of 3e-5 and a batch size of 16. The number of epochs is set to 5.

For the frequency-aware randomization process, we set $f_{thres} = 200$, $n_s = 20$ and $n_f = 10$. In the adopted frequency dictionary, 5.5k out of 50k words have a frequency lower than $f_{thres} = 200$ and therefore regarded as rare words. r is set to different values for training (25%) and inference (30%) due to different aims. In training, to avoid introducing excessive noise and reduce the prediction accuracy for non-adversarial samples, r is set to be relatively low. On the contrary, in inference, our aim is to perplex the heuristic attack mechanism. The more randomization we add, the more perplexities the attack mechanism receives, therefore we set a relatively higher value for r. More details on the choice of these hyperparameters will be discussed in the analysis section.

5 Experimental Results

5.1 Main results

Following (Jin et al., 2019), we leverage BERT$_{\text{BASE}}$ (Devlin et al., 2019) as baseline PrLM and TextFooler as attack model. Table 2 shows the performance of ADFAR and other defense frameworks. Since randomization may lead to a variance of the results, we report the results based on the average of five runs. Experimental results indicate that ADFAR can effectively help PrLM against AWS. Compared with DISP (Zhou et al., 2019) and SAFER (Ye et al., 2020), ADFAR achieves the best performance for adversarial samples. Meanwhile, ADFAR does not hurt the performance for non-adversarial samples in general. On tasks such as MR and IMDB, ADFAR can even enhance the baseline PrLM.

DISP leverages two extra PrLMs to discriminate and recover the perturbed tokens, which introduce extra complexities. SAFER makes the prediction of an input sentence by averaging the prediction results of its perturbed alternatives, which multiply the inference time. As shown in Table 3, compared with previous methods, ADFAR achieves a significantly higher inference speed.

Model	Parameters	Inference Time
BERT$_{\text{BASE}}$	110M	15.7ms (100%)
BERT$_{\text{BASE}}$ + DISP	330M	38.9ms (247%)
BERT$_{\text{BASE}}$ + SAFER	110M	27.6ms (176%)
BERT$_{\text{BASE}}$ + ADFAR	110M	18.1ms (115%)

Table 3: Parameters and Inference Time statistics. The inference time indicate the average inference time for one sample in MR dataset using one NVIDIA RTX3090.

5.2 Results with Different Attack Strategy

Since ADFAR leverages the adversarial samples generated by TextFooler (Jin et al., 2019) in training, it is important to see whether ADFAR also performs well when facing adversarial samples generated by other AWS models. We leverage PWWS (Ren et al., 2019) and GENETIC (Alzantot et al., 2018) to further study the performance of ADFAR.

Attack	MR		SST2	
	BERT	+ADFAR	BERT	+ADFAR
Attack-Free	86.2	86.6	93.1	92.3
PWWS	34.2	74.2	54.3	80.5
Genetic	21.3	70.4	38.7	72.2
TextFooler	16.9	66.0	39.8	73.8

Table 4: Performance of BERT and BERT with ADFAR when facing various AWS models. The results are based on the average of five runs.

As shown is Table 4, the performance of ADFAR is not affected by different AWS models, which further proves the efficacy of our method.

[¶]https://github.com/huggingface

5.3 Results with Other PrLMs

Table 5 shows the performance of ADFAR leveraging RoBERTa$_{\text{BASE}}$ (Liu et al., 2019) and ELECTRA$_{\text{BASE}}$ (Clark et al., 2020) as PrLMs. In order to enhance the robustness and performance of the PrLM, RoBERTa extends BERT with a larger corpus and using more efficient parameters, while ELECTRA applies a GAN-style architecture for pre-training. Empirical results indicate that ADFAR can further improve the robustness of RoBERTa and ELECTRA while preserving their original performance.

PrLM	MR		SST2	
	Orig. Acc.	Adv. Acc.	Orig. Acc.	Adv. Acc.
BERT	86.2	16.9	93.1	39.8
+ADFAR	86.6	66.0	92.3	73.8
RoBERTa	88.3	30.4	93.4	37.4
+ADFAR	87.2	71.0	93.2	77.6
ELECTRA	90.1	33.6	94.2	40.4
+ADFAR	90.4	71.2	95.0	83.0

Table 5: Results based with various PrLMs.

6 Analysis

6.1 Ablation Study

ADFAR leverages three techniques to help PrLMs defend against adversarial samples: adversarial training, frequency-aware randomization and anomaly detection. To evaluate the contributions of these techniques in ADFAR, we perform ablation studies on MR and SST2 using BERT$_{\text{BASE}}$ as our PrLMs, and TextFooler as the attack model. As shown in Table 6, the frequency-aware randomization is the key factor which helps PrLM defense against adversarial samples, while anomaly detection plays an important role in preserving PrLM's prediction accuracy for non-adversarial samples.

Model	MR		SST2	
	Orig. Acc.	Adv. Acc.	Orig. Acc.	Adv. Acc.
BERT	86.2	16.9	93.1	39.8
+ Adv	85.6	34.6	92.6	48.8
+ FR	85.0	72.8	90.6	82.6
+ AD	86.6	66.0	92.3	73.8

Table 6: Ablation study on MR and SST2 using BERT$_{\text{BASE}}$ as PrLM, and TextFooler as attack model. Adv represents adversarial training, FR indicates frequency-aware randomization and AD means anomaly detection. The results are based on the average of five runs.

6.2 Anomaly Detection

In this section, we compare the anomaly detection capability between ADFAR and DISP (Zhou et al., 2019). ADFAR leverages an auxiliary anomaly detector, which share a same PrLM with the original text classifier, to discriminate adversarial samples. DISP uses an discriminator based on an extra PrLMs to identify the perturbed adversarial inputs, but on token level. For DISP, in order to detect anomaly on sentence level, input sentences with one or more than one adversarial tokens identified by DISP are regarded as adversarial samples. We respectively sample 500 normal and adversarial samples from the test set of MR and SST to evaluate the performance of ADFAR and DISP for anomaly detection.

Table 7 shows the performance of ADFAR and DISP for anomaly detection. Empirical results show that ADFAR can predict more precisely, since it achieves a significantly higher F_1 score than DISP. Moreover, ADFAR has a simpler framework, as its anomaly detector shares the same PrLM with the classifier, while DISP requires an extra PrLM. The results also indicate that the current heuristic AWS strategy is vulnerable to our anomaly detector, which disproves the claimed undetectable feature of this very adversarial strategy.

Method	MR			SST2		
	Precision	Recall	F_1	Precision	Recall	F_1
DISP	68.0	92.0	73.2	59.5	94.2	72.9
ADFAR	90.1	84.0	86.9	88.0	90.0	88.9

Table 7: Performance for anomaly detection.

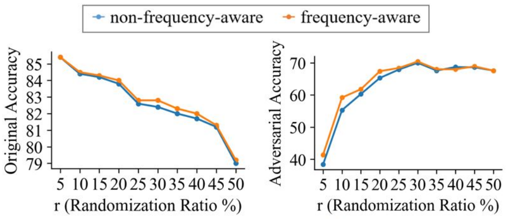
6.3 Effect of Randomization Strategy

As the ablation study reveals, the frequency-aware randomization contributes the most to the defense. In this section, we analyze the impact of different hyperparameters and strategies adopted by the frequency-aware randomization approach, in inference and training respectively.

6.3.1 Inference

The frequency-aware randomization process is applied in inference to mitigate the adversarial effects. Substitution candidate selection and synonym set construction are two critical steps during this process, in which two hyperparameters (r and n_s) and the frequency-aware strategy are examined.

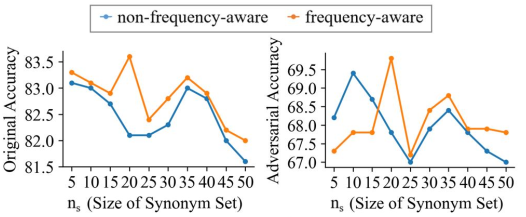
Selection of Substitution Candidates The influence of different strategies for substitution candidate selection in inference is studied in this section. The impact of two major factors are measured: 1) the substitution ratio r and 2) whether to apply a frequency-aware strategy. In order to exclude the disturbance from other factors, we train BERT on the original training set and fix n_s to 20. Firstly, we alter the value of r from 5% to 50%, without applying the frequency-aware strategy. As illustrated by the blue lines in Figure 4, as r increases, the original accuracy decreases, while the adversarial accuracy increases and peaks when r reaches 30%. Secondly, a frequency-aware strategy is added to the experiment, with $f_{thres} = 200$. As depicted by the yellow lines in Figure 4, both original and adversarial accuracy, the general trends coincide with the non-frequency-aware scenario, but overall accuracy is improved to a higher level. The highest adversarial is obtained when r is set to 30% using frequency-aware strategy.



(a) Results on normal samples (b) Results on adversarial samples

Figure 4: Effect of the substitution ratio r and the frequency-aware strategy in substitution candidate selection during inference.

Construction of Synonym Set The influence of different strategies for synonym set construction in inference is evaluated in this section. The impact of two major factors are measured: 1) the size of a single synonym set n_s and 2) whether to apply a frequency-aware strategy. In order to exclude the disturbance from other factors, we train BERT on the original training set and fix r to 30% . Firstly, we alter the value of n_s from 5 to 50, without applying the frequency-aware strategy. The resulted original and adversarial accuracy are illustrated by the blue lines in Figure 5. Secondly, a frequency-aware strategy is added to the experiment, with $n_f = 50\% * n_s$. As depicted by the yellow lines in Figure 5, the original accuracy and the adversarial accuracy both peaks when $n_s = 20$, and the overall accuracy is improved to a higher level compared to the non-frequency-aware scenario.

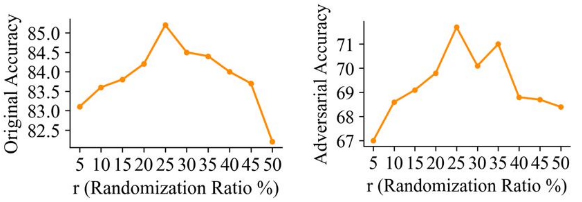


(a) Results on normal samples (b) Results on adversarial samples

Figure 5: Effect of the size of synonym set n_s and the frequency-aware strategy in construction of synonym set.

6.3.2 Training

The frequency-aware randomization process is applied in training to augment the training data, and hereby enables the PrLM to better cope with randomized samples inference. Based on this purpose, the frequency-aware randomization process in training should resemble the one in inference as much as possible. Therefore, here we set an identical process for synonym set construction, i.e. $n_s = 20$ and $n_f = 50\% * n_s$. However, for the substitution selection process, to avoid introducing excessive noise and maintain the accuracy for the PrLM, the most suitable substitution ratio r might be different than the one in inference. Experiments are conducted to evaluate the influence of r in training. We alter the value of r from 5% to 50%. In Figure 6, we observe that $r = 25\%$ results in highest original and adversarial accuracy.



(a) Results on normal samples (b) Results on adversarial samples

Figure 6: Effect of the size of synonym set n_s and the frequency-aware strategy in construction of synonym set.

7 Conclusion

This paper proposes ADFAR, a novel framework which leverages the frequency-aware randomization and the anomaly detection to help PrLMs defend against adversarial word substitution. Empirical results show that ADFAR significantly outperforms those newly proposed defense methods over various tasks. Meanwhile, ADFAR achieves a remarkably higher inference speed and does not reduce the prediction accuracy for non-adversarial sentences, from which we keep the promise for this research purpose.

Comprehensive ablation study and analysis indicate that 1) Randomization is an effective method to defend against heuristic attack strategy. 2) Replacement of rare words with their more common alternative can help enhance the robustness of PrLMs. 3) Adversarial samples generated by current heuristic adversarial word substitution models can be easily distinguished by the proposed auxiliary anomaly detector. We hope this work could shed light on future studies on the robustness of PrLMs.

BERT-Proof Syntactic Structures:
Investigating Errors in Discontinuous Constituency Parsing

Maximin Coavoux
Univ. Grenoble Alpes, CNRS, Grenoble INP, LIG
`maximin.coavoux@univ-grenoble-alpes.fr`

Abstract

The combined use of neural scoring systems and BERT fine-tuning has led to very high results in many natural language processing (NLP) tasks. These high results raise two important questions about the contribution and the limitations of pretrained-language models: (i) what are the remaining errors in the best-performing systems? (ii) what are the types of test examples where pretrained language models help the most? In this paper, we investigate both questions for the task of English discontinuous constituency parsing on the Penn Treebank, for which recent models obtain close to 95 F_1 score. To do so, we propose two methods for automatically analysing the errors of discontinuous parser. First, we annotate and release a test-suite focused on the syntactic phenomena responsible for discontinuities in the Penn Treebank, enabling us to obtain a per-phenomenon evaluation of a parser's output. Second, we extend the Berkeley Parser Analyser — a tool that classifies parsing errors according to predefined structural patterns —, to discontinuous trees. We apply both methods to characterize errors of a state-of-the-art transition-based discontinuous parser, and to provide an overview of the contribution of BERT to this task.

1 Introduction

Discontinous constituency trees are phrase-based syntactic representations where the constraint stating that a single phrase must yield a continuous sequence of tokens is lifted. Such representations are well-suited for modelling long-range dependencies, that typically arise for some syntactic phenomena, such as extractions or scrambling. For example, Figure 1 presents a discontinous VP modelling the relationship between the verb *want* and its extracted complement *How many*.

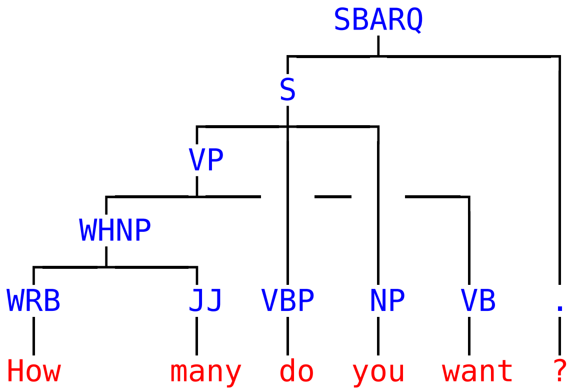

Figure 1: Discontinuous constituency tree.

In constituency treebanks, these long range dependencies are sometimes represented with typed empty categories (traces), coindexed with a displaced phrase (Marcus et al., 1993). However, projective parsers usually ignore them.[1] Indeed, the norm in Penn Treebank constituency parsing is to preprocess empty categories out of the corpus, leaving out important linguistic information.

Formally, discontinuous constituency trees interpret as derivations from mildly context-sensitive grammar formalisms, such as linear context-free rewriting systems (Vijay-Shanker et al., 1987, LCFRS) or multiple context-free grammars (Seki et al., 1991, MCFG). As a result, exact parsing of discontinuous structures has high computational complexity. For example, CKY-style parsing of an LCFRS is $\mathcal{O}(n^{3f})$ in time (Kallmeyer, 2010), where f is the fan-out of the grammar: the maximum number of spans in a grammar rule.[2]

The current state of the art for English discontinuous constituency parsing on the Discontinuous Penn Treebank has reached 94.8% F_1 score (Corro, 2020) obtained by a span-based chart parser that combines a neural scoring system and pretrained contextualized embeddings (Devlin et al., 2019,

---

[1] Except for some work on parsing traces, e.g. Gabbard et al. (2006); Kummerfeld and Klein (2017).

[2] If $f = 1$, the grammar is equivalent to a CFG.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3259–3272
August 1–6, 2021.

BERT). However, such a high score can be misleading. Despite ensuring comparability across different parsers, the exclusive use of classical evaluation metrics (F-score, precision, recall, as is standard) is hard to interpret and does not disclose information about the syntactic capabilities of a parser. In discontinuous parsing, the standard evaluator `discodop`[3] (van Cranenburgh et al., 2016) provides metrics that only focus on discontinuous constituents (discontinuous F-score, discontinuous precision, discontinuous recall). However, these scores aggregate information across many distinct syntactic phenomena.

In this paper, we propose to automatically analyse the errors of discontinuous English parsers in order to provide a fine-grained overview of their current limitations. To do so, we pursue two complementary approaches. First, we construct a test suite focused on 6 syntactic phenomena responsible for the discontinuities in the Discontinuous Penn Treebank (Evang, 2011). Second, we adopt an error-correction based approach: we search for a sequence of error-correcting tree modifications that lead from the predicted tree to the gold tree, and classify the sequence of tree modifications based on structural patterns. This is a direct extension of Berkeley Parser Analyser (Kummerfeld et al., 2012) to English discontinuous parsing.

A secondary motivation for this work is to characterize the contribution of BERT to discontinuous constituency parsing. An active current line of research consists in assessing the syntactic knowledge learned by language models (Linzen et al., 2016; Marvin and Linzen, 2018; Gulordava et al., 2018), including those with structural supervision (Kuncoro et al., 2018; Wilcox et al., 2019; Hu et al., 2020). They usually do so by constructing test items: minimal pairs of sentences, such that one is grammatical and the other is not (thus isolating a single grammatical constraint). Then, they observe whether the language model assigns higher probability to the grammatical alternative. In these papers, the observation of the syntactic ability of the models is indirect. We argue that fine-grained evaluation methods will help comparing the syntactic capabilities of parsers when they have access to BERT or not, which will provide a complementary view to this line of research. Therefore, we apply both proposed error analyses methods to a state-of-the-art transition-based discontinuous parser in several settings: without pretraining, with fast-text embeddings (Mikolov et al., 2018a; Grave et al., 2018), with BERT pretraining.

In summary, we make the following contributions:

- We construct a test-suite for automating a fine grained evaluation of English discontinuous parsers on target phenomena.
- We extend the Berkeley parser analyser to deal with English discontinuous constituency trees.
- We use these two evaluation methods to characterize the errors of a neural discontinuous parser, trained in several pretraining settings.

We provide the test suite and the error analyser as supplementary material.

2 Related Work

To address the limitations of using exclusively an F-score to evaluate constituency parsers, prior work focused on alternative finer-grained evaluation methods. We review some of them, both from the projective and discontinuous constituency parsing litterature.

Manual error analysis For discontinuous constituency parsing, Evang (2011) performed manual error analysis by extracting discontinuous trees from the evaluation corpus, classifying them according to the phenomenon at the origin of the discontinuities, and manually checking if a PLCFRS chart-parser recognized them. Coavoux et al. (2019) used the same strategy to evaluate a neural transition-based discontinuous parser. However, manual error analysis is quite time-consuming and needs to be performed again for evaluating each new parser output. Thus, it is difficult to integrate it in an evaluation pipeline or to deploy it for many parsers.

Automatic error analysis Kummerfeld et al. (2012) introduced a method that consists in searching for a sequence of atomic tree-modifications (such as: inserting a node, removing a node, moving a node) that leads from a predicted constituency tree to the gold tree. Then, they classify the tree modifications according to predefined structural patterns, e.g., 'PP-attachment', 'NP-attachment', 'labelling error'. Their method led to identify most frequent patterns of error, and characterize the improvement obtained with techniques such as reranking. However, the structural patterns used to clas-

---

[3] `https://github.com/andreasvc/disco-dop/`

sify mistakes depend both on the language of the treebank and on its annotation strategies. Therefore, error patterns need to be designed when adapting the error analyser to another treebank (Kummerfeld et al., 2013). Moreover, their method and software do not handle discontinuous constituents, hence our proposal.

Targeted evaluation Another line of work on fine-grained parser evaluation focused on specific structures or phenomena. Ratnaparkhi et al. (1994) introduced a collection of English sentences with PP-attachment ambiguities, in order both to improve evaluation on this type of structure, and foster research on improving their resolution. Kübler et al. (2009) introduced a test suite for German that encompasses a wider range of syntactic structures (such as coordination of unlike constituents or extraposed relative clauses). However, they focus on projective constituency representations.

For discontinuous structures, Maier et al. (2014) released `discosuite`, a testsuite for German. They annotated a set of sentences from the Tiger corpus (Brants et al., 2004), with the syntactic phenomena responsible for the tree discontinuities. They released their annotations, such that researchers can run their parsers on the sentences and compute a per-phenomenon evaluation of the parser. To the best of our knowledge, such a test suite only exists for German. In this article, we introduce one for English, along with an evaluation script that provides per-phenomenon statistics.

We focus our analysis on English, since the resources we introduce are for this language. However, we also provide results on German using `discosuite`.

3 Test Suite Annotation

This section describes our methodology to annotate a set of discontinuous constituency trees with the syntactic phenomena responsible for the discontinuities. We first extract all discontinuous trees from the validation section of the discontinuous version of the Penn Treebank (Evang, 2011; Evang and Kallmeyer, 2011), except those for which the discontinuities are only due to punctuation attachment. We obtain 266 trees, which corresponds to 16% of the corpus. Then, we manually assign one or several categories from the following set, previously proposed for manual error analysis by Evang (2011) and reused by Coavoux et al. (2019). We provide an example sentence from the corpus for each category, with the main discontinuous constituent highlighted in bold:

1. *wh*-extraction: *[. . .] the most recent period* ***for which*** *results were* ***broken out*** *[. . .]*
2. circumpositioned quotation: ***While Mayor Norman found the market's performance Monday reassuring,*** *he says,* ***he remains uneasy.***
3. fronted quotations: ***The proposed changes "all make a lot of sense to me,"*** *he* ***added.***
4. *it*-extraposition: *While* ***it*** *is possible* ***that the Big Green initiative will be ruled unconstitutional*** *[. . .]*
5. discontinuous dependencies: *[. . .] provided little help for copper as* ***word*** *spread* ***that a three-month strike at the Highland Valley mine in British Columbia was about over*** *[. . .]*
6. subject-verb inversion: ***Added*** *another executive at a big bank:* ***"We were all a little goosey over the weekend trying to forecast what would happen Monday, but it's been very quiet.***

There are several subtypes of *wh*-extractions in the data: relative clauses, verbal adjunct clauses, complement clauses, indirect and direct questions. They all include a *wh* word among *how, when, which, that, where, what, why, whenever*. Circumpositioned and fronted phrases only include quotations, and systematically feature a speech verb, usually *says* or *said*. *It*-extrapositions feature an expletive *it* in the interpretation location of an extraposed clausal argument. The category of discontinuous dependencies contains other cases where a constituent is split by an intervening phrase. It mostly includes extraposed modifiers, such as the extraposed clause in example 5 above,

Not all occurrences of these phenomena result in a discontinuous tree (Evang, 2011). For example, a sentence containing both a fronted quotation and a subject-verb inversion will not result in a discontinuity. In some trees, there are also several occurrences of phenomena producing discontinuities. We release these annotations as a csv file, provided as supplementary material.

Per-phenomenon evaluation method In order to obtain a per-phenomenon evaluation of the predictions of discontinuous parsers, we first extract individual evaluations for each discontinuous tree, as provided by the standard evaluator for discontinuous parsing (van Cranenburgh et al., 2016, dis-

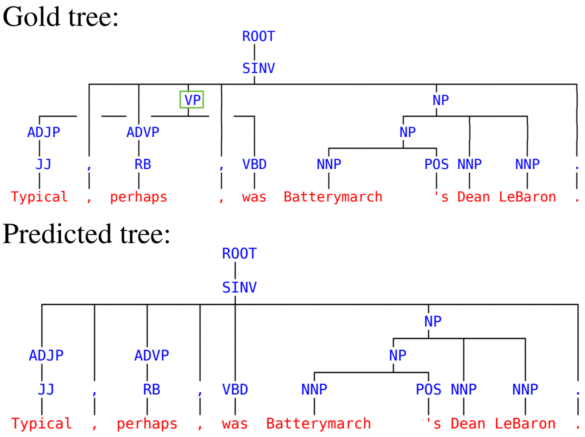

Figure 2: Error correction: add a missing node.

codop). These include the number of gold, correct, and incorrect discontinuous constituents, both in the labelled and unlabelled case.[4]

We consider that the annotated target phenomenon on the sentence is perfectly predicted if the sentence discontinuous F-score is 100, and partially predicted if it is > 0. As such, this evaluation is recall-oriented: we focus on how well the gold phenomena are predicted, but we do not take into account false positives (which would require us to assign a phenomenon to predicted trees with incorrect discontinuous constituents).

4 Error-Correction-Driven Analyser

We now focus on automatically classifying errors according to structural patterns. To do so, we build on Kummerfeld et al. (2012) and proceed in two steps: (i) finding a sequence of atomic tree modifications that transforms a predicted tree to the corresponding gold tree; (ii) classifying steps in the transformation sequence according to predefined structural patterns. For step (i), we use a greedy search algorithm, that first corrects errors on discontinuous nodes, and then backoffs to Kummerfeld et al. (2012)'s method for projective error correction. Thus, we focus in this section on *discontinuous* error corrections.

We use 4 atomic tree modifications:

i change label of discontinuous node;
ii create a discontinuous node;
iii delete a discontinuous node;
iv move a node, resulting in a discontinuity.

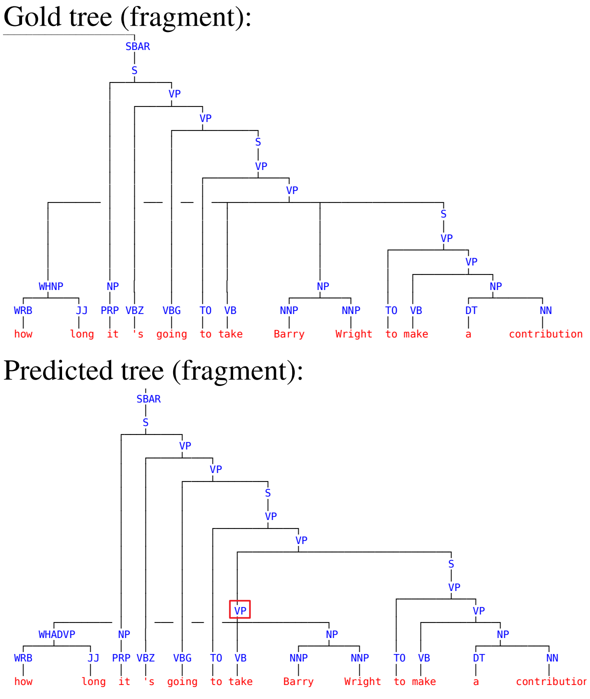

Figure 3: Error correction: remove an extra node.

The creation of a discontinuous node (ii) consists in gathering several nodes with the same parent, attaching them as the children of a new node, which is attached in turn to their original parents. For example, in Figure 2, the parser missed a VP node. The correction consists in creating a discontinuous VP node with two children (ADJP and VBD nodes) and attaching it to the SINV node.

To delete a discontinuous node (iii), we simply attach its children to their grandparent node. For example, in Figure 3, the children of the highlighted VP to be deleted (lower part) will be attached to the higher VP. For both node creation and node deletion, the corrected tree has only a single different node with the original predicted tree.

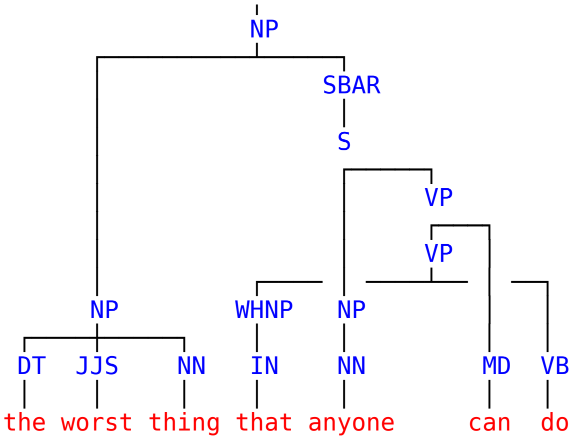
Finally, the moving of a node involves reattaching a node to a different parent. For example, in Figure 4, the correction of the predicted tree will consist in attaching the WHNP to the lowest VP, resulting in two missing discontinuous constituents (both VPs, see gold tree). A side effect is that the moving will also result in a unary S constituent that should be deleted in another correction step.

In order to find a sequence of error-correcting modifications, we perform a greedy search. While there is a false positive or a false negative discontinuous constituent in the current tree, we try to apply actions (i-iv) in this order of priority. Modifications (i-iii) cannot introduce new errors, whereas

---

[4] In the unlabelled case, we remove duplicate constituents (that correspond to unary rewrites) before evaluation as they are not interpretable. Therefore, it might happen that the labelled result is higher than the corresponding unlabelled one.

Gold tree (fragment):



Predicted tree (fragment):

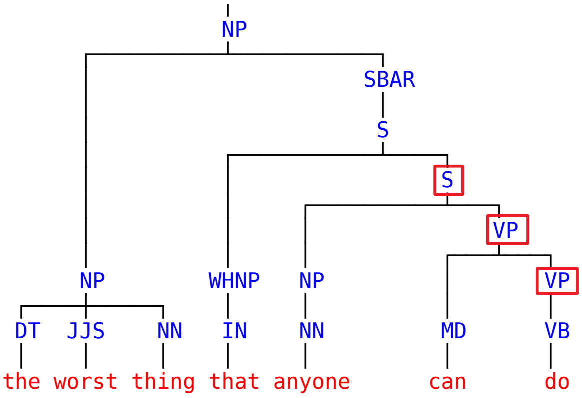


Figure 4: Error correction: move a node.

moving a node (iv) may do so in some cases.[5] We ensure that moving a node is only performed if the correction does not increase the gross number of errors by more than 1.

Once we have found the correction sequence, we classify errors according to patterns defined by Kummerfeld et al. (2012):

- PP attachment;
- NP internal structure;
- Modifier Attachment;
- Unary constituent;
- Different label;
- Clause attachement;
- Coordination;
- NP attachment;
- VP attachment.

Once all discontinuous errors are corrected, we run the original code from Kummerfeld et al. (2012) to compute statistics about projective constituent mistakes.

5 Parser

We use a Python reimplementation of the parser described by Coavoux et al. (2019), augmented with a mechanism to integrate and fine-tune BERT (Devlin et al., 2019). We release our code with pretrained models for replication purposes.[6]

The parser is based on a simple transition system (ML-GAP) that features the GAP action (Coavoux and Crabbé, 2017) to construct discontinuous constituents, and separates structural and labelling actions (Cross and Huang, 2016). The scoring system has two submodules:

- A sentence encoder that constructs contextualized embeddings for each token and is run before parsing;
- A feed-forward network that predicts the next action from the contextualized embeddings of tokens extracted from specific positions in the parsing configuration.

In the remainder of the paper, we call ML-GAP the baseline parser that has only access to the training corpus and has no pretrained parameters, ML-GAP+FT, when it has access to fasttext pretrained embeddings (Mikolov et al., 2018b), and ML-GAP+BERT, the parser that uses the `bert-base-cased` pretrained language model to compute token representations and finetunes it.

Token and sentence encoder The parsers differ in the way they represent the tokens $(w_1, w_2, \ldots w_n)$ in a sentence. The ML-GAP parser computes character-based word embeddings with a character bi-LSTM: $(\mathbf{c}_1, \ldots \mathbf{c}_n)$, where $\mathbf{c}_i = \text{bi-LSTM}(w_i)$, and concatenates them to word embeddings: $([\mathbf{c}_1, \mathbf{w}_1], \ldots [\mathbf{c}_n, \mathbf{w}_n])$. The ML-GAP+FT parser replaces learned word embeddings by (frozen) fast-text embeddings. The ML-GAP+BERT parser also uses a character bi-LSTM, but its output is concatenated with the contextualized embeddings from BERT: $([\mathbf{c}_1, \mathbf{b}_1], \ldots [\mathbf{c}_n, \mathbf{b}_n])$, where $(\mathbf{b}_1, \mathbf{b}_2, \ldots, \mathbf{b}_n)$ is the output of the last layer BERT for the corresponding tokens. When BERT segments a token into several subtokens, we use the vector corresponding to the first subtoken. Alternative methods are available (using the last subtoken or an aggregation of the subtoken vectors) but they do not seem to have an effect on parsing (Kitaev et al., 2019).

---

[5] The effect of creation/deletion of a single node is purely local, whereas the moving of the node may impact many other nodes. For example in Figure 4, the moving changes the yield of 3 nodes.

[6] `https://gitlab.com/mcoavoux/mtgpy-release-findings-2021`, also archived at `http://doi.org/10.5281/zenodo.4775955`

Then, the token embeddings are fed to a bi-LSTM sentence encoder, as usually done in parsing (Stanojević and Alhama, 2017; Coavoux and Cohen, 2019; Corro, 2020; Stanojević and Steedman, 2020). In preliminary experiments, we alternatively used a self-attentive encoder (Vaswani et al., 2017), as done successfully in recent work in projective constituency parsing (Kitaev and Klein, 2018; Kitaev et al., 2019). However, it proved hard to optimize (high variance across experiments) and did not obtain better results than a bi-LSTM.

Action scorer and features We use two distinct feed-forward networks to score respectively structural actions (SHIFT, MERGE, GAP) and labelling actions (NO-LABEL, {LABEL-X | X is a non-terminal}). They both have an identical architecture and only differ in the number of units in the output layer. We use a single hidden layer with a tanh activation. We apply dropout to its input, and layer normalization (Ba et al., 2016) to the hidden layer. We use a softmax normalization to compute scores for possible output labels.

Table 2: Detailed results on the development and test sets of the DPTB. P and R are precision and recall; DP, DR, DF are the discontinuous precision, recall and F-score.

The choice of the structural or labelling classifier is entirely determined by the parsing configuration and depends on the type of the next action. The input to both classifiers is the concatenation of contextualized vectors extracted from a list of positions in the parsing configuration and specified as a list of feature templates.

In the ML-GAP transition system, a parsing configuration is defined by 3 data structures: a stack s containing subtrees, a double-ended queue d also containing subtrees, and a buffer b containing the yet unprocessed tokens. We use the following 11 templates:[7]

- the left-most and right-most token of first and second element in s and d (8 templates in total: $s_0.l$, $s_0.r$, $s_1.l$, $s_1.r$, $d_0.l$, $d_0.r$, $d_1.l$, $d_1.r$);[8]
- the next token in the buffer (b_0);
- the contextualized embeddings corresponding to the start of sentence and end of sentence symbols.

Overall results We report overall development and test results in Table 1 (see Appendix A for details about training), and compare them to published results on the DPTB dataset. For a more comprehensive evaluation of the parser, including results on the Tiger (Brants et al., 2002)[9] and Negra (Skut et al., 1997) German corpora, we refer the reader to Table 7 of Appendix B.

The ML-GAP setting improves over Coavoux et al. (2019) by 0.4 and 3.1 respectively for the F and DF metrics, which we attribute to the hyperparameter search. In both the supervised setting and the 'pretrained embeddings' setting, our parser's results lag behind Corro (2020), the current state of the art. However it is noticeably more accurate on discontinuous constituents (more than 10 absolute DF difference).

In the BERT-finetuning setting, the F measure of the ML-GAP+BERT model slightly outperforms the span-based parser of Corro (2020). The use

---

[7] This is an extension over the set of 7 templates from Coavoux et al. (2019).

[8] We use s_i (resp. d_i) to address the $i-1^{\text{th}}$ subtree of s (resp. d), and $.l/.r$ to address the left-most or right-most token yielded by the subtree.

[9] We use the SPMRL split (Seddah et al., 2013).

Table 3: Per-phenomenon results on the test suite for the ML-GAP+BERT model. Its absolute improvements over respectively the ML-GAP+FT and the ML-GAP model are in parentheses. We handle separately sentences that have several occurrences of phenomena resulting in discontinuities (+ symbol), we exclude combinations with fewer than 5 occurrences.

of BERT seems to cancel the benefits of the exact decoding permitted by the span-based approach of Corro (2020). On the DF metric, the gap is even larger (13.6 absolute difference). We attribute this difference to the fact that Corro (2020)'s parser is restricted to a certain type of discontinuities and cannot construct certain trees. Moreover, the transition-based paradigm enables a parser to use more fine-grained features than span-based parsers, which is particularly helpful for predicting discontinuous constituents.

6 Results and Discussion

In this section, we focus on the comparisons of our 3 models to assess the contribution of BERT to discontinuous parsing. We first focus on English, using the two resources we introduced in Sections 3 and 4. Then we provide and discuss results on German, using `discosuite` (Maier et al., 2014).

6.1 English

The improvements brought by BERT may come from its syntactic knowledge. However, they might also be a result of its extended lexical knowledge (providing more lexical information about out-of-vocabulary or rare words that might be known but do not take part in discontinuous structures in the training set). The ML-GAP+FT model provides a control setting, where the 'static' pretrained embeddings provide additional lexical information.

Overall effect of pretraining We provide detailed results (precision, recall, F) in Table 2. It had been reported that discontinuous parsers often have a large gap between precision (higher) and recall (lower) on discontinuities on both German and English corpora (Maier, 2015; Coavoux and Cohen, 2019; Stanojević and Steedman, 2020; Corro, 2020). The use of BERT tends to fill this gap, with a much stronger effect on recall (+15 DR on development set over **ml-gap**) than on precision (+4 DP). BERT leads the parser to better detect syntactic discontinuities compared to a supervised model (ML-GAP).

On the contrary, ML-GAP+FT provides only a small improvement over ML-GAP (+2.2 dev DF), which is split almost equally between precision (+2.0 DP) and recall (+2.5 DR). The striking difference between ML-GAP+FT and ML-GAP+BERT strongly suggests that BERT's contribution cannot be reduced to its extended lexical knowledge.

Per-phenomenon evaluation We report results on the test suite in Table 3, in the labelled case (upper part) and the unlabelled case (lower part). For each metric, we report the result of the ML-GAP+BERT model, as well as its absolute difference with, respectively the ML-GAP+FT and the ML-GAP model.

First, when comparing ML-GAP+BERT and ML-GAP, we observe a large improvement on all phenomena and almost all metrics. When comparing

Table 4: Error types for both models (development set). Absolute differences with the ML-GAP model are given in parentheses.

labelled and unlabelled results, we observe very small differences (< 1) except for the case of circumpositioned quotations. This is due to some cases where the discontinuous quotation phrase has an unfrequent label (FRAG or SINV). Overall, subject inversions,[10] fronted quotations and circumpositioned quotations are almost perfectly detected by the ML-GAP+BERT system with DF scores over 95, and high exact match (at least in the unlabelled case for circumpositioning). On the other hand, discontinuous dependencies and *it*-extrapositions, and to a lower extent extractions, have DF scores below 90, despite the huge effect of BERT (respectively +35.2 and +25 absolute improvement on exact match for discontinuous dependencies and *it*-extrapositions).

Secondly, the improvement brought by fast-text embeddings is consistently very small (around +2F), except on 2 types of phenomena: *it*-extrapositions (where BERT does not improve over fast-text), and to a lower extent discontinuous dependencies (+6F for fast-text, +37.8F for BERT). This result suggests that the difficulty to parse these phenomena stemmed, at least partly from a lack of lexical knowledge.

Error Analysis We report results of the error type classifier for both models in Table 4. For each error type, we report (i) the overall count of occurrences, (ii) the number of occurrences where the correction involved a discontinuous node among them, and (iii) the total number of nodes involved (a single error can cause multiple wrong nodes), as done by Kummerfeld et al. (2012).

Overall, we observe an important decrease across all types of errors, with error reduction rates often close to 40% (e.g. 45% fewer occurrences of PP attachment errors) for ML-GAP+BERT and around 20% for ML-GAP+FT.

The picture is slightly different if we look at errors involving discontinuous constituents. Indeed, the use of BERT drastically reduces the main sources of errors (PP/VP/NP attachment, modifier attachment, coordination), while having no effect on other types of structure (NP internal structure, unary constituent, label). In contrast, fast-text only improves modifier and NP attachments, and even introduces clause attachment errors.

6.2 German

In order to provide additional context to our results on English, we further experiment with the same parsing models on German, using the test-suite built by Maier et al. (2014) on the German Tiger corpus. They constructed this test-suite by first identifying and classifying discontinuous phenomena in the 1500 first sentences of the Tiger corpus; and then they selected 15[11] sentences for each identified phenomenon. In total, `discosuite` contains 180 occurrences across 151 sentences. Each occurrence corresponds to a single discontinuous constituent.

We train our parsers on a modified version of the SPMRL Tiger split, where the 151 sentences are removed from the training set. We then parse the 151 sentences and use the labelled and unlabelled recall on target constituents to evaluate the corresponding phenomena. We provide results on the testsuite in Table 5, using the same settings as in English (ML-GAP, ML-GAP+FT, ML-GAP+BERT). We refer the reader to Maier et al. (2014) for the descriptions of specific phenomena. To the best of our knowledge, no prior parsing work used this testsuite for evaluation since its release.

Due to a finer-grain classification, there are only few instances for each type. Hence, we only comment on general patterns. Overall, fast-text provides small improvement on 6 types of phenomena (over 14). In constrast, BERT improves on every type of phenomenon, with largest increases for extrapositions of an element of a coordination, extrapositions involving a focus adverb (eg. adverb in the main clause modifying a subordinate clause), and local movement (involves discontinuities that

---

[10] Note that we have a small sample for this phenomenon (5 instances).

[11] or fewer for rarer phenomena.

do not cross clause boundaries). These are also the most difficult phenomena to predict correctly (< 50 recall).

We observe there is not a large difference between labelled and unlabelled scores, suggesting that finding the correct structure is the main difficulty.

7 Conclusion

We introduced two resources for fine-grained automatic error analysis of English discontinuous constituency parsers. First, we construct and release a test-suite for the range of syntactic phenomena responsible for the discontinuous structures in the discontinuous version of the Penn Treebank. Second, we extend the Berkeley parser analyser to the analysis of discontinuous constituency trees. We apply these resources to study the contribution of BERT to discontinuous parsing of English.

Overall, on almost all phenomena, BERT brings an improvement over a fast-text baseline. We found that BERT leads to almost perfect detection for some phenomena (subject inversion, fronted quotations, circumpositioned quotations). Moreover, there is still a wide room for improvement for extractions (despite the high frequency of this type of structures in the corpus), *it*-extrapositions, and discontinuous dependencies. In future work, we plan to address these limitations with targeted data-augmentation methods. We also plan to evaluate other pretrained language models to assess whether they exhibit the same error patterns as BERT.

Acknowledgments

I thank Sacha Beniamine, Caio Corro, Didier Schwab and 2 sets of 3 reviewers for feedback on previous versions of this paper. All trees are drawn with `discodop`.

A Training Details

The parser uses the pytorch library (Paszke et al., 2019) and the `transformers` interface (Wolf et al., 2020) to fine-tune BERT. For all 3 models (ML-GAP, ML-GAP+FT, ML-GAP+BERT), we only tuned the batch size and the learning rate. We report all hyperparameters and final configurations in Table 6 of Appendix A. We used the Adam optimizer (Kingma and Ba, 2015), divide learning rate by 2 when the model shows no improvement on the dev set for 5 epochs and stop training after 3 such cycles with no improvement. Finally, we maintain the average of parameters across iterations during training, and use the averaged parameters (instead of the final parameters) for the final model. We trained the parsers on gold sequences of configurations (teacher-forcing). We use a deterministic

DoT: An efficient Double Transformer for NLP tasks with tables

Abstract

Transformer-based approaches have been successfully used to obtain state-of-the-art accuracy on natural language processing (NLP) tasks with semi-structured tables. These model architectures are typically deep, resulting in slow training and inference, especially for long inputs. To improve efficiency while maintaining a high accuracy, we propose a new architecture, DoT, a double transformer model, that decomposes the problem into two sub-tasks: A shallow pruning transformer that selects the top-K tokens, followed by a deep task-specific transformer that takes as input those K tokens. Additionally, we modify the task-specific attention to incorporate the pruning scores. The two transformers are jointly trained by optimizing the task-specific loss. We run experiments on three benchmarks, including entailment and question-answering. We show that for a small drop of accuracy, DoT improves training and inference time by at least 50%. We also show that the pruning transformer effectively selects relevant tokens enabling the end-to-end model to maintain similar accuracy as slower baseline models. Finally, we analyse the pruning and give some insight into its impact on the task model.

1 Introduction

Recently, transfer learning with large-scale pretrained language models has been successfully used to solve many NLP tasks (Devlin et al., 2019; Radford et al., 2019; Liu et al., 2019). In particular, transformer models have been used to solve tasks that include semi-structured table knowledge, such as table question answering (Herzig et al., 2020) and entailment (Wenhu et al., 2019; Eisenschlos et al., 2020) – a binary classification task to support or refute a sentence based on the table's content.

While transformer models lead to significant improvements in accuracy, they suffer from high computation and memory cost, especially for large inputs. The total computational complexity per layer for self-attention is $O(n^2d)$ (Vaswani et al., 2017), where n is the input sequence length, and d is the embedding dimension. Using longer sequence lengths translates into increased training and inference time.

Improving the computational efficiency of transformer models has recently become an active research topic. To the best of our knowledge, the only technique that was applied to NLP tasks with semi-structured tables is heuristic pruning. Eisenschlos et al. (2020) show on the TABFACT data set (Wenhu et al., 2019) that using heuristic pruning accelerates the training time while achieving a similar accuracy. This raises the question of whether a better pruning strategy can be learned.

We propose to use DoT, a double transformer model (Figure 1): A first transformer – which we call *pruning transformer* – selects k tokens given a query and a table and a task-specific transformer solves the task based on these tokens. Decomposing the problem into two simpler tasks imposes additional structure that makes training more efficient: The first model is shallow, allowing the use of long input sequences at moderate cost, and the second model is deeper and uses the shortened input that solves the task. The combined model achieves a better efficiency-accuracy trade-off.

The pruning transformer is based on the TAPAS QA model (Herzig et al., 2020). TAPAS answers questions by selecting tokens from a given table. This problem is quite similar to the pruning task. The second transformer is a task-specific model adapted for each task to solve: We use another TAPAS QA model for QA and a classification model (Eisenschlos et al., 2020) for entailment. In Section 2, we explain how we jointly learn both models by incorporating the pruning scores into the attention mechanism.

DoT achieves a better trade-off between effi-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3273–3283
August 1–6, 2021.

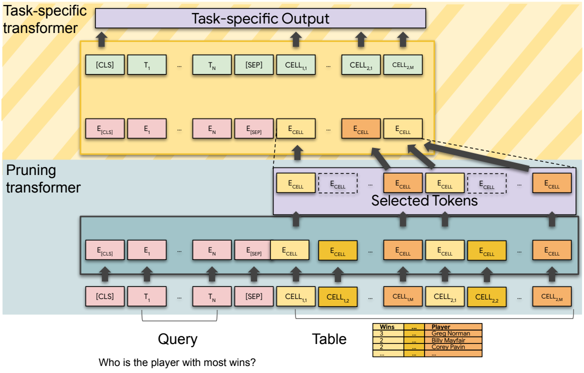

Figure 1: Pruning with a double transformer DoT. The pruning model selects the k most relevant tokens and passes them to the task model. The pruning model is small, allowing the use of long input sequences.

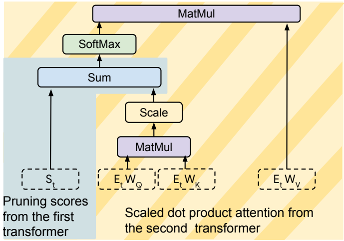

Figure 2: Scaled dot product attention of the task model. We change the attention architecture (Vaswani et al., 2017) – the dashed bloc – by adding the pruning scores – the solid bloc. The pruning scores affect the task model's attention in all layers. This enables back propagation for both models based on a single loss.

ciency and accuracy on three datasets. We show that the pruning transformer selects relevant tokens, resulting in higher accuracy for longer input sequences. We study the meaning of relevant tokens and show that the selection is deeply linked to solving the main task by studying the answer token scores. We open source the code in `http://github.com/google-research/tapas`.

2 The DoT Model

As show in Figure 1, the double transformer DoT is composed of two transformers: the *pruning transformer* selects the most relevant k tokens followed by a task-specific model that operates on the selected tokens to solve the task. The two transformers are learned jointly. DoT loss is detailed in Appendix A.2. We explore learning the pruning model using an additional loss in Appendix C.2.

Let q be the query (or statement) and T the table. The transformer takes as input the embedding $E = [E_{[CLS]}; E_q; E_{[SEP]}; E_T]$, composed of the query and table embeddings. The pruning transformer computes the probability $P(t|q,T)$ of the token t being relevant to solve the example. We derive the pruning score $s_t = \log(P(t|q,T))$ and keep the top-k tokens. The pruning scores are then passed to the task transformer as shown in Figure 2.

To enable the joint learning, we change the attention scores of the task model. For a normal transformer (Vaswani et al., 2017), given the input embedding E_t at position t, for each layer and attention head, the self-attention output is given by a linear combination of the value vector projections using the attention matrix.

Each row of the attention matrix is obtained by a softmax on the attention scores $z^{<t,t'>}$ given by

$$z^{<t,t'>} = \frac{E_t W_Q^\top (E_{t'} W_K^\top)^\top}{\sqrt{d_k}} \qquad (1)$$

where W_Q and W_K represent the query and key projections for that layer and head. In our task model we add a negative bias term and replace this equation with

$$z^{<t,t'>|s_t} = z^{<t,t'>} + s_t \qquad (2)$$

Thus, the attention scores provide a notion of token *relevance* – detailed in Appendix A.1 – and enable end-to-end learning of both models, letting DoT define the top-K tokens.

Unlike previous soft-masking methods (Bastings et al., 2019; De Cao et al., 2020), ours coincides exactly with removing the input token t when $P(t|q,T) \to 0$. We prove this formally in Appendix A.3.

We explore two different pruning strategies: token selection defined as discussed above and column selection where we average all token scores in each column.

3 Experimental Setup

We compare our approach against models using heuristic pruning.

Cell concatenation (CC) The TAPAS model uses a default heuristic to limit the input tokens. The objective of the algorithm is to fit an equal number of tokens for each cell. This is done by first selecting the first token from each cell, then the second and so on until the desired limit is reached.

Heuristic exact match (HEM) (Eisenschlos et al., 2020). This method scores the columns based on their similarity to the question, where similarity is defined by token overlap.

We introduce a notation to clarify the setup: $DoT(1^{st}_{type} \xrightarrow{top\text{-}k} 2^{nd}_{type})$. The *type* correspond to the model size: small (s), medium (m) or large (l) as defined in Turc et al. (2019). For example, $CC \xrightarrow{1024} DoT(s \xrightarrow{256} l)$ denotes a CC pre-processing to select 1024 tokens passed to the DoT model: one small pruning model that selects 256 tokens and feeds them into a large task model.

Baselines and DoT (hyper-parameters in Appendix B.1) are initialized from models pre-trained with a MASK-LM task, the intermediate pre-training data (Eisenschlos et al., 2020) and following Herzig et al. (2020) on SQA (Iyyer et al., 2017). The DoT transformers' complexity – detailed in Appendix B.3 – is similar to a normal transformer where only some constants are changed.

We evaluate DoT on three datasets.

WIKISQL (Zhong et al., 2017) is a corpus of $80,654$ questions with SQL queries, related to $24,241$ Wikipedia tables. Here we train and test in the weakly-supervised setting where the answer to the question is the result of the SQL applied to the table. The metric we use is denotation accuracy.

WIKITQ (Pasupat and Liang, 2015) consists of $22,033$ question-answer pairs on $2,108$ Wikipedia tables. The questions are complex and often require comparisons, superlatives or aggregation. The metric we use is the denotation accuracy as computed by the official evaluation script.

TabFact (Wenhu et al., 2019) contains 118K statements about 16K Wikipedia tables, labeled as either entailed or refuted. The dataset requires both linguistic reasoning and symbolic reasoning with operations such as comparison, filtering or counting. We use the classification accuracy as metric.

In all our experiments we report results for DoT using token selection for WIKISQL and TabFact and a column selection for WIKITQ.

4 Results

The baseline TAPAS model outperforms the previous state-of-the-art on all datasets (Table 1): $+2.1$ for WIKISQL ($CC \xrightarrow{1024}$ TAPAS(l)), $+1.07$ for TabFact ($HEM \xrightarrow{512}$ TAPAS(l)), and $+1.3$ for WIKITQ ($HEM \xrightarrow{1024}$ TAPAS(l)).

Efficiency accuracy trade-off Table 1 reports the accuracy test results along with the average number of processed examples per second NPE/s computed at training time. Using HEM as pre-processing step improves DoT models compared to CC for both WIKISQL and TabFact. $DoT(m)$ and $DoT(s)$ reach better efficiency accuracy trade-off for WIKISQL: with a small drop of accuracy by 0.4% (respectively 0.7%), they are 3.5 (respectively 4.6) times faster than the best baseline. For TabFact dataset, DoT is compared to a faster baseline than the one used for WIKISQL as it takes only 512 input tokens instead of 1024. $DoT(s)$ still achieves a good trade-off: with a decrease of 0.4% of accuracy it is 1.5 times faster. Unlike the previous datasets, WIKITQ is a harder task to solve and requires passing more data. By restricting $DoT(m)$ to select only 256 tokens we decrease the accuracy by a bigger drop 3.9% to be 3.5 times faster compared to $HEM \xrightarrow{1024}$ TAPAS(l).

Small task models The previous results, raise the question of whether a smaller task model can reach a similar accuracy. To answer this question, we compare $\xrightarrow{1024} DoT(s \xrightarrow{256} l)$ to $\xrightarrow{1024}$ TAPAS(s) and $\xrightarrow{256}$ TAPAS(l) in Table 2. DoT outperforms the smaller models showing the importance of using both transformers.

5 Analysis

Accuracy for long input sequences To study the long inputs, we bucketize the datasets per example input length. We compare $DoT(m \xrightarrow{256} l)$ to different $CC \dashrightarrow$ TAPAS(l) models in Table 3. For the bucket > 1024 the DoT model outperforms the 256 and 512 length baselines for all tasks. This indicates that the pruning model extracts two times more relevant tokens than the heuristic CC.

For the bucket $[512, 1024]$, we expect all models to reach a higher accuracy, as we expect lower loss of context than for the bucket > 1024 when applying CC. The results shows that DoT gives a similar accuracy to $\xrightarrow{512}$ TAPAS for WIKISQL and TabFact– in the margin error – and a slightly lower accuracy for WIKITQ: The pruning transformer selects only 256 top-K tokens compared to $\xrightarrow{512}$ TAPAS that selects twice more. Thus, the task-specific transformer has access to less tokens, therefore to possibly less context that can lead to an accuracy drop. This drop is small compared to $\xrightarrow{256}$ TAPAS baseline drop. DoT still outperforms $\xrightarrow{256}$ TAPAS for all datasets.

Pruning relevant tokens We inspect the pruning transformer on the WIKISQL and WIKITQ datasets, where the set of answer tokens is given.

Table 3: The denotation accuracy for test, computed over bucketized datasets per sequence length. The pruning transformer prunes efficiently –two times better: $DoT(\xrightarrow{256} l)$ reaches accuracy close and higher than using $CC \xrightarrow{512}$ heuristic with TAPAS(l).

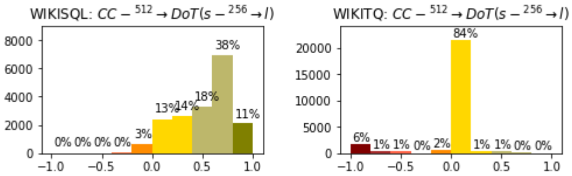

Figure 3: Distribution of the answer token scores minus the average scores of the top-K tokens. The difference is larger when the pruning transformer attributes a higher score to the answer tokens.

We compute the difference between the answer token scores and the average scores of the top-K tokens, and report the distribution in Figure 3. The pruning transformer tends to attribute high scores to the answer tokens, suggesting that it learns to answer the downstream question – a positive difference – especially for WIKISQL. The difference is lower for WIKITQ as it is a harder task: The set of answer tokens is larger, especially for aggregation, making their scores closer to the average.

Pruning transformer depth We study the pruning transformer complexity impact on the efficiency accuracy trade-off. Figure 4 compares the results of medium, small and mini models – complexity in Appendix B.3. For all datasets the *mini* model drops drastically the accuracy. The pruning transformer must be deep enough to learn the top-K tokens and attribute token scores that can be used by the task-specific transformer. For both WIKISQL and TabFact the small model reaches a better accuracy efficiency trade-off: Using a small instead of medium – 4 hidden layers instead of 8 – drops the accuracy by less than 0.4% – in the margin error – while accelerating the model times 1.3. In other words there is no gain of using a more complex model to select the top-K tokens especially when we restrict K to 256.

Restricting K can lead to a drop in the accuracy. Even by increasing the pruning complexity, DoT cannot recover the full drop. This is the case of WIKITQ. This dataset is more complex, it requires more reasoning including operation to run over multiple cells in one column. Thus selecting the top 256 tokens is a harder task compared to previous detests. We reduce the task complexity by using column selection instead of token selection. For this dataset using medium pruning transformer, $DoT(m)$ reaches a better accuracy efficiency trade-off: 2 points higher in accuracy compared to using a small transformer.

Effects of HEM and CC on DoT Table 1 and Figure 4 compare the effect of using HEM and

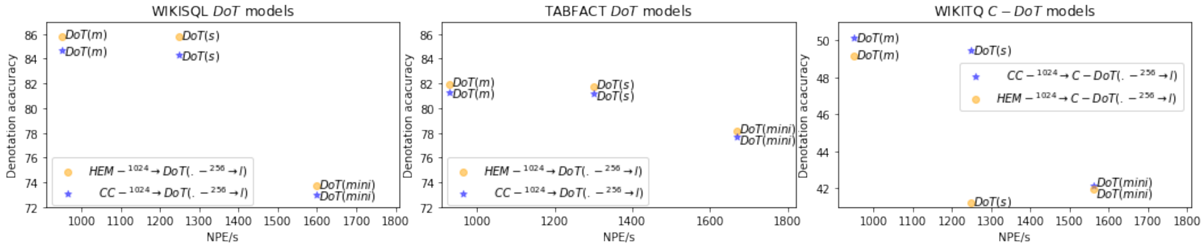

Figure 4: DoT models efficiency accuracy trade-off. The DoT models are displayed according to their accuracy in function of the average number of processed examples par second. The models are faster being closer to the right side of the figures and have higher accuracy being closer to the top. This figure compares the efficiency accuracy trade-off of using different pruning transformers – medium, small and mini – and study the impact of HEM and CC on DoT. We use token selection for both WIKISQL and TABFACT and column selection for WIKITQ.

CC on DoT models. As both heuristics are applied in the pre-processing step, using HEM or CC along with a similar DoT model, doesn't change the average number of processed examples per second NPE/s computed over the training step. For both WIKISQL and TABFACT we use a token based selection to select the top-K tokens. Combining the token based strategy with HEM, outperforms on accuracy the token pruning DoT combined with CC. For WIKITQ, the top-K pruning is a column based selection. Unlike the token selection the column pruning combined with HEM gives a lower accuracy.

6 Related work

Efficient Transformers Improving the computational efficiency of transformer models, especially for serving, is an active research topic. Proposed approaches fall into four categories. The first is to use knowledge distillation, either during the pre-training phase (Sanh et al., 2019), or for building task-specific models (Sun et al., 2019), or for both (Jiao et al., 2020). The second category is to use quantization-aware training during the fine-tuning phase of BERT models, such as (Zafrir et al., 2019). The third category is to modify the transformer architecture to improve the dependence on the sequence length (Choromanski et al., 2020; Wang et al., 2020). The fourth category is to use pruning strategies such as McCarley (2019), who studied structured pruning to reduce the number of parameters in each transformer layer, and Fan et al. (2020) who used structured dropout to reduce transformer depth at inference time. Our method most closely resembles the last category, but we focus our efforts on shrinking the sequence length of the input instead of model weights. Eisenschlos et al. (2020) explore heuristic methods based on lexical overlap and apply it to tasks involving tabular data, as we do, but our algorithm is learned end-to-end and more general in nature.

Interpretable NLP Another related line of work attempts to interpret neural networks by searching for *rationales* (Lei et al., 2016), which are a subset of words in the input text that serve as a justification for the prediction. Lei et al. (2016) learn the rationale as a latent discrete variable inside a computation graph with the REINFORCE method (Williams, 1992). Bastings et al. (2019) propose instead using stochastic computation nodes and continuous relaxations (Maddison et al., 2017), based on reparametrization (Diederik and Max, 2014) to approximate the discrete choice of a rationale from an input text, before using it as input for a classifier. Partially masked tokens are then replaced at the input embedding layer by some linear interpolation. We rely on a soft attention mask instead as a way to partially reduce the information coming from some tokens during training. To the best of our knowledge these methods have not been investigated in the context of semi-structured data such as tables or evaluated with a focus on efficiency.

7 Conclusion

We introduced double transformer (DoT) where an additional small model prunes the input of a larger second model. This accelerates the training and inference time at a low drop in accuracy. As future work we will explore hierarchical pruning and adapt DoT to other semi-structured NLP tasks.

Appendix

A DoT model

A.1 Attention scores defines the meaning of relevant tokens.

We study, the updates of the pruning scores according to the attention scores needs. We note the set of relevant tokens R. The output probability given by the pruning transformer is in $(0, 1)$ making s_t in $(-\infty, 0)$. Lets suppose that the token t is not needed to answer the question, then the attention scores are decreased $z^{<i,t,t'>|s_t} \rightarrow -\vec{\infty}$ for all the tokens $t' \in R$ for all the layers i. The model updates both parts of $z^{<i,t,t'>}$ making s_t converging to $-\infty$, then $\lim_{s_t \rightarrow -\infty} z^{<i,t,t'>|s_t} = -\vec{\infty}$. Thus, the meaning of relevant token is defined by the attention scores updates: The pruning scores decreases for non relevant tokens and increase for relevant ones.

A.2 DoT loss

The DoT loss is similar to TAPAS model loss – noted as $J_{SA} = J_{aggr} + \beta J_{scalar}$ in (Herzig et al., 2020) – computed over the task-specific transformer where the attention scores are modified. More precisely, we modify only the scalar loss of the task specific model J_{scalar}. We incorporate the pruning scores $S = \{s_t \forall t \in T_{top_k=256}\}$, and we note $J_{scalar|S}$. The DoT loss is then compute only over the top-K tokens: $J_{DoT} = J_{aggr} + \beta J_{scalar|S}$.

For TABFACT dataset, Eisenschlos et al. (2020) modified the TAPAS loss – used for QA tasks – to adapt it to the entailment task: Aggregation is not used, instead, one hidden layer is added as output of the [CLS] token to compute the probability of Entailment. We use a similar loss for TABFACT where the attention scores are modified.

A.3 Feed-forward pass: Safe use of shorter inputs for the task-specific transformer

The top-K selection enables the use of shorter inputs for the task-specific. We prove that using input length equal to K is equivalent to using input length higher than K, without any loss of context. Note that the pruning scores are the same for both inputs, where the top-K are scored non-zero and we impose the other tokens to be scored zero.

Theorem A.1. *Given a transformer and a set of tokens as input I. Let t be one of the input tokens $t \in I$. If the transformer verifies the following conditions, that holds for all layers i.*

1. *$\forall t' \in I$ that attends to t, , $z^{<i,t,t'>} = -\vec{\infty}$.*
2. *For t attends to any $t' \in I$, $z^{<i,t',t>} = -\vec{\infty}$.*

Then applying this transformer on I is equivalent to applying it on $I - \{t\}$

Proof. We look at the different use cases.

$\forall i$ layers, any token $t' \in I - \{t\}$ attending to any token $t'' \in I - \{t\}$: the soft-max scores $a^{<i,t',t''>}$ have the same formula using I or $I - \{t\}$ as input.

Lets fix $t' = t$. The token t attending to any token $t'' \in I$: The first condition 1 gives $\forall t''$ that attends to t, $z^{<i,t,t''>} = -\vec{\infty}$. That follows $exp(z^{<i,t,t''>}) = \vec{0}$ then $a^{<i,t,t''>} = \vec{0}$.

Similarly, if $t' = t$. Any token $t'' \in I$ attending to t: The second condition 2 gives $\forall t'$ that attends to t, $z^{<i,t,t''>} = -\vec{\infty}$. That follows $exp(z^{<i,t',t>}) = \vec{0}$ then $a^{<i,t',t>} = \vec{0}$. $\square$

Remark. *Given a transformer and a set of tokens as input I. Let t be one of the input tokens $t \in I$ with t is not selected by the pruning transformer scored zero – not the first-k tokens. Using DoT, $s_t = -\infty$. That follows $z^{<i,t,t'>} = -\vec{\infty}$.*

The case $t' = t$, for any token $t'' \in I$ attending to t we have: $\forall i \neq 0$, the input $E_t = \sum_{t'' \in I} a^{<i,t,t''>}$. As $z^{<i,t,t'>} = -\vec{\infty}$, $E_t = \vec{0}$, E_t zero out all the variables making $exp(z^{<i,t',t>})$ a constant and $a^{<i,t',t>}$ independent of t'. This is equivalent to $\forall i \neq 0$, t doesn't attend to any $t' \in I$.

Only for the first layer $i = 0$, we add an approximation to drop the attention (t attending to $t' \in I$). We consider the impact of t on the full attention is small as we stuck multiple layers. We experimented with a task-specific model with a big input length $> k$ and compare it to a task-specific model with input length $= k$. The two models gives similar accuracy. In our experiment we report only the results for the model with input length $= k$.

This makes the attention scores similar to the ones computed over $t \notin I$.

B Experiments

In all the experiment we report the median accuracy and the error margin computed over 3 runs. We estimate the error margin as half the inter quartile range, that is half the difference between the 25^{th} and 75^{th} percentiles.

B.1 Models hyper-parameters

We do not perform hyper-parameters search for DoT models we use the same as TAPAS baselines.

Dataset	**lr**	ρ	**hidden dropout**	**attention dropout**	**num steps**
WIKISQL	$6e^{-5}$	0.14	0.1	0.1	$50,000$
TABFACT	$2e^{-5}$	0.05	0.07	0.0	$80,000$
WIKITQ	$1.9e^{-5}$	0.19	0.1	0.1	$50,000$

Table 4: Hyper-parameters used per dataset. Reports the learning rate (lr), the warmup ratio (ρ), the hidden dropout, the attention dropout and the number of training steps (num steps) used for each dataset. These hyper-parameters are the same for all the baselines and DoT models.

For WIKISQL and WIKITQ we use the same hyper-parameters as the one used by (Herzig et al., 2020) and for TABFACT the one used by (Eisenschlos et al., 2020). Baselines and DoT are initialized from models pre-trained with a MASK-LM task and on SQA(Iyyer et al., 2017) following Herzig et al. (2020).

We report the models hyper parameters used for TAPAS baselines and DoT in Table 4. The hyper-parameters are fixed independently of the pre-processing step or the input size: For all the pre-processing input lengths – $\{256, 512, 1024\}$–, for both CC and HEM we use the same hyper-parameters. Additionally, we use an Adam optimizer with weight decay for all the baselines and DoT models –the same configuration as BERT.

B.2 state-of-the-art

We report state-of-the-art for the three datasets in Table 5.

B.3 Models complexity

In all our experiments we use different transformer sizes called large, medium, small and mini. These models correspond to the BERT open sourced model sizes described in Turc et al. (2019). We report all models complexity in Table 6. The sequence length changes the total number of used parameters. The formula to count the number of parameters is given by Table 7. The number of used parameters equals to $V \times H + (2+3L)I \times H + I + (256*4+17+9L)H + (1+2L \times H) \times Hi$. The number of parameters of each model is reported in Table 8

The number of parameters is not proportional to the computational time as multiple operations involves multiplying tensors of shapes $[I, H] \times [H, H]$.

C Analysis

We report additional results for the analysis.

Table 9: The denotation accuracy for test, computed over bucketized datasets per sequence length.

C.1 Pruning transformer enables reaching high accuracy for long input sequences

To study the model accuracy on different input sequence lengths, we bucketize the datasets. Table 9 reports the accuracy results computed over the test set for all buckets. We use $DoT(m \xrightarrow{256} l)$ model for the three datasets, a token based pruning for both WIKISQL and TABFACT and a column based pruning for WIKISQL. For a length > 1024, the DoT model outperforms the 256 and 512 length baselines for all tasks. For the bucket $[512, 1024]$, DoT model gives close results to 512 length baseline. This indicates that the pruning model extracts twice more relevant tokens than the heuristic CC. For smaller input lengths the baseline models outperform DoT. One cause could be the hyper-parameters tuning as we do not tune the hyper parameters for DoT.

C.2 Choice of joint learning: Is it better to impose the meaning of relevant tokens?

According to the analysis done in Section 5, the pruning model –jointly learned– is selecting the tokens to solve the main task. This raises a question of whether adding a pruning loss similar to the task-specific loss can improve the end-to-end accuracy. We not $J_{pruning-scalar}$ the pruning loss and $J_{task-specific-scalar}$ the task-specific loss. Both are similar to J_{scalar} defined by (Herzig et al., 2020) where the attention scores are not affected by the pruning scores. We additionally not $J_{task-specific-scalar|S}$ the task specific loss affected by the set of pruning scores S.

We compare the joint learning model $J\text{-}DoT(.)$ – defined in Appendix A.2 – to a model learned using an additional pruning loss $P\text{-}DoT(.) = J_{aggr} + \beta(J_{task-specific-scalar} + J_{pruning-scalar})$, and another using both $PJ\text{-}DoT(.) = J_{aggr} + \beta(J_{task-specific-scalar|S} + J_{pruning-scalar})$. Table 10 shows that for both WIKISQL and WIKITQ joint learning achieves higher accuracy for similar efficiency. For TABFACT the median is in the margin error but the best model using the joint learning outperforms the other learning strategies.

D All models results

We report all DoT results in Table 11. $C - DoT$ indicates the column based selection: For each token from one column, the pruning score attributes a column score instead of a token score. The column score is computed as an average of its tokens' scores.

Dataset	WIKISQL			TABFACT			WIKITQ		
Model	**test accuracy**	**Best**	NPE/s	**test accuracy**	**Best**	NPE/s	**test accuracy**	**Best**	NPE/s
$CC \xrightarrow{1024} P\text{-}DoT(m \xrightarrow{256} l)$	80.4 ± 0.6	82.11	950	79.7 ± 0.5	80.20	930	43.5 ± 0.6	44.54	950
$CC \xrightarrow{1024} PJ\text{-}DoT(m \xrightarrow{256} l)$	82.9 ± 0.6	83.21	950	78.0 ± 0.3	78.41	930	46.4 ± 0.8	48.43	950

Table 10: Test denotation accuracy using different DoT training losses. We compare a joint learning $J\text{-}DoT$ model – that enables the back propagation of the pruning transformer by modifying the attention scores – to two different DoT models where we modify the learning strategy. $P\text{-}DoT$ disables the buck-propagation to the pruning transformer through the attention scores, instead it uses an additional pruning loss similar to the task-specific loss. The second strategy, $JP\text{-}DoT$ is a hybrid method where the joint learning is used along with an additional pruning loss. $J\text{-}DoT$ achieves higher accuracy for similar efficiency, for both WIKISQL and WIKITQ. For TABFACT the median is in the margin error but the best model using the joint learning outperforms the other learning strategies.

Table 11: Summary of all the experiments' results on the accuracy efficiency trade-off. The state-of-the-art (detailed in Appendix B.2) correspond to the values of (Min et al., 2019) for WIKISQL, (Eisenschlos et al., 2020) for TABFACT and (Yin et al., 2020) for WIKITQ. For each dataset, the state-of-the-art, the best baseline model on accuracy, and the DoT models that reach the best accuracy efficiency trade-off are highlighted.

Grammatical Error Correction as GAN-like Sequence Labeling

Abstract

In Grammatical Error Correction (GEC), sequence labeling models enjoy fast inference compared to sequence-to-sequence models; however, inference in sequence labeling GEC models is an iterative process, as sentences are passed to the model for multiple rounds of correction, which exposes the model to sentences with progressively fewer errors at each round. Traditional GEC models learn from sentences with fixed error rates. Coupling this with the iterative correction process causes a mismatch between training and inference that affects final performance. In order to address this mismatch, we propose a GAN-like sequence labeling model, which consists of a grammatical error detector as a discriminator and a grammatical error labeler with Gumbel-Softmax sampling as a generator. By sampling from real error distributions, our errors are more genuine compared to traditional synthesized GEC errors, thus alleviating the aforementioned mismatch and allowing for better training. Our results on several evaluation benchmarks demonstrate that our proposed approach is effective and improves the previous state-of-the-art baseline.

1 Introduction

Sequence-to-sequence neural solutions (Parnow et al., 2020) have been quite successful in comparison to their statistical counterparts (Sutskever et al., 2014), but these approaches suffer from a couple key problems, which has given rise to sequence labeling approaches for GEC (Omelianchuk et al., 2020). Such approaches task models with generating a list of labels to classify the grammatical errors in a sentence before correcting these errors.

Sequence labeling approaches have recently gained popularity in GEC and are currently state-of-the-art. One typical aspect of sequence labeling approaches is labeling and correcting sentences through an iterative process. As successive edits will depend on how other errors are corrected in a sentence, using an iterative process and correcting only the most salient errors in each round allows models to achieve better performance; however, because of this process, models are tasked with handling sentences with varying rates of errors, as during each round of inference for a given sentence, a model encounters a sentence with progressively fewer errors. This of course causes an exposure bias problem, as the training data does not match the test data, and suggests that providing the model with training data with varying error rates will lead to better performance.

To combat this exposure bias, we propose a new approach for training a sequence labeling GEC model that draws from GANs (Goodfellow et al., 2014), which consist of a generator that generates increasingly realistic fake inputs and a discriminator that is tasked with differentiating these fake inputs from real inputs. Other GEC works like (Raheja and Alikaniotis, 2020) directly used GANs to produce grammatically correct sentences given grammatically incorrect ones. This contrasts our work, which uses aspects of a GAN to enhance the training process rather than using a GAN itself as the correcting model. Our model consists of three components: an encoder, a Grammatical Error Detector, and a Grammatical Error Labeler. By sampling from the error distribution in the error labeler, our model can synthesize sentences with new errors creating new sentence pairs for further training data. As a result, our Detector continually

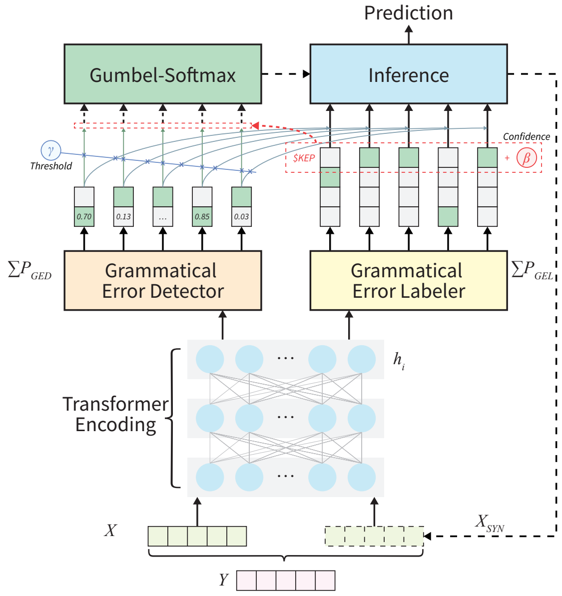

Figure 1: An overview of our model.

improves its ability to detect errors and essentially acts as a discriminator of errors, and our Labeler continually improves the authenticity of its error distribution and becomes a better generator of errors. This process allows us to counter the exposure bias problem sequence labeling GEC models face because in addition to allowing us to generate new errorful sentences whose errors are increasingly representative of those in real data, we can also use control parameters to set the error rates of these sentences and accommodate our iterative inference process.

2 Our Approach

We formulate the GEC task as a problem of sequence labeling and create a neural sequence labeling model based on a deep pre-trained Transformer encoder to deal with this problem. Inspired by the work of (Omelianchuk et al., 2020), our full model's overall architecture diagram is shown in Figure 1. There are three main components in our basic neural GEC model: a deep pre-trained Transformer Encoder, a Grammatical Error Detector, and a Grammatical Error Labeler. To accommodate our new GAN-like training process, we add a Gumbel-softmax sampling component to the basic GEC model.

2.1 Background and Notation

First, in training, given incorrect input sentence $X = x_1, x_2, ..., x_n$ and its corrected version $X_c = y_1, y_2, ..., y_m$, the model predicts a corrective label sequence $T = t_1, t_2, ..., t_n$ by minimizing the token-level Levenshtein distance on the span-based alignments of X and X_c. The corrective label set is given as $\mathcal{T} = \{\$KEP, \$DEL, \$APP, \$REP\} \cup \{\$CAS, \$MRG, \$SPL, \$NNUM, \$VFORM\}$, in which the first set consists of the basic text editing transformation operations and the second consists of g-transformations as defined by (Omelianchuk et al., 2020) for GEC[1]. Aligning sentences using these transformations in preprocessing, reduces what would be a sequence generation task that handles unequal source-target lengths to a set of label classification problems. In this formulation, the neural sequence labeling model trains to optimize the input sequence's negative log-likelihood loss for an input sequence:

$$\mathcal{J}(\theta) = -\sum_{i=1}^{n} \log p(t_i|x, \theta),$$

where p is the conditional probability that the model outputs at each position i.

2.2 Deep Pre-trained Transformer Encoder

As in most neural sequence labeling models (Ma and Hovy, 2016), a neural encoder such as a BiLSTM (Hochreiter and Schmidhuber, 1997) or a Transformer (Vaswani et al., 2017; Li et al., 2021) is used to extract context-aware features from the input sequence. Deep pre-trained language models such as BERT (Devlin et al., 2019; Zhang et al., 2020b), RoBERTa (Liu et al., 2019), and XLNet (Yang et al., 2019) have recently demonstrated the efficacy of Transformer models trained on large-scale unlabeled data in various NLP tasks. We leveraged these very beneficial models by using a pre-trained language model as our encoder. We define the contextualized features captured by the neural encoder as:

$$h_i = [\mathbf{Enc}(X)]_i,$$

where **Enc** represents the encoder, and $[\cdot]_i$ represents the output of the i-th position after encoding.

2.3 Grammatical Error Detector and Labeler

Next, we adopt a a Grammatical Error Detector (GED) to detect the presence of errors and a Gram-

---

[1] The label set here only presents the transformations' basic names. Some transformations require additional parameters because they are context-specific and thus have many different versions.

matical Error Labeler (GEL) to predict detailed error labels. With these labels, corrections are applied to sentences, and this process is typically iterative, as some corrections may depend on others, and applying corrections only once may not be enough to fully correct the sentence. During iterative correction, the model needs to assess at each round whether more correction is required. To this end, we use the GED to determine the degree of error for an entire sentence and control the iterative correction process.

Specifically, we use a binarization Y_b of the corrective labels Y as the training target of the GED and use Y as the training target of the GEL. To obtain label probabilities grammatical error detection and labeling, two linear layers with softmax layers are appended to the encoder:

$$P^i_{\text{GED}} = \mathbf{softmax}(\mathbf{MLP}_{\text{GED}}(h_i)),$$

$$P^i_{\text{GEL}} = \mathbf{softmax}(\mathbf{MLP}_{\text{GEL}}(h_i)).$$

The binary classification probabilities in the GED output do not necessarily control the inference process's iterations. Rather, after using the GEL error label probabilities as thresholds for sentence positions, we also use the sum of these probabilities as a threshold for attempting another round of correction on the whole sentence. The model continues correcting the sentence until either it reaches a preset maximum number of iterations or no longer satisfies the following condition: $\sum_i [P^i_{\text{GED}}]_{err=1} > \gamma$, where γ is the minimum error probability threshold for a sentence.

Additionally, since GEC usually corrects a small portion of a sentence (and there are therefore no errors in most of the input), the corrective label prediction task is an imbalanced classification problem. We alleviate this imbalance classification issue by taking advantage of this prior knowledge and adding a fixed and preset confidence β to the label \$KEP to keep a position unchanged when applying corrections:

$$[P^i_{\text{GEL}}]_{\$\text{KEP}} = [P^i_{\text{GEL}}]_{\$\text{KEP}} + \beta.$$

2.4 GAN-like Sequence Labeling Training

While we adopt sequence labeling instead of sequence-to-sequence modeling in this paper and therefore avoid the exposure bias problem caused by left-to-right sequence generation, our model still faces exposure bias because of the iterative correction process, which, through its iterative correction process, tasks the model with handling much more varied error rates in inference compared to in training, where it handles static data and does not use multiple-round corrections. To address this issue, we borrow the idea of a GAN (Goodfellow et al., 2014) and propose a GAN-like iterative training approach for a sequence labeling GEC model. GANs, whose training objective can be formulated as a minimax game between a generator that creates increasingly realistic fake outputs and a discriminator that must differentiate these outputs from their real counterparts, have been suggested for sequence-to-sequence text generation (Li et al., 2020; Zhang et al., 2020a; Li et al., 2018) as they do not suffer from exposure bias.

Algorithm 1 GAN-like Sequence Labeling Training

```
Require: Genuine GEC parallel dataset $\mathcal{D} = \{(\mathbf{X}, \mathbf{Y})\}$
    Synthesized GEC parallel dataset $\mathcal{D}_{\text{SYN}} = \{\}$
    Number of training stages $\mathcal{N}$
    Number of training epochs $M$
    Sentence error probability threshold $\gamma$
    Additional confidence $\beta$ for label $\texttt{\$KEP}$
for $i$ in 1, ..., $N$ do
    Initialize model parameters from previous training stage $\theta_{\text{i}} \leftarrow \theta_{\text{i-1}}$ when $i > 1$
    for $j$ in 1, ..., $M$ do
        for $k$ in 1, ..., $|\mathcal{D} \cup \mathcal{D}_{\text{SYN}}|$ do
            Encode each sentence $\mathbf{X}_k$ as $\mathbf{H}_k$
            $P^k_{\text{GED}} = \mathbf{Softmax}(\text{MLP}_{\text{GED}}(\mathbf{H}_k))$
            $P^k_{\text{GEL}} = \mathbf{Softmax}(\text{MLP}_{\text{GEL}}(\mathbf{H}_k))$
            $loss_{\text{GED}} = \mathbf{CrossEntropy}(P^k_{\text{GED}}, \mathbf{Y}^k_{err})$
            $loss_{\text{GEL}} = \mathbf{CrossEntropy}(P^k_{\text{GEL}}, \mathbf{Y}^k_{label})$
            $loss = loss_{\text{GED}} + loss_{\text{GEL}}$
            Update the model parameter $\theta_i$ with $loss$
        end for
    end for
    $\mathcal{D}_{\text{SYN}} = \{\}$
    for $k$ in 1, ..., $|\mathcal{D}|$ do
        Encode each sentence $\mathbf{X}_k$ as $\mathbf{H}_k$
        $P^k_{\text{GED}} = \mathbf{Softmax}(\text{MLP}_{\text{GED}}(\mathbf{H}_k))$
        $P^k_{\text{GED}} = \sum[P^k_{\text{GED}}]_{err=1} > \gamma$
        $P^k_{\text{GEL}} = \mathbf{Softmax}(\text{MLP}_{\text{GEL}}(\mathbf{H}_k))$
        $[P^k_{\text{GEL}}]_{\$\text{KEP}} = [P^k_{\text{GEL}}]_{\$\text{KEP}} + \beta$
        $P^k_{\text{GEL}} = \mathbf{GumbelSoftmax}(P^k_{\text{GEL}})$
        Use $P^k_{\text{GED}}$ and $P^k_{\text{GEL}}$ to produce sampled sequence $\mathbf{X}^k_{\text{SYN}}$
        $\mathcal{D}_{\text{SYN}} = \mathcal{D}_{\text{SYN}} \cup \{(\mathbf{X}^k_{\text{SYN}}, \mathbf{Y}_k)\}$
    end for
end for
```

In our model, the GEL module can be considered a discriminator, as it must differentiate whether tokens are erroneous, and by adding a sampling module to the GED module, we can create a generator that outputs grammatical errors (rather than corrections) that are increasingly realistic. We can then pair these sampling outputs with their golden sequence in the training dataset to create new training

samples. This trains the model with more samples and more varied errors and alleviates the exposure bias issue. Separate cross-entropy losses are calculated for the Grammatical Error Detector and Labeler, and we detail the whole algorithm for our training process in Algorithm 3.

3 Detailed Training Process

To synthesize new errors based on a genuine grammatical error distribution, we add a sampling module to a trained GED module. Specifically, we use Gumbel-softmax sampling, a simple and efficient way to draw samples z from a categorical distribution with class probabilities P_{GEL} using the Gumbel-Max trick (Gumbel, 1954; Maddison et al., 2014):

$$z = \texttt{one\_hot}\left(\mathbf{argmax}_j\left[g_j + \log[P^i_{\text{GEL}}]_j\right]\right) \quad (1)$$

where $g_1 ... g_j$ are i.i.d samples drawn from $\text{Gumbel}(0,1)$[2]. We use the softmax function as a continuous, differentiable approximation to $\mathbf{argmax}$:

$$[y_i]_k = \frac{\exp((\log([P^i_{\text{GEL}}]_k) + g_k)/\tau)}{\sum_{j=1}^{|C|}\exp((\log([P^i_{\text{GEL}}]_j) + g_j)/\tau)}, \quad (2)$$

where $|C|$ is the number of classes, τ is the softmax temperature. Altering γ and β allows us to synthesize input samples of different error rates.

4 Experiments

4.1 Setup

To isolate our GAN-like Sequence Labeling Training (GST) approach, we use the same model setting and training details as in (Omelianchuk et al., 2020). The training data includes PIE's synthetic data (Awasthi et al., 2019), NUCLE (Dahlmeier et al., 2013), Lang-8 (Tajiri et al., 2012), FCE (Yannakoudakis et al., 2011), Cambridge Learner Corpus (the publicly available portion) (Nicholls, 2003), and WI+LOCNESS (Bryant et al., 2019). Our models are evaluated on the test sets of CoNLL-2014 (Ng et al., 2014), BEA-2019 (Bryant et al., 2019), and JFLEG (Napoles et al., 2017) with the official M^2 (Dahlmeier and Ng, 2012), ERRANT (Bryant et al., 2017), and GLEU(Napoles et al., 2015) scorers, respectively.

4.2 Results and Analysis

Our results on the three test datasets are listed in Table 1. Our baseline model achieves the best single model CoNLL-2014 $F_{0.5}$, BEA-2019 $F_{0.5}$, and JFLEG GLEU scores, showing that the baseline we use is very strong. The results on the three

---

[2] The $\text{Gumbel}(0,1)$ distribution can be sampled using inverse transform sampling by drawing $u \sim \text{Uniform}(0,1)$ and computing $g = -\log(-\log(\text{u}))$.

Model	CoNLL-2014 (test)		
	P	**R**	**$F_{0.5}$**
Baseline	72.1	42.0	63.0
Baseline + Extended Training	73.5	40.1	63.0
Intermediate Outputs	73.2	39.8	62.7
GST	72.6	42.5	63.6

Table 3: Comparing GST training with additional baselines.

benchmarks are further improved using the GST approach, which demonstrates that the GST approach can effectively alleviate the exposure bias issue. With GST, we achieved new best results on the CoNLL-2014 test dataset, surpassing ensemble methods while only using a single model.

In order to illustrate the benefits of sampling using Gumbel-Softmax, we replaced it with random sampling and Multinomial. The comparison is shown in Table 2. Random sampling actually hampers performance, which shows that synthetic sentences not based on a genuine error distribution do not alleviate exposure bias. Both GumbelSoftmax and Multinomial, which use a genuine error distribution, improve the model, though Gumbel-Softmax appears to be more suitable for sampling in sequence labeling modeling.

In Figure 2, we show how the performance changes with increasing rounds of GST training. In the first few rounds, due to the model's re-adaptation to new errors, there was a drop in performance on the test datasets; however, as the number of training rounds increased, performance on the test set gradually improved and finally stabilized.

Intermediate Outputs and Longer Training In this experiment, we explored using intermediate outputs from our iterative inference process as additional training outputs to highlight the impact of generating new erroneous sentence by sampling from the real error distribution with our GST approach. For this experiment, we use our baseline architecture. As seen in the results in Table 3, whereas GST leads to a 0.6 $F_{0.5}$ gain over the baseline, using intermediate training outputs paired with golden sentences for additional training actually leads to worse performance, yielding a 0.3 $F_{0.5}$ loss in comparison to the baseline.

To confirm that GST's performance gain is not due to the added training time, we also train the baseline for a commensurate amount of additional steps but find that this does not have any effect on model performance. This experiment demonstrates that our model does bring improvement to the baseline without relying on additional training steps. We also note that as our model is not significantly different in size from our baseline, our improvement is also not brought about by simply using a larger model.

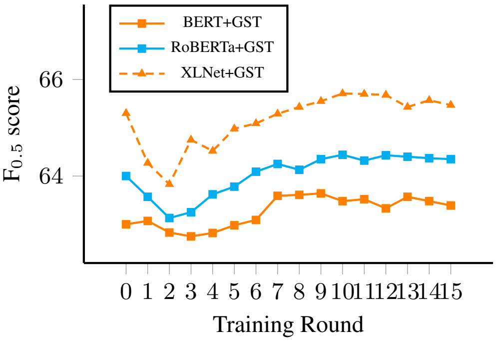

Figure 2: The GEC performance versus the the GST rounds on the CoNLL-2014 test set.

Model	CoNLL-2014 (test)		
	P	**R**	**$F_{0.5}$**
Baseline	72.1	42.0	63.0
GST	72.6	42.5	63.6
Baseline w/o BERT	65.0	32.6	54.2
GST w/o BERT	64.9	35.6	55.7

Table 4: Evaluating GST without pre-trained language models.

Performance with out Pre-trained Language Models We additionally explored the performance of our system in the absence of contextualized pre-trained language models. As we expected, these models make our model much more resilient to the exposure bias problem, and as seen in Table 4, the improvement brought about GST is therefore much more evident. In comparison to the baseline, using GST brings an improvement of 1.5 $F_{0.5}$ points.

5 Conclusion

In this paper, we studied the exposure bias problem GEC sequence labeling models face. To alleviate this issue, we proposed a novel GAN-like training method for the GEC sequence labeling model. Through evaluation on three GEC benchmarks, we demonstrate that our novel training approach further improves a strong baseline model, illustrating the effectiveness of our training approach. Notably, with the help of pre-trained language models and our training approach, we achieved state-of-the-art results on the CoNLL-2014 benchmark.

Abstract

Incorporating external knowledge into Named Entity Recognition (NER) systems has been widely studied in the generic domain. In this paper, we focus on clinical domain where only limited data is accessible and interpretability is important. Recent advancement in technology and the acceleration of clinical trials has resulted in the discovery of new drugs, procedures as well as medical conditions. These factors motivate towards building robust zero-shot NER systems which can quickly adapt to new medical terminology. We propose an auxiliary gazetteer model and fuse it with an NER system, which results in better robustness and interpretability across different clinical datasets. Our gazetteer based fusion model is data efficient, achieving +1.7 micro-F_1 gains on the i2b2 dataset using 20% training data, and brings + 4.7 micro-F_1 gains on novel entity mentions never presented during training. Moreover, our fusion model is able to quickly adapt to new mentions in gazetteers without re-training and the gains from the proposed fusion model are transferable to related datasets.

1 Introduction

Named entity recognition (NER) (Lample et al., 2016; Ma and Hovy, 2016) aims to identify text mentions of specific entity types. In clinical domains, it's particularly useful for automatic information extraction, e.g., diagnosis information and adverse drug events, which could be applied for a variety of downstream tasks such as clinical event surveillance, decision support (Jin et al., 2018), pharmacovigilance, and drug efficacy studies.

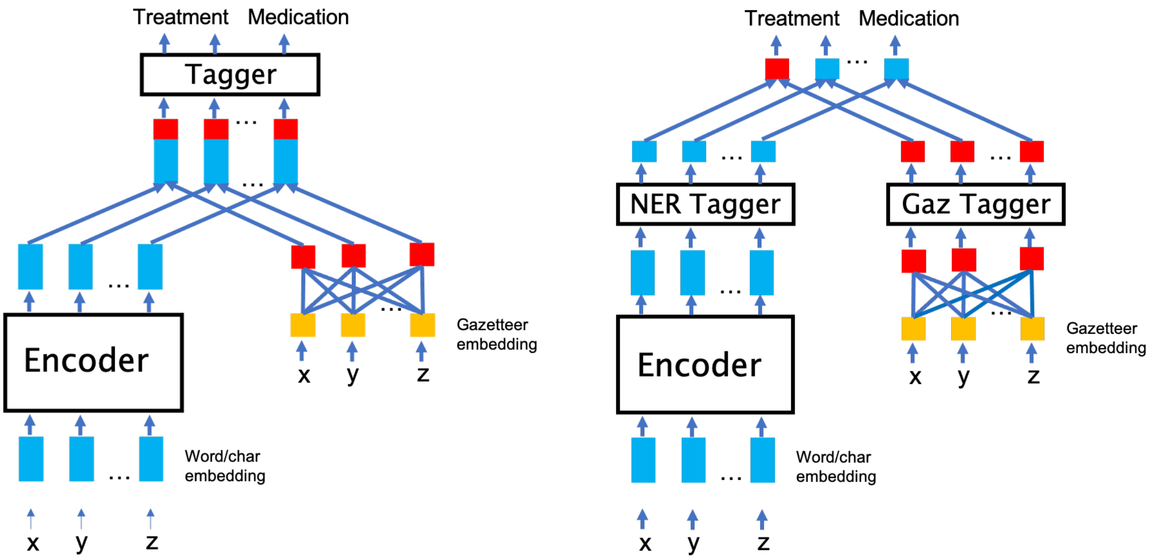
We have witnessed a rapid progress on NER models using deep neural networks. However, applying them to clinical domain (Bhatia et al., 2019) is hard due to the following challenges: (a) accessibility of limited data, (b) discovery of new drugs, procedures and medical conditions and the (c) need for building interpretable and explainable models. Motivated by these, we attempt to incorporate external name or ontology knowledge, e.g., *Remdesivir* is a `DRUG` and *COVID-19* is a `Medical Condition`, into neural NER models for clinical applications.

Recent work on leveraging external knowledge can be categorized into two categories - Gazetteer embedding and Gazetteer models. Recent work has primarily focused on gazetteer embeddings. Song et al. (2020) feed the concatenation of BERT output and gazetteer embedding into Bi-LSTM-CRF. Peshterliev et al. (2020) use self-attention over gazetteer types to enhance gazetteer embedding and then concatenate it with ELMO, char CNN and GloVe embeddings. By contrast, the basic idea of gazetteer model is to treat ontology knowledge as a new clinical modality. Magnolini et al. (2019) combine outputs of Bi-LSTM and gazetteer model and feed them into CRF layer. Liu et al. (2019a) apply hybrid semi-Markov conditional random field (HSCRF) to predict a set of candidate spans and rescore them with a pre-trained gazetteer model.

In this paper, we combine the advantages of both worlds. Unlike the work of Peshterliev et al. (2020), we build self-attention over entity mentions and their context rather than over different gazetteer types. For example, *Take Tylenol 3000* *`(NUM)`* *mg* *`(METRIC)`* *per day*, in which *Tylenol* is more likely to be a `DRUG` given `NUM`, `METRIC` in context. Moreover, we study two fusion methods to integrate information from two modalities.

- *Early fusion*. Similar to Magnolini et al. (2019), NER model and gazetteer model apply a shared tagger, as shown in Fig. 1a
- *Late fusion*. For better interpretability and flexibility, we allow NER and gazetteer models to apply separate taggers and fuse them before taking softmax, as shown in Fig. 1b

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3291–3295
August 1–6, 2021.



(a) Early fusion (b) Late fusion

Figure 1: Model Architecture. (a) Early fusion. The outputs of NER and gazetteer are concatenated and fed into a shared tagger. (b) Late fusion. NER and gazetteer apply separate taggers and two modalities are fused by taking element-wise max pooling.

Unlike the work of Liu et al. (2019a), NER and gazetteer models are jointly learned end-to-end.

Our contributions are as follows. (1) We propose to augment NER models with an auxiliary gazetteer model via *late fusion*, which provides better interpretability and flexibility. Interestingly, the NER model can preserve the gains even if the gazetteer model is unplugged at inference time. (2) Our thorough analysis shows that the fusion model is data efficient, explainable and is able to quickly adapt to novel entity mentions in gazetteers. (3) Experiments show that the fusion model consistently brings gains cross different clinical NER datasets.

2 Approach

2.1 NER model

NER is a sequence tagging problem by maximizing a conditional probability of tags $\mathbf{y}$ given an input sequence $\mathbf{x}$. We first encode $\mathbf{x}$ into hidden vectors and apply a tagger to produce output $\mathbf{y}$.

$$\mathbf{r} = \text{Encoder}_R(\mathbf{x}) \quad (1)$$

$$\mathbf{o}^r_t = \text{Tagger}_R(\mathbf{r}_t) \quad (2)$$

$$\mathbf{y}_t = softmax(\mathbf{o}^r_t) \quad (3)$$

2.2 Gazetteer model

We embed gazetteers into $\mathbf{E} \in \mathbb{R}^{M\times K\times d}$, where M is the number of gazetteers (e.g, drugs, medical condition), K is the number of gazetteer labels (e.g, B-Drug, E-Drug), and d is the embedding size. We define $\mathbf{E}^g_t = [\mathbf{E}_{0,z^0_t}; \mathbf{E}_{1,z^1_t}; \cdots, \mathbf{E}_{M,z^M_t}]$, where z^j_t is the gazetteer label of token $\mathbf{x}_t$ in gazetteer j. In order to model the association of name knowledge between entity mentions and their contexts, we compute context-aware gazetteer embedding using scaled dot-product self-attention

$$\mathbf{g}_t = softmax\Big(\frac{\mathbf{E}^g_t(\mathbf{E}^g_{t'})^T}{\sqrt{d}}\Big)\mathbf{E}^g_t, \ \forall|t-t'| \le w \quad (4)$$

where w is the size of attention window.

Similar to the NER model, we apply a tagger to produce output $\mathbf{y}$

$$\mathbf{o}^g_t = \text{Tagger}_G(\mathbf{g}_t) \quad (5)$$

$$\mathbf{y}_t = softmax(\mathbf{o}^g_t) \quad (6)$$

2.3 Fusion: NER + gazetteer

To better use information from both modalities, we investigate two different fusion methods to combine information from NER and gazetteer.

- *Early fusion.* In Fig. 1a, we concatenate $\mathbf{r}_t$ with $\mathbf{g}_t$, and feed it into a shared tagger

$$\mathbf{y}_t = softmax\Big(\text{Tagger}_{RG}\big([\mathbf{r}_t; \mathbf{g}_t]\big)\Big) \quad (7)$$

- *Late fusion.* In Fig. 1b, we directly fuse $\mathbf{o}^r_t$ and $\mathbf{o}^g_t$ by performing element-wise max pooling

$$\mathbf{y}_t = softmax\big(\max(\mathbf{o}^r_t, \mathbf{o}^g_t)\big) \quad (8)$$

3 Experiments

3.1 Experimental setup

LM pre-training. We continue to pre-train RoBERTa$_{\text{base}}$ (L=12, H=768, A=12) (Liu et al.,

Table 1: Results on i2b2 (Med, TTP) and DCN (Med, DS). We report micro-F_1 score, each is averaged over 3 random seeds.

	i2b2		DCN	
	Med	TTP	Med	DS
NER w/o fusion	92.26	87.22	84.51	83.99
Early fusion	92.14	87.42	84.82	84.51
Early fusion + attention	92.44	87.43	84.99	84.47
Late fusion	92.37	87.32	84.84	84.58
Late fusion + attention	92.35	87.41	84.82	84.37

2019b) on MIMIC-III dataset (Johnson et al., 2016), which comprises deidentified clinical data from $\sim$ 60k intensive care unit admissions.

Fine-tuning on clinical NER datasets. We fine-tune RoBERTa$_{\text{mimic}}$ and learn a gazetteer model (w/ NER tagger) from scratch on clinical datasets.

- i2b2 - We use public datasets from the 2009 and 2010 i2b2 challenges for medication (Med) (Uzuner et al., 2010), and "test, treatment, problem" (TTP) entity extraction. We follow the original data split from Chalapathy et al. (2016) of 170 notes for training and 256 for testing.
- De-identified clinical notes (DCN) - Second dataset (Bhatia et al., 2018) consists of 1,500 de-identified, annotated clinical notes with medications (Med) and medical conditions (DS). We follow i2b2 challenge guidelines for data annotation.

We extract medical condition and drug dictionaries from UMLS(Bodenreider, 2004) (ontology knowledge graph) based on graph as well semantic meanings. We followed different steps to prune the dictionaries based on different medical ontologies such as RxNorm for medication ($\sim$100k concepts), ICD-10 CM and SNOMED for medical conditions ($\sim$500k concepts). We employ Inside, Outside, Begin, End and Singleton (IOBES) format for both tags and gazetteers[1].

We minimize the cross-entropy loss during training and report micro-F_1 score at test time. We use RoBERTa$_{\text{mimic}}$ as NER encoder and parameterize Taggers via Multi-layer Perception (MLPs). We use BertAdam optimizer, learning rate $5e^{-5}$, and dropout 0.1. We tune hyper-parameters $d \in [2, 12]$ (best:8) and $w \in [2, 10]$ (best:5) on validation set.

Table 2: Performance on unseen entity mentions. Models are trained using 20% training data. We report performance of Medication in i2b2 Med and Treatment in i2b2 TTP.

	Medication	Treatment
NER w/o fusion	76.96	72.40
Late fusion w/ attention	81.63 **(+4.7)**	74.30 **(+1.9)**

Table 3: Ablation study on individual modules.

R_0	RG	R	R_0G
76.23	96.33	90.71	85.75

3.2 Results.

We report overall results in Table 1. We observe that incorporating name knowledge consistently boost performance on all datasets by $0.18 \sim 0.59$ micro-F_1 gains. Overall, two fusion methods achieve comparable results.

3.3 Analysis

We investigate the effectiveness of late fusion on handling three challenges: novel entity mentions, little data access and interpretability.

3.3.1 Novel entity mentions

New drugs and medical condition come out very frequently. For example, "remdesivir"and "Baricitinib" for COVID-19. To investigate the effect of late fusion on unseen entity mentions, we focus on answering questions: whether it can generalize well on unseen entity mentions, and whether it is able to correct prediction once novel entity names are added into gazetteer without re-training?

Zero-shot. We report results on unseen entity mentions not presented in train and validation sets. In Table 2, we see that late fusion brings significant improvement: $+4.7$ F1 for medication (i2b2 Med) and $+1.9$ F1 for Treatment (i2b2 TTP).

"One"-shot in gazetteer. We evaluate the ability of late fusion to quickly adapt to non-stationary gazetteers, e.g., specialists might add new entity mentions into gazetteers or give feedback when models make incorrect prediction.

For this analysis, we split entity mentions in training set into two parts: 70% labelled and 30% in gazetteer, and compare models:

- $\mathbf{R}_0$: NER model only
- $\mathbf{RG}$: $\mathbf{R} + \mathbf{G}$ via late fusion
- $\mathbf{R}$: Unplug $\mathbf{G}$ from $\mathbf{RG}$ after training
- $\mathbf{R}_0\mathbf{G}$: Fix $\mathbf{R}_0$ and learn $\mathbf{G}$ via late fusion

where $\mathbf{R}$ is NER model and $\mathbf{G}$ is gazetteer model.

---

[1] We do string matching for gazetteers by following (Chiu and Nichols, 2016). For example, if A, B and AB are all in gazetteers, we'll label AB as AB. The basic idea is to start from bigger spans, so we first check for ABC, if not found then AB, if not found then A and B.

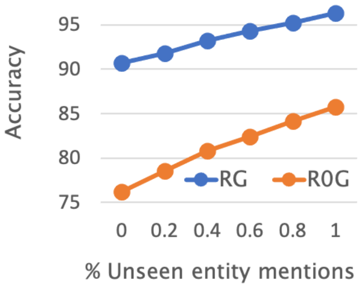


Figure 2: Quick adaptation to non-stationary gazetteers. As we increase the number of unseen entity mentions included in gazetteers, the performance goes up without re-training.

Table 4: Cross-evaluation on i2b2 Med and DCN Med. Column: dataset models are trained on. Row: dataset models are evaluated on.

	i2b2	DCN
i2b2	94.54 → 94.77 (+0.23)	68.78 → 69.68 (+0.9)
DCN	59.98 → 60.08 (+0.1)	90.02 → 90.71 (+0.69)

In Table 3, we observe that $\mathbf{G}$ plays two roles: (1) $\mathbf{R} > \mathbf{R}_0$. $\mathbf{G}$ can regularize $\mathbf{R}$ to gain better generalization ability, and (2) $\mathbf{R}_0\mathbf{G} > \mathbf{R}_0$ and $\mathbf{RG} > \mathbf{R}$. Besides serving as a regularizer, $\mathbf{G}$ provides extra information at test time.

Moreover, we evaluate late fusion by varying the number of unseen entity mentions included in gazetteers. In Fig. 2, without re-training models, late fusion can adapt to new mentions and obtain linear gains, which enables effective user feedback.

Overall, the ability to detect and adapt to novel entity mentions, without re-training models, is useful with accelerated growth in drug development as well as in practical settings where entity extraction is one of the components to build knowledge graph and search engines (Wise et al., 2020; Bhatia et al., 2020). For example, linking new drugs discovered in clinical trails of COVID-19 to standardized codes in ICD-10 [2] or SNOMED [3].

3.3.2 Limited data access

Typically, data accessible to use in the clinical domain is quite limited. In this section, we focus on evaluating fusion model in low-resource settings as well as investigate whether the gain is transferable across related datasets. Here we present results with late fusion methodology.

Low-resource setting We evaluate late fusion by reducing training data size from 100% to 20%. Fig. 3 shows late fusion gains more when less training data is present. With 20% training data, late fusion is able to boost performance over the baseline model by 1.7 micro-F_1 on i2b2 Med dataset.

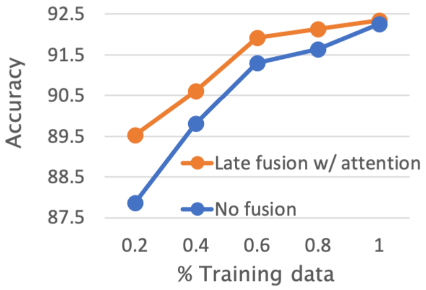

Figure 3: Accuracy vs. Training data size on i2b2 Med. We randomly sample $20\%, 40\%, \cdots, 100\%$ of training data and report micro-F_1 score averaged over 3 random seeds.

Table 5: Qualitative examples.

(1) Treated for $\underbrace{\text{COPD flare}}_{\text{B-R, I-R}}$ with supplemental DuoNebs	
NER w/o fusion	B-R, O
Late fusion w/o attention	B-R, O
Late fusion w/ attention	B-R, I-R
(2) Postop day 0, increase $\underbrace{\text{sodium}}_{\text{S-M}}$, free water added	
$\mathbf{R}$: O, $\mathbf{G}$: S-M, $\mathbf{RG}$: S-M	

Transfer learning. To verify the generalization ability of late fusion, we train models on one dataset and report evaluation on another data source. We re-train models on i2b2 Med and DCN Med using common entity types: Dosage, Medication, Frequency, and Mode. Table.4 shows that the gains from gazetteer enhanced fusion models are preserved in i2b2 → DCN and DCN → i2b2.

3.3.3 Interpretability

Explainable and controllable models are very important for clinical applications. Unfortunately, it is extremely challenging for deep neural networks. We illustrate two qualitative examples in Table.5. Late fusion models are trained on i2b2 Med using 20% training data.

(1) Late fusion correctly predicts *flare* as I-R (Reason) since *COPD flare* is a `Medical Condition`.

(2) By looking into individual predictions from $\mathbf{R}$ and $\mathbf{G}$, we notice that correct prediction is caused by name knowledge in gazetteers.

Overall, late fusion provides us a tool for diagnosis system: to answer questions whether NER or gazetteer model failed and explain why mentions belong to a particular entity type.

4 Conclusion

We studied fusion methods to improve NER system by leveraging name knowledge from gazetteers. We did a thorough analysis on the effectiveness of fusion methods on handling limited data and non-stationary gazetteers. In addition, we demonstrated that fusion models are explainable and can be used to improve NER systems. Future research should extend our approach to structured knowledge to further improve NER system and gain better interpretability.

Abstract

Knowledge Graph (KG) completion has been excessively studied with a massive number of models proposed for the Link Prediction (LP) task. The main limitation of such models is their insensitivity to time. Indeed, the temporal aspect of stored facts is often ignored. To this end, more and more works consider time as a parameter to complete KGs. In this paper, we first demonstrate that, by simply increasing the number of negative samples, the recent ATTH model can achieve competitive or even better performance than the state-of-the-art on Temporal KGs (TKGs), albeit its nontemporality. We further propose HERCULES, a *time-aware* extension of ATTH model, which defines the curvature of a Riemannian manifold as the product of both relation and time. Our experiments show that both HERCULES and ATTH achieve competitive or new state-of-the-art performances on ICEWS04 and ICEWS05-15 datasets. Therefore, one should raise awareness when learning TKGs representations to identify whether time truly boosts performances.

1 Introduction

The prevalent manner to store factual information is the ⟨*s, p, o*⟩ triple data structure where s, p and o stand for the *subject*, *predicate* and *object* respectively. An *entity* denotes whether a subject or an object while a *relation* denote a predicate that links two entities. A collection of triples defines a Knowledge Graph (KG) noted $\mathcal{G}(\mathcal{E}, \mathcal{R})$ with $\mathcal{E}$ the set of entities, *i.e.* subjects and objects, corresponding to the nodes in the graph and $\mathcal{R}$ the set of predicates corresponding to directed edges. Shedding light on the type of connections between entities, KGs are powerful to work with for numerous downstream tasks such as question-answering (Bordes et al., 2014; Hao et al., 2017; Saxena et al., 2020), recommendation system (Yu et al., 2014; Zhang et al., 2016; Zhou et al., 2017), information retrieval (Lao and Cohen, 2010; Rocktäschel et al., 2015; Xiong et al., 2017), or reasoning (Xian et al., 2019; Chen et al., 2020). However, KGs are sometimes incomplete and part of the knowledge is missing. A major concern was therefore raised to predict missing connections between entities, stimulating research on the Link Prediction (LP) task. Intuition is to map each entity and relation into a vector space to learn low-dimensional embeddings such that valid triples maximize a defined scoring function and that fallacious triples minimize it. An approach is efficient if it can model multiple relational patterns. Some predicates are symmetric (*e.g. marriedTo*), asymmetric (*e.g. fatherOf*), an inversion of another relation (*e.g. fatherOf* and *childOf*) or a composition (*e.g. grandfatherOf*). Distinct strategies were introduced by explicitly model those patterns (Bordes et al., 2013; Yang et al., 2015; Trouillon et al., 2016; Sun et al., 2019). However, hierarchical relations have remained challenging to model in Euclidean space. As demonstrated in Sarkar (2011), tree structures are better embedded in hyperbolic spaces. Thus, hyperbolic geometry reveals to be a strong asset to capture hierarchical patterns. Nevertheless, the aforementioned approaches represent embeddings as invariant to time. For example, while writing this article, the triple ⟨*Donald Trump, presidentOf, U.S.*⟩ is correct but will be erroneous at reading time due to the meantime United States presidential inauguration of Joe Biden. To address this issue, recent works considered using quadruplet written as ⟨*s, p, o, t*⟩ by adding a time parameter t. Then, we note a Tem-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3296–3308

poral Knowledge Graph (TKG) as $\mathcal{G}(\mathcal{E}, \mathcal{R}, \mathcal{T})$ with $\mathcal{T}$ the set of timestamps. Stating a precise time can be advantageous for diverse applications (disambiguation, reasoning, natural language generation, etc). Recent works toward TKG representations are essentially extensions of existing timeless KG embeddings that incorporate the time parameter in the computation of their scoring function.

Similar to our work, Han et al. (2020) developed DYERNIE, an hyperbolic-based model inspired from MURP (Balažević et al., 2019a). DYERNIE uses a product of manifolds and adds a (learned) Euclidean time-varying representation for each entity such that each entity further possesses an *entity-specific velocity vector* along with a static (*i.e.* time-unaware) embedding.

In this paper, we first demonstrate that an optimized number of negative samples enables the ATTH model (Chami et al., 2020) to reach competitive or new state-of-the-art performance on temporal link prediction while being unaware of the temporal aspect. We further introduce HERCULES[1], an extension of ATTH. HERCULES differs from DYERNIE in that:

- Following Chami et al. (2020), we utilize Givens transformations and hyperbolic attention to model different relation patterns.
- A single manifold is used.
- Curvature of the manifold is defined as the product of both relation and time parameters.

To the best of our knowledge, this is the first attempt to leverage the curvature of a manifold to coerce time-aware representation. We also provide an ablation study of distinct curvature definitions to investigate the surprising yet compelling results of ATTH over time-aware models.

2 Related Work

In this section, we present existing methods on both KG and TKG vector representation.

2.1 Timeless Graph Embeddings

Previous works on KG completion essentially focused on undated facts with the ⟨*s, p, o*⟩ formalism. Bordes et al. (2013) initially proposed the TRANSE model considering the relation p as a translation between entities in the embedding space. Several variants were then designed. TRANSH (Wang et al., 2014) adds an intermediate projection onto a relation-specific hyper-plane while TRANSR (Lin et al., 2015) maps entities to a relation-specific space of lower rank. However, translation-based approaches cannot model symmetric relations. DISTMULT (Yang et al., 2015) solves this issue by learning a bilinear objective that attributes same scores to ⟨*s, p, o*⟩ and ⟨*o, p, s*⟩ triples. COMPLEX Trouillon et al. (2016) subsequently came up with complex embeddings. Tensor factorization techniques were also proposed. RESCAL (Nickel and Tresp, 2013) applies a three-way tensor factorization. TUCKER (Balažević et al., 2019b) uses *Tucker decomposition* and demonstrates that TUCKER is a generalization of previous linear models. More recently, ROTATE (Sun et al., 2019) considered relations as rotations in a complex vector space which can represent symmetric relations as a rotation of π. QUATE (Zhang et al., 2019) further generalizes rotations using quaternions, known as *hypercomplex* numbers ($\mathbb{C} \subset \mathbb{H}$). A key advantage of quaternions is its non-commutative property allowing more flexibility to model patterns. Nonetheless, memory-wise, QUATE requires 4 embeddings for each entity and relation. To this extent, hyperbolic geometry provides an outstanding framework to produce shallow embeddings with striking expressiveness (Sarkar, 2011; Nickel and Kiela, 2017). Both MURP (Balažević et al., 2019a) and ATTH (Chami et al., 2020) learn hyperbolic embeddings on a n-dimensional Poincaré ball. Different to MURP, ATTH uses a trainable curvature for each relation. Indeed, Chami et al. (2020) have shown that fixing the curvature of the manifold can jeopardize the quality of the returned embeddings. Therefore, defining a parametric curvature for a given relation helps to learn the best underlying geometry.

2.2 Time-Aware Graph Embeddings

The above-mentioned techniques nevertheless disregard the temporal aspect. Indeed, lets consider the two following quadruplets ⟨*Barack Obama, visits, France, 2009-03-11*⟩ and ⟨*Barack Obama, visits, France, 2014-04-21*⟩. Non-temporal models would exhibit the same score for both facts. However, the second quadruplet is invalid[2] and

---

[1] **H**yperbolic Representation with Tim**E** and **R**elational **CU**rvatures for Tempora**L** Knowledg**E** Graph**S**

[2] In fact, Barack Obama visited Japan on April 21, 2014, not France

should therefore get a lower score. For this reason, several works contributed to obtain time-aware embeddings. Thanks to the existing advancements on graph representations, many strategies are straightforward extensions of static approaches. TTRANSE (Leblay and Chekol, 2018) alters the scoring function of TRANSE to encompass time-related operations such as time translations. Likewise, TA-TRANSE (García-Durán et al., 2018) uses LSTMs (Hochreiter and Schmidhuber, 1997) to encode a temporal predicate which carries the time feature. By analogy with TRANSH, HYTE (Dasgupta et al., 2018) learns time-specific hyperplanes on which both entities and relations are projected. Then, another family of temporal extensions are derived from DISTMULT such as KNOW-EVOLVE (Trivedi et al., 2017), TA-DISTMULT (García-Durán et al., 2018), or TDISTMULT (Ma et al., 2019) that also utilize a bilinear scoring function. DE-SIMPLE (Goel et al., 2020) provides diachronic entity embeddings inspired from diachronic word embeddings (Hamilton et al., 2016). Recently, ATISE (Xu et al., 2019) embeds entities and relations as a multi-dimensional Gaussian distributions which are time-sensitive. An advantage of ATISE is its ability to represent time uncertainty as the covariance of the Gaussian distributions. TERO (Xu et al., 2020b) combines ideas from TRANSE and ROTATE. It defines relations as translations and timestamps as rotations. As far as we are aware, DYERNIE (Han et al., 2020) is the first work to contribute to hyperbolic embeddings for TKG. It achieves state-of-the-art performances on the benchmark datasets ICEWS14 and ICEWS05-15. Time is defined as a translation on a product of manifolds with trainable curvatures using a *velocity vector* for each entity.

In our work, we demonstrate that using a single manifold with learnable relational and time curvatures is sufficient to reach competitive or new state-of-the-art performances.

3 Problem Definition

Lets consider a valid quadruplet $\langle s,\ p,\ o,\ t\rangle \in \mathcal{S} \subset \mathcal{E} \times \mathcal{R} \times \mathcal{E} \times \mathcal{T}$, with $\mathcal{E}$, $\mathcal{R}$ and $\mathcal{T}$ the sets of entities, relations and timestamps respectively and $\mathcal{S}$ the set of correct facts. A scoring function $f : \mathcal{E} \times \mathcal{R} \times \mathcal{E} \times \mathcal{T} \rightarrow \mathbb{R}$ is defined such that $f(s, p, o, t)$ is maximized for any quadruplet $\in \mathcal{S}$, and minimized for corrupted quadruplet ($\notin \mathcal{S}$). Throughout the optimization of the foregoing constraint, representations of entities, relations and times are learned accordingly. The resulting embeddings should then capture the multi-relational graph structure. Thus, f is gauging the probability that an entity s is connected to an entity o by the relation p at time t.

4 Hyperbolic Geometry

Hyperbolic geometry belongs to non-Euclidean geometry. In contrast to Euclidean geometry relying on Euclid's axioms (Heath and Euclid, 1956), non-Euclidean geometry rejects the fifth axiom known as the parallel postulate. It states that given a point x and a line l_1, there exists a unique line l_2 parallel to l_1 passing through x. This is only possible due to a (constant) zero curvature of the space. The curvature defines how much the geometry differs from being flat. The higher the absolute curvature, the curvier. Euclidean space has a zero curvature hence called *flat space*. When represented in an Euclidean space, straight lines become curved, termed as *geodesics* (Fig. 1).

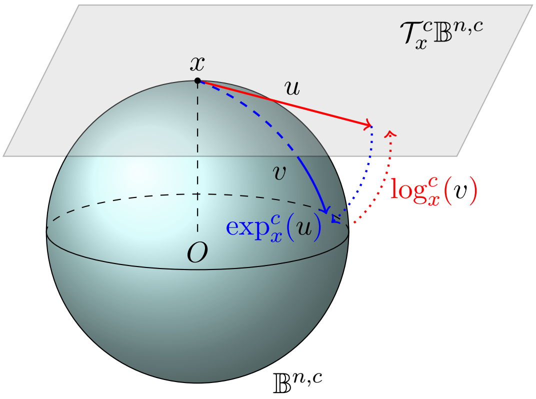

Figure 1: Illustration of the exponential and logarithmic maps between the Poincaré ball $\mathbb{B}^{n,c}$ and the tangent space $\mathcal{T}_x^c\mathbb{B}^{n,c}$.

Hyperbolic geometry comes with a constant negative curvature. In our study, as Nickel and Kiela (2017); Han et al. (2020); Chami et al. (2020), we make use of the Poincaré ball ($\mathbb{B}^{n,c}$, $g^{\mathbb{B}}$) which is a n-dimensional Riemannian manifold $\mathbb{B}^{n,\,c} = \{x \in \mathbb{R}^n : \|x\|^2 < \frac{1}{c}\}$ of constant curvature $-c$ ($c > 0$) equipped with Riemannian metric $g^{\mathbb{B}}$ and where $\|.\|$ denotes the L_2 norm. The metric tensor $g^{\mathbb{B}}$ gives information about how distances should be computed on the manifold and is defined as $g^{\mathbb{B}} = (\lambda_x^c)^2 I_n$ with the *conformal factor* $\lambda_x^c = \frac{2}{1-c\|x\|^2}$ and I_n the identity matrix of size $n \times n$. We write $\mathcal{T}_x^c\mathbb{B}^{n,c}$ the n-dimensional tangent space at $x \in \mathbb{B}^{n,c}$. At the difference of $\mathbb{B}^{n,c}$, $\mathcal{T}_x^c\mathbb{B}^{n,c}$ locally follows an Euclidean geometry. As illustrated in Fig. 1, we can project $v \in \mathbb{B}^{n,c}$ on $\mathcal{T}_x^c\mathbb{B}^{n,c}$ at x via the logarithmic map. Inversely, we can map a point $u \in \mathcal{T}_x^c\mathbb{B}^{n,c}$ on $\mathbb{B}^{n,c}$ at x via the exponential map. A closed-form of those mappings exist when x corresponds to the origin (Eqs. 1 and 2).

$$\exp_{\mathbf{0}}^c(u) = \tanh(\sqrt{c}\|u\|)\frac{u}{\sqrt{c}\|u\|} \tag{1}$$

$$\log_{\mathbf{0}}^c(v) = \tanh^{-1}(\sqrt{c}\|v\|)\frac{v}{\sqrt{c}\|v\|} \tag{2}$$

Contrary to $\mathcal{T}_x^c\mathbb{B}^{n,c}$, the Euclidean addition on the hyperbolic manifold does not hold. Alternately, we use the Möbius addition (Vermeer, 2005; Ganea et al., 2018) satisfying the boundaries constraints of the manifold. It is however non-commutative and non-associative. The closed-form is presented in Eq. 3.

$$x \oplus_c y = \frac{(1 - 2cx^T y - c\|y\|^2)x + (1 + c\|x\|^2)y}{1 - 2cx^T y + c^2\|y\|^2\|x\|^2} \tag{3}$$

The distance between two points x and y on $\mathbb{B}^{n,c}$ is the hyperbolic distance $d_{\mathbb{B}^{n,c}}(x, y)$ defined as:

$$d_{\mathbb{B}^{n,c}}(x, y) = \frac{2}{\sqrt{c}}\tanh^{-1}(\sqrt{c}\|-x \oplus_c y\|) \tag{4}$$

5 From ATTH to HERCULES

Given a quadruplet, ⟨*s, p, o, t*⟩, we note e_s^H, r_p^H and e_o^H the hyperbolic embeddings of the subject, predicate and object respectively.[3] ATTH uses relation-specific embeddings, rotations, reflections and curvatures. The curvature is defined as depending on the corresponding relation *p* involved. Precisely, a relation *p* is attributed with an individual parametric curvature c_p. The curvature c_p is defined in Eq. 5 as:

$$c_p = \sigma(\mu_p) \tag{5}$$

where μ_p is a trainable parameter $\in \mathbb{R}$ and σ is a smooth approximation of the ReLU activation function defined in $[0, +\infty]$. With such approach, the geometry of the manifold is learned, thus modified for a particular predicate. The curvature dictates how the manifold is shaped. Changing the curvature of the manifold implies changing the positions of projected points. This means that for distinct relations, the same entity will have different positions because of the different resulting geometries for each relation. For example, lets consider the triples t_1 := ⟨*Barack Obama, visit, France*⟩ and t_2 := ⟨*Barack Obama, cooperate, France*⟩. The Euclidean representations of entities *Barack Obama* and *France* from both facts will be projected onto the riemannian manifold. However, the structure (i.e. curvature) of the manifold changes as a function of the relation of each fact (*i.e.* '*visit*' and '*cooperate*'). Therefore, the resulting hyperbolic embbeding of *Barack Obama* of t_1 will not be the same resulting hyperbolic embedding of *Barack Obama* in t_2. By analogy, the same holds for entity *France*.

In order to learn rotations and reflections, ATTH uses 2 × 2 Givens transformations matrices. Those transformations conserve relative distances in hyperbolic space and can therefore directly be applied to hyperbolic embeddings (isometries). We note $W_{\Theta_p}^{rot}$ and $W_{\Phi_p}^{ref}$ the block-diagonal matrices where each element on their diagonals is given by $G^+(\theta_{p,i})$ and $G^-(\phi_{p,i})$ respectively, with i the i^{th} element of the diagonal (Eqs. 6 and 7).

$$G^+(\theta_{p,i}) = \begin{bmatrix} \cos(\theta_{p,i}) & -\sin(\theta_{p,i}) \\ \sin(\theta_{p,i}) & \cos(\theta_{p,i}) \end{bmatrix} \tag{6}$$

$$G^-(\phi_{p,i}) = \begin{bmatrix} \cos(\phi_{p,i}) & \sin(\phi_{p,i}) \\ \sin(\phi_{p,i}) & -\cos(\phi_{p,i}) \end{bmatrix} \tag{7}$$

Then, the rotations and reflections are applied only to the subject embedding as describe in Eq. 8.

$$q_{rot}^H = W_{\Theta_p}^{rot} e_s^H \qquad q_{ref}^H = W_{\Phi_p}^{ref} e_s^H \tag{8}$$

Furthermore, to represent complex relations that can be a mixture of rotation and reflection, ATTH utilizes an hyperbolic attention mechanism. The attention scores $\alpha_{q_{rot}^H}^p$ and $\alpha_{q_{ref}^H}^p$ are computed in the tangent space by projecting the hyperbolic rotation embedding q_{rot}^H and hyperbolic reflection embedding q_{ref}^H with the logarithmic map (Eq. 2). More specifically, ATTH implements a tangent space average to implement the typical weighted average as proposed in Liu et al. (2019) and Chami et al. (2019). Then, the attention vector is mapped back to manifold using the exponential map (Eq. 1). We

---

[3] Since ATTH is not considering time, the parameter t is not used.

have then:

$$ATT(q^H_{rot}, q^H_{ref}, p) = \exp^{c_p}_{\mathbf{0}}(\alpha_{q^H_{rot}} \log^{c_p}_{\mathbf{0}}(q^H_{rot}) + \alpha_{q^H_{ref}} \log^{c_p}_{\mathbf{0}}(q^H_{ref})) \tag{9}$$

AttH finally applies a translation of the hyperbolic relation embedding r^H_p over the resulting attention vector (Eq. 9). As mentioned in Chami et al. (2020), translations help to move between different levels of the hierarchy.

$$Q(s,p) = ATT(q^H_{rot}, q^H_{ref}, p) \oplus_{c_p} r^H_p \tag{10}$$

The scoring function is similar to the one used in Balažević et al. (2019a) and Han et al. (2020) defined as:

$$s(s,p,o,t) = -d^{c_p}(Q(s,p), e^H_o)^2 + b_s + b_o \tag{11}$$

where b_s and b_o stand for the subject and object biases, respectively.

We then propose Hercules, a time-aware extension of AttH. Hercules redefines the curvature of the manifold as being the product of both relation and time as illustrated in Eq. 12:

$$c^t_p = \sigma(\mu_p \times \tau_t) \tag{12}$$

with τ_t a learnable parameter $\in \mathbb{R}$. A trade-off therefore exists between relation and time. A low value of either μ_p or τ_t will lead to a flatter space while higher values will tend to a more hyperbolic space. The main intuition of Hercules is that both relation and time directly adjust the geometry of the manifold such that the positions of projected entities are relation-and-time-dependent. This is advantageous in that no additional temporal parameters per entity are needed. Since the whole geometry has changed for specific relation and time, all future projections onto that manifold will be aligned to the corresponding relation and timestamp. We investigate different curvature definitions and time translation in our experiments (see Section 6). The scoring function of Hercules remains same as AttH.

When learning hyperbolic parameters, the optimization requires to utilize a Riemannian gradient (Bonnabel, 2013). However, proven to be challenging, we instead learn all embeddings in the Euclidean space. The embeddings can then be mapped to the manifold using the exponential map (Eq. 1). This allows the use of standard Euclidean optimization strategies.

6 Experiments

We outline in this section the experiments and evaluation settings.

6.1 Datasets

For fair comparisons, we test our model on same benchamark datasets used in previous works, *i.e.* ICEWS14 and ICEWS05-15. Both datasets were constructed by García-Durán et al. (2018) using the Integrated Crisis Early Warning System (ICEWS) dataset (Boschee et al., 2018). ICEWS provides geopolitical information with their corresponding (event) date, *e.g.* ⟨*Barack Obama, visits, France, 2009-03-11*⟩. More specifically, ICEWS14 includes events that happened in 2014 whereas ICEWS05-15 encompasses facts that appeared between 2005 and 2015. We give the original datasets statistics in Table 2. To increase the number of samples, for each quadruplet ⟨*s, p, o, t*⟩ we add ⟨*s,* p^{-1}*, o, t*⟩, where p^{-1} is the inverse relation of *p*. This is a standard data augmentation technique usually used in LP (Balažević et al., 2019a; Goel et al., 2020; Han et al., 2020).

6.2 Evaluation Protocol & Metrics

Given a (golden) test triple ⟨*s, p, o, t*⟩, for each entity $s' \in \mathcal{E}$, we interchange the subject *s* with s' and apply the scoring function f on the resulting query ⟨s'*, p, o, t*⟩. Since replacing *s* by all possible entity s' may end up with a correct facts, we filter out those valid quadruplets and give them extremely low scores to avoid correct quadruplets to be scored higher than the tested quadruplet in final ranking (Bordes et al., 2013). We then rank the entities based on their scores in descending order. We store the rank of the correct entity *s* noted z_s. Thus, the model should maximize the returned score for the entity *s* such that $z_s = 1$. The same process is done using the object *o*.

To evaluate our models, we make use of the Mean Reciprocal Rank (MRR). We also provide the Hits@1 (H@1), Hits@3 (H@3) and Hits@10 (H@10) which assess on the frequency that the valid entity is in the top-1, top-3 and top-10 position, respectively.

6.3 Implementation Details

To ensure unbiased comparability, the same training procedure and hyper-parameters are shared for

Model	**Parameters**
TTransE	$(\lvert\mathcal{E}\rvert + 2\lvert\mathcal{R}\rvert + \lvert\mathcal{T}\rvert) \cdot n$
TComplEx	$(2\lvert\mathcal{E}\rvert + 4\lvert\mathcal{R}\rvert + 2\lvert\mathcal{T}\rvert) \cdot n$
HyTE	$(\lvert\mathcal{E}\rvert + 2\lvert\mathcal{R}\rvert + \lvert\mathcal{T}\rvert) \cdot n$
ATISE	$(\lvert\mathcal{E}\rvert + 2\lvert\mathcal{R}\rvert) \cdot n$
TERO	$(\lvert\mathcal{E}\rvert + 2\lvert\mathcal{R}\rvert + \lvert\mathcal{T}\rvert) \cdot n$
DyERNIE	$2 \cdot (\lvert\mathcal{E}\rvert + 2\lvert\mathcal{R}\rvert) \cdot n + 2 \cdot \lvert\mathcal{E}\rvert$
AttH	$(\lvert\mathcal{E}\rvert + 2\lvert\mathcal{R}\rvert) \cdot n + \lvert\mathcal{E}\rvert + 2\lvert\mathcal{R}\rvert(1 + 3n)$
Hercules	$(\lvert\mathcal{E}\rvert + 2\lvert\mathcal{R}\rvert) \cdot n + \lvert\mathcal{E}\rvert + 2\lvert\mathcal{R}\rvert(1 + 3n) + \lvert\mathcal{T}\rvert$

Table 1: Number of parameters per models with respect to the embedding dimension n.

Table 2: ICEWS14 and ICEWS05-15 Datasets Statistics

AttH and Hercules.[4] Number of epochs and batch size were set to 500 and 256, respectively. We minimized the cross-entropy loss using negative sampling, where negative samples corrupt the valid object only (uniformly selected). After validation, we noticed that best results were obtained using 500 negative samples. We chose the Adam optimizer (Kingma and Ba, 2014) with an initial learning rate of 0.001. The final models for evaluation were selected upon the MRR metric on the validation set. We re-train ATISE and TeRo using the same parameters as mentionned in Xu et al. (2019) and Xu et al. (2020b) but varying dimensions.[5]

6.4 Results

We report models performances on the link prediction task on TKGs. Additional analyses on the results are also given.

6.4.1 Link Prediction results

We provide link prediction results on ICEWS14 and ICEWS05-15 for AttH, Hercules and different models from the literature. As Han et al. (2020), we adopted a dimension analysis to investigate behaviors and robustness of approaches. When possible, we re-run official implementation of models. Otherwise, official or best results in literature are reported. Results are shown in Table 3.

As expected, hyperbolic-based strategies (*i.e.* DyERNIE, AttH and Hercules) perform much better at lower dimensions, outperforming most of other approaches with ten times less dimensions. We report an average absolute gain of 11.6% points in MRR with only 10 dimensions over the median performance of other approaches with 100 dimensions. This strengthens the effectiveness of hyperbolic geometry to induce high-quality embeddings with few parameters.

Astonishingly, we notice that AttH model is highly competitive despite the absence of time parameter. AttH exhibits new state-of-the-art or statistically equivalent performances compared to DyERNIE and Hercules. We remark no statistically significant differences in performances between hyperbolic models.[6] Importantly, unlike other research carried out in this area, time information here does not lead to any notable gain. This seems to indicate that other parameters should be considered. We examine this phenomenon in section 6.4.2.

On ICEWS14, for *dim* $\in \{20, 40, 100\}$, both AttH and Hercules outperform DyERNIE by a large margin. We witness an improvement of 2.5% and 5% points in MRR and Hits@1 with 100-dimensional embeddings. On ICEWS05-15, AttH and Hercules yield comparable achievements with the state-of-the-art. In contrast to DyERNIE,

---

[4] We used the official implementation of AttH available at `https://github.com/HazyResearch/KGEmb`. We adapted it to implement Hercules.

[5] We used the official implementation available at `https://github.com/soledad921/ATISE`

[6] We performed the Mixed-Factorial Analysis of Variance (ANOVA), in which the independent variables are *the dimension* and *the model* and the dependent variable is *the metric*. We consider two groups one for each dataset. We report p-values of 0.842, 0.872, 0.926 and 0.229 for MRR, H@1, H@3 and H@10 respectively.

it is noteworthy that ATTH and HERCULES utilize a single manifold while reaching top performances.

We also distinguish tempered results on Hits@10 metric for ATTH and HERCULES models. This suggests that during optimization, ATTH and HERCULES favor ranking some entities on top while harming the representation of others.

6.4.2 Is Time *All* You Need ?

In this section, we investigate the influence of the temporal parameter on performances.

First, besides time translation, we probe different curvature definitions to identify fluctuation in performances. We analyze how time information alters the LP results by adding time as part of the curvature (*i.e.* HERCULES) and as a translation. We also explore if incorporating the Euclidean dot product of the subject and object embeddings (noted $\langle e_s^{\mathbb{E}}, e_o^{\mathbb{E}} \rangle$) into the curvature helps to learn a better geometry. An ablation study is given in Table 4.

Albeit counter-intuitive, we observe that our results corroborate with our initial finding: time information is not the culprit of our high performances. More strikingly, a simple relational curvature (*i.e.* ATTH) is sufficient to perform best on ICEWS14 (*dim* = 40). Neither the inclusion of a time translation, similarly to TTRANSE, nor the Euclidean dot product provide interesting outcomes.

We then probe the sensitivity of HERCULES towards temporal feature by performing LP with incorrect timestamps. Our intuition is to inspect whether feeding invalid timestamps during evaluation exhibits significant variation or not compared to the reference performances, *i.e.* LP results with initial (non-corrupted) testing samples. To do so, for each testing quadruplet, we replace the (correct) time parameter with each possible timestamp from $\mathcal{T}$. We therefore collect multiple LP performances of HERCULES corresponding to each distinct timestamp. We plot the distribution of resulting performances of temporally-corrupted quadruplets from ICEWS14 (*dim*=100) in Fig. 2. We can observe that despite erroneous timestamps, LP results show insignificant discrepancies with the initial HERCULES performance (dashed red line). The standard deviations from HERCULES reference performance for MRR, H@1, H@3, H@10 metrics are 1.78×10^{-4}, 3.18×10^{-3}, 1.05×10^{-2}, 3.55×10^{-3} respectively. This indicates that HERCULES gives little importance to the time parameter and thus only relies on the entity and the predicate to perform knowledge graph completion. This further highlights our finding that timestamp is not responsible for our attracting performances.

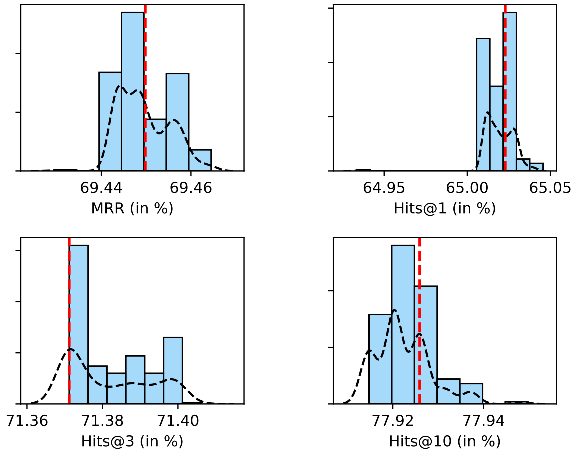

Figure 2: Distribution of performances of HERCULES on temporally-corrupted quadruplets from ICEWS14 with *dim*=100. A smooth approximation of the distribution is drawn as a dashed black curve. The reference performance is indicated with a dashed red line.

We therefore assume that the optimization procedure may be involved. We consequently question the effect of negative sampling. Precisely, we train HERCULES with *dim* = 40 by tuning the number of negative samples between 50 to 500. We plot the learning curves in Fig. 3.

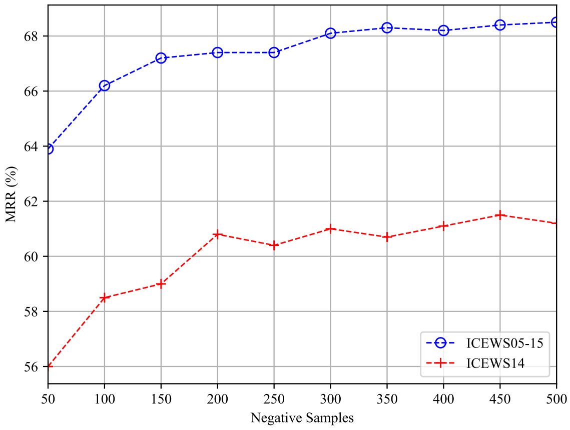

Figure 3: Performance of HERCULES (*dim* = 40) on ICEWS14 and ICEWS05-15 with varying number of negative samples.

For both, ICEWS14 and ICEWS05-15, negative sampling shows considerable gain as the number of samples increases. We record an absolute gain of 5% points in MRR from 50 to 500 samples. We can see a rapid growth in MRR when the number of samples is inferior to 200. Adding 50 samples is equivalent to about 2% points gain in MRR. Then,

performances reach a plateau around 300 negative samples. We conjecture that a diversity in negative samples is enough to learn good representations. Notwithstanding that a large number of negative samples heavily constraints the location of entities in space, the resulting embeddings might benefit from it to be better positioned relatively to others.

We conclude that despite the present time parameter, an optimal negative sampling enables to reach new state-of-the-art outcome. Therefore, we argue that time is not the only parameter that should be considered when performing LP. We highlight that one should be raising awareness when training TKG representations to identify if time is truly helping to boost performances.

6.4.3 ATTH versus HERCULES

We explore here how the geometry of HERCULES differs from ATTH. To do so, we inspect the absolute difference of their learned curvatures Δ_c. We plot Δ_c with respect to the relations and timestamps for *dim* = 40 on ICEWS14 in Fig. 4.[7] Similar plots are given for ICEWS05-15 in Appendix A.1.

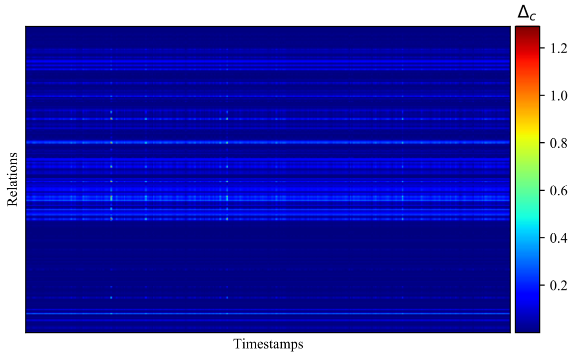

Figure 4: Absolute curvatures differences between ATTH and HERCULES given specific relation and time on ICEWS14 dataset (*dim* = 40).

Besides rare steep discrepancy in curvatures (*i.e.* $\Delta_c > 1.0$), HERCULES is akin to ATTH concerning learned geometries. We report that 85.0% and 95.6% of Δ_c's are smaller than 0.1 on ICEWS14 and ICEWS05-15 respectively. We point out that some timestamps affect *globally* all relations, albeit very limited. This can be seen in Fig. 5 by the aligned vertical strips. It indicates that HERCULES uses its additional time parameter to learn a slightly different manifold but nonetheless quite similar to ATTH.[8] We provide further analysis on the shifts of the curvatures while increasing embeddings dimension in Appendices A.2 and A.3.

We depict an example of learned hyperbolic representation of ICEWS14 entities of ATTH and HERCULES for the relation '*make a visit*' and timestamp set to 01-01-2014 in Fig. 5. We plot embeddings of ICEWS05-15 in Appendix A.4.

7 Conclusion

In this paper, we have demonstrated that without adding neither time information nor supplementary parameters, the ATTH model astonishingly achieves similar or new state-of-the-art performances on link prediction upon temporal knowledge graphs. In spite of the inclusion of time with our proposed time-aware model HERCULES, we have shown that negative sampling is sufficient to learn a good underlying geometry. In the future, we plan to explore new mechanisms to incorporate temporal information to improve performances of ATTH.

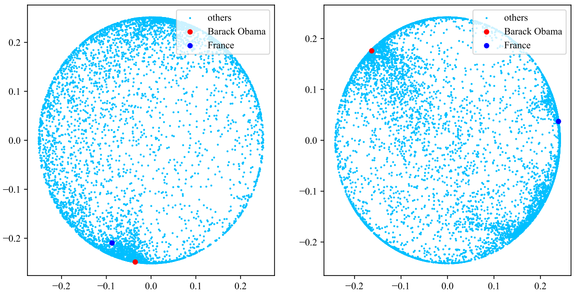

Figure 5: Illustration of two-dimensional hyperbolic entity embeddings learned by ATTH (left) and HERCULES (right) on ICEWS14 for predicate '*make a visit*' and timestamp set to 01-01-2014.

A Appendices

A.1 ATTH versus HERCULES

We plot the absolute difference in curvatures between ATTH and HERCULES for *dim* = 40 on ICEWS05-15 in Fig. 6. As in ICEWS14 dataset, we observe that learned geometries on ICEWS15 dataset by ATTH and HERCULES are alike. Time is showing insubstantial impact on the curvature.

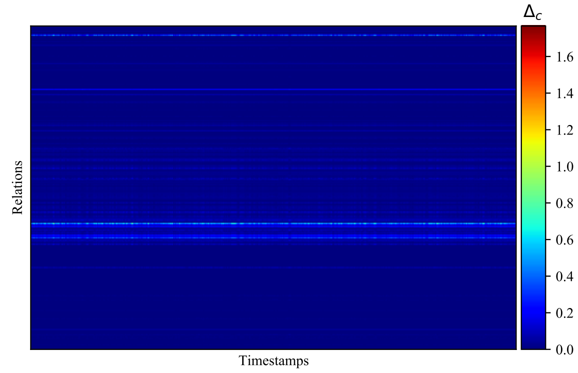

Figure 6: Absolute curvatures differences between AttH and Hercules given specific relation and time on ICEWS05-15 dataset (*dim* = 40).

A.2 AttH versus AttH

We inspect how the curvature of AttH fluctuates while increasing the embedding dimension. We compare curvatures shifts between *dim* = 40 and *dim* = 100. We plot Δ_c in Fig. 7.

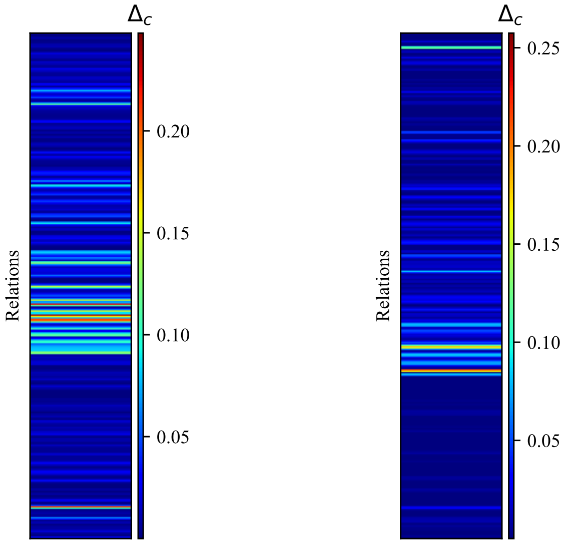

Figure 7: Absolute curvatures differences of AttH between *dim* = 40 and *dim* = 100 given specific relation and time on ICEWS14 dataset (left) and ICEWS05-15 dataset (right). No timestamps since AttH is a time-unaware model.

The fluctuation in curvature is moderate while dimension of embeddings increases. We can see that variation is almost inferior to 0.2. This underlines that geometry does not change much for a specific relation when the dimension grows. For some relations, we note however that curvature is knowing significant dissimilitudes.

A.3 Hercules versus Hercules

We report the dissimilarities in curvature for different relations and timestamps on ICEWS14 and ICEWS05-15 in Fig. 8 and Fig. 9.

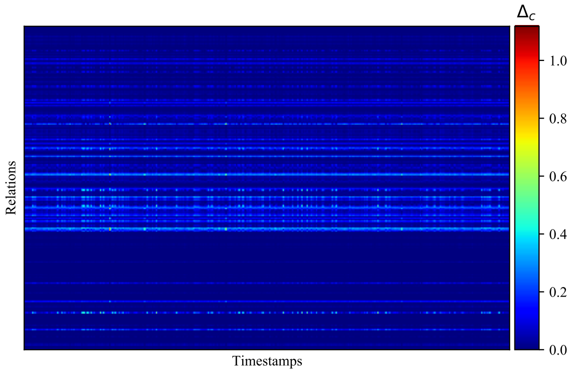

Figure 8: Absolute curvatures differences of Hercules between *dim* = 40 and *dim* = 100 given specific relation and time on ICEWS14 dataset.

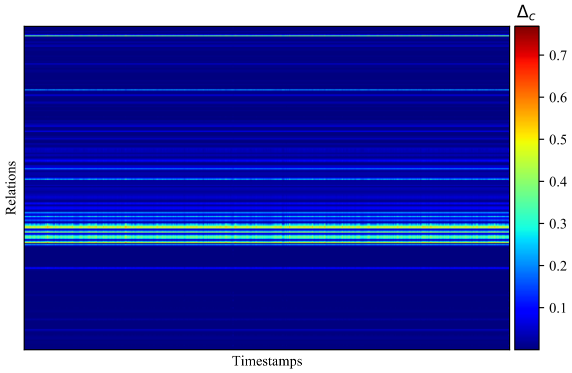

Figure 9: Absolute curvatures differences of Hercules between *dim* = 40 and *dim* = 100 given specific relation and time on ICEWS05-15 dataset.

We note that around 87.7% and 91.1% of variations are smaller than 0.1 on ICEWS14 and ICEWS05-15 respectively. This seems to indicate that despite the dimensionality gap, the learned geometry for each relation does not differ much between *dim* = 40 and *dim* = 100.

A.4 Two-Dimensional Hyperbolic Embeddings

We give an illustration of learned embeddings on ICEWS05-15 by AttH and Hercules models in Fig. 10.

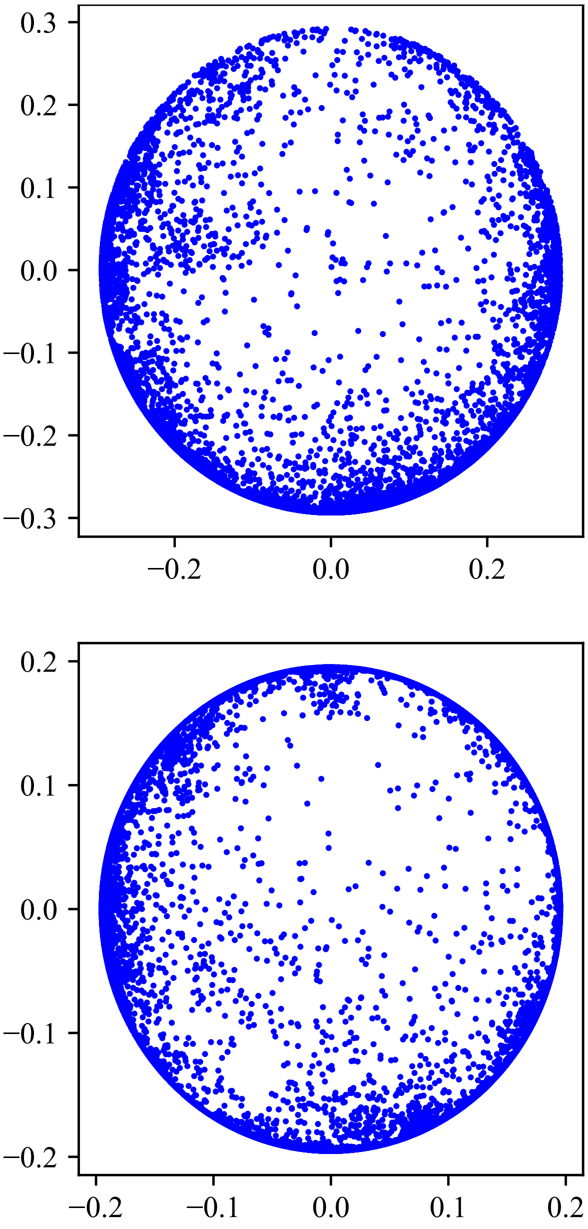

Figure 10: Illustration of two-dimensional hyperbolic embeddings learned by AttH (top) and Hercules (bottom) on ICEWS05-15.

DISFL-QA: A Benchmark Dataset for Understanding Disfluencies in Question Answering

disfl-qa@google.com

Abstract

Disfluencies is an under-studied topic in NLP, even though it is ubiquitous in human conversation. This is largely due to the lack of datasets containing disfluencies. In this paper, we present a new challenge question answering dataset, DISFL-QA, a derivative of SQUAD, where humans introduce contextual disfluencies in previously fluent questions. DISFL-QA contains a variety of challenging disfluencies that require a more comprehensive understanding of the text than what was necessary in prior datasets. Experiments show that the performance of existing state-of-the-art question answering models degrades significantly when tested on DISFL-QA in a zero-shot setting. We show data augmentation methods partially recover the loss in performance and also demonstrate the efficacy of using gold data for fine-tuning. We argue that we need large-scale disfluency datasets in order for NLP models to be robust to them. The dataset is publicly available at: `https://github.com/google-research-datasets/disfl-qa`.

1 Introduction

During conversations, humans do not always premeditate exactly what they are going to say; thus a natural conversation often includes interruptions like repetitions, restarts, or corrections. Together these phenomena are referred to as *disfluencies* (Shriberg, 1994). Figure 1a shows different types of conventional disfluencies in an utterance, as described by Shriberg (1994).

Repetition	When is Eas ugh Easter this year?
Correction	When is Lent I meant Easter this year?
Restarts	How much no wait when is Easter this year?

(a) Conventional categories of *Disfluencies*. The ***reparandum*** (words intended to be corrected or ignored), ***interregnum*** (optional discourse cues) and ***repair*** are marked.

Passage: *The Normans (Norman: Nourmands; French: Normands; Latin: Normanni) were the people who in the 10th and 11th centuries gave their name to Normandy, a region in France. They were descended from Norse ("Norman" comes from "Norseman") raiders and pirates from Denmark, Iceland and Norway who, under their leader Rollo, …*

q_1: In what country is Normandy located?
dq_1: In what country is **Norse** found **no wait** **Normandy not Norse**?
T5(q_1): France ✓
T5(dq_1): Denmark ✗

q_2: When were the Normans in Normandy?
dq_2: **From which countries no tell me when were the Normans in Normandy**?
T5(q_2): 10th and 11th centuries ✓
T5(dq_2): Denmark, Iceland and Norway ✗

(b) Contextualized *Disfluencies* in DISFL-QA (§2).

Figure 1: **(a)** Categories of disfluencies (Shriberg, 1994) **(b)** A passage and questions (q_i) from SQUAD, along with their disfluent versions (dq_i) and predictions from a T5-QA model.

With the growing popularity of voice assistants, such disfluencies are of particular interest for goal-oriented or information seeking dialogue agents, because an NLU system, trained on fluent data, can easily get misled due to their presence. Figure 1b shows how the presence of *disfluencies* in a question answering (QA) setting, namely SQUAD (Rajpurkar et al., 2018), affects the prediction of a state-of-the-art T5 model (Raffel et al., 2020). For example, the original question q_1 is seeking an answer about the location of *Normandy*. In the disfluent version dq_1 (which is **semantically equivalent** to q_1), the user starts asking about *Norse* and then corrects themselves to ask about the *Normandy* instead. The presence of this correctional disfluency confuses the QA model, which tend to rely on shallow textual cues from question for making predictions.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3309–3319
August 1–6, 2021. ©2021 Association for Computational Linguistics

Unfortunately, research in NLP and speech community has been impeded by the lack of curated datasets containing such disfluencies. The datasets available today are mostly conversational in nature, and span a limited number of very specific domains (e.g., telephone conversations, court proceedings) (Godfrey et al., 1992; Zayats et al., 2014). Furthermore, only a small fraction of the utterances in these datasets contain disfluencies, with a limited and skewed distribution of disfluencies types. In the most popular dataset in the literature, the SWITCHBOARD corpus (Godfrey et al., 1992), only 5.9% of the words are *disfluencies* (Charniak and Johnson, 2001), of which > 50% are *repetitions* (Shriberg, 1996), which has been shown to be the relatively simpler form of disfluencies (Zayats et al., 2014; Jamshid Lou et al., 2018; Zayats et al., 2019).

To fill this gap, we present DISFL-QA, the first dataset containing *contextual disfluencies* in an information seeking setting, namely question answering over Wikipedia passages. DISFL-QA is constructed by asking human raters to insert disfluencies in *questions* from SQUAD-v2, a popular question answering dataset, using the passage and remaining questions as context. These contextual disfluencies lend naturalness to DISFL-QA, and challenge models relying on shallow matching between question and context to predict an answer. Some key properties of DISFL-QA are:

- DISFL-QA is a targeted dataset for disfluencies, in which all questions (≈12k) contain disfluencies, making for a much larger disfluent test set than prior datasets.
- Over 90% of the disfluencies in DISFL-QA are corrections or restarts, making it a much harder test set for disfluency correction (§2.2).
- DISFL-QA contains wider diversity in terms of semantic distractors than earlier disfluency datasets, and newer phenomenon such as coreference between the *reparandum* and the *repair* (§2.3).

We experimentally reveal the brittleness of state-of-the-art LM based QA models when tested on DISFL-QA in zero-shot setting (§4.1). Since collecting large supervision datasets containing disfluencies for training is expensive, different data augmentation methods for recovering the zero-shot performance drop are also evaluated (§3.3). Finally, we demonstrate the efficacy of using the human annotated data in varying fractions, for both end-to-end QA supervision and disfluency generation based data augmentation techniques (§4.2).

We argue that creation of datasets, such as DISFL-QA, are vital for **(1)** improving understanding of disfluencies, and **(2)** developing robust NLU models in general.

2 DISFL-QA: Adding Disfluencies to QA

DISFL-QA builds upon the existing SQUAD-v2 dataset, a question answering dataset which contains curated paragraphs from Wikipedia and associated questions. Each question associated with the paragraph is sent for a human annotation task to add a contextual disfluency using the paragraph as a source of distractors. Finally, to ensure the quality of the dataset, a subsequent round of human evaluation with an option to re-annotate is conducted.

2.1 Source of Questions

We sourced passages and questions from SQUAD-v2 (Rajpurkar et al., 2018) development set. SQUAD-v2 is an extension of SQUAD-v1 (Rajpurkar et al., 2016) that contains unanswerable questions written adversarially by crowd workers to look similar to answerable ones from SQUAD-v1. We use both answerable and unanswerable questions for each passage in the annotation task.

2.2 Annotation Task

To ensure high quality of the dataset, our annotation process consists of 2 rounds of annotation:

First Round of Annotation. Expert raters were shown the passage along with all the associated questions and their answers, with one of the question-answer pair highlighted for annotation.[1] The raters were instructed to use the provided context in crafting disfluencies to make for a non-trivial dataset.

The rater had to provide a disfluent version of the question that (a) is *semantically equivalent* to the original question (b) is *natural*, i.e., a human can utter them in a dialogue setting. When

Table 1: Example passage and fluent questions from the SQUAD dataset and their disfluent versions provided by human raters, categorized by the type of disfluency along with their estimated percentage in the DISFL-QA dataset.

writing the disfluent version of a question, we instructed raters not to include partial words or filled pauses (e.g., "*um*", "*uh*", "*ah*" etc.), as they can be detected relatively easily (Johnson and Charniak, 2004; Jamshid Lou and Johnson, 2017). Raters were shown example disfluencies from each of the categories in Table 1. On average, raters spent 2.5 minutes per question. Introduction of a disfluency increased the mean length of a question from 10.3 to 14.6 words.

Human Evaluation + Re-annotation. To assess and ensure high quality of the dataset, we asked a another set of human raters the following yes/no questions:

1. Is the disfluent question *consistent* with respect to the fluent question? i.e., the disfluent question is semantically equivalent to the original question in that they share the same answer.

2. Is the disfluent question *natural*? Naturalness is defined in terms of human usage, grammatical errors, meaningful distractors etc.

After the first round of annotation, we found that the second pool of raters found the disfluent questions to be consistent and natural 96.0% and 88.5% of the time, with an inter-annotator agreement of 97.0% and 93.0%[2], respectively. This suggests that the initial round of annotation resulted in a high quality dataset. Furthermore, for the cases identified as either inconsistent or unnatural, we conducted a second round of re-annotation with updated guidelines to make required corrections.

2.3 Categories of Disfluencies

To assess the distribution of different types of disfluencies, we sampled 500 questions from the training and development sets and manually annotated the nature of disfluency introduced by the raters. Table 1 shows the distribution of these categories in the dataset.

A notable difference between DISFL-QA and SWITCHBOARD (Godfrey et al., 1992) is that DISFL-QA contains a larger fraction of corrections and restarts, which have been shown to be the hardest disfluencies to detect and correct (Zayats et al., 2014; Jamshid Lou et al., 2018; Yang et al., 2020). From Table 1, we can see that ≈30% and >65% of the disfluencies in DISFL-QA are restarts and corrections respectively.

In addition to the specific categories men-

---

[2] Cohen's $\kappa = 0.55$, indicating moderate agreement.

Dataset	Switchboard	Disfl-QA
Domain	Telephonic Conversations	Wikipedia Passages
Goal-oriented	No	Yes
Contextual	No	Yes
Size (# sentences)	7.9k	11.8k
Disfluencies	20%	100%
Correction & Restarts	<50%	>90%
Coreferences	<1%	≈10%

Table 2: Comparison of Disfl-QA with Switchboard. Disfl-QA is more diverse, contains harder disfluencies and new phenomenon like coreference.

tioned in Table 1, the dataset includes other challenging phenomena which are shared across these categories. For instance, example below shows disfluencies which introduce *coreferences* between the *reparandum* and the *repair* (mentions marked **[.]**), allowing more complex corrections not present in existing datasets:

Who does BSkyB have an operating license from ? → **Who removed [BSkyB's] operating license no scratch that who do [they] have [their] operating license from** ?

Table 2 summarizes the key differences between Disfl-QA and the Switchboard dataset.

3 Experimental Setup

3.1 Models to Compare

We use two different modeling approaches to answer disfluent questions in Disfl-QA.

LMs for QA. We use BERT (Devlin et al., 2019) and T5 (Raffel et al., 2020) as our QA models in the standard setup which has shown to achieve state-of-the-art performance for SQuAD. We fine-tune BERT for a span selection task, whereby predicting `start` and `end` probabilities for all the tokens in the context.

T5 is finetuned under the standard *text2text* formulation, when given (question, passage) as input the model generates the answer as the output. For predicting `<no answer>`, the model was trained to generate *"unknown"*.

LMs for Disfluency Correction. We also fine-tune the above LMs as disfluency correction models. Given the disfluent question as input, a correction model predicts the fluent question, which is then fed into a QA model. For BERT, we use the state-of-the-art BERT-based disfluency correction model by Jamshid Lou and Johnson (2020) trained on Switchboard. We also train T5 models on Disfl-QA to prevent the distribution skew between Switchboard and Disfl-QA, and account for new phenomena like coreferences.

Rule	Fluent	Disfluent
Q	What was the Norman religion?	What was **replaced with** **no no** what was the Norman religion?
V	When was the Duchy of Normandy founded?	When was the Duchy of Normandy **offered** **ugh I mean** **founded**?
Adj	What is the original meaning of the word Norman?	What is the **English** **rather** **original** meaning of the word Norman?
Adv	Who did Beyoncé perform privately for in 2011?	Who did Beyoncé perform **publicly** **oops** **privately** for in 2011?
Ent	Who was a prominent Huguenot in Holland?	Who was a prominent **Saint Nicholas** **no I mean** Huguenot in Holland?

Table 3: Example of synthetically generated disfluent questions using the contextual heuristics.

3.2 Training Settings

We train the BERT and T5 variants on the following two data configurations:

ALL where the model is trained on all of SQuAD-v2, including the non-answerable questions. Evaluation is done against the entire test set.

ANS where the model is trained only on answerable questions from SQuAD-v1, without the capabilities of handling non-answerable questions.

3.3 Datasets

Human Annotated Datasets. We use 3 datasets in our experiments: SQuAD-v1, SQuAD-v2, and Disfl-QA. We split the 11,825 annotated questions in Disfl-QA into train/dev/test set containing 7182/1000/3643 questions, respectively. The split was also done at an article level such that the questions belonging to the same passage belong in the same split. For zero-shot experiments, we only use the train of SQuAD.

Evaluation is done on the subset of SQuAD-v2 development set that corresponds to the Disfl-QA test to ensure fair comparison.

Heuristically Generated Data. We also generate disfluencies heuristically to validate the importance of human annotated disfluencies. Inspired by the disfluency categories seen in our annotation task, we derive the following heuristics to

Model	Train	Eval	HasAns-F1	NoAns-F1	Overall-F1
BERT-QA	**ALL**	SQuAD	83.87	70.55	77.46
		Heuristics	51.45 ↓ 32.42	74.49 ↑ 3.94	62.53 ↓ 14.93
		Disfl-QA	40.97 ↓ 42.90	75.97 ↑ 5.42	57.81 ↓ 19.65
	ANS	SQuAD	89.63	-	89.63
		Heuristics	80.52 ↓ 9.11	-	80.52 ↓ 9.11
		Disfl-QA	78.88 ↓ 10.75	-	78.88 ↓ 10.75
T5-QA	**ALL**	SQuAD	91.38	87.67	89.59
		Heuristics	39.98 ↓ 51.40	92.57 ↑ 4.90	65.27 ↓ 24.32
		Disfl-QA	35.31 ↓ 56.07	90.06 ↑ 2.39	61.64 ↓ 27.95
	ANS	SQuAD	93.71	-	93.71
		Heuristics	81.73 ↓ 12.01	-	81.73 ↓ 12.01
		Disfl-QA	80.39 ↓ 13.32	-	80.39 ↓ 13.32
Disfluency Correction + T5-QA	**ALL**	SQuAD	91.38	87.67	89.59
		Heuristics	42.83 ↓ 48.55	92.18 ↑ 4.51	66.56 ↓ 23.03
		Disfl-QA	43.61 ↓ 47.77	89.55 ↑ 1.88	65.71 ↓ 23.88
	ANS	SQuAD	93.71	-	93.71
		Heuristics	82.27 ↓ 10.44	-	82.27 ↓ 10.44
		Disfl-QA	82.64 ↓ 11.07	-	82.64 ↓ 11.07

Table 4: Breakdown of zero-shot performance of fine-tuned BERT and T5 QA models, trained only on the SQuAD dataset, and evaluated on SQuAD, Heuristics (§3.3), and Disfl-QA test sets. We also evaluate the performance by using state-of-the-art disfluency detection model by Jamshid Lou and Johnson (2020) in a pipelined fashion.

augment our data with *silver*[3] standard disfluencies: (i) Switch-Q which inserts prefix of another question as a prefix to the original question, and (ii) Switch-X, where X could be verb, adjective, adverb, or entity, and is inserted as a reparandum in the question.

To facilitate contextual disfluencies, we use the reparandums from the context. For Switch-Verb/Adj/Adv/Ent, this was done by picking tokens and phrases from the context passage. For Shift-Q, we used other questions associated with the same passage. We used spaCy[4] NER and POS tagger to extract relevant entities and POS tags, and sample interregnum from a list of fillers. Table 3 shows an example from each of the heuristics. We then finally combine all the heuristics (All in Table 3) by uniformly sampling a single disfluent question from the set of possible transformations of the question.

3.4 Evaluation Method

In all our experiments, we evaluate QA performance using the standard SQuAD-v2 evaluation script which reports EM and F1 scores over the `HasAns` (asnwerable) and `NoAns` (non-answerable) slices along with the overall scores. For brevity, we report only the F1 numbers as we observed similar trends in EM and F1 across our experiments.

4 Experiments

We conduct experiments with Disfl-QA to answer the following questions: **(a)** Are state-of-the-art LM based QA models robust to introduction of disfluencies in the questions under a zero-shot setting ? **(b)** Can we use heuristically generated synthetic disfluencies to aid the training of QA models to handle disfluencies ? **(c)** Given a small amount of labeled data, can we recover performance by fine-tuning the QA models or training a disfluency correction model to pre-process the disfluent questions into fluent ones before inputting to the QA models ? **(d)** In the above setting, can we train a generative model to generate more disfluent training data ?

4.1 Zero-Shot Performance

Table 4 shows the performance of different variants measuring their zero-shot capabilities.

Performance of BERT-QA and T5-QA. We see from Table 4 that when tested directly on on heuristics and Disfl-QA test sets, both the BERT-QA and T5-QA models exhibit significant performance drop, as compared to the performance on the fluent benchmark of SQuAD. The performance drop for the complete models is greater

---

[3] The *silver* nature of the data is due to the fact that we can not enforce naturalness or semantic equivalence of §2.

[4] `https://spacy.io/`

Original	`HasAns`		`NoAns`
Prediction	`NoAns`	`WrongAns`	`HasAns`
SQuAD	71	150	216
Disfl-QA	1091	168	174

Table 5: Breakdown of prediction errors for the T5-QA-ALL model on the fluent and disfluent questions. `WrongAns` represents that the model predicted an incorrect span from context.

when compared to their answerable-only counterparts. The best performing T5-ALL model shows a **drop of 27.95 F1** points for the complete setup and **13.32 F1** point for the answerable only T5-ANS model. This shows BERT and T5 are not robust when questions contain disfluencies.

Disfluency Correction + T5-QA. We use the BERT based state-of-the-art disfluency correction (Jamshid Lou and Johnson, 2020) as a pre-processing step before feeding the input to our T5-QA model. The models trained on Switchboard are not able to fill a significant performance gap, with the complete and answerable models recovering 4.07 and 2.25 F1 points, respectively. We will revisit this setting in the few-shot experiments.

Disfl-QA test-set vs. Heuristics test-set. Next, we compare the performance of heuristically generated disfluent questions against the human annotated questions. In general, human annotated disfluent questions exhibit larger performance drop compared to heuristics, across different models.

Taking a closer look at the T5-ALL model shows that Disfl-QA shows a bigger drop in `HasAns` cases and smaller increase in `NoAns` cases, as compared to the heuristics test set. For the T5-ANS model, Disfl-QA shows a larger drop in performance which is attributed to the model picking wrong answer span. Based on this, we hypothesize that between the two datasets, heuristics are able to confuse the models in over-predicting `<no answer>`, but Disfl-QA is superior when it comes to confuse the models to picking a different answer span altogether (as seen in Table 4 for models in ANS setting). This demonstrates that collecting a dataset like Disfl-QA via human annotation holds value for contextual disfluencies.

	HasAns F1	**NoAns F1**	**Overall F1**
Fluent (⋆)	91.38	87.67	89.59
Zero-Shot	35.21	90.06	61.64
+ Sw-Adj	68.49	86.24	77.03
+ Sw-Adv	67.37	85.27	75.98
+ Sw-ENT	**74.76**	**85.95**	**80.14**
+ Sw-Q	70.03	78.94	74.31
+ Sw-Verb	68.01	87.16	77.22
+ All	**78.86**	**85.96**	**82.27**

Table 6: Performance on Disfl-QA with individual (Sw-XX) and combined (All) heuristics based data augmentation and fine-tuning.

Performance Gap Breakdown. For models trained on ALL setting, we find that the performance drop is largely due to the drop in F1 (over **50** points) on `HasAns` questions as opposed to `NoAns` questions, where it is almost negligible or even positive in some cases. Upon closer analysis (Table 5) we find that a major fraction of prediction errors for `HasAns` is attributed to `HasAns` → `NoAns` errors, instead of `HasAns` → `WrongAns`.[5]

We believe that the disfluencies are causing the answerable questions to resemble the non-answerable ones as seen by both BERT and T5 models under ALL setting. This results in an overly conservative model in terms of answerability and instead resorts to over-predicting `<no answer>`, causing gain in non-answerable recall at the cost of precision. In contrast, for a comparable ANS model the drop in F1 is smaller, primarily due to relatively easier decision making, i.e. not required to decide when to answer vs. not.

Fine-tuning on Heuristic Data. In this experiment, we fine-tune on heuristically generated data from §3.3 and directly test on Disfl-QA. Table 6 compares the performance of the heuristics fine-tuned model on the Disfl-QA test-set. The overall heuristics trained model (All) is able to cover a significant performance drop from 61.64 to 82.27, an increase of 20.63 F1 points. However, this still is 7.32 F1 points short of the fluent performance.

Amongst the individual heuristics, we observe the following order of effectiveness w.r.t. performance on the `HasAns` cases: ENT > SQ > ADJ > VERB > ADV. One possible expla-

---

[5] We use the standard SQuAD evaluation script and mark a prediction as `WrongAns` iff F1(pred,gold)< 0.8.

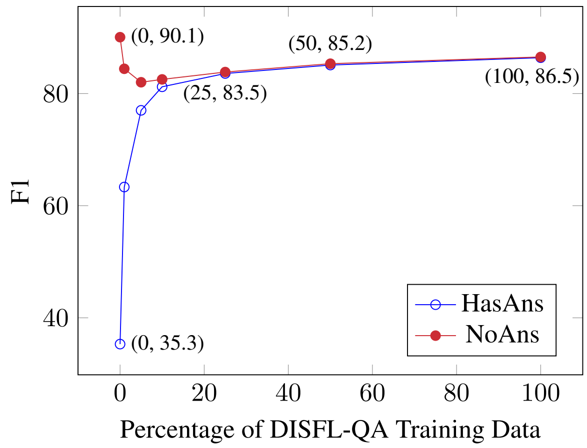

Figure 2: Few shot performance for different fraction of training data. We can see that performance on `HasAns` cases increases monotonically with increase in gold data. However, for the `NoAns` cases, the performance first takes a drop (compared to zero-shot) and then increases.

	HasAns F1	**NoAns F1**	**Overall F1**
Fluent (⋆)	91.38	87.67	89.59
Zero-Shot	35.21	90.06	61.64
Heuristics	78.86	85.96	82.27
Direct Supervision			
25% Data	83.58	83.84	83.71
+ Q → DQ	86.44	84.53	85.52
+ CQ → DQ	87.47	83.11	85.37
50% Data	85.09	85.33	85.20
100% Data	86.40	**86.53**	**86.46**
+ Q → DQ	86.95	85.73	86.33
+ CQ → DQ	**87.29**	85.22	86.29
Pipelined			
DQ → Q	87.65	**86.70**	**87.19**
CDQ → Q	**87.99**	86.02	87.04

Table 7: Performance on the test set of DISFL-QA when using gold human annotated data in training different components.

nation for SWITCH-ENT and SWITCH-Q being more effective is the fact that our original annotated dataset has a relatively high percentage of entity and interrogative correction.

4.2 Few Shot Performance

Next, we evaluate the performance of the models when we use a part of human annotated gold disfluent data for training: (i) direct end-to-end supervision, (ii) generation based data augmentation, and (iii) training disfluency correction models.

Direct Supervision (*k*-shot). In this setting, we pick a SQUAD-v2 T5 model and then perform a second round of fine-tuning with varying percentages of DISFL-QA gold training data. We experiment with $1, 5, 10, 25, 50$, and 100 percent of the total gold data.

Figure 2 shows the performance for the `HasAns` and `NoAns` cases as we increase the amount of training data. The `HasAns` performance increases gradually from 35.31 F1 points, in the zero-shot setting, to 86.40 F1 points with complete training data. Interestingly, for the `NoAns` cases, the performance first drops from 90.06 F1 points, in the zero-shot setting, to 82.02 F1 with 5% data and then monotonically increasing to 86.53 F1 with complete data. This can be attributed to the fact that the zero-shot models were under-predictive (high recall, low precision for `<no asnwer>`) due to lack of robustness to disfluent inputs.

Furthermore, Table 7 compares the performance of using the gold training data of DISFL-QA against the heuristics data. It shows that the models trained with disfluent data from DISFL-QA are able to cover a major gap in answerable slice, which wasn't possible with the heuristically generated data. Direct supervision bring an additional performance improvement of 4.19 F1 points over the heuristics.

Generation Based Data Augmentation. We use the T5 model for synthetically generating disfluent question from fluent question in the *text2text* framework. We use the training set of DISFL-QA to train the following generative models: (i) context-free generation (Q → DQ), and (ii) context-dependent generation (CQ → DQ) which use passage as well for generation.

Table 8 shows example generation from the two models. We observe that CQ → DQ is able to learn meaningful contextual disfluency generation, whereas Q → DQ can lead to non-meaningful or inconsistent disfluencies due to lack to context.

We then pick 5k random (question, answer) pairs from SQUAD training data and apply our generative model to produce disfluent training data for the QA models. Table 7 shows the performance of using data augmentation. We perform data augmentation under two different train data settings: (1) 25% data, and (2) 100% data. Interestingly, for the models trained on 25% train data + generated data, we observe a gain of 1.81 F1

Passage: ...*Whereas a **genome sequence** lists the order of every DNA base in a genome, a **genome map** identifies the landmarks. A genome map is less detailed than a genome sequence and aids in navigating around the genome* ...

Fluent Question : What does a genome map list the order of ?
T5 Q → DQ : What is no what does a genome map list the order of ?
T5 CQ → DQ : What does a genome sequence list the order of no sorry what does a genome map list the order of?

Passage: ...*The presence of **fat** in the small intestine produces hormones that stimulate the release of pancreatic lipase from the pancreas and **bile** from the liver which helps in* ...

Fluent Question : What is one molecule of fat ?
T5 Q → DQ : What is one molecule of protein no fat ?
T5 CQ → DQ : What is one molecule of bile no wait fat ?

Passage: ...*In 1964, **Nikita Khrushchev** was removed from his position of power and replaced with **Leonid Brezhnev**. Under his rule, the Russian SFSR* ...

Fluent Question : When did Leonid Brezhnev die ?
T5 Q → DQ : When was the age of Leonid Brezhnev ?
T5 CQ → DQ : When did Nikita Khrushchev *er* I mean Leonid Brezhnev die ?

Table 8: Example disfluent question (DQ) as generated by the Q → DQ and CQ → DQ T5 generative models for data augmentation. We observe that CQ → DQ generates meaningful disfluencies compared to context-free generation, the latter leading to irrelevant or inconsistent questions in some cases.

points (83.71 → 85.52) in the overall performance which is close to the absolute performance of using 50% gold data. However, for the setup with 100% gold data + generated data, we did not observe a similar improvement in the overall performance.

Pipelined: Disfluency Correction + QA. Unfortunately, existing disfluency correction models and datasets assume that fluent text is a subsequence of the disfluent one, and hence these approaches cannot solve disfluencies in Disfl-QA involving coreference. For fair comparison, we train a T5 generation model as a Disfl-QA specific disfluency correction model using the training set of Disfl-QA, with a simple DQ → Q and CDQ → Q T5 task formulation.

With this pipelined approach, we get further improvements with an overall F1 of 87.19 (Table 7), however, still lacking by ≈2.4 F1 points compared to the fluent dataset. This shows that such complex cases require better modeling, preferably in an end-to-end setup.

5 Related Work

5.1 Disfluency Correction

The most popular approach in literature poses disfluency correction as a sequence tagging task, in which the fluent version of the utterance is obtained by identifying and removing the disfluent segments (Zayats et al., 2014; Ferguson et al., 2015; Zayats et al., 2016; Lou and Johnson, 2017; Jamshid Lou and Johnson, 2020; Wang et al., 2020). . Traditional disfluency correction models use syntactic features (Honnibal and Johnson, 2014), language models (Johnson et al., 2004; Zwarts and Johnson, 2011), discourse markers (Crible, 2017), or prosody-based features for learning (Zayats and Ostendorf, 2019; Wang et al., 2017) while recent disfluency correction models largely utilize pre-trained neural representations (Lou et al., 2018). Most of these models depend on human-annotated data. As a result, recently, data augmentation techniques have been proposed (Yang et al., 2020; McDougall and Duckworth, 2017) to alleviate the strong dependence on labeled data. However, the resulting augmented data either via heuristics (Wang et al., 2020) or generation models (Yang et al., 2020) is often limited in terms of disfluencies types and may not well capture natural disfluencies in daily conversations.

5.2 Question Answering Under Noise

In the QA literature, our work is related to two threads that aim to improve robustness of QA models: (i) QA under adversarial noise, and (ii) noise arising from speech phenomena.

Prior work on adversarial QA have predominantly generated adversaries automatically (Zhao et al., 2018), which are verified by humans to ensure semantic equivalence (i.e. answer remains same after perturbation). For instance, Ribeiro et al. (2018) generated adversaries using paraphrasing, while Mudrakarta et al. (2018) perturbed questions based on attribution. Closest work to ours is Jia and Liang (2017), who modified SQuAD to contain automatically generated adversarial sentence insertions.

Our work is more closely related to prior work on making NLP models robust to noise arising from speech phenomena. Earlier work (Surdeanu et al., 2006; Leuski et al., 2006) have built QA models which are robust to disfluency-like phenomenon, but they were limited in the corpus complexity, domain, and scale. Recently there has been renewed interest in constructing audio enriched versions of existing NLP datasets, for example, the SPOKEN-SQUAD (Li et al., 2018) and SPOKEN-COQA (You et al., 2020) with the aim to show the effect of speech recognition errors on QA task. However, since collecting audio is challenging, another line of work involves testing the robustness of NLP models to ASR errors in transcribed texts containing synthetic noise using TTS → ASR technique (Peskov et al., 2019; Peng et al., 2020; Liu et al., 2020; Ravichander et al., 2021). Our work suggests a complementary approach to data collection to surface a specific speech phenomenon that affects NLP.

6 Conclusion

This work presented DISFL-QA, a new challenge set containing contextual semantic disfluencies in a QA setting. DISFL-QA contains diverse set of disfluencies rooted in context, particularly a large fraction of corrections and restarts, unlike prior datasets. DISFL-QA allows one to directly quantify the effect of presence of disfluencies in a downstream task, namely QA. We analyze the performance of models under varying when subjected to disfluencies under varying degree of gold supervision: zero-shot, heuristics, and *k*-shot.

Large-scale LMs are not robust to disfluencies. Our experiments showed that the state-of-the-art pre-trained models (BERT and T5) are not robust when directly tested on disfluent input from DISFL-QA. Although a naturally occurring phenomenon, the noise introduced by the disfluent transformation led to a non-answerable behavior at large.

Contextual heuristics partially recover performance. We derived heuristics, in attempt to resemble the contextual nature of DISFL-QA, by introducing semantic distractors based on NER, POS, and other questions. In our experiments, we found that heuristics are effective in: (1) confusing the models in zero-shot setup, and (2) partially recovering the performance drop on DISFL-QA with fine-tuning. This indicates that the heuristics might be capturing some key aspects of DISFL-QA.

Efficacy of gold training data. We use the gold data for supervising various models: (i) end-to-end QA model, (ii) disfluency correction, and (iii) disfluency generation (for data augmentation). For all the experiments, gold supervision outperforms heurisitics' supervision significantly. Furthermore, we observed that in a low resource setup generation based data augmentation can match the performance of a high resource modeling setup.

7 Discussion

While DISFL-QA aims to fill a major gap between speech and NLP research community, understanding *disfluencies* holistically requires the following:

General disfluencies focused NLP research. We believe understanding of disfluencies is a key ingredient for enabling natural human-machine communication in the near future, and call upon the NLP community to devise generalized few-shot or zero-shot approaches to effectively handle disfluencies present in input to NLP models, without requiring task specific disfluency datasets.

Constructing datasets for spoken problems. We would also like to bring attention to the fact that being a speech phenomenon, a spoken setup would have been an ideal choice for disfluencies dataset. This would have accounted for higher degree of confusion, hesitations, corrections, etc. while recalling parts of context on the fly, which otherwise one may find hard to create synthetically when given enough time to think.

However, such a spoken setup is extremely tedious for data collection mainly due to: (i) privacy concerns with acquiring speech data from real world speech transcriptions, (ii) creating scenarios for simulated environment is a challenging task, and (iii) relatively low yield for cases containing disfluencies. In such cases, we believe that a targeted and purely textual mode of data collection can be more effective both in terms of cost and specificity.

Abstract

Existing bias mitigation methods to reduce disparities in model outcomes across cohorts have focused on data augmentation, debiasing model embeddings, or adding fairness-based optimization objectives during training. Separately, certified word substitution robustness methods have been developed to decrease the impact of spurious features and synonym substitutions on model predictions. While their end goals are different, they both aim to encourage models to make the same prediction for certain changes in the input. In this paper, we investigate the utility of certified word substitution robustness methods to improve equality of odds and equality of opportunity on multiple text classification tasks. We observe that certified robustness methods improve fairness, and using both robustness and bias mitigation methods in training results in an improvement in both fronts.

1 Introduction

As natural language processing (NLP) technologies are increasingly used in essential real-world applications, such as social media, healthcare, personal assistants and law (He et al., 2020; Ahmad et al., 2020), it is important to ensure these systems do not create unintended outcomes for end-users or offer disparate experiences to customers from diverse backgrounds. This includes ensuring that model performance does not significantly differ across people belonging to different cohorts, such as different gender or race groups.

A major subset of industry NLP applications lies in text classification, such as domain and intent classification in voice assistants (Su et al., 2018) or code tagging in healthcare (Kemp et al., 2019). In this study, we focus on toxicity classification (Dixon et al., 2018) and occupation classification of Wikipedia biographies (De-Arteaga et al., 2019). For toxicity classification, ensuring fairness means ensuring that a model can identify toxicity to a similar accuracy across all examples regardless of the protected groups present in the example. Past studies (e.g, (Dixon et al., 2018; Zhang et al., 2020; Zhao and Chang, 2020)) have shown that toxicity classification models will falsely classify text containing certain protected attributes as toxic. Leading social media platforms and internet companies use toxicity classification models for content moderation (Gorwa et al., 2020), thus having bias in such models can lead to increased silencing of under-served groups. Similarly, for occupation classification, a fair model should correctly identify occupations given a biography, regardless of the protected group that a person belongs to (De-Arteaga et al., 2019).

Recently, several studies have demonstrated societal bias in NLP systems (Hutchinson et al., 2020; Tan and Celis, 2019; Liang et al., 2020) and various approaches have been proposed to mitigate the bias. These approaches include creating balanced datasets (Park et al., 2018; Zhao et al., 2018a), developing methods optimized for particular fairness notions (Zhang et al., 2017, 2020), model calibration (Zhao et al., 2017; Jia et al., 2020), and reducing representational bias (Bolukbasi et al., 2016b; Zhao et al., 2018b; Liang et al., 2020).

Separately, certified robustness approaches (Jia et al., 2019; Ye et al., 2020) have been developed to ensure robustness against word substitution attacks. Specifically, these strategies ensure small perturbations in the input embedding space do not alter model predictions. Despite never having been discussed in prior literature, this corresponds to notions of fairness, since protected attribute information (e.g. gender) is often irrelevant to the task

August 1–6, 2021.

at hand (i.e. "She is a good singer" and "He is a good singer" should have the same sentiment label). Thus, we posit that word substitution robustness methods can be used to make models invariant to protected attribute tokens and identifiers.

We explore the effect of robustness methods on fairness with GloVe-based CNN models (Kim, 2014) trained with Interval Bound Propagation (IBP) (Jia et al., 2019), and BERT (Devlin et al., 2019a) trained with SAFER (Ye et al., 2020). We compare the effect of these robustness methods to popular bias mitigation methods. We find that robustness methods achieve promising performance on fairness metrics exceeding that of bias mitigation methods in several text classification tasks on gender and sexual orientation dimensions. Furthermore, training on both fairness and robustness exceeds performance over robustness and bias mitigation methods alone. Comprehensive analysis and visualization demonstrate that the robust methods decrease feature importance on gender tokens.

Our contributions are two-fold. First, we show that certified robustness methods can be used and integrated with bias mitigation methods to effectively improve models' performance on several notions of fairness, notably equality of opportunity and equality of odds. Secondly, by integrating robustness methods with fairness, we can improve a model's robustness while reducing bias, which is important in creating trustworthy NLP systems. Our study's practical implications include applications to models used in the industry that can handle customer inputs that may differ from the training data (robust) and that minimize any unintended consequences on the customers (fair). With this study, we aim to motivate future work geared towards developing methods that jointly optimize for multiple trustworthy aspects of models; specifically, those addressing model robustness and fairness.

2 Mitigating Bias through Certified Robustness Methods

In the following, we first define the notions of fairness considered in this paper. Then, we discuss certified robustness methods, and how they can be applied to reduce bias in models.

2.1 Fairness Notions

We focus on measuring two notions of fairness in this paper – equalized odds and equality of opportunity, as they are commonly used in quantifying bias in NLP applications. We describe the metrics associated with these notions in Section 3. We give application examples of these notions on toxicity and occupation classification for English texts.

Equalized Odds A model achieves *Equalized Odds* (Hardt et al., 2016) with respect to a protected attribute A and outcome Y if $P(\bar{Y} = 1|A = 0, Y = y) = P(\bar{Y} = 1|A = 1, Y = y)$, for $y \in \{0, 1\}$. Protected attributes are traits or characteristics that cannot be discriminated against by law[1]. Intuitively, this means that the model should have equal true positive and false positive rates across groups. For toxicity classification, equalized odds implies that a model should be able to effectively detect toxicity on comments that include identifiers across all protected attribute cohorts, while not silencing any one cohort. Prior studies demonstrate that models disproportionately predict sentences associated with LGBTQ individuals as toxic, which may further silence discussion around LGBTQ issues and the voices of LGBTQ people (Oliva et al., 2020).

Equality of Opportunity A model achieves *Equality of Opportunity* (Hardt et al., 2016) with respect to a protected attribute A and outcome Y if $P(\bar{Y} = 1|A = 0, Y = 1) = P(\bar{Y} = 1|A = 1, Y = 1)$. This is a relaxation of Equalized Odds to the positive outcome, in which the model must have equal true positive rates across groups. For occupation classification, equality of opportunity implies that a model is able to correctly classify biographies of people from all groups, thus enabling equity in positive outcomes such as appropriate and useful matches in job recommendation sites.

Due to bias in the training data, off-the-shelf models often contain biases and disparities in model performance against underrepresented groups. Various bias mitigation approaches have been proposed to ensure the fairness in model predictions. We include a diverse array of bias mitigation methods, spanning embedding debiasing, in-training, and post-processing, as baselines. These consist of instance weighting (Zhang et al., 2020), *HardDebias* word embeddings (Bolukbasi et al., 2016a), and adversarial debiasing (Zhang et al., 2018). See more discussion in Sec. 3.

2.2 Certified Robustness for Bias Mitigation

Designed for a different purpose, certified robustness methods present ways to train models that satisfy guarantees of word substitution robustness. By adapting certified robustness methods to fairness applications, we aim to make models invariant to spurious protected attribute information present in inputs, and thus improve in equality of opportunity and equalized odds.

Formally, a model f is *certifiably robust* if, for any example sentence x, and sentences x' that consist of x modified with word substitutions, $f(x) = f(x') = y$. In the robustness context, word substitution consists of swapping a word with its synonyms (usually defined using retrofitted word embeddings). For example, if x = "The waiter talked to the customer about their problems," x' may consist of the sentences "The waitress talked to the customer about their qualms." In the context of fairness, we consider 'waiter' and 'waitress' or gender pronouns to carry the same meaning in the context of toxicity and occupation classification, and to have the same label.

In this paper, we use two recently developed certified robustness methods, Interval Bound Propagation (IBP) (Jia et al., 2019) and SAFER (Ye et al., 2020). Given a set of perturbations for each word, these two models ensures that word substitution do not affect model predictions. In particular, for each word, and a polytope spanned by the potential substitutions for that word in the embedding space, these methods ensure that swapping the word with any point in the polytope will not change the model predictions. To accomplish this, IBP minimizes the upper bound of the set of losses over perturbation sets, and SAFER uses a model-agnostic randomized smoothing technique.

Both IBP and SAFER encourage models to be robust to spurious word substitutions, which include tokens that contain protected attribute information. The perturbations included in the original paper from Alzantot et al. (2018) are based on a GloVe embedding that has been modified such that synonyms are close together. While the perturbation set does not include explicit gender and sexual orientation swaps ('boy' is not included in the perturbation set for 'girl', while 'girls', and 'women' are), we posit that certified robustness methods can still be applied to bias mitigation by improving robustness in examples that contain identifiers of underrepresented groups. Doing so will decrease model performance disparity in underrepresented group cohorts, and thus fulfill fairness notions.

IBP (Jia et al., 2019) IBP computes bounds on the model loss based on bounds on the input. The robustness goal of the IBP method is to minimize $\max F(x, \theta)$. Here, $F(x, \theta)$ denotes the set of losses of a model over $B_{perturb}$, where $B_{perturb}$ is the set of perturbations for an example sentence x. Formally, $F(x, \theta) = (f(\bar{x}, \theta) | \bar{x} \in B_{perturb})$. The full loss for IBP is $(1 - \lambda) f(x, \theta) + \lambda \mu^{final}(x, \theta)$, where μ^{final} is the upper bound on the loss $f(x, \theta)$ and $\lambda \in [0, 1]$.

SAFER (Ye et al., 2020) Unlike IBP, SAFER does not require any changes to the model training. Instead, it employs a randomized smoothing mechanism in which an input is perturbed before being fed to the model during the training time. Specifically, SAFER creates random word substitutions using a perturbation set derived from a synonym network. Ye et al. (2020) determine certified robustness of a model on an example by certifying that, given an example z, model score $s(z)$, and $y_B = \text{argmax}_{c \in Y, c \neq y}\, s(z)$, the model score of the gold label y is higher than the model score of the highest scoring non-gold label y_B by a constant.

3 Empirical Study on the Connection between Fairness and Robustness

To better understand the connection between fairness and certified robustness in the context of text classification, we empirically analyze models augmented with various combinations of robustness and fairness methods, as enumerated below.

1. **Classifier (Baseline)**: The base text classification models. We consider two types of classification models that widely used in the literature, CNN (Kim, 2014) and BERT (Devlin et al., 2019b).
2. **Classifier + Fairness**: Text classifiers trained with bias mitigation techniques (see Sec. 2).
3. **Classifier + Robustness**: Text classifiers trained with robustness methods (see Sec. 2).
4. **Classifier + Robustness + Gender Word Perturbations**: To ensure that the model becomes robust against gender substitutions, we add definitional gender pairs (e.g., swapping he with she) (Bolukbasi et al., 2016b) in the permutation set of IBP and SAFER.
5. **Classifier + Robustness + Fairness**: Text classifier trained with both fairness and ro-

bustness objectives.

We aim to answer the following research questions based on the aforementioned configurations. (1) *What is the effect of robustness methods on mitigating bias* (compare configuration 3 with 1 and 2)? (2) *What is the effect of adding gender word substitutions to the robustness perturbation sets* (compare configurations 3 and 4)? (3) *What is the effect of integrating bias mitigation and robustness methods* (compare configuration 5 with 1 and 3)?.

In particular, to answer the last question, we consider combining popular bias mitigation approaches with IBP as follows.

- **Debiased Word Embeddings + IBP**: We replace the GloVe embeddings in the baseline CNN model with the *HardDebias* embeddings obtained from (Bolukbasi et al., 2016b), while keeping the rest of the IBP training methodology the same.
- **Instance weighting + IBP**: We add the instance weights to each sample in the loss computation during IBP training.
- **Adversarial Training + IBP**: We perform multitask training, alternating between optimizing for robustness loss and adversarial debiasing loss. We initialized our adversarial training with the IBP-trained model.

Datasets We use the following two text classification datasets to validate our hypothesis on different data distributions.

- *Jigsaw Toxicity*[2] is a dataset for toxicity classification that consists of 1,804,874 training examples, which we split into train and validation sets of size 1,443,900 and 360,974 respectively. We take 97,320 examples from the public leaderboard as the test set.
- *Bias in Bios* (De-Arteaga et al., 2019) [3] is a dataset for occupation classification derived from Common Crawl corpus. It consists of 178,619 train and 91,917 test examples.

Evaluation Metrics We evaluate models on three dimensions: (1) raw task performance, (2) model fairness, and (3) model robustness. For the raw task performance, we follow prior work in using accuracy and area under the ROC curve (AUC) to evaluate the performance of a model on the Bias in Bios dataset and the Jigsaw Toxicity dataset respectively. To measure the robustness of a model, we follow Jia et al. (2019) and Ye et al. (2020) to use the certified robustness accuracy (CRA). For fairness, we follow the discussion in Section 2.1 to evaluate a model based on *equalized odds* and *equal opportunity*.

For fairness, we measure two metrics - i.e, True Positive Equality Difference (TPED) and False Positive Equality Difference (FPED). The FPED and TPED is calculated as:

$$\sum_{z \in Z} |f_z - f_{overall}|,$$

where f is FPR or TPR depending on whether we are computing FPED or TPED, and Z refers to the set of all classes in a protected group. Note that TPED and FPED metrics do not take into account how well the model does - for example, a model that achieves a true positive rate of 0.0 for all groups will still have a TPED of 0.

For Bias in Bios dataset, we chose equality of opportunity to measure fairness, since it is important to ensure job candidates are matched with job recommendations that are relevant to them. Since equality of opportunity necessitates equality in true positive rates across cohorts, we use TPED as the fairness evaluation metric for Bias in Bios. For Jigsaw Toxicity, we define fairness by equalized odds, since it is important for toxicity classifiers to be able to detect toxicity in content containing identifiers across all groups, while not silencing any one. The combination of FPED with TPED aligns with the *Equalized Odds* definition of fairness (Borkan et al., 2019), thus we define a score *EOdds* as FPED + TPED for ease of analysis. Equalized odds is satisfied when FPED = 0 and TPED = 0, and thus when *EOdds* = 0.

For the scope of this paper and the limitations of the dataset, we study binary gender for Bias in Bios, and both gender (male, female, transgender, and non-binary) and sexual orientation (homosexual/straight, heterosexual, gay, lesbian, bisexual) for Jigsaw Toxicity classification. While we acknowledge that there are a multitude of important attributes, we constrain the scope of this study to the attributes present in text classification datasets.

Experiment Details All the experiments were conducted on p3dn.24xlarge and p3.2xlarge AWS compute nodes.[4] The IBP runs took 48 hours for

IBP + Adversarial Training	0.725	0.112	0.693

Table 2: Experiment results on CNN models on the Bias in Bios dataset. We see that our best performing model consists of initiating IBP training with $HardDebias$ embeddings.

Jigsaw Toxicity and 34 hours for Bias in Bios, while SAFER took 53 hours with evaluation for Jigsaw Toxicity and 37 hours for Bias in Bios.

For the experiments with CNN, we follow Jia et al. (2019) to configure the IBP schedule and CNN models. In particular, we used a CNN model with a hidden size of 100 and kernel size of 3 with the GloVe embedding (Pennington et al., 2014) as inputs. For IBP, we linearly increased the weight on the certified robustness objective from 0 to 0.8 for 40 epochs, before training for 20 epochs on the full certified robustness objective.

For the experiments with BERT, we follow Ye et al. (2020) to configure the BERT model and SAFER experiment. We use `bert-base-uncased`, and take the top-100 words that are closest in cosine similarity for each token as the token's perturbation set. We describe the remaining hyper-parameter details (learning rate, epochs, dropout probability) in the the appendix, which we obtained after a hyper-parameter search on the development set.

4 Results

The results for Jigsaw Toxicity and Bias in Bios are in Tables 1, 2, 3 and 4.

Effect of certified robustness methods for mitigating bias We observe that adding IBP during training achieves better performance on fairness over othe bias mitigation approaches across Jigsaw Toxicity and Bias in Bios. In Jigsaw Toxicity, EOdds improves from 0.508 to 0.184, and in Bias in Bios, TPED improves from 0.131 to 0.127. Similarly, training models with SAFER results in an improvement in performance in all fairness metrics, with an improvement in EOdds from 0.553 to 0.286 in Jigsaw Toxicity and an improvement in TPED from 0.148 to 0.134 in Bias in Bios.

Effect of adding gender word substitutions to the robustness perturbation sets While adding gender word substitutions further improves fairness in Bias in Bios, it results in worse fairness scores in Jigsaw Toxicity than plain certified robustness methods. In Bias in Bios, IBP_{gender} results

Model	Raw task (↑)	Fairness (↓)			Robustness (↑)
	AUC	EOdds	FPED	TPED	CRA
Baseline	0.914	0.553	0.290	0.263	0.950
SAFER	0.918	**0.286**	**0.144**	**0.142**	**0.967**
SAFER$_{\text{gender}}$	**0.968**	0.347	0.176	0.171	0.917

Table 3: Model performance on BERT (Baseline) and SAFER on the Jigsaw dataset. Similar to the observation with IBP, SAFER improves both the fairness and robustness metrics.

Model	Raw task (↑)	Fairness (↓)	Robustness (↑)
	AUC	TPED	CRA
Baseline	**0.796**	0.148	0.164
SAFER	0.744	0.134	0.726
SAFER$_{gender}$	0.761	**0.097**	**0.733**

Table 4: Model performance on BERT (baseline) with SAFER on the Bias in Bios dataset.

in a lower TPED than all fairness only baselines. This trend holds in SAFER, where SAFER$_{gender}$ achieves lower TPED than SAFER. In Jigsaw Toxicity, adding gender words to the perturbation set degrades performance in equalized odds for both IBP and SAFER. This may be because the list of gender word substitutions do not include words relating to sexual orientation and non-binary gender, and thus may only improve fairness amongst examples containing male and female identifiers.

Effect of integrating bias mitigation methods with certified robustness methods Training model with both IBP and bias mitigation methods improves fairness metrics over fairness-only baselines in both datasets. In Bias in Bios, the model that comes closest to fulfilling equality of opportunity is the one trained with both IBP and $HardDebias$, which achieves a TPED of 0.101. In Jigsaw Toxicity, we see a similar trend, with improvements in EOdds after adding IBP training to instance weighting, $HardDebias$, and adversarial training. The model trained with both IBP and instance weighting achieves a EOdds score of 0.165, which is the lowest among all approaches

We also note that for Jigsaw Toxicity, instance weighting mitigates bias more effectively than $HardDebias$ and adversarial training (both in isolation and in combination with robustness methods). This is not the case for Bias in Bios, where $HardDebias$ and adversarial training is more effective than instance weighting in mitigating bias. This may be due to the fact that instance weighting mitigates bias explicitly for a wider array of sexual orientations and gender demographics than the other two methods. The original $HardDebias$ method only projects away the gender direction from embeddings. For adversarial debiasing, we train the adversary with the subset of the training set that is annotated for the presence of protected attribute groups, which is highly skewed towards male and female. Thus, $HardDebias$ and adversarial training may mitigate bias for binary gender, but fall short in mitigating bias for non-binary gender and sexual orientations. Conversely, instance weighting, which mitigates bias for a wider array of demographics, does not mitigate bias on gender in Bias in Bios as well as the other methods.

Additional Observations Outside of the effects of robustness on fairness, we observe differing effects of the methods on certified robustness and raw accuracy. As expected, IBP and SAFER improves performance on certified robustness on both datasets. However, we also observe degradataions in raw task accuracy in experiments with robustness methods. Combining robustness with bias mitigation methods results in a degradataion of raw task performance over fairness-only baselines. Additionally, fairness-only training results in differing effects on certified robustness accuracy. Adversarial debiasing improves certified accuracy in both datasets, while *HardDebias* embedding-initiated training results in an increase in certified robustness in Jigsaw Toxicity, but a decrease in Bias in Bios. This difference in findings may be due to the shorter length of examples in Jigsaw Toxicity, which has a median length of 34, compared with the median length of 72 in Bias in Bios, which in turn determines the number of possible perturbations used to calculate certified accuracy and the difficulty in achieving high CRA.

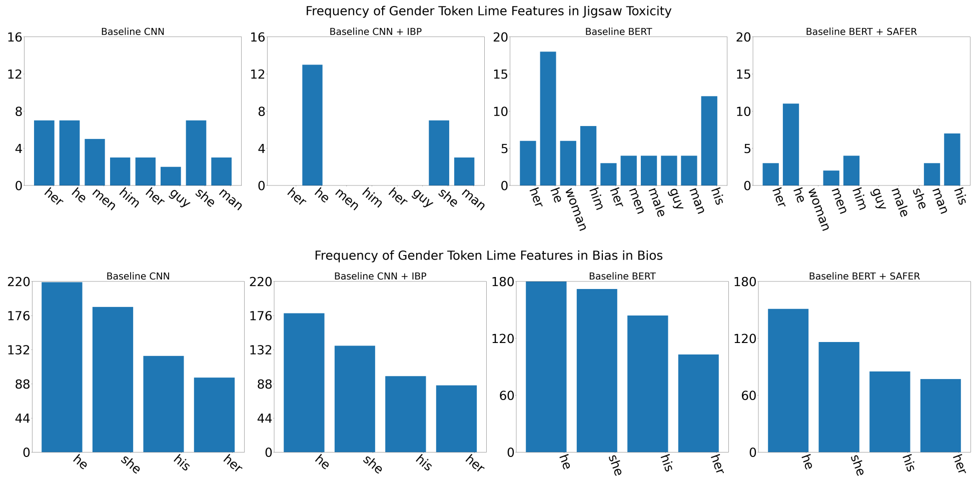

Figure 1: Frequency of gender token features as extracted by LIME for baseline and IBP trained models for Jigsaw Toxicity and Bias in Bios. We see a decrease in number and frequency of gender tokens in the list of top-5 (for Jigsaw Toxicity) and top-50 (for Bias in Bios) most important features.

5 Analysis

In this section, we study how robustness training affects the features our models use for classification. We posit that robustness training encourages models to focus more on predictive attributes than on protected attributes. To gain insight into this, we use LIME (Ribeiro et al., 2016) on the baseline, IBP, and SAFER trained models and extract token features importance as assigned by the model. We run LIME on the subset E of examples that are misclassified by our baseline model as toxic that are correctly classified by the IBP model. We take the top k features for each of the examples (where $k = 5$ for Jigsaw and $k = 50$ for Bias in Bios) over E, and then count the number of gender tokens that appear in that list. For Jigsaw Toxicity, the number of examples that we run LIME on is 488 for CNN experiments and 182 for BERT experiments. For Bias in Bios, we run LIME over a random subset of 500 examples from E for both CNN and BERT experiments.

For Jigsaw Toxicity, we see from Figure 1 that LIME extracts less gender tokens in the top-5 features of the IBP-trained and SAFER-trained model compared to the baseline model. Notably, there are 37 gender tokens that appear in the CNN model, while only 23 in the IBP-trained model. Similarly, 69 gender tokens appear in the baseline BERT model while only 37 appear in the SAFER-trained one. For Bias in Bios, we see a similar trend from Figure 1. The number of important gender token features decreases from 626 to 500 after IBP training, and from 626 to 429 after SAFER.

In addition, we compute the gradient with the output with respect to the input on several examples from Jigsaw Toxicity, which is shown in Table 5. We observe that the baseline model focuses on tokens related to protected groups, while the IBP model takes into account all parts of the sentence.

6 Related Work

Much work has been done in studying fairness in various NLP models (Mehrabi et al., 2019; Sun et al., 2019; Blodgett et al., 2020). In toxicity classification, Adragna et al. (2020) and (Zhang et al., 2020) study the fairness in predicting toxic internet contents in which the contents contain demographic identity-terms (e.g., “gay”, “black”). In occupation classification, De-Arteaga et al. (2019) and Romanov et al. (2019) study the impact of including explicit gender indicators such as a person’s names or a pronoun in online biographies.

Some notable bias mitigation methods, which we also use in this paper, include instance weighting (Zhang et al., 2020), embedding debiasing (Bolukbasi et al., 2016a; Wang et al., 2020), and adversarial debiasing (Zhang et al., 2018). In particular, Bolukbasi et al. (2016a) proposed to reduce representational harm existent in word embeddings. Zhang et al. (2020) proposed instance weighting, a method to debias text classification models for bias against examples containing demographic identity-terms by weighting the instances in the loss function, and that is optimized for demographic pairty. Zhang et al. (2018) presents an adversarial training approach to achieve various notions of fairness

Table 5: Gradient saliency examples on Jigsaw Toxicity. Highlights show larger value of the output gradient with respect to the token embedding. The baseline CNN model focuses on some tokens related to protected groups (e.g., woman), while IBP encourages the model to take into account other parts of the sentence, resulting in less bias.

that is achieved by training an adversary to identify information on protected groups and training the model to minimize the adversary loss. These approaches are designed for reducing specific types of bias exhibited in data.

On the robustness front, it has been shown that models are susceptible to adversarial word substitution attacks (Ebrahimi et al., 2018; Jia and Liang, 2017). Parallel to the development of methods developed to reduce word substitution robustness in the NLP domain (e.g., (Miyato et al., 2017; Huang et al., 2019; Zhou et al., 2021)), many studies has been done in the computer vision domain to ensure that models are robust to image noising (Kannan et al., 2018; Szegedy et al., 2014).

In the intersection of area between fairness and robustness of model training, there is limited prior work in the NLP area. Nanda et al. (2020) investigate and define *robustness bias*, a notion of fairness in which a model must be impervious to perturbations to the same degree for all subgroups, and investigate robustness bias in the computer vision domain. Adragna et al. (2020) examine the use of invariant risk minimization in improving the fairness on out-of-distribution data for toxicity classification. Their robustness approach is inspired from domain generalization and it allows to learn models that have invariant performance across different label distributions. This differs from the word substitution notions of robustness that our methods are optimized for. Chang et al. (2020) shows that achieving equalized odds is incongruent with adversarial robustness on the COMPAS (J. Larson and Angwin, 2017) and the Adult dataset (Dua and Graf, 2017), which is outside the NLP domain. The closest work to ours is in counterfactual logit pairing (Garg et al., 2019), which encourages a model to be robust to protected attributes for counterfactual fairness. However, logit pairing does have the certified characteristic of the robustness methods we use in this study.

7 Conclusion

We present a study that investigates the effect of optimizing for word substitution robustness on fairness. We find that, in both CNN and BERT models, adding robustness methods such as IBP and SAFER to the training process improves fairness metrics over adding bias mitigation methods alone. Given these promising results, we encourage future explorations in using robustness methods to not only improve fairness metrics, but to also optimize for both fairness and robustness, two important aspects of creating trustworthy NLP.

Future work may include studying the effects of robustness and fairness in attributes other than gender and sexual orientation, extending our study to other word substitution based robustness methods, and exploring more sophisticated methods to combine robustness and bias mitigation methods during training. We also intend on extending the study to investigating the impact of privacy preserving training methods on both, robustness and fairness.

Broader Impact

We limit the scope of this paper to gender and sexual orientation in this initial effort, and future work must be done on mitigating bias in other protected attribute dimensions such as race, ethnicity, neurodiversity, etc. Additionally, this work draws importance to the need to extend fairness methods to groups beyond binary gender. In our IBP_{gender} experiments, we only consider swapping binary gender pairs from prior literature to provide an anchor for our analysis. We see from our results that methods that mitigate for binary gender such as *HardDebias* and IBP_{gender} do not reduce harm for all gender or sexual orientation, especially for non-binary gender and non-heterosexual sexual orientation groups. We will extend the study in the future by developing fairness methods that directly mitigate for non-heterosexual sexual orientations and non-binary genders pairs using sociology literature.

The language used in this paper is English. We recognize that the presented methods rely on the availability and quality of the set of words associated to a fairness task. Scaling to languages beyond English–such as gendered languages like Spanish–need more careful analysis. Another limitation of this method is that word substitution may lead to non-sensible sentences and inappropriate grammar especially in complex fairness domains where it is difficult to find word-to-word mapping (e.g., mapping names of religious artifacts like Christmas tree or Diwali lights, etc are not trivial).

Our experiments and results show that pursuing fairness can help in improving robustness and vice versa. With these findings, we hope to inspire researchers to investigate novel approaches that focus on jointly achieving robust and fair models. We also hope that this work will lead to more investigations around achieving multiple objectives such as privacy, robustness and fairness together in the NLP research community.

A Appendices

Appendix A. Hyperparameter Settings We perform hyperparameter search on the dev set using random search with 12 trials, with initial learning rate range between $1 * 10^{-2}$ to $1 * 10^{-7}$, a dropout probability range of 0.1 to 0.5, and number of epochs between 10 and 60.The final hyperparameter settings are shown in Table 6. We choose our hyperparameters based on the one that minimizes FPED + TPED + (1 - CRA) + (1 - *tp*), where *tp* refers to task performance.

Additionally, for adversarial debiasing, we tune the adversary loss weight from $\alpha = 0.1$ to $\alpha = 3$, and choose $\alpha = 1$ for the weight. We pretrain our classifier and adversary for 2 epochs each.

Experiment	**Learning Rate**	**Dropout Prob**	**Number of epochs**
GloVe + CNN (Jigsaw)	1e-2	0.5	20
GloVe + CNN (Bias in Bios)	1e-3	0.1	15
BERT + SAFER (Jigsaw)	5e-6	0.1	20
BERT + SAFER (Bias in Bios)	1e-5	0.1	15

Table 6: Hyperparameter settings for our experiments. We use the same hyperparameters across our fairness and robustness experiments.

A Joint Model for Structure-based News Genre Classification with Application to Text Summarization

Zeyu Dai, Ruihong Huang
Department of Computer Science and Engineering
Texas A&M University
{jzdaizeyu, huangrh}@tamu.edu

Abstract

Journalists usually organize and present the contents of a news article following a well-defined structure. In this paper, we propose a novel joint model for structure-based news genre classification that simultaneously identifies one of four commonly used news structures (including *Inverted Pyramid* and three other structures) for a news article as well as recognizes a sequence of news elements within the article that define the corresponding news structure. Experiments show that the joint model consistently outperforms its variants that perform two tasks independently, which supports our motivation that preserving the two-way dependencies and constraints between a type of news structure and its sequence of news elements enables the model to better predict both of them. Although being not perfect, the system predicted news structure type and news elements have improved the performance of text summarization when incorporated into a recent neural network system.

1 Introduction

Journalists usually organize and report the contents of news following a well-defined structure. For example, when writing news briefs or breaking news, the *Inverted Pyramid* structure (Pottker, 2003) is often adopted to present the most newsworthy and key events first and then provide any additional details. However, while being commonly used, *Inverted Pyramid* is not the only news structure, there exist several other commonly used news structures as well, for example, a structure called *Kabob* is commonly used to present a narrative hook (Myers and Wukasch, 2003) first and then report the main story, where the narrative hook catches the reader's attention so that reader is willing to keep reading. Recognizing the overall structure of a news article can benefit many NLP tasks and applications, such as text summarization, text segmentation, discourse analysis, information extraction and text quality assessment, and many others.

Our recent research (Dai et al., 2018) first defines a small set of news elements, specifically five news elements, and then formally defines four commonly used news structures based on their different ways to select and organize news elements. News elements are defined based on their functions in a news story (introducing the main story or event, catching the reader's attention or providing details, etc.) as well as their writing styles (narrative or expository, also known as modes of discourse). Specifically, five news elements are defined, including two ledes, *Standard Lede* and *Image Lede*, with their functions as either introducing the main story or catching the reader's attention, as well as three other categories, *Synopsis*, *Narration* and a catch-all category *Body Section*. Each news element is realized as a set of one or more consecutive paragraphs in a news article. Using the well-defined news elements, four news structures, *Inverted Pyramid*, *Kabob*, *Martini Glass* and *Narrative* are introduced. The *Inverted Pyramid* structure can be represented as a *Standard Lede* followed by a *Body Section*, while the *Kabob* structure can be represented as an *Image Lede* followed by a *Synopsis* and a *Body Section*. Two more news structures, *Martini Glass* and *Narrative*, are defined and each of them has the *Narration* news element. We defer more details about news elements and news structures to the section 3.

Our previous work (Dai et al., 2018) created a dataset (the News Genre dataset) with both news structures and news elements annotated for structure-based news genre categorization, and has conducted news structure classification as a text classification task by building a machine learning classifier (SVM) using n-grams and several structure indicative features. However, we have not attempted to further recognize the annotated news elements within a news article yet. As each news

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3332–3342
August 1–6, 2021.

element carries a specific function in building a news story and features a writing style (narrative or expository), the recognized news elements are expected to be useful for many NLP applications.

In this work, we take one step further and propose to recognize both the news structure type of a news article as well as its corresponding news elements. We first implemented two pipeline approaches that first predict document-level news structure (or paragraph-level news element) tags using one single model, and then incorporate the predicted tags as features into another single model for predicting news element (or news structure) tags. Then, inspired by the idea that the overall news structure of a document determines the sequence of news elements within the document, and vice versa, we aim to recognize both the type of news structure and its news elements simultaneously in a joint model. Specifically, we build our joint model on top of a hierarchical BiLSTM neural networks that learn paragraph and document representations for predicting both a news structure type for a document and a sequence of news element tags for its paragraphs. The intrinsic evaluation on the News Genre dataset shows that the joint model consistently outperforms the pipeline models that accomplish two tasks independently, and achieves noticeable performance gains for predicting all four types of news structures and all five types of news elements, which supports our motivation that preserving the two-way dependencies and constraints between a news structure and its news elements enables the system to better predict both of them.

We believe that the identified news structures and news elements can be useful for many text-level NLP applications and tasks. In this paper, we further conduct experiments and use system predicted news structure and news element tags for improving text summarization. Informed by the predicted news structure genres, we expect to better locate the key event descriptions of a news story, and therefore improve the performance of extractive summarization models. Especially, we expect that recognizing news structures and news elements can boost the text summarization performance on news articles of a particular news structure, the *Kabob* structure, which is the second most frequent news genre and covers roughly 28% of news articles based on the annotated News Genre dataset.

For news documents with the *Kabob* structure, the beginning paragraphs (corresponding to a news element called *Image Lede*) do not directly present the key events of news, instead, the following paragraphs (corresponding to a news element called *Synopsis*) will summarize the main story. Therefore, this news genre brings additional difficulty to locate the correct paragraphs for extracting summary, and accordingly, recognizing this genre and its news elements is likely to noticeably improve text summarization performance on documents with the *Kabob* structure the most. Indeed, the extrinsic evaluation on the CNN/DailyMail dataset (Hermann et al., 2015) shows that a simple method for incorporating news genre tags as word features into a recent extractive summarization system (Liu and Lapata, 2019) improves the three ROUGE (Lin, 2004) scores, R-1, R-2 and R-L, consistently for all four types of news structure genres, with the *Kabob* structure receiving the largest improvements of 0.37, 0.14 and 0.34 points on R-1, R-2 and R-L respectively.

2 Related Work

News structures have been extensively studied in the area of linguistics and journalism (Schokkenbroek, 1999; Van Dijk, 1985; Ytreberg, 2001). However, few computational studies tried to automatically categorize news articles according to news structures using data-driven methods. Our previous work (Dai et al., 2018) is the first work we are aware of that formulated four news structures using a small set of predefined news elements, created the first dataset for structure-based news genre categorization, and proposed a feature-based classifier to predict the news structure type of a document. With the motivation to better serve the needs of downstream applications, we developed a computational system to recognize news elements within a document as well as the overall news structure type. We built a joint model for these two tasks to preserve the two-way dependencies and constraints between them, and have empirically improved the performance of both tasks.

In the previous work, several well-studied genre-independent discourse structures have been explored for improving many NLP applications. For example, discourse structures including the RST-style tree structure (Mann and Thompson, 1988) and the PDTB-style discourse relations (Prasad et al., 2008) have been shown useful for a range of NLP applications, such as sentiment analysis (Bhatia et al., 2015; Märkle-Huß et al., 2017), text summarization (Marcu, 1997; Louis et al., 2010) and machine translation (Li et al., 2014; Guzmán et al., 2014). In addition, text segmentation (Hearst, 1994) that divides a text into a sequence of topically coherent segments by detecting topic transition boundaries have been shown useful for text summarization (Barzilay and Lee, 2004), sentiment analysis (Sauper et al., 2010) and dialogue systems (Shi et al., 2019). We believe that the genre-specific news structures can effectively complement the genre-independent discourse structures, and both of them are essential for achieving deep story-level text understanding.

In this work, we further apply our system predicted news structure and news element tags to help the task of extractive summarization, which aims to extract a summary by identifying the most important sentences in a news article. Nallapati et al. (2017) presents one of the earliest neural network systems for extractive summarization that adopt an RNN-based encoder for abstracting sentence representations. More recent work achieves higher performance for extractive summarization using more sophisticated neural network structures. SUMO (Liu et al., 2019) introduces structured attention to induce a dependency tree representation of a document while generating a summary. Liu and Lapata (2019) adapts BERT (Devlin et al., 2019) to text summarization which obtains contextualized representations of a document and its sentences using BERT's encoder by stacking several inter-sentence Transformer layers. Dong et al. (2019) fine-tunes a new Unified pre-trained Language Model (UniLM) for text summarization by employing a shared Transformer network and utilizing specific self-attention masks to control which context the predicting summary conditions on. The extrinsic evaluation on text summarization using (Liu and Lapata, 2019) as baseline demonstrates the usefulness of our system predicted genre-specific news structure tags in downstream NLP tasks.

In addition, our work is also related to text genre identification (Santini, 2007; Mehler et al., 2010; Rehm, 2002), but we focus on the genres of news structure which come from the area of journalism.

3 Structure-based News Genres

As shown in Figure 1, our previous work (Dai et al., 2018) formally defined four commonly used news structures based on the selection and organization of five predefined news elements.

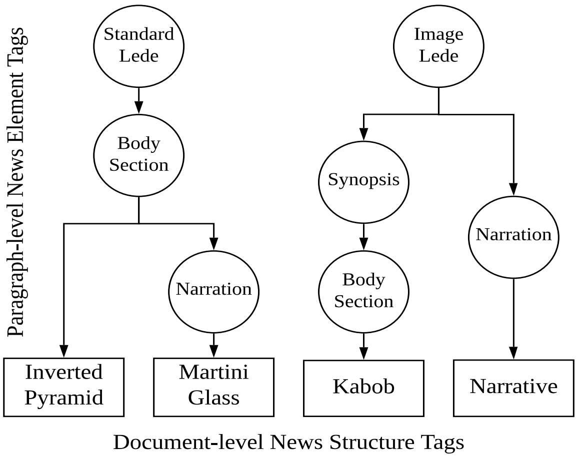

Figure 1: Four News Structures: Document-level News Structure Tags (in rectangle) and Paragraph-level News Element Tags (in circle). A News Element may include one or more consecutive paragraphs.

3.1 Five Paragraph-level News Elements

Standard Lede is used to introduce the key events and main story at the beginning of a news article; written in the expository style.

Image Lede [1] is used to catch the reader's attention by telling an anecdote, quoting a catchy slogan, or revealing an impressive fact or statistics (Jou, 2014); written in either narrative or expository style. Image Lede is located at the beginning of a news article as well, however, unlike Standard Lede, it does not directly discuss the key events of a news article, therefore, it may not represent a good summary of the news article.

Synopsis must follow an Image Lede and acts as a bridge that connects an Image Lede with the rest of a story. The function of Synopsis is to summarize the key events and main story of a news article; written in the expository style.

Narration gives great details about key events and often contains a sequence of events (or subevents) in chronological order (Mani, 2012); written in the narrative style (Lavelle, 1997).

Body Section presents additional details and supplementary information about key events; written in the expository style. Paragraphs that do not belong to any of the four above categories were annotated as a Body Section (Dai et al., 2018).

3.2 Four Document-level News Structures

Inverted Pyramid, known as the most popular news article structure (Pottker, 2003), presents the

---

[1] In some news articles, an image is presented first to catch the readers' eyes and the Image Lede acts as the description of the image.

content in the descending order of importance and relevance (Scanlan, 2003). For this structure, key events and main story will be introduced first, then additional information will be provided later. This structure is represented as a Standard Lede followed by a Body Section, shown in Figure 1.

Martini Glass (Jou, 2014) begins by presenting a summary of a story following the Inverted Pyramid structure, and then transitions into a chronological elaboration of the story in detail. Therefore, the Martini Glass structure contains a Standard Lede, an optional Body Section and a Narration.

Kabob (Jou, 2014) first tries to catch the reader's eyes using an anecdote (or a catchy slogan, etc), then introduces the key events, and discusses the main story with more details at last. Therefore, the Kabob structure is defined to start with an Image Lede, then uses a Synopsis as the transition, and finally ends with a Body Section.

Narrative structure presents a chronologically ordered sequence of events with a greater amount of details than normal news articles. Dai et al. (2018) annotated this news structure when the majority of paragraphs form a single Narration with an optional preceding Image Lede.

3.3 The News Genre Dataset

Dai et al. (2018) created the first structure-based news genre dataset [2]. This dataset contains 853 English news articles across four news domains, including politics, crime, business and disaster. In this dataset, each article was annotated with a news structure label and a sequence of news element tags for its paragraphs. The same news element tag will be assigned to all paragraphs in a consecutive sequence that a news element spans over.

The four common news structures applied to most of the annotated news articles, with only 21 documents were not annotated with any of the four news structures and did not receive paragraph-level news element tags either, so we removed these 21 documents in our experiments. Table 1 shows the statistics of news structure and news element tags, from which we can see that the distribution of news structures is highly imbalanced, with *Inverted Pyramid* and *Kabob* as two major structure types.

News Structure	#	News Element	#
Inverted Pyramid	482	Standard Lede	519
Martini Glass	37	Image Lede	244
Kabob	237	Synopsis	237
Narrative	76	Narration	113
Total	832	Body Section	746

Table 1: Data Statistics of the News Genre Dataset.

4 Model

4.1 The Joint Model for Predicting both News Structures and News Elements

Figure 2 illustrates the overall architecture of our joint model, which can simultaneously predict both document-level news structure label and paragraph-level news element tags. The model processes a whole news article containing a sequence of paragraphs each time, and predicts a document-level label as well as a sequence of paragraph-level tags with one tag for each paragraph using the standard BIO tagging schema (Ratinov and Roth, 2009) for sequence labeling. Specifically, we treat the news element *Body Section* as the "other" (or 'O') tag since this tag can't help determine document-level news structure type (shown in Figure 1) and was used as a catch-all "other" label during the data annotation as well. For other paragraph-level news element tags except for the *Body Section*, we assign a "B-" prefix to the first paragraph that starts the news element and assign "I-" prefix to other paragraphs inside the same news element.

The model employs the two-level hierarchical BiLSTM layers (Schuster and Paliwal, 1997) with max-pooling (Collobert and Weston, 2008) operation in between to learn both word and paragraph representations, followed by a max-pooling operation to calculate the document representation and a softmax classification layer for predicting the document-level label. Added on top of the paragraph-level representations, a linear-chain Conditional Random Field (CRF) layer (Lafferty et al., 2001) is utilized to jointly decode a sequence of paragraph-level tags considering their inter-dependencies. As shown in Figure 2, the model consists of the following components:

Feature-rich Word Vector: Given a sequence of words $(w_1, w_2, ..., w_L)$ as the input document, for each word w_i, we construct a feature-rich word vector by concatenating its word embedding $\boldsymbol{w}_i^{word}$ with its character-level representation [3], and extra

---

[2] Available at `https://github.com/ZeyuDai/Fine-grained_Structure-based_News_Genre_Categorization`

[3] For character-level representation, we adopted one layer

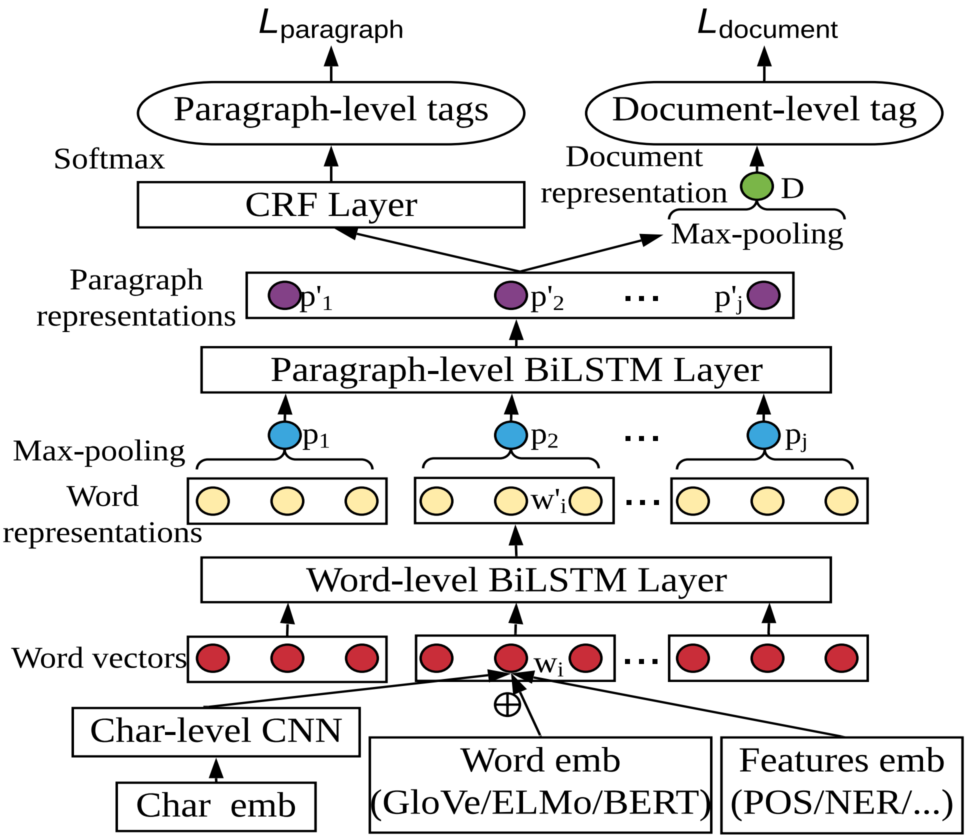

Figure 2: The Joint Model Architecture for both Document-level and Paragraph-level News Genre Tags Prediction.

word-level features embedding [4] as:

$$\boldsymbol{w}_i = [\boldsymbol{w}_i^{word}; \boldsymbol{w}_i^{char}; \boldsymbol{w}_i^{features}]$$

To take advantage of the recent progress about contextualized word representation from pre-trained language models, our framework supports three options including 300 dimensional GloVe (Pennington et al., 2014), 1024 dimensional ELMo (Peters et al., 2018) and the "bert-base-cased" version of BERT (Devlin et al., 2019) to initialize [5] the $\boldsymbol{w}_i^{word}$.

Word-level BiLSTM Layer: Given a sequence of feature-rich word vectors $(\boldsymbol{w}_1, \boldsymbol{w}_2, ..., \boldsymbol{w}_L)$ as the input, the word-level BiLSTM layer will refine the word w_i's hidden representation $(\boldsymbol{w}_i')$ by modeling the word-level inter-dependencies:

$$\boldsymbol{w}_i' = BiLSTM(\boldsymbol{w}_1, ..., \boldsymbol{w}_i, ..., \boldsymbol{w}_L)$$

Paragraph-level BiLSTM Layer: Given a sequence of word representations $(\boldsymbol{w}_1', \boldsymbol{w}_2', ..., \boldsymbol{w}_L')$, we build the paragraph representation $(\boldsymbol{p}_j)$ for the j-th paragraph in the document, by applying max-pooling operation over the sequence of word representations for all words within the j-th paragraph:

$$\boldsymbol{p}_j = \max_{w_i \in p_j} \boldsymbol{w}_i'$$

Then, the paragraph-level BiLSTM layer will update the j-th paragraph's hidden representation $(\boldsymbol{p}_j')$ by modeling the paragraph-level inter-dependencies:

$$\boldsymbol{p}_j' = BiLSTM(\boldsymbol{p}_1, \boldsymbol{p}_2, ..., \boldsymbol{p}_j, ...)$$

Softmax Classification Layer for Document-level News Structure Type Prediction: We compute the document representation $(\boldsymbol{D})$ by applying max-pooling operation over all paragraph representations $(\boldsymbol{p}_1', \boldsymbol{p}_2', ..., \boldsymbol{p}_j', ...)$.

Then, for the i-th training instance with $\boldsymbol{y}_{doc\_gold}^{(i)}$ as the gold annotation of document-level tag, our model predict the document-level tag $\boldsymbol{y}_{doc\_pred}^{(i)}$ using the softmax classification layer:

$$\boldsymbol{y}_{doc\_pred}^{(i)} = softmax(\boldsymbol{W}_{doc}\boldsymbol{D}^{(i)} + \boldsymbol{b}_{doc})$$

---

of CNN with 50 hidden units followed by a max-pooling layer.

[4] For word-level features, we collected the corresponding paragraph's position (PARA) index, capitalization (CAP) flag, Part-of-speech (POS) tag and named entity (NER) tag of each word. The embedding sizes for PARA/CAP/POS/NER were 20/5/35/20 respectively. We used Standford CoreNLP toolkit (Manning et al., 2014) to generate POS and NER tags.

[5] GloVe embeddings were fixed during training. For ELMo and BERT, we also froze its parameters during model training.

And we want to minimize the following cross-entropy loss during model training:

$$L_{document} = -\sum_{i} \boldsymbol{y}^{(i)}_{doc\_gold} * \log \boldsymbol{y}^{(i)}_{doc\_pred}$$

CRF Layer for Paragraph-level News Elements Sequence Labeling: For the task of sequence labeling, it is important to model the label dependencies (e.g., “I-*” must follow “B-*” in BIO tagging schema.) and capture the label continuity and transition patterns. Therefore, a CRF layer is added on top of the paragraph-level BiLSTM layer to jointly decode the news element tags sequence.

For the i-th training instance, given the annotated paragraph-level news element tags sequence $\boldsymbol{y}^{(i)}_{para\_gold} = (y^{(i)}_1, y^{(i)}_2, ..., y^{(i)}_j, ...)$ and hidden paragraph representations $\boldsymbol{P'}^{(i)} = (\boldsymbol{p'}^{(i)}_1, \boldsymbol{p'}^{(i)}_2, ..., \boldsymbol{p'}^{(i)}_j, ...)$, we minimize the following CRF loss during model training:

$$L_{paragraph} = -\sum_{i} \log p(\boldsymbol{y}^{(i)}_{para\_gold} | \boldsymbol{P'}^{(i)})$$

For model testing, we use the Viterbi algorithm to search for the optimal label sequence.

Joint Model vs. Single Model Training: The overall loss function for training our joint model is:

$$L = L_{document} + L_{paragraph}$$

Clearly, we can easily make it a single-task model for either document-level news structure type prediction or paragraph-level news element sequence labeling, by removing unrelated loss term from the overall loss function. We will compare the performance of our joint model with single models in the following intrinsic evaluation section 5.

4.2 Parameter Settings and Implementation Details

We manually tuned all hyperparameters of our model based on the development set using the macro-average F1-score as the selection criterion. After the hyperparameter search, we used the hidden size of 512 (tuned from the list [100, 300, 512, 1024]) for each BiLSTM layer and all hidden representations ($\boldsymbol{w'}_i, \boldsymbol{p}_j, \boldsymbol{p'}_j, \boldsymbol{D}$). For regularization, we applied 50% (tuned from [10%, 20%, 30%, 50%]) dropout to both input and output vectors of each BiLSTM layer. To alleviate the problem of gradient exploding for BiLSTM training, we clipped the gradient L2 norm at threshold 5.0 (tuned from [5.0, 10.0]) and utilized L2 regularization with coefficient 10^{-6}. Parameters were optimized using SGD optimizer with momentum 0.9 (tuned from [0.9, 0.95] and no momentum) and initial learning rate 0.015 (tuned from [0.0001, 0.001, 0.01, 0.015, 0.05, 0.1]), decreasing by 5% after each epoch. The batch size was 32 (tuned from [8, 16, 32, 64]) in the normal case, but it will be much smaller (1 or 2 depending on the model size) when using BERT because of the GPU CUDA memory limitation.

News Structure	#	News Element	#
Inverted Pyramid	434	Standard Lede	467
Martini Glass	33	Image Lede	219
Kabob	214	Synopsis	214
Narrative	69	Narration	102
Total	750	Body Section	673

Table 2: Data Statistics of the Cross-validation Set.

We implemented our model using Pytorch, with ELMo from AllenNLP [6] and BERT-base from HuggingFace [7]. Since BERT used the subword tokenizer, we used the first token’s representation as word embedding if one word was split into several subword tokens. We trained our model for 50/20/3 epochs when using GloVe/ELMo/BERT word embeddings respectively, considering that different word representation techniques require a different number of fine-tuning epochs. To diminish the effects of randomness in neural network training, we ran our proposed model, its variants as well as our own baselines using 5 different random seeds and the reported performance is the average score across 5 runs. The full model training took around 8-12 hours on one NVIDIA GTX 1080Ti GPU.

5 Intrinsic Evaluation

5.1 Experimental Settings

Considering that the News Genre corpus is relatively small and cross-validation is more robust for a small dataset, we followed our previous work (Dai et al., 2018) and evaluated our models using 5-fold cross-validation. Specifically, we created our own cross-validation/development set splits containing 750/82 news articles respectively, and randomly split the cross-validation set into five folds with even domain distribution. Table 2 reports the distribution of news structure and element tags on

Table 3: Intrinsic Evaluation Results on the Cross-validation Set of News Genre Dataset using 5-fold Cross-validation. We report accuracy (Acc), macro-average F1-score (Mac), and class-wise F1-scores for document-level structure and paragraph-level element tags, including Inverted Pyramid (IP), Martini Glass (MG), Kabob (Kab), Narrative (Nar), Standard Lede (SL), Image Lede (IL), Synopsis (Sy), Narration (Na) and Body Section (BS).

the cross-validation set. The hyperparameter tuning was conducted on the development set using the cross-validation set for model training.

5.2 Baselines

Feature-based (Dai et al., 2018): To compare with previous work, we replicated the feature-based model of (Dai et al., 2018) that performs document-level news structure type classification only.

Pipeline (doc → para) && Pipeline (para → doc): We implemented two pipeline approaches that first predict document-level news structure (or paragraph-level news element) tags using our single model, and then incorporate the predicted tags as word-level features (with embedding size 10) into another single model for predicting paragraph-level (or document-level) tags. The pipeline approach that first predicts document-level news structure tags is marked as Pipeline (doc → para); the reverse one is marked as Pipeline (para → doc).

5.3 Experimental Results

Table 3 summarizes the evaluation results on the cross-validation set using 5-fold cross-validation. The first row shows the performance of our replicated feature-based baseline (Dai et al., 2018) which achieves similar performance as in the original paper. The second section reports the performance of our models for predicting both document-level news structure types and paragraph-level news element tags, which compares the results of our models trained with different loss functions (joint model vs. single model) when using different word embeddings (GloVe vs. ELMo vs. BERT).

We can see that the joint model consistently outperforms (statistical significant t-test with $p < 0.05$) the corresponding single model independent from the word embeddings, which supports our motivation that document-level news structure type identification can not be separated from learning paragraph-level news element representations and features, and vice versa. Among the three word representation techniques, the ELMo word embeddings consistently give the best performance, followed by BERT and GloVe. One possible reason why BERT performs worse in our experiments is that we have to use a very small batch size and large learning rate when using BERT due to the limitation of GPU CUDA memory. The best joint model using the ELMo embeddings achieves 80.0% accuracy and 56.0% macro F1-score for predicting document-level news structure types, which outperforms the previous feature-based baseline by a large margin, and simultaneously achieves 78.3% accuracy and 53.2% macro F1-score for identifying paragraph-level news element tags.

The third section shows the performance of the two pipeline models. Note that, for fair comparisons, both pipeline models use the ELMo word embeddings that perform the best for our tasks (in both single and joint models). We can see that our joint model consistently outperforms both pipeline approaches. This is reasonable because pipeline models suffer from error propagation which poses an even bigger challenge in our task when the predicted news element sequence can not be compatible with any of the four news structure types.

In addition, Table 4 reports the experimental results on the development set, where we used the whole cross-validation set for training the models. On the development set, we observe similar comparisons among models and consistent performance gains achieved by the joint model.

Table 4: Intrinsic Evaluation Results on the Development Set using the whole Cross-validation Set for Training.

5.4 Qualitative Analysis

To better understand the strengths and weaknesses of the joint model, we analyze the news structure and news element tags prediction made by our single model and joint model (both using ELMo embeddings) on the development set. Among the 82 documents, we find that the joint model clearly made less inconsistent predictions than the single model (18 vs. 27) where the predicted news element sequence can not be compatible with the predicted news structure type, e.g., *Inverted Pyramid* structure with *Image Lede* news element. This result proves the effectiveness of our joint model that preserves the two-way dependencies between the predicted news structure type and news elements.

We further examine the wrong predictions generated by our best joint model. About 70% errors happen because the model failed to distinguish the first news element between *Standard Lede* and *Image Lede*, which can be improved if the model is aware of the key events (Choubey et al., 2018) in a news article. The remaining errors come from identifying the *Narration* paragraphs written in narrative style, which by itself is a challenging task.

6 Extrinsic Evaluation on Text Summarization

We expect the news genre tags predicted by our joint model to be useful for extracting news summaries because our tags (e.g., *Standard Lede* in *Inverted Pyramid*; and *Synopsis* in *Kabob*) can help locate the key event descriptions of a news story which should be the right section to select sentences for extractive summarization.

To verify our expectations, we choose a recent BERT-based framework for text summarization proposed by Liu and Lapata (2019), which used to achieve the state-of-the-art performance on the CNN/DailyMail dataset (Hermann et al., 2015). We use exactly the same experiment settings as in (Liu and Lapata, 2019) and implement our text summarization models based on their source code [8]. We leave all components of the summarization model unchanged, but add an embedding layer to the input of BERT, which encodes the paragraph-level news elements and document-level news structure tags generated by our system trained on the whole cross-validation set. Specifically, the embedding layer will encode each tag or the combination of a news structure type and a news element tag (e.g., Kabob-Image Lede) into a vector with 10 dimensions, which will be concatenated with the original BERT's word embeddings. For each input token, the added embedding layer will incorporate its news structure information (e.g., the paragraph-level tag for the paragraph where the token locates in) into the hidden token representation, and therefore influence the model.

Model	R-1	R-2	R-L

Table 6: Text Summarization Results divided by News Structure Genres. Each cell reports R-1/R-2/R-L scores.

the system predicted paragraph-level news element tags into the baseline (Liu and Lapata, 2019) improves the R-1, R-2 and R-L by 0.17, 0.04 and 0.11 points respectively, which is non-trivial considering the difficulties of text summarization. Adding our document-level news structure types into the summarization model further improves the performance slightly, which outperforms the baseline by 0.23 R-1, 0.06 R-2 and 0.15 R-L.

6.2 Effects on Different News Genres

To understand which type of news structure is the bottleneck for news summarization, we evaluate the ROUGE scores on each subset of the CNN/DailyMail test set divided by our predicted news structure types, and report the text summarization results in Table 6. We can see that *Kabob* structure is the most difficult genre for news summarization, which is not surprising because news documents with the *Kabob* structure will not present the key events at the beginning of the story, and therefore brings additional difficulty to locate the correct paragraphs for extracting summary. By incorporating our news structure types and news element tags into the model, all genres of news documents receive better performance for extractive summarization. Especially for the news articles with the *Kabob* structure, our news genre tags improve the ROUGE scores by 0.37, 0.14 and 0.34 points on R-1, R-2 and R-L respectively, which is the largest improvement among four types of news structures.

7 Conclusion

We have presented a joint neural network model for structure-based news genre identification that predicts both the news structure type for a document and a sequence of news element tags for its paragraphs. The joint model preserves the two-way dependencies and constraints between a type of news structure and its sequence of news elements, and consistently outperforms its variants that perform two tasks independently or in a pipeline. While being imperfect, the system predicted news structure types and news element tags have been shown effective for improving text summarization models.

For the future work, we will further improve the performance on identifying minority classes of news structures and news elements (e.g., *Narration*), by conducting semi-supervised learning. Meanwhile, we are keen to explore uses of our news genres in other applications as well, such as text quality assessment and information extraction.

Abstract

The exploitation of syntactic graphs (SyGs) as a word's context has been shown to be beneficial for distributional semantic models (DSMs), both at the level of individual word representations and in deriving phrasal representations via composition. However, notwithstanding the potential performance benefit, the syntactically-aware DSMs proposed to date have huge numbers of parameters (compared to conventional DSMs) and suffer from data sparsity. Furthermore, the encoding of the SyG links (i.e., the syntactic relations) has been largely limited to linear maps. The knowledge graphs' literature, on the other hand, has proposed light-weight models employing different geometric transformations (GTs) to encode edges in a knowledge graph (KG). Our work explores the possibility of adopting this family of models to encode SyGs. Furthermore, we investigate which GT better encodes syntactic relations, so that these representations can be used to enhance phrase-level composition via syntactic contextualisation.

1 Introduction

Representing words in terms of their syntactic co-occurrences has been long proposed, both for count-based (Padó and Lapata, 2007; Weir et al., 2016), and neural (Hermann and Blunsom, 2013; Levy and Goldberg, 2014; Komninos and Manandhar, 2016; Czarnowska et al., 2019; Vashishth et al., 2019) models of word meaning. Tested on benchmark word similarity tasks, such models often perform favourably to models based on proximal co-occurrence, particularly when the similarity or substitutability of two words is considered rather than their relatedness (Levy and Goldberg, 2014). However, the real promise of distributional models based on syntactic rather than proximal co-occurrence, is the potential for carrying out syntax-sensitive composition. For example, in the Anchored Packed Tree (APT) model (Weir et al., 2016) lexemes, phrases, and sentences are represented as collections of typed occurrences, and composition is carried out by contextualising each element in its syntactic role. This leads to syntax-sensitive representations for phrases. For example, *glass window* and *window glass* have different representations due to the different syntactic roles played by each constituent.

Alongside count-based models, a variety of neural ones have been proposed to encode syntactic structure, focusing on different depths of the graph (Levy and Goldberg, 2014; Komninos and Manandhar, 2016; Marcheggiani and Titov, 2017; Vashishth et al., 2019; Emerson, 2020)). Of particular note here, Levy and Goldberg (2014) and Komninos and Manandhar (2016) each proposed models (DEP and EXT, respectively) which learn from local dependency relations, by extending the Skip-Gram with Negative sampling (SGNS) architecture from `word2vec` (Mikolov et al., 2013). Given a tuple of *(target, context)* words, e.g. *(rain,like)*, a standard SGNS model can be trained to encode the probability of it being a true or a randomly sampled tuple. DEP and EXT, on the other hand, make use of both standard and syntactically contextualised tuples e.g., (*rain_*$\overline{dobj}$, $like$)[1]. Whilst DEP was tested solely on word similarity tasks, Komninos and Manandhar (2016) applied large neural architectures to sentence level tasks and were thus able to demonstrate a positive impact of applying an additive composition strategy to syntax-aware representations.

There is of course an explosion in the number of parameters to be learnt in both DEP and EXT due to the many possible word-relation combinations which form the target vocabulary for these models (see Table 1). A possible solution, pro-

August 1–6, 2021.

posed by Czarnowska et al. (2019), is the Dependency Matrix (DM) model which uses linear maps in the form of square matrices to encode relations. Here, the training objective is changed from predicting *(target, context)* pairs to *(target, relation, context)* triples, e.g., *(rain,$\overline{dobj}$,like)*. This model produced comparable results with DEP and EXT at the word level. Furthermore, compositional experiments on short phrases, specifically relative clauses, produced encouraging results when using the learned transformations. Yet, despite considerably reducing the number of parameters, this model still makes use of large word spaces and the square linear map is still costly to train.

Model	Learnable Parameters
DEP	223M
DM	51.6M
MuRE	21.5M
RotE	21.5M
RefE	21.5M
AttE	21.6M

Table 1: Learnable parameters for each model, given the same word (72k) and relation (88) vocabularies from the `text8` (parsed) corpus, and vector size of n=300.

The reformulation of the SGNS objective introduced by DM (i.e., moving from *(target,context)* tuples to *(target,relation,context)* triples) closely resembles a common practice in the knowledge graphs (KGs) literature (e.g. (Trouillon et al., 2017; Balazevic et al., 2019; Chami et al., 2020)). Here, large, mainly factual, graphs are fed to neural models in the form of *(head,relation,tail)*. Compared to the syntactically-aware DSMs discussed above, many of the models proposed to encode KGs make use of a substantially lower number of parameters to encode both word and relations, as shown in Table 1. Furthermore, in order to represent the heterogeneous types of relations in KGs, researchers have experimented with models based on different types of geometric transformations (GTs). These include, but are not limited to, stretch (Balazevic et al., 2019), rotation (Sun et al., 2019; Chami et al., 2020), reflection (Chami et al., 2020) and attention (Chami et al., 2020). However, in the KG literature, limited attention has been paid to the compositional nature of phrases. Single-token oriented vocabularies (where *New York* is represented by *New_York*), used in most KGs, work well for real-world entities, such as people or cities, but are problematic when considering compositional phrases such as *small cake*. As discussed by Toutanova et al. (2015), treating these phrases in the same way forces the vocabulary to grow immensely, and prevents the model from reasoning over new phrases in a compositional fashion. Hence, developing successful composition strategies is of interest to the KG community as well as more widely in Natural Language Inference (NLI).

Given the success that DM and other models have obtained in modelling syntax and syntactically driven composition, we propose to overcome the parameter and word-relation vocabulary problems by using GT models to encode syntactic graphs. We focus our investigation on four state of the art models from the knowledge-graphs literature, namely MuRE (Balazevic et al., 2019), and the three GTs-based models proposed by Chami et al. (2020): RotE, RefE and AttE. Despite the simplicity, MuRE has obtained competitive results, when compared to more complex models (Chami et al., 2020)). Rotation has been used to model composition of relation representations (Sun et al., 2019). Attention has been frequently proposed as a plausible mechanism for composition (e.g. Hudson and Manning (2018); Tay et al. (2019); Yin et al. (2020); Russin et al. (2020)), whilst reflection is relatively under-studied (Chami et al., 2020). Furthermore, as discussed in Section 3, these models allow for an interesting comparison, as they can be grouped into three categories: tail modifiers (DM), head modifiers (RotE, RefE, AttE), and full modifiers (MuRE). Hence, we explore some of the transformational properties required to enable the successful encoding of syntactic relations, where success is defined in terms of their potential to support phrasal composition.

Our contributions are as follows. First, we show how lighter-weight models based on GTs can be used to encode both word and syntactic relations, frequently outperforming DM both in word similarity and compositional benchmarks. Second, for each model, we propose a tailored composition strategy, based on syntactic contextualisation of one (or more) of the phrase constituents. We hence show how to exploit the learned syntactic representations for composition, by comparing syntax-driven strategies for composition with simple addition. Third, we provide an analysis of which type of GTs better encode relations for syntactic contextualisation and enhanced composition.

2 Related Work

Knowledge graphs are complex data structures where nodes are concepts or entities (usually content words like *dog* or *Campari*) and edges are relations (e.g. `is_a`, `produced_in`) connecting entities to one another (e.g. *dog* `is_a` *mammal*, *Campari* `produced_in` *Italy*). Table 2 reports the number of distinct entities, relations and triples for three of the most investigated KGs, namely, FB15k-237 (Toutanova and Chen, 2015) YAGO3-10 (Mahdisoltani et al., 2015), and WN18RR (Dettmers et al., 2018), as well as a syntactic graph (SyG) constructed from the parsed corpus `text8`. The way these graphs are structured can vary significantly. Chami et al. (2020) showed how, among the presented KGs, only WN18RR has a significantly hierarchical structure.

Dataset	entities	relations	triples	graph type
WNRR18	31k	11	87k	KG
FB15k-237	15k	237	272k	KG
YAGO3-10	123k	33	1M	KG
`text8`	72k	88	12M*	SyG

Table 2: Statistics for the training splits of different datasets (* number of unique items, with observed repetitions, items raise to 18M).

Research on models for representing KGs has mainly focused on the ability to predict new connections between existing nodes. To overcome the problem of testing items that do not occur in the training set, many models have adopted negative sampling (NS) strategies in the training phase. The vocabulary of KG datasets is also largely single-token oriented. Models able to handle multi-token items have been proposed (Toutanova et al., 2015, 2016; Sun et al., 2019), but they focus on the composition of relations rather than entities, e.g., how a complex relation such as `married_to:son_of` might be split into multiple constituents and composed. Also relevant, Toutanova and Chen (2015) showed how syntax-augmented triples extracted from documents (e.g. $(Obama, \texttt{nsubj:born\_in:obj}, USA)$) can be beneficial for KGs models, but did not investigate representing syntax or composition via embeddings.

Previous works (e.g. (Marcheggiani and Titov, 2017; Vashishth et al., 2019)) showed how SyGs could be encoded via graph convolutional networks (GCN) (Kipf and Welling, 2017). These large models are able to encode larger graphs (up to the sentence level), via sequences of convolutions along the edges of the graph. Such convolutions are frequently relation-specific and are also encoded via square matrices.

3 Theoretical Approach

In both the semantic (KG) and syntactic (SyG) domain, the starting point is typically a dataset D of positive triples (h, r, t), with $h, t \in V = \{1, .., |V|\}$ and $r \in R = \{1, .., |R|\}$, where V and R are the sets of the indexes for the vocabulary of entities / words and relations, respectively. In both domains, the shared goals are: i) map entities $v \in V$ to embeddings e_v where $e \in \mathbb{R}^{|\mathsf{V}| \times n}$, n being the dimensionality of the vectors; ii) map relations $r \in R$ in one – or more – space $\mathbb{R}^{|\mathsf{R}| \times *}$. In this work, we focus on constructing a syntactic dataset of positive training triples from a corpus as in Czarnowska et al. (2019). All of the models we investigate rely on a negative sampling mechanism that generates a dataset D' of false triples. Each model was presented in its own original work with a tailored way to generate D'. Unless otherwise stated, we make use of the original mechanism.

As already discussed, we are interested in both word level and compositional level evaluation. Testing at the word level, e.g., using word similarity benchmarks, simply requires extraction of the word embeddings. Compositional tests, on the other hand, also require syntactic analysis of the phrase and extraction and application of the relation embeddings. The first step, is to generate a parsed version of the phrase. For example, syntactic analysis of the phrase $pour\ tea$ will produce the root-as-head (Rh) (h, r, t) triple $(pour, dobj, tea)$, and the root-as-tail (Rt) (h, r, t) triple $(tea, \overline{dobj}, pour)$. Such duplicity of representations was handled in DM by obtaining both representations and then summing the cosine similarities obtained when comparing each of the two representations with a given target. Whilst reasonably effective in the DM evaluation, this does not provide a single phrase-level representation and would become unwieldy for longer phrases and sentences. Weir et al. (2016) argued in favour of considering the syntactic root as the main element of any multi-token linguistic item. In our example, to compare *pour tea* with *drink water*, this would require us to consider the syntactic root in the context of its dependent i.e., how similar is the verb *pour* when contextualised by the direct object *tea* to the verb *drink* when contextualised by the `direct_object` *water*? In models which modify the head of the triple (e.g., (Chami et al., 2020), this would correspond to using the root-as-tail (Rt) analysis of the phrase. Here, we compare the two strategies empirically. Further, inspired by the growing success of (very large) bi-directional models such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018) and also by recent evidence from the neuroscientific literature (Mollica et al., 2020; Fedorenko et al., 2020), suggesting that sentence processing strongly relies on identifying and composing smaller units of meaning, such as phrases, regardless of order of their constituents, we also propose a third compositional strategy which is bi-directional in nature. Here, the phrase-level representation is the sum of the root-as-head and the root-as-tail representations, making it more agnostic to the direction of the relation as well as the word order. However, phrases with different structures such as *glass window* and *window glass* will still have different representations due to the different roles played by each word in each relation.

In summary, we propose and investigate three different syntax-aware (*syn*) composition strategies: *syn*-Rh and *syn*-Rt, different solely in where the root is placed in the $(head, relation, tail)$ triple; and *syn*-BiD (for bi-directional), constructed by adding the representations obtained by *syn*-Rh and *syn*-Rt. We now describe in detail the models investigated, together with our tailored *syn* composition strategy for each of them.

DM This model is an extension of SGNS, where a linear map, in the form of a $n \times n$ matrix, projects a word from the context space (e') into the target space (e), as in Equation 1:

$$u = e_h^T \cdot (W_r e_t^{'}) \tag{1}$$

where $e, e' \in \mathbb{R}^{|\mathrm{V}| \times n}$, and $W \in \mathbb{R}^{|\mathrm{R}| \times n \times n}$. Since the tail word is projected into the space occupied by the head word, we refer to this model as a tail-modifier. u is then used to compute standard SGNS loss (Equation 2):

$$\sum_{(h,r,t)\,\in\, D} \log \sigma(u) \;+ \sum_{(h,r,t)\,\in\, D'} \log \sigma(-u) \tag{2}$$

Phrase representations will be constructed following our three syntactic composition strategies. As a baseline, common to all models, we use addition (*add*) of the queried head and tail entities embeddings, as in Equation 3 [2]:

$$e_{add} = e_h + e_t \tag{3}$$

We propose *syn* composition for the DM model to be obtained via u (Equation 1), as in Equation 4:

$$e_{syn} = e_h + (W_r e_t^{'}) \tag{4}$$

MuRE This architecture falls into the family of translation models (Chami et al., 2020). Here, both the entities go through a transformation and so we refer to this model as a full-modifier. The tail entity is shifted with a translation (i.e. offset), and a stretch, in the form of a $n \times n$ diagonal matrix, is applied to the head entity. Embeddings are then fed to a distance function $d(x, y) = \|x - y\|$ and the model minimises the Bernoulli negative log-likelihood loss, using Equation 5, to estimate the probability of the triple being from D:

$$p(h, r, l) = \sigma(-d(W_r e_h, e_t + w_r)^2 + b_h + b_t) \tag{5}$$

Here, $W \in \mathbb{R}^{|\mathrm{R}| \times n \times n}$ contains $|R|$ diagonal matrices (each corresponding to a relation-specific stretch), $w \in \mathbb{R}^{|\mathrm{R}| \times n}$ hosts $|R|$ translation vectors, and $b \in \mathbb{R}^{|\mathrm{V}| \times n}$ the entity biases. Again, additive composition is carried out by adding the queried embedding for the phrase's constituents. Syntactic composition is implemented by adapting the model's score function (Equation 6):

$$e_{syn} = W_r e_h + (e_t + w_r) \tag{6}$$

RotE, RefE These models optimise a full cross-entropy loss. Like MuRE, square distance between two vectors is used as a score function. Unlike the previous model, they apply a Givens rotation (Rot) or reflection (Ref), as defined in Chami et al. (2020), and a translation to the head entity. Thus, we refer to these models as head-modifiers. Syntactic composition is defined via the score functions in Equations 7 and 8:

$$e_{syn} = (\mathrm{Rot}(T_r) e_h + t_r) + e_t \tag{7}$$

$$e_{syn} = (\mathrm{Ref}(F_r) e_h + f_r) + e_t \tag{8}$$

where $T, F \in \mathbb{R}^{|\mathrm{R}| \times \frac{n}{2}}$ each contain $|R|$ diagonal matrices (each corresponding to a relation-specific Givens rotation or reflection), and $t, f \in \mathbb{R}^{|\mathrm{R}| \times n}$ are relation-specific translations.

---

[2] This corresponds to simple-sum composition in the original work by Czarnowska et al. (2019).

AttE Intuitively, AttE is designed to model the contribution of different GTs (in this case just rotation and reflection). This is achieved via a self-attention mechanism. Given two embeddings x, y, and an attention vector a, attention scores are computed via Equation 9:

$$(\alpha_x, \alpha_y) = \text{Softmax}(a^T x, a^T y) \tag{9}$$

These scores are then averaged (Equation 10):

$$\text{Att}(x, y; a) = (\alpha_x x + \alpha_y y) \tag{10}$$

To actively select the most suitable transformation for a given triple, rotation and reflection are applied to the head-entity embedding (Equation 11):

$$\mathrm{q}_{\text{Rot}} = \text{Rot}(T_r)e_h,\ \mathrm{q}_{\text{Ref}} = \text{Ref}(F_r)e_h \tag{11}$$

The two representations are than combined using a self attention mechanism (Equation 12):

$$Q(h, r) = \text{Att}(\mathrm{q}_{\text{Rot}}, \mathrm{q}_{\text{Ref}}; a_r) + p_r \tag{12}$$

with $p \in \mathbb{R}^{|\mathrm{R}| \times n}$ as the relation-specific translation. Q and the e_t are then used as arguments for d as in Equation 5. Syntactically contextualised composition (*syn*) for AttE is implemented via Equation 13:

$$e_{syn} = Q(h, r) + e_t \tag{13}$$

4 Experiments

Our main aim is to investigate the potential of models in terms of constructing high quality word representations and their support for composition. To this end, experiments were carried out with a set of models trained on KGs, and a second set of models trained on SyGs. This allows us to investigate the value of encoding distributional information from SyGs or whether KGs alone might be a sufficient source of data to obtain competitive results. We hypothesise that when using KGs alone: i) word similarity tasks might yield high results; ii) compositional evaluation will yield poor results. As for models trained on SyG, we expect to see: i) a generally improved performance on most tasks, when compared to models trained on KGs; ii) larger models to be penalised across benchmarks and for syntactically-contextualised (*syn*) composition.

4.1 Experimental setup

Benchmarks We divide our quantitative experiments between word similarity and composition tasks. For the word similarity tasks, we focus on SimLex (Hill et al., 2015), MEN (Bruni et al., 2014), and both similarity (WS_s) and relatedness (WS_r) split of the WordSim353 (Finkelstein et al., 2001) datasets. For every word pair, we produce a model's prediction using cosine similarity (CS). We compare model predictions and human judgements using Spearman's ρ.

For the compositional investigation, we focus on the Mitchell and Lapata (2010) (ML10) dataset. Items in this benchmark consist of pairs of two-token phrases (e.g. *(pour tea–drink water)*) paired with human judgements on their similarity. Phrases are composed using the four different presented strategies and the obtained representations are compared via CS. Again, CS and human ratings are compared via ρ. We selected this benchmark for two main reasons: i) the models' structures lend themselves straightforwardly to syntactically contextualised (*syn*) composition strategies for a two-token item[3]; ii) the dataset is pre-split into three syntactic-relation classes (i.e. adjective-nouns (AN), verb-objects (VO) and noun-nouns (NN)) and this division offers an opportunity for a more in-depth investigation on how different models and operations manage to embed different syntactic relations.

We trained each set of models with three random initialisation, and report the mean and standard error (SE) of the obtained ρs.

Implementation For MurE, RotE, RefE and AttE we adapt the original PyTorch code. Since an official release of the DM is not available, we implemented a PyTorch version of the model[4].

We trained the first set of GT models on the WN18RR dataset, tuning negative sampling rate (NS), optimiser and learning rate using mean reciprocal rank (MRR) on the development set[5]. Epochs were kept stable at 50 and n to 300. We focused on WN18RR as YAGO3-10 shares a minimal vocabulary with the selected word-similarity and compositional benchmarks. FB15k-237, on the other hand, has all the entities encrypted. The models obtained from this training set were then evaluated on both word-similarity and compositional tasks (see Table 3) to provide a baseline for the SyG models.

---

[3] Czarnowska et al. (2019) proposed a more complex composition strategy, specifically for relative clause phrases which we do not consider here.

Table 3: Spearman ρs' (mean ± SE) obtained on all selected benchmarks, for knowledge-graph models trained on WN18RR dataset.

A second set of models was trained on the `text8`[6] corpus, parsed with spaCy (Honnibal and Johnson, 2015). Following Czarnowska et al. (2019), minimum item count, epochs, NS, optimiser and learning rate were fine-tuned on SimLex. Hyperparameters are selected from the union of the ones proposed in (Balazevic et al., 2019; Czarnowska et al., 2019; Chami et al., 2020). All the models share the same number of dimensions, i.e., $n = 300$. For a fair comparison, all experiments for this set have been conducted on the vocabulary shared across the models. Final coverage and best hyperparamenters are reported in Appendix A.2 and A.1. All models were trained using NVIDIA Titan V GPUs.

4.2 Results

WN18RR trained models We begin our quantitative investigation evaluating models from the knowledge graph literature, trained on WN18RR, on all benchmarks. Looking at Table 3, we note that these models, compared to models trained on `text8` or similar distributional models trained on much larger corpora, achieve competitive results on the word similarity benchmarks, especially in the historically challenging SimLex dataset, despite the small vocabulary and training samples.

A possible explanation for these results lies in how entities co-occur in the training data. First of all, WN18RR has a limited vocabulary (see Table 2), and is poorly populated by adjectives. Furthermore, noun and verbs, two part of speech (POS) that frequently co-occur between each other in natural language, here mainly occur within each other (i.e. verb with verb, noun with noun). In few cases, especially for verbs, the co-occurrences are not only limited to the same POS, but interest the very same word. All models perform much worse on the relatedness split of WS-353 than the similarity split. This might be expected, for models trained on WordNet data. As predicted, the performance is generally poor for composition benchmarks. An exception seems to be the VO subset, where models achieve results that, as will be presented shortly, are competitive also for `text8`-trained models.

Word similarity Our motivation for experiments with models trained on `text8` is to understand whether models previously proposed for representing KGs are competitive with distributional models such as DM in their ability to embed word and syntactic relations. Results for word-similarity are presented in Table 4.

RefE	.18±.01	.63±.01	.70±.01	.56±.00
AttE	.16±.00	.61±.00	.69±.01	.57±.01

Table 4: Spearman ρs' (mean ± SE) obtained on word-word similarity benchmarks, with models trained on `text8` corpus.

First, scores on SimLex are much lower than: i) those achieved by the KG-trained models; ii) those presented elsewhere for DM in the literature (Czarnowska et al., 2019). We note that the corpus we used to train the models is significantly smaller than the one used to train DM by the original authors, and we assume that this, combined with the low frequency of SimLex items in our corpus, is the main reason for these differences. Results for DM on the other word similarity benchmarks are much closer to the performance achieved by the original authors and, on these benchmarks, DM clearly outperforms the baseline of models trained on WN18RR. However, most notably, GT models trained on the same data as DM, not only achieve comparable results to DM, but they almost always outperform it, both in similarity-based and relatedness-based benchmarks. Moreover, DM seems to show the highest variation, especially for WN_s and WN_r.

Composition Table 5 shows the results for all `text8`-trained models on the compositional

	syn-BiD	.48±.00	**.38±.01**	**.46±.01**	**.44±.01**
AttE	*add*	.46±.01	.35±.01	.41±.01	.41±.00
	syn-Rh	.47±.01	.35±.00	.43±.01	.41±.01
	syn-Rt	.45±.01	.29±.01	.43±.01	.39±.00
	syn-BiD	.48±.02	.36±.00	.46±.00	.43±.00

Table 5: Spearman ρs' (mean ± SE) obtained on Mitchell and Lapata (2010) benchmark, with models trained on `text8` corpus. Phrasal composition is carried out by element-wise addition (*add*), and the three proposed syntax (*syn*) aware strategies: root as head (*syn*-Rh), root as tail (*syn*-Rt) and bidirectional (*syn*-BiD). **Best results for each Phrase Type**.

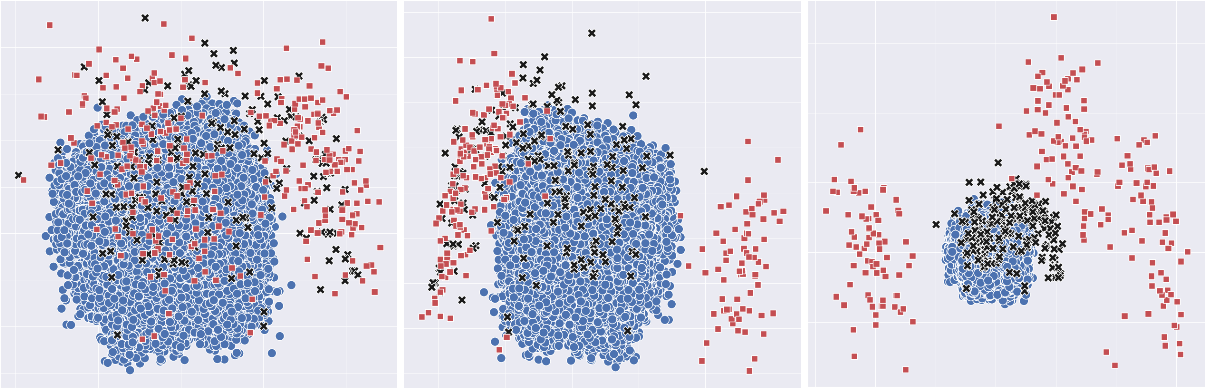
benchmark. Again, GT models show competitive results, and generally outperform DM, which fails at improving its performance with *syn* composition. This last evidence is reversed in all other models. That is, they all achieve best performance with one of the syntax-aware composition methods. Looking closer, we can see that, in most cases, the best *syn* method is the bi-directional one, with the exceptions of MUuRE, RotE and RefE's AN phrases. Notably, *syn*-BiD is almost never a mere average of the two representations that originated it. In many cases, and especially for AttE, *syn*-BiD representations produce a significantly larger gain in performance, when compared to both *syn*-Rt and *syn*-Rh. From the single model perspective, the best performing one is RefE. Syntax-aware methods based on reflection always outperform the additive baseline, and also obtained the best score in the average sections, via bi-directional composition. Again, DM is the model showing the highest variation in results. This provides further evidences in favour of the lightweight models taken from the KG literature

4.3 Statistical Analysis

All correlations were tested for significance, adopting the Holm correction (Holm, 1979) to account for the large number of tests, and we observed no $p < .05$. As the main interest of our work was the compositional investigation (reported in Table 5), a global comparison was conducted to test whether observed differences in correlations were also significant. We adopted a paired two-tail bootstrap analysis (Berg-Kirkpatrick et al., 2012; Søgaard et al., 2014; Dror et al., 2018), performed independently between results from the three seeds. Given the large number of comparisons, a Holm correction was adopted within the same Phrase Type. Results (see A.3 for more details) showed that, among all models, the only one that generated a number of insignificant differences was DM, mainly pertaining to different strategies for composing NN items.

4.4 Qualitative Analysis

We now investigate the impact of relation representations on word vectors and composition from a qualitative point of view. Here, we focus on the model that quantitative tests indicated as the most promising one: RefE. We will start at the word level, looking at syntactically contextualised single words. The interest here, is to see if clear relation-driven clusters can be identified within a reduced space. To do so, we contextualise the set of roots from ML10 (e.g. *amount* in *vast amount*), and reduce the dimensions through PCA. Results in Figure 2 suggest that the three syntactic relations adopted for contextualisation (i.e. `amod`, `dobj`,



(a) *syn*-Rt

(b) *syn*-Rh

(c) *syn*-BiD

Figure 1: PCA visualisation of RefE vector space. Images show the same word (●) and *add*-composed vectors (×), in the context of representations composed with the four different syntax-aware (🟥) composition methods. All composed vectors represent the set of phrases from the Mitchell and Lapata (2010) benchmark.

`nmod`) appear to generate as many distinguishable clusters. Despite being limited, these results support evidence for syntactic subspace probed out of mBert (Chi et al., 2020).

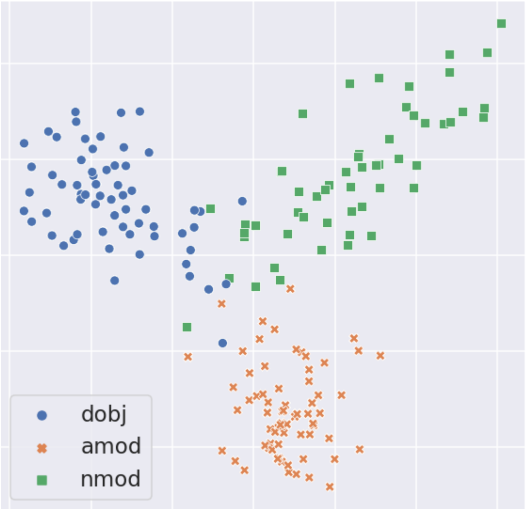


Figure 2: PCA visualisation of syntactically contextualised root-items from ML10 phrases using RefE and reflection. AN roots are contextualised using `amod`(×), VO via `dobj` (●), NN via `nmod` (🟩).

Concluding, we explore how composition strategies behave with respect to the word representations. To do so, we concatenate representations obtained by *add*-composing the set of ML10 items with the full original space, and each syntax-aware strategy separately. The three obtained sets of concatenation (i.e. word–*add*–*syn*-Rt; word–*add*–*syn*-Rh; word–*add*–*syn*-BiD) is then independently reduced to n=2 through principal component analysis (PCA). Results are reported in Figure 1. As it can be observed throughout the three reductions, and mostly in Figure 1c, phrase representations obtained via simple addition mainly lie within the perimeter of the word space. A similar pattern is observed in Figure 1a, with *syn*-Rt. Phrases composed by using the root as the head of the triple are still fairly close to the word-space perimeter, but tend to abandon its centre. Lastly, Figure 1c shows how bi-directional representations lie scattered fairly distant from the word and *add*-composed representations. This last observation is contrary to theories suggesting that representations at every level (word, phrase, sentence, etc..) should lie within the same space (e.g. Weir et al. (2016)). However, it may support recent work from neuroscience (e.g. Ding et al. (2016)) suggesting that the brain networks processing word, phrases and sentences do not completely overlap.

5 Discussion

Our results strongly suggest that light-weight models presented in the knowledge-graphs literature can be efficiently applied to syntactic-graphs, and be converted to distributional models that are consistently able to make use of the learned word and relation representations to improve semantic phrase-composition. From the model-theoretical point of view, evidence suggests that constraining linear maps with a reflection (together with a non-linear translation) seems to be the most efficient way of encoding syntactic relations. Our quantitative results also contribute to the debates on how sequential language data, or English at least, should be processed and what the role of syntactic information should be. As mentioned in

Section 3, the models selected distinguish between being tail (DM), head (RotE, RefE and AttE) and full (MuRE) modifiers. Further, we can change the syntactic focus of any of these models by adopting the *syn*-Rt composition strategy instead of the *syn*-Rh strategy. However, in our experiments, the head-modifier models (RotE, RefE and AttE) outperformed the tail-modifier and full models (DM and MuRE) and achieved a better results with the *syn*-Rh strategy than the *syn*-Rt strategy, i.e., when the syntactic root of the phrase was taken as the head of the triple rather than as the tail. In other words, it appears better to contextualise the root and compose with its dependent, which opposes the linguistic arguments put forward by Weir et al. (2016). However, even more notably, the *syn*-BiD composition strategy, which combines the *syn*-Rh and *syn*-Rt representations, generally gave a further boost to performance. This is further evidence that bi-directional information is more informative than uni-directional information, not just in large neural models such as LSTMs and transformers, and supports recent theory from neuroscience which argues that what is crucial for composition is not the overall structure nor the root, but that we can identify a phrase's constituents and the relation they have (Mollica et al., 2020). Evidence in favour of the fact that composition strongly relies on local dependencies based on syntactic structure was also found by Saphra and Lopez (2020). Such work suggests that LSTMs learn to compose following a hierarchical structure, driven by syntax, and that they rely on the learned short sequences to build longer and more reliable ones. Taken altogether, the evidence from different language-related fields is becoming more compelling that syntax and phrase composition should play an important role in the composition of larger units of meaning.

6 Conclusions and Further Work

We have shown how GT models previously proposed for encoding KGs can be adapted to encode syntactic information in a distributional model. We have demonstrated the high quality nature of the distributional word representations and the potential for using syntactically-contextualised composition strategies for phrases. In particular, we have demonstrated the competitiveness of lighter-weight GT models when compared to more general models based solely on unconstrained linear maps, such as DM. Further, our analysis has shown how learned representations for syntactic relations can be efficiently exploited at the word level, transforming a word through part-of-speech related regions of the space, and at the phrase level, generating superior composed representations. Furthermore, we have shown, among the different GTs, reflection seems to be the most promising for encoding syntactic relations. Future work will focus on composition on larger scale, syntactic-relation composition, and whether syntactic and semantic graph can be simultaneously embedded using this framework.

Acknowledgements

Abstract

We introduce a collection of recognizing textual entailment (RTE) datasets focused on figurative language. We leverage five existing datasets annotated for a variety of figurative language – simile, metaphor, and irony – and frame them into over 12,500 RTE examples.We evaluate how well state-of-the-art models trained on popular RTE datasets capture different aspects of figurative language. Our results and analyses indicate that these models might not sufficiently capture figurative language, struggling to perform pragmatic inference and reasoning about world knowledge. Ultimately, our datasets provide a challenging testbed for evaluating RTE models.

1 Introduction

Figurative language is ubiquitous in many forms of discourse from novels, poems, and films, to scientific literature and social media conversations (Ghosh, 2018). It is often used to convey intimacy (Gerrig and Gibbs Jr, 1988), humour (Roberts and Kreuz, 1994), intense emotions (Fussell and Moss, 1998), or veiled politeness (Jorgensen, 1996). Despite its ubiquity, figurative language remains "a bottleneck in automatic text understanding" (Shutova, 2011).

Recognizing Textual Entailment (RTE), the task of identifying whether one sentence (context) likely entails another (hypothesis), is often used as a proxy to evaluate how well Natural Language Processing (NLP) systems understand natural language (Cooper et al., 1996; Dagan et al., 2006; Bowman et al., 2015). Figurative language is defined as any figure of speech which depends on a non-literal meaning of some or all of the words used. Thus, understanding figurative language can be framed as an RTE task (figurative language expression vs. intended meaning), where the figurative language expression is the *context* and the intended meaning is the *hypothesis* in an RTE framework (See examples in Table 1).

Simile	▶ I start to prowl across the room like a **tightrope walker on dental floss**. I start to prowl across the room *recklessly*.	✗
	▶ They had shut him in a basement that looked like a **freight elevator**. They had shut him in a basement that looked *dangerously claustrophobic*.	✓
Metaphor	▶ He **weathered** the costs for the accident. He *avoided* the costs for the accident.	✗
	▶ The bus **bolted** down the road. The bus *paced* down the road.	✓
Irony	▶ Made $174 this month, gonna buy a yacht! I don't make much money.	✗
	▶ Fans seem restless, gee, don't understand them. Fans seem restless - don't know the reason behind it.	✓

Table 1: Example RTE pairs focused on similes, metaphors, and irony that RoBERTa *incorrectly* labels. ▶ indicates a context and the following sentence is its corresponding hypothesis. ✓ and ✗ respectively indicate that the context entails, or does not entail the hypothesis. **Bold** text represent simile and metaphors and *Italic* represent their entail/not entail interpretations (top two rows).

We investigate how suitable are state-of-the-art RTE models trained on current RTE datasets to capture figurative language. We focus on three specific types of figurative language: similes, metaphors, and irony. Similes evoke comparisons between two seemingly different objects, metaphors expand the imagination beyond the literal narrative, and irony conveys the opposite of what is said.

We leverage five existing datasets annotated for these types of figurative language to create over

12,500 RTE examples that require understanding or identifying these phenomena. We evaluate how well standard neural RTE models capture these aspects of figurative language. Our results demonstrate that, although, systems trained on a popular RTE dataset may capture some aspects of various types of figurative language, they fail on cases where the interpretation relies on pragmatic inference and reasoning about world knowledge. We release the code and the data. [1]

2 Related Work

We follow recent work that test for an expanded range of inference patterns in RTE systems (Bernardy and Chatzikyriakidis, 2019) by evaluating how well RTE models capture specific linguistic phenomena, such as pragmatic inferences (Jeretic et al., 2020), veridicality (Ross and Pavlick, 2019), and others (Pavlick and Callison-Burch, 2016; White et al., 2017; Dasgupta et al., 2018; Naik et al., 2018; Glockner et al., 2018; Kim et al., 2019; Kober et al., 2019; Richardson et al., 2020; Yanaka et al., 2020; Vashishtha et al., 2020; Poliak, 2020).

We are not the first to explore figurative language in RTE. Agerri (2008) analyze examples in the Pascal RTE-1 (Dagan et al., 2006) and RTE-2 (Bar-Haim et al., 2006) datasets that require understanding metaphors and Agerri et al. (2008) present an approach for RTE systems to process metaphors. Poliak et al. (2018)'s diverse collection of RTE datasets includes examples based on figurative language, but focuses only on identifying puns.

3 Dataset Creation

We create RTE test sets that focus on similes, metaphors, and irony. We provide further background for these types of figurative language and describe the methods used for creating these test sets. Table 2 reports the final test sets' statistics.

3.1 Simile

Comparisons are inherent linguistic devices that express the likeness of two entities, concepts, or ideas. When used figuratively, comparisons are called similes. Similes are used to spark the reader's imagination by making descriptions more emphatic or vivid (Paul et al., 1970). Similes use a common PROPERTY to compare two concepts often referred to as the TOPIC (the logical subject) and the VEHICLE (the logical object of comparison). For example, in the simile "Love is like an unicorn", love (TOPIC) is compared to a unicorn (VEHICLE), portraying the implicit property "rare". Recently Chakrabarty et al. (2020) released a test set of 150 literal sentences from subreddits r/WritingPrompts and r/Funny, each aligned with two human-written paraphrases with similes that retain the original meaning.

Data		Total	E	NE
Simile		600	300	300
Metaphor		613	307	306
Irony Meaning	$SIGN_{2000}$	2,000	133	1867
	S_{im}-H_{int}	4,762	-	4,762
Irony Intention		4,601	2,212	2,389

Table 2: Dataset statistics and class distribution, *Entailment* (E) and *Not-Entailment* (NE) for each type of figurative language.

To create our RTE test set that focuses on similes, we treat these simile-literal aligned sentences as entailed context-hypothesis pairs. Given a literal input, "They had shut him in a basement that looked **dangerously claustrophobic**", an expert annotator re-framed it as "They had shut him in a basement that looked *like a freight elevator*".[2] We create Not-Entailed examples by flipping the literal verb/property with their respective antonyms and use the original (Literal, Simile) pairs as Entailed. For instance, in the case of an existing context-hypothesis pair expressing *Entailment* - "Hitler skittered off like **an enthusiastic sloth**" → "Hitler skittered off *slowly*" - we alter "slowly" to "fast" to make it a pair of *Not-Entailment* (NE) instance.

3.2 Metaphor

Metaphors express deep feelings and complex attitudes (Veale et al., 2016). Understanding metaphors requires comprehending abstract concepts and making connections between seemingly unrelated ideas to appropriately deviate from literal meaning (Gutierrez et al., 2016; Mohammad et al., 2016; Kintsch and Bowles, 2002; Glucksberg, 1998).When generating metaphoric paraphrases, Chakrabarty et al. (2021) create a diverse test set of 150 literal sentences curated from different domains and genres and asked two expert annotators to create metaphorical sentences, resulting in a total

---

[1] `https://github.com/tuhinjubcse/Figurative-NLI`

[2] Note, such re-framing task (content generation task) does not involve assigning a label to a text fragment, thus, computing inter-annotator agreement is not applicable here.

Genre	PairID	Example
Slate	143311e	► Praise from a stranger is **like a glass of water** served at a restaurant in: You drink it warily, if at all, fearing it may be tainted Praise from someone you do not know can be taken lightly
Fiction	60838c	► The stars are no more like the sun than the glow of my cigarette is **like a forest fire**. The sun is comparable to the stars because they are the same.
Telephone	99298c	► But uh still I I question the ability of some of the teachers to uh really do a **bang-up job** and yet others i know are just wonderful All teachers sucks

Table 3: Examples from MNLI that include figurative language. ► indicates a context and the following line is its corresponding hypothesis.

of 300 metaphorical examples. The expert annotators re-framed the literal sentences independently by replacing the literal verb with a metaphorical verb. For instance, an expert reframed the literal sentence “The tax cut will help the economy" to “The tax cut will **fertilize** the economy".

Since the most frequent type of metaphor is expressed by verbs (Martin, 2006; Steen, 2010) these literal and metaphorical paraphrases differ only by the verb they use. In an RTE framework, we treat these metaphorical-literal pairs as entailed context-hypothesis examples. To create Not-Entailed examples, we generate hypotheses by manually swapping the literal verb in the entailed hypothesis with its antonym. Note that for both simile and metaphor, automatic substitution using available lexicons is problematic as it often leads to ungrammatical sentences. Manually replacing the words with its antonym guarantees a high quality test set. We use antonyms to create Not-Entailed examples for Simile and Metaphors which contain both Neutral and Contradiction classes. Such lexical replacement using antonyms would clearly lead to higher quality contradiction example creation. On the contrary, creating neutral examples by lexical perturbation is challenging and if not done properly, it can lead to grammatical errors or incoherent sentences.

3.3 Irony

When using irony, speakers usually mean the opposite of what they say (Sperber and Wilson, 1981; Dews et al., 2007). We develop different test sets focusing on whether the RTE models should *understand the conveyed meaning* of ironic examples or should *identify the speaker's ironic intent* (i.e., identify if an utterance is ironic or not) given the hypothesis that the speaker was ironic.

Understanding Ironic Meaning (IMeaning) Peled and Reichart (2017) used skilled annotators to create a parallel dataset between tweets with verbal irony and their non-ironic rephrasings (15K pairs). Annotators also had the option to copy the original tweet or just to paraphrase it, in case the ironic intent is not easy to identify. Likewise, Ghosh et al. (2020) released a parallel dataset of speakers' ironic messages (S_{im}) and hearers' interpretations (H_{int}) of the speaker's intended meaning. This dataset (S_{im}-H_{int}) contains 4,761 ironic-literal pairs. We use both datasets in our experiments and henceforth denote them as $SIGN$ and S_{im}-H_{int}, respectively. For both datasets, the original *ironic* messages are treated as the contexts and the *intended* meanings are the hypotheses. However, all RTE contexts do not contradict their corresponding hypotheses. For instance, in case of Peled and Reichart (2017), the authors allowed annotators to not rephrase the ironic sentences with their opposite *intended meanings* (in case the sarcastic or ironic intent was not clear). Thus, for evaluation purposes (see Table 4), we annotated a subset of 2,000 random pairs from $SIGN$ and evaluated the RTE models on that subset (denoted as $SIGN_{2000}$ henceforth). Around 93% of the RTE pairs in $SIGN_{2000}$ are Not-Entailed examples and 100% of RTE pairs in S_{im}-H_{int} are Not-Entailed examples.

Recognizing Ironic Intent (IIntent) We leverage additional ironic examples from Van Hee et al. (2018). Following Poliak et al. (2018)'s method for recasting annotations for puns and sentiment, we use *templates* to generate contexts (a) and hypotheses (b). We use all the ironic tweets ($training$ and $test$) released by Van Hee et al. (2018) to generate 4,598 RTE pairs. Akin to Poliak et al. (2018), we

Testset / Model	Simile	Metaphor	IMeaning		IIntent
			$sm - im$	$SIGN_{2000}$	
NBoW	51.17	54.81	86.37	71.50	**61.72**
InferSent	55.01	65.75	71.62	68.84	11.72
RoBERTa-large	**85.47**	**88.09**	**94.76**	**93.42**	52.81

Table 4: Accuracy of different models on our datasets focusing on similes, metaphors, and irony.

replace *Name* with names sampled from a distribution of names based on the US census data.[3]. The templates are a) *Name* tweeted that *tweet*, b) *Name* was ironic.

4 Experimental Setup

MNLI (Williams et al., 2018) is one of the widely used large-scale corpora that contains instances of figurative language (Table 3). Following recent work, we evaluate RTE models trained on MNLI (Williams et al., 2018) using three standard neural models: bag of words (NBoW) model, InferSent (Conneau et al., 2017), and RoBERTa-large (Liu et al., 2019). In NBoW, word embeddings for contexts and hypotheses are averaged separately, and their concatenation is passed to a logistic regression softmax classifier. InferSent encodes the context and hypotheses independently using a BiLSTM, then their sentence representations are fed to a MLP.[4] For RoBERTa, we use the model fine-tuned on MNLI from the Transformer's library (Wolf et al., 2020). We expect models trained on MNLI to capture some forms of figurative language that often appear in works of fictions, conversations, speeches, and magazines like Slate. Table 3 illustrates a few examples from MNLI that include figurative language

5 Results and Discussions

Table 4 reports models' accuracy on our figurative language RTE datasets. We observe that for similes, metaphors and irony meaning, RoBERTa-large drastically outperforms the other two models. For Irony datasets, NBoW outperforms InferSent. While all models perform poorly on IIntent, InferSent's very low accuracy stands out. The low performances might be due to the templatic nature of this recast dataset which might be very different from the MNLI training data.[5] We now turn to an in-depth analysis of RoBERTa's performance across these datasets.

Ironic Meaning. RoBERTa-large attains over 90% accuracy on the two datasets focused on ironic meaning. When analyzing these examples, a vast majority of the hypotheses in both datasets use lexical antonyms ("flattering" ↔ "disgusting) or negation ("is great" ↔ "is not great") to represent the intended meaning. Thus, the presence of antonyms might be enough for RoBERTa to correctly predict that the hypothesis is not-entailed by the context.

However, this does not hold true for hypotheses where the intended meanings were represented via more complex rephrasing. Ghosh et al. (2020) conducted a thorough study of the *linguistic strategies* that annotators have used for the rephrasing tasks. They presented a linguistically motivated typology of the strategies (e.g., "Lexical and phrasal antonyms", "Negation", "Weakening the intensity of sentiment", "Interrogative to Declarative Transformation", "Counterfactual Desiderative Constructions", and "Pragmatic Inference") and empirically validated the strategies over the $SIGN$ and S_{im}-H_{int} datasets.[6] During our analysis, we observe that for the vast majority of cases where RoBERTa predicts incorrectly, the examples contain Rhetorical Questions ("nice having finals on birthday?" ↔ "do not like finals ..."), pragmatic inferences ("Made $174 this month ... a yacht!" ↔ "I don't make much money"), or desiderative constructions of *[I wish] (that)* ("glad you related the news" ↔ "[I wish] that you have told me sooner". We also observe that RoBERTa-large's predictions are regularly incorrect when the ironic messages contain certain irony markers (Ghosh and Muresan, 2018), such as metaphor ("shoe smell like bed of roses" ↔ "smells bad"), alternate spelling where the speaker frequently overstate the magnitude of an ironic event ("dancing in heels is grrrrreat" ↔ "... hurts your feet") or hashtags that are composed of multi-word expressions that capture the irony ("god bless you ... #notinthemood).

			Gold	Pred
Simile	►	Your guardian angel is just a little too much like a **nerd at a comic convention**. Your guardian angel is just a little too *enthusiastic*	✓	✗
	►	Growing up, people always thought you were like a **social pariah**. Growing up, people always thought you were *ordinary*	✗	✓
	►	They all agree the books are good reads, but they are like **pseudo science fiction**. They all agree the books are good reads, but they are *too unrealistic*.	✓	✗
Metaphor	►	The smell of smoke **carpeted** on the delinquent. The smell of smoke *took off* on the delinquent	✗	✓
	►	As they strike the ground, they are **effaced**. As they strike the ground, they are *remembered*	✗	✓
	►	The avalanche **polvarized** anything standing in its way. The avalanche *protected* anything standing in its way.	✗	✓
Irony	►	Life was never been perfect and would never be. Life has never been perfect and would never be.	✓	✗
	►	The highlight of my day figuring out how to make contact sheets . . . such a boring life. My entire day was occupied in making contact sheets in design such a waste.	✓	✗
	►	Gotta read 70ish+ pages today #great #mysundayfunday #thisshouldbefun. I have to read 70ish+ pages today. This is bad.	✗	✓

Table 5: Examples from our Simile, Metaphor, and Irony datasets where Roberta-large fine-tuned on MNLI fails to classify the sentence pairs correctly. Gold and Pred means the true label and the predicted label respectively. ► indicates a context and the following sentence is its corresponding hypothesis. ✓ and ✗ respectively indicate that the context entails, or does not entail the hypothesis.

Simile. Likewise, for the simile dataset, we notice that RoBERTa-large often fails to reason with implicit knowledge about the physical and visual world knowledge (Table 5). This is inline with Weir et al. (2020)'s finding that transformer-based contextual language models poorly capture knowledge grounded in visual perceptions. For example, RoBERTa-large incorrectly predicts that the context "You wake one morning to find your entire family lying like **gray slabs of cement**" does not entail the hypothesis "You wake one morning to find your entire family lying *unconscious*". Nevertheless, RoBERTa-large correctly predicts that, "my eyes teared up . . . turning like a **ripening tomato**" entails "my eyes teared up . . . face *turning red*". We hypothesize that here RoBERTa-large was able to identify the association between "ripening tomato" and "red" that resulted in the correct prediction.

Metaphor. We notice RoBERTa-large makes wrong predictions when it encounters *unconventional* metaphors (Table 5). Metaphors are deemed unconventional depending on "how well-worn or how deeply entrenched a metaphor is in everyday use by ordinary people for everyday purposes" (Gelo and Mergenthaler, 2012). For instance, for a unconventional (metaphoric, literal) pair, "night sky **flurried** with the massive bombardment" → "night sky *doused* with the massive bombardment" (i.e., "flurried" ↔ "doused") the model fails. On the contrary, the model correctly predicts the following conventional (metaphoric, literal) pair - "sudden fame **kindled** her ego" → ". . . *increased* her ego" (i.e., "kindled" ↔ "increased").

6 Conclusion

To understand the figurative language inference capabilities of RTE models, we introduce datasets adapted from existing corpora focusing on similes, metaphors, and irony. By testing models trained on MNLI, we find that while the RoBERTa-large model is able to capture some aspects of figurative language, it fails when the interpretation requires word knowledge and pragmatic inferences. We hope this work will spark additional interest in the research community to incorporate and test for figurative language in their NLU systems.

7 Ethical Considerations

We leverage freely available open source datasets and software tools to create RTE datasets that involve similes, metaphors, and irony. We are granted the rights to further annotate and distribute the existing datasets as part of our RTE setup. This research is exempt from institutional review boards since we do not study human subjects and all social media data used is publicly available.

Abstract

Abstractive neural summarization models have seen great improvements in recent years, as shown by ROUGE scores of the generated summaries. But despite these improved metrics, there is limited understanding of the strategies different models employ, and how those strategies relate their understanding of language. To understand this better, we run several experiments to characterize how one popular abstractive model, the pointer-generator model of See et al. (2017), uses its explicit copy/generation switch to control its level of abstraction (generation) vs extraction (copying). On an extractive-biased dataset, the model utilizes syntactic boundaries to truncate sentences that are otherwise often copied verbatim. When we modify the copy/generation switch and force the model to generate, only simple paraphrasing abilities are revealed alongside factual inaccuracies and hallucinations. On an abstractive-biased dataset, the model copies infrequently but shows similarly limited abstractive abilities. In line with previous research, these results suggest that abstractive summarization models lack the semantic understanding necessary to generate paraphrases that are both abstractive and faithful to the source document.

1 Introduction

Recent years have seen great improvements in "abstractive" summarization models – models that not only concatenate text from the source document, but can additionally paraphrase to generate summary text. Once limited to sentence compression (Rush et al., 2015), abstractive models now generate multi-sentence summaries (See et al., 2017), even for relatively long documents (Cohan et al., 2018). However, extractive models and mixed models with significant extractive components continue to show strong performance, and the extent and manner in which abstraction is used by summarization models is not well understood.

Previous work has raised concerns about whether models are able to paraphrase in ways that lead to better summaries. Abstractive models often generate summaries that are either ungrammatical or unfaithful to the source document (Maynez et al., 2020; Durmus et al., 2020; Kryscinski et al., 2020) and are prone to repetition in their outputs (See et al., 2019; Holtzman et al., 2020). These issues raise questions about *how* neural summarizers generate novel text. Abstractive summarization is differentiated from extractive summarization by the model's ability to paraphrase, but paraphrasing ability is not directly measured by popular metrics, leading to a lack of understanding of the generative process. Some previous research has aimed to alleviate these issues in evaluation: Zhang et al. (2018a) propose evaluating summaries with human evaluations of informativeness and coherence, and Ganesan (2018) implements a metric to reward models that paraphrase via simple synonym substitutions according to WordNet. However, synonym substitution is just one form of paraphrasing, and truly abstractive models should be capable of more complex paraphrasing strategies.

To understand how abstraction manifests in neural summarization models, we study a model that has an explicit abstraction/extraction switch, the pointer-generator model of See et al. (2017). The training objective of this model causes it to choose the best summarization strategy (abstractive vs extractive) in different contexts, permitting us to determine the environments where abstractive summarization is an effective summarization strategy. First, we show how the switch varies across a full summary and is influenced by the decoder's copy and generation distributions. Next, we present a behavioral probe of the abstraction/extraction switch, to observe how the switch reacts to lexical, struc-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3362–3376
August 1–6, 2021. ©2021 Association for Computational Linguistics

tural, and distributional information as it decodes a summary. Finally, we modify the switch value, forcing more frequent paraphrase generation during decoding, revealing the limits of the model's paraphrasing capabilities. Ultimately, we find across both the CNN/DailyMail and XSum datasets that the model's abstractive capabilities are limited; the model understands how to identify and combine constituents from the source text in a grammatical fashion, but lacks the semantic understanding required to produce grammatical, faithful and meaningful paraphrases.

2 Model

2.1 The Pointer-Generator Model

We study the pointer-generator model released by See et al. (2017), which uses an explicit switch, p_{gen}, that blends abstractive and extractive summarization strategies. We briefly review the pointer-generator model here; for more details, see the original paper of See et al. (2017).

The final output distribution for a particular word in the summary $P(w)$ is a weighted sum of the generation distribution and the copy distribution, weighted by p_{gen} and $1 - p_{\text{gen}}$, respectively. This is described by Equation 9 in See et al. (2017), modified for clarity here:

$$P(w) = p_{\text{gen}} P_{\text{vocab}}(w) + (1 - p_{\text{gen}}) P_{\text{copy}}(w) \quad (1)$$

$P_{\text{vocab}}(w)$ is the generation distribution over the model's vocabulary, and $P_{\text{copy}}(w)$ is the copy distribution over the tokens in the source document. The p_{gen} switch explicitly weights the influence of the generation and copy mechanisms on $P(w)$. For each time step t, p_{gen} is a function of the context vector h_t^*, the decoder state s_t and the decoder input x_t,

$$p_{\text{gen}} = \sigma(\delta_{h_t^*}^T h_t^* + \delta_s^T s_t + \delta_x^T x_t + \beta_{\text{ptr}}) \quad (2)$$

where σ is the sigmoid function and $\delta_{h_t^*}$, δ_s, δ_x and β_{ptr} are learned parameters.

See et al. (2017) also use a coverage mechanism aimed at reducing repetition, defining the coverage vector c^t as

$$c^t = \sum_{t'=0}^{t-1} P_{\text{copy}(w_t)} \quad (3)$$

which is passed as another input to the attention mechanism.

2.2 Data

We analyze pointer-generator behavior when trained on an extractive-biased dataset, CNN/DailyMail, and on an abstractive-biased dataset, XSum. The CNN/DailyMail dataset is made up of multi-sentence summaries of news articles from CNN and Daily Mail. XSum (Narayan et al., 2018) is a summarization dataset that uses the first sentence of a news article as a summary of the article. The dataset treats the remainder of the article as the source document. As a result, the summaries are both shorter and more difficult to copy from the source document, compared to the CNN/DailyMail dataset.

2.3 Training

Our experiments on CNN/DailyMail use the trained model released by See et al. (2017), which includes the coverage mechanism described above. We decode summaries on the test set of at most 120 tokens using beam search with beam width 4, as in the original paper. For XSum, we trained our own model on the XSum training partition, using the code released by See et al. (2017).[1]

Like Narayan et al. (2018), we do not include the coverage mechanism for the XSum model. When coverage is used for the XSum model, ROUGE scores (Lin, 2004) slightly decrease, and the produced summaries contain more severe hallucinations. However, adding coverage does "fix" some degenerate summaries that produce the same sequence of tokens repeatedly – see Appendix B for an example.

For both datasets, in addition to the output summaries, we record the value of the p_{gen} switch for each emitted token, as well as the generation distribution and the copy distribution at each time step.

3 Experiments

In Section 3.1 we qualitatively analyze the evolution of the per-token p_{gen} and uncertainty in the extractive/abstractive components over the course of randomly selected summaries. Section 3.2 provides quantitative evidence of our observations across the full test sets, by modeling the lexical, structural, and distributional (P_{vocab} and P_{copy}) environments that drive the variability of the p_{gen} switch.

Finally, in Section 3.3 we manipulate p_{gen} of the CNN/DailyMail model to generate summaries

that are more abstractive than those of the base model, in order to disentangle any abstractive *behavior* from abstractive *capabilities*, finding that the model's abstractive capabilities are largely limited to lexical paraphrases, and that forcing the model to generate more novel text yields unfaithful summaries.

3.1 Token-level Analysis

3.1.1 Model

The p_{gen} switch explicitly tells us how much weight is assigned to the generation and copy distributions. See et al. (2017) make qualitative claims about the environments where p_{gen} is highest: "We find that p_{gen} is highest at times of uncertainty such as the beginning of sentences, the join between stitched-together fragments, and when producing periods that truncate a copied sentence." In this section, we evaluative these observations on randomly selected summaries generated with each model.

We quantify the notion of "uncertainty" from See et al. (2017) using information-theoretic entropy (Shannon, 1948) of the distribution that predicts the next word w_i of a generated summary:

$$H_\theta(w_i) = \mathbb{E}_{P_\theta}\left[-\log P_\theta(w_i)\right]. \tag{4}$$

where P_θ is the predictive distribution over the model vocabulary V_θ at a given time step. In our experiments, we use *normalized* entropy, which divides the equation above by $\log_2 |V_\theta|$, to limit the domain to $[0, 1]$ regardless of the vocabulary size. We calculate model-internal entropies H_{gen} and H_{copy} by setting P_θ equal to P_{vocab} and P_{copy}, respectively.

Given the entropy of the copy and generation distributions at each decoder time step, we investigate the relationship between p_{gen}, H_{gen}, and H_{copy} by calculating per-token *correlation contributions*. Intuitively, correlation contribution measures how much an individual token contributes to either positive or negative correlation between p_{gen} and the model entropies.

The Pearson correlation coefficient between two sequences $\mathbf{x} = [x_1, \ldots, x_n]$ and $\mathbf{y} = [y_1, \ldots, y_n]$ can be written as

$$r = \frac{\sum_{i=1}^{n}(x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{n}(x_i - \bar{x})^2 \sum_{i=1}^{n}(y_i - \bar{y})^2}} \tag{5}$$

We calculate the correlation contribution of the pair (x_i, y_i) at index i to be

$$\text{CC}_i = \frac{n(x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{n}(x_i - \bar{x})^2 \sum_{i=1}^{n}(y_i - \bar{y})^2}} \tag{6}$$

Note that the correlation between $\mathbf{x}$ and $\mathbf{y}$ is equal to the average of $\text{CC}_1, \text{CC}_2, \ldots, \text{CC}_n$, but unlike r, the correlation coefficient, each component CC_i is not bounded by $[-1, 1]$.

3.1.2 Results

Across the test splits, the Pearson correlation betwen p_{gen} and H_{gen} is -0.47 for CNN/DailyMail and -0.55 for XSum. The correlation between p_{gen} and H_{copy} is 0.12 for CNN/DailyMail and 0.54 for XSum. This suggests that the higher-certainty (lower H) distribution is weighted more heavily when combining the generation and copy distributions, since p_{gen} is high when H_{gen} is low, and low when H_{copy} is low.

Visualizing the correlation contributions across a sentence helps us understand how individual tokens are decoded as a function of uncertainty in the abstractive and extractive components of the model. We randomly sample articles from each dataset's test split, and visualize the correlation contributions for the generated summaries in Figure 1. Additional examples may be found in Appendix A.

CNN/DailyMail: The tokens that correlate high p_{gen} with low H_{gen} (high certainty in the abstractive component) are frequently punctuation, and periods in particular. This punctuation appears to be used to truncate sentences at a syntactic boundary, a behavior we quantify in Section 3.2. The correlation of high p_{gen} and high H_{copy} (low certainty in the extractive component) comes from tokens including "has", "managed", ".", and "sterling"; all tokens that appear multiple times in the source document. This suggests a possible role played by generation to tie break when the copy distribution has low certainty about which continuation to copy next.

XSum: The XSum model uses the copy mechanism very infrequently; p_{gen} is frequently large. When p_{gen} is small, we tend to observe uncertainty in the generative component and certainty in the copy component, according to entropy measures. In Figure 1, we see this happens when the proper noun "smiler", a rollercoaster name, is generated. It also happens at the beginning of a quotation, indicating that the model has learned that quotations should be copied from the source document, rather than generated.

Overall, we see a strong contrast in p_{gen} values between the two models. On the extractive-biased CNN/DailyMail dataset, the model learns to copy frequently, generating where necessary to truncate sentences. On the generative-biased XSum dataset, the model acts nearly like a simple seq2seq model, only infrequently using the copy mechanism for the sake of proper nouns and quotations.[2]

3.2 Probing p_{gen}

In the previous section, we made qualitative observations about the relationship between p_{gen} and model entropies, as well as the linguistic environments where p_{gen} is highest. In this section, we

---

[2] This can also be seen in the contrasting gaps between the seq2seq and pointer-generator ROGUE scores reported by See et al. (2017) and Narayan et al. (2018). The former sees a 9-point gap in ROUGE-1, while the latter reports a 1-point gap.

quantify these relationships by predicting p_{gen} with a linear model of lexical, syntactic and distributional factors.

3.2.1 Model Features

In this section, we describe the four feature sets we use to model p_{gen}. These include model-internal entropy measures from the See et al. (2017) summarizer, model-external entropy measures derived from pretrained language models, structural features derived from syntactic parses of summaries, and part-of-speech tags.

Summarization model entropies: We use H_{gen} and H_{copy} as features, hypothesizing, like See et al. (2017), that the uncertainty in the copy and generation distributions will have a significant effect on p_{gen}.

Language model entropies: We also use entropy from three types of language models with varying degrees of lexical and structural expressiveness: a trigram model,[3] a top-down incremental constituency parser (Roark, 2001; Roark et al., 2009), and a unidirectional recurrent neural language model (van Schijndel et al., 2019). These models allow us to directly measure how much p_{gen} may be influenced by lexical, syntactic, and distributional uncertainty in the generated summary independent of the summarization objective.

Structural Features: The summarization model may also condition its decision to copy or generate on the current syntactic environment. While pointer-generator models do not explicitly model syntax, they may exhibit some implicit syntactic knowledge, such as the ability to identify and copy whole constituents. As mentioned above, See et al. (2017) claim that p_{gen} is high at the "the join between stitched-together fragments." Structural features allow us to quantify this, seeing whether the model has learned to prefer copying or generation in particular syntactic environments.

We incorporate two structural measures into our model: the root distance of word w_i, denoted as $\text{D}_{\text{root}}(w_i)$ and the edge distance between word w_{i-1} and w_i, denoted as $\text{D}_{\text{edge}}(w_{i-1}, w_i)$. These measures are calculated on parse trees of generated summaries.[4] Root distance is the distance in the parse tree from the current word to the root node, and corresponds to the depth of the word in the parse tree. This measure will tell us if there is an association between depth in the tree and the decision to copy or generate. Edge distance is the number of intervening edges between the current and previous word in the summary. Edge distance will be smaller within a constituent than across two constituents. This measure allows us to test whether the decision to copy or generate is associated with the size of the syntactic boundary between words.

Part of Speech: In addition to structure, the summarization model may condition its decision to copy or generate on the syntactic category of the most recently generated word. For example, in our preliminary qualitative observations of the CNN/DailyMail model, we found that p_{gen} was higher when decoding punctuation, main verbs and conjunctions. To test the association between part-of-speech and p_{gen} formally, we include the part-of-speech label of the current word in our model.

3.2.2 CNN/DailyMail Results

We predicted p_{gen} using four single feature-set linear models, and a single linear model including all features. We conducted ANOVA tests on all combinations of nested models, and found that each set of features significantly improves the p_{gen} model (all $p < 0.00001$; see Table 1).

Entropies: The coefficients for the model-internal entropy measures H_{gen} and H_{copy} intuitively indicate that as uncertainty in the generation distribution increases, the model is less likely to generate, and as uncertainty in the copy distribution increases, the model is less likely to copy; these relationships were previously explored in Section 3.1.

The three language model entropy estimates are significantly associated with p_{gen}. However, the coefficients are all very small and this feature set individually does the poorest job of explaining p_{gen}'s variance of all the sets we analyzed. This could be due to the fact that, with the exception of the n-gram model, the language model entropy estimates come from different training data than the summarization model. Regardless, while language model entropies significantly improved p_{gen} prediction, the other feature sets showed a much stronger relationship with p_{gen}. Therefore we do not focus on language model entropies in subsequent sections.

Structural Features: Both structural features are significantly associated with p_{gen}. A model fit using only D_{edge} and D_{root} explains 20% of p_{gen}'s

Table 1: Table of slope coefficients β in the full linear model of p_{gen} in the CNN/DailyMail model. Reported below the name of the feature set is the adjusted R^2 of a model fit only to that feature set. The eight part of speech tags with the largest magnitude β are reported. All reported β are significant via t-test (all $p < 0.00001$).

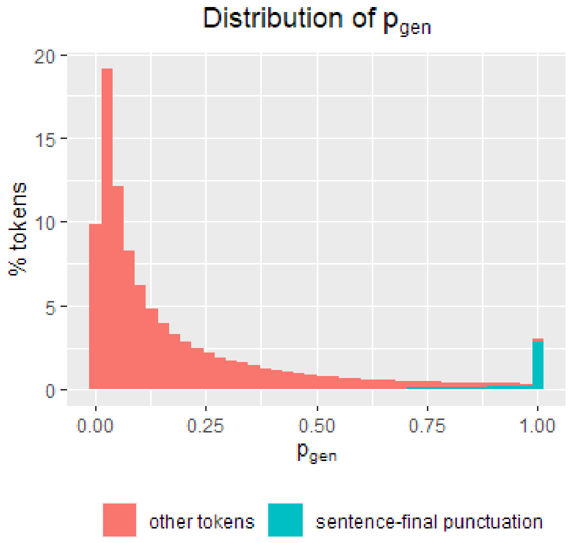

Figure 2: Distribution of p_{gen} across all tokens in the test split of the CNN/DailyMail corpus. Sentence-final punctuation makes up 5% of tokens in the dataset, which accounts for 22% of p_{gen}'s mass

variance ($R^2 = 0.204$). Edge-distance is positively associated with p_{gen}, meaning the larger the syntactic boundary between the previous and current word, the more likely the summarization model is to generate. This provides evidence that the model has some knowledge of syntactic boundaries, and uses the generation component as a means of joining together clauses, in line with the observations of See et al. (2017). We also find that distance to the root node of the parse is negatively associated with p_{gen}. This means that words which are higher in the parse tree are more likely to be generated than copied. Conversely, this means that generated components are unlikely to be associated with complex, deeply nested phrasing, suggesting **the generation component only produces simple shallow substitutions** rather than structurally complex paraphrases or even simple substitutions that modify structurally complex copied elements.

Part-of-Speech: The part of speech tags with the highest negative association with p_{gen} (i.e. those most likely to be copied) are $ (currency symbols), UH (interjection), # (pound symbol), followed by NNP (singular proper nouns). These results are perhaps unsurprising, as interjections and proper nouns are difficult to paraphrase and are often out-of-vocabulary in the generation component of the summarization model. $ and # serve as prefixes to numerical values which cannot be faithfully paraphrased and therefore should be copied directly from the source text. The tag for a cardinal number (CD) also has a relatively strong negative correlation with p_{gen} (β = -0.088).

The part-of-speech tags with the highest positive association with p_{gen} (i.e. those most likely to be generated) are "." (sentence-final punctuation), "," (comma), ":" (colon), and WRB (wh-adverbs, such as "where" or "when"). All of these categories can link two clauses or complete sentences, consistent with the "stitching" hypothesis of See et al. (2017).

The mean p_{gen} value of all tokens in the test dataset was 0.204, while the mean p_{gen} value for sentence-final tokens was 0.915. Further inspection of the p_{gen} distribution reveals a cluster of outliers at p_{gen} = 1.0. Figure 2 shows the distribution of p_{gen} values. We find that, of all tokens with $p_{\text{gen}} > 0.95$, 92.1% are sentence-final punctuation. Despite making up 5% of all tokens, periods account for 22.1% of the total mass of p_{gen} in the dataset. This suggests that sentence final punctuation is entirely controlled by the generation distribution. Additionally, we find that of all 5-grams in generated-summaries ending with sentence-final punctuation, 52% are also present in the article text, compared to 12% in the reference summaries. Despite the large p_{gen} values exhibited by sentence-final punctuation, the model only generates punctuation in novel contexts less than half of the time, suggesting that **even when the model heavily utilizes its generative component, it essentially generates a copy**

of the source text.

Our explanatory model of p_{gen} shows that model entropy, syntactic depth, syntactic boundary size, and part-of-speech are associated with p_{gen}. The strongest predictor of p_{gen} is the part-of-speech of the current word, with copying most strongly associated with numbers, number prefixes and proper nouns, and generation most strongly associated with punctuation. We find that sentence-final punctuation is handled almost entirely by the generative component of the model, despite the fact that sentence-final punctuation occurs in novel contexts less than half of the time.

3.2.3 XSum Results

Overall, we find that the variance of p_{gen} in the XSum model is well explained by model-internal entropy, and relatively poorly explained by linguistic features. We believe this is driven by the categorically different behaviors of each model.[5] While the CNN/DailyMail model only uses the generative component to join together copied constituents, the generative component dominates the XSum model's behavior. The mean p_{gen} value across all tokens in the XSum dataset was 0.828, compared to 0.204 in the CNN/DailyMail dataset. While the structural features $\text{D}_{\text{edge}}(w_{i-1}, w_i)$ and $\text{D}_{\text{root}}(w_i)$ explained 20.4% of the variance of p_{gen} in the CNN/DailyMail model, these features only explain 4.9% of the variance in the XSum model. Part of speech also does a poorer job of explaining the variance in XSum's p_{gen}. While part of speech explains 59.3% of the variance of p_{gen} in the CNN/DailyMail model, part of speech tags only explain 23.0% in the XSum model.

While the CNN/DailyMail model assigned an abnormally high p_{gen} value to punctuation, we do not observe this behavior in the XSum model. The CNN/DailyMail model appeared to make use of the ".", ":" and "," tokens to join together copied sentences, but none of these tokens are a significant predictor of p_{gen} in the XSum model. This suggests that the XSum model does not use the generation distribution to connect copied clauses.

While the XSum model appears not to use the copy and generation distributions in the same way as the CNN/DailyMail model, we still observe some clear and intuitive associations between part of speech tags and p_{gen}. In particular, the XSum model appears to use the copy distribution to handle words which are likely to be out-of-vocabulary for the generation distribution. For example, singular and plural proper nouns, interjections and foreign words (NNP, NNPS, UH, and FW respectively) are associated with low values of p_{gen} (copying), while all types of verbs are associated with large values of p_{gen} (generation).

We conclude that the CNN/DailyMail model primarily makes use of lexical and syntactic information such as clause boundaries and punctuation to modulate between copying and generation. By contrast, the XSum model primarily relies on the generation distribution, and backs off to the copy distribution at times of high generation uncertainty or high copy certainty, such as when copying a quote or a proper name.

3.3 Modifying p_{gen}

3.3.1 Model

Taking advantage of the smooth interpolation between the generation and copy distribution, we experiment with forcing the CNN/DailyMail model to be more abstractive. This, we expect, will allow us to differentiate between the abstractive *behavior* we observe in the model summaries and the abstractive *capabilities* that the model may have but which it only uses infrequently in practice. We do so by artificially modifying p_{gen} during decoding. If $p_{\text{min}} \in [0, 1]$ is a parameter that represents the minimum value of p_{gen} we allow, we then modify p_{gen} as follows:

$$p^*_{\text{gen}} = p_{\text{min}} + (1 - p_{\text{min}})p_{\text{gen}} \tag{7}$$

This may be viewed as a linear interpolation from the range $[0, 1]$ to $[p_{\text{min}}, 1]$. As p_{min} grows, the model is forced to rely more heavily on the generation distribution rather than the copy distribution.[6]

3.3.2 Results

We use the same randomly sampled articles used in Section 3.1.[7] Generated summaries for p_{min} values in $[0, 0.25, 0.50, 0.75, 1.0]$ can be found in Table 2.

Consistent with previous studies, we find that the model is effective at producing grammatical output. At small values of p_{gen}, the model mostly copies sentences verbatim, but shows the ability to cut a sentence short in a grammatical manner. For example, "raheem sterling has admitted he is not

---

[5] The full table of model coefficients can be found in Table 5 of Appendix C.

[6] We do not run this experiment on the XSum model because it already usually has a large p_{gen}.

[7] We see similar patterns in other randomly-sampled summaries, shared in Appendix B.

Article Text: raheem sterling has admitted he is not ready to sign a new contract at liverpool deal despite being offered a # 100,000-a-week deal to stay with the merseyside club . the 20-year-old wideman edged closer towards an anfield exit after revealing in an interview with the bbc on wednesday that he would have signed for a lot less a year ago . however , despite being one of liverpool 's star men , sterling has struggled to repeat the impressive form he showed for the reds last season . the england international has managed just six goals this season - one less than stoke frontman jon walters - while his conversion rate and minutes per goal ratio have worsened as the graphic below shows . raheem sterling has managed just six goals this season - one less than stoke forward jon walters -lrb- left -rrb- .

$\mathbf{p}_{\min} = \mathbf{0.75}$: raheem sterling has admitted he is not ready to sign a new deal . the 20-year-old has scored just six premier league goals this season . the 20-year-old has scored just three goals this season .
$\mathbf{p}_{\min} = \mathbf{1}$: man utd face manchester city in the premier league on saturday . the striker has scored just four premier league goals this season . the 19-year-old has scored just three goals this season . click here for all the latest premier league news .

Table 2: Summaries generated for the same randomly selected article with varying values of p_{min}. Differences from the base model summary are highlighted in blue, while non-faithful text is highlighted in red.

ready to sign a new contract at liverpool deal..." is shortened to "raheem sterling has admitted he is not ready to sign a new contract."

At greater values of p_{gen}, the model continues sentences in a consistent fashion despite substituting nouns or verbs at the beginning or middle of the sentences. For example, "sterling has managed just six goals..." at $p_{\text{min}} = 0$ becomes "the 20-year-old has scored just six premier league goals" at $p_{\text{min}} = .75$. However, we do not observe significant paraphrasing beyond these simple substitutions, and at high values of p_{min}, where the model is forced to rely heavily on the generation distribution, we begin to observe hallucinations where the model inserts inaccurate information about the player's age and the number of goals scored. When $p_{\text{min}} = 1$, the model generates a completely hallucinated sentence, "man utd face manchester city in the premier league on saturday" and a non-informative advertisement "click here for all the latest premier league news."

4 Discussion

Understanding the limitations preventing abstractive summarization models from paraphrasing effectively is our ultimate aim, but answering that question requires an understanding of current models' abstraction capabilities. In this paper, we analyze the abstractions of which the pointer-generator model (See et al., 2017) is capable.

When trained on CNN/DailyMail, we find that sentence truncation is the most common form of paraphrasing. Punctuation tokens are associated with high generation rates and low entropy in the generation distribution. Additionally, high p_{gen} often results in generating the token that comes next in a phrase already being copied verbatim, suggesting that high p_{gen} merely gives the model the *option* to generate novel text, but that the model rarely makes use of it. Artificially increasing p_{gen} does not significantly change this behavior, introducing increased rates of synonym substitution as well as increased rates of non-faithful hallucination.

When trained on XSum, the model makes much less use of the copy mechanism, largely generating novel text with a few exceptions, including the copying of proper nouns and parts of quotations. The model generally produces topical summaries, but ones that aren't necessarily grammatical or faithful to the original article. For example, the randomly selected summary used in Figure 1 repeats itself and wanders, "... on the smiler rollercoaster on the smiler rollercoaster in the south west 200 years ago as 'phenomenal'". This comes after a hallucination, "firefighters are continuing to search for a man" even though the article describes the rescue from the rollercoaster crash in the past tense. We hypothesize that the phrase "firefighters are continuing to search" is a relatively common phrase in news articles that the model learned from the training data. Such frequency biases likely contribute to the faithfulness issues in abstractive summarizers reported in previous literature.

Our results give context to previous observations that summarization model unfaithfulness increases with abstraction (Maynez et al., 2020; Durmus et al., 2020; Kryscinski et al., 2020) and that abstractive models are prone to output repetition (See et al., 2019; Holtzman et al., 2020). To faithfully paraphrase, a model must understand both the syntax and the semantics of the original text. The models we studied were able to recognize syntactic boundaries, proper nouns, and noun phrases that could be substituted with synonyms. However, the models didn't appear to comprehend the meaning of the text well enough to generate faithful complex paraphrases. This is unacceptable in high-risk domains such as healthcare; Zhang et al. (2018b) train a model to summarize radiology findings, but only 67% of their summaries are judged at least as good as human summaries, in a domain where errors can have a major impact on human lives.

In our work, the explicit switch between abstractive and extractive modes enabled us to directly observe the conditions under which abstractive summarization was chosen as a strategy, and to force an abstractive summarization strategy to disentangle paraphrasing behavior from capabilities. We found that the See et al. (2017) model trained on CNN/DailyMail did learn simple forms of paraphrasing, despite the extractive bias of the dataset. We conclude that pointer-generator models are *capable* of simple paraphrasing regardless of training data, even though they *behave* in ways that rely on the frequency biases of the training dataset. However, they also appear *incapable* of producing significant paraphrases that are grammatical, non-repetitive, and faithful to the source document. This suggests that using an abstractive-biased dataset alone is not enough for a model to learn robust and faithful paraphrasing strategies. Rather, when trained on XSum, the pointer-generator model seems to simply learn that it should not copy from the source text. Future work should investigate how either datasets or models can improve the training signal that allows the model to understand the underlying semantics of the source document.

Related to our work, Xu et al. (2020) studied the summarization strategies of state-of-the-art transformer summarization models. Since their models did not contain an explicit copy/generation switch, they used n-gram overlap between source documents and summaries as a proxy to measure a summary's "extractiveness." They found a similar result to ours, that high n-gram overlap ("copying") corresponded to low entropy in the decoder's output distribution when the model was trained on CNN/DailyMail.[8] Their findings suggest that our results likely generalize to a much broader class of summarization models than the pointer-generator models studied here.

Finally, Liu and Liu (2010) found that ROUGE metrics poorly correlate with human evaluations, leading to recent models being evaluated with human judgements, but these evaluations often disagree on what they are measuring, whether it is faithfulness, informativity, or the unqualified "quality" of a summary (Zhang et al., 2018a, 2020; Dou et al., 2020). Developing best practices on how abstractive summarizers should be evaluated for their paraphrasing ability is another problem we leave for future work.

5 Conclusion

In this paper, we presented three experiments that evaluate the abstraction capabilities of the pointer-generator neural summarization model. Our results conclude that on extractive training data, the model uses only simple paraphrasing strategies that truncate sentences at syntactic boundaries, allowing the model to stay grammatically accurate as well as faithful to the source document. We explore two ways to make the model use abstractive summarization strategies: modifying the model so that it relies more heavily on its abstractive component, and training a new model on an abstractive-biased dataset. In both cases, the model shows simple paraphrasing capabilities but frequently generates unfaithful paraphrases. These results highlight current limitations of abstractive summarization, where in lieu of semantic understanding, models must rely on extractive heuristics in order to stay faithful.

Acknowledgements

We thank our reviewers for their helpful suggestions. We also thank Esin Durmus, Ryan Benmalek, and Claire Cardie for helpful discussions about abstractive summarization. Finally, we thank Shashi Narayan and Shay Cohen for helping us reproduce their pointer-generator model trained on XSum.

---

[8] Their findings are more difficult to interpret when trained on XSum, partially due to the lack of an explicit extractive/abstractive summarization switch in their models.

Abstract

We aim to renew interest in a particular multi-document summarization (MDS) task which we call AgreeSum: agreement-oriented multi-document summarization. Given a cluster of articles, the goal is to provide abstractive summaries that represent information common and faithful to all input articles. Given the lack of existing datasets, we create a dataset for AgreeSum, and provide annotations on article-summary entailment relations for a subset of the clusters in the dataset. We aim to create strong baselines for the task by applying the top-performing pretrained single-document summarization model PEGASUS onto AgreeSum, leveraging both annotated clusters by supervised losses, and unannotated clusters by T5-based entailment-related and language-related losses. Compared to other baselines, both automatic evaluation and human evaluation show better article-summary and cluster-summary entailment in generated summaries. On a separate note, we hope that our article-summary entailment annotations contribute to the community's effort in improving abstractive summarization faithfulness.

1 Introduction

Recent works have made great progress in single-document summarization (SDS) thanks to the encoder-decoder framework and pretraining procedures (Cho et al., 2014; Rush et al., 2015; Narayan et al., 2018; Zhang et al., 2020a). There is a growing interest in multi-document summarization (MDS; Zopf, 2018; Fabbri et al., 2019; Liu and Lapata, 2019; Chu and Liu, 2019; Wang et al., 2020b, et seq.), with applications in search engines, news clustering, timeline generation, and other areas. Past MDS research has primarily focused on summarizing articles such that the summary covers an event "comprehensively" while "avoiding redundancy" (Fabbri et al., 2019). We can say that most existing MDS tasks summarize the "union" of the articles.

In this paper, we discuss *agreement-oriented multi-document summarization* (AgreeSum), in which we aim to *abstractively* summarize the "intersection" of the articles. More specifically, the input to the task is a cluster of articles, and the expected output is a summary that represents information common and faithful to all input articles in the cluster (Section 3). A few works (discussed in Section 2) have investigated the problem, without using modern neural-network-based methods. The motivation for reviving interest in AgreeSum is twofold. First, given that certain microscopic details are not likely present in all articles in a given cluster, they would be filtered out through AgreeSum. If the source articles reflect different points of view, AgreeSum provides a way of capturing the common ground.

The second motivation for AgreeSum lies in the pursuit of summarization faithfulness. AgreeSum is timely, given that recent works have shown difficulty of producing faithful abstractive summaries (Falke et al., 2019; Maynez et al., 2020; Kryscinski et al., 2020; Durmus et al., 2020; Zhou et al., 2021), though in the SDS setting. AgreeSum could allow practitioners of abstractive summarization systems to carefully study topics related to faithfulness and hallucination.

Given the scarcity of readily available data, we create a dataset[1] based on English Wikipedia current events portal (WCEP)[2]. WCEP contains neutral human-written news summaries with links

August 1–6, 2021.

to news articles (with usually one link per summary). We first extract human-written summaries on WCEP, the linked articles, and semantically similar articles to the linked articles, in order to obtain article clusters associated with summaries. We then annotate the entailment relationship for a subset of the cluster-summary pairs (i.e., whether or not a given article from the cluster semantically entails the summary). From there, we build cluster-summary pairs for AgreeSum (Section 3.2).

We build upon previous SDS research, using the top-performing pretrained PEGASUS model (Zhang et al., 2020a) as the starting point for our models. Using our dataset, we first examine a few baseline models and show that several pretraining-based summarization models fail at generating summaries that satisfy AgreeSum's requirements. We also propose an approach that integrates both supervised (using the annotated portion of the dataset) and unsupervised losses (namely, an entailment loss and a language loss to be discussed later, using both the annotated portion and the unannotated portion) while leveraging PEGASUS. We show the effectiveness of a simple policy gradient-based algorithm (Sutton et al., 2000) in which the rewards are based on a T5-based article-summary entailment model (Raffel et al., 2020). To summarize the contributions:

- We introduce the AgreeSum task and the WCEP-based dataset (§3.2).

- A subset of *article*-summary pairs are annotated with entailment information (§4). On a separate note, the article-summary-level recognizing textual entailment (RTE)[3] task could stand as a challenging task on its own. The annotations could be of interest to the research in improving abstract summarization faithfulness, in the context of not only AgreeSum but also general single-document summarization tasks.

- We develop simple ways of applying PEGASUS to AgreeSum. We provide a few baselines as well as a model that uses unsupervised entailment-related and language-related losses to complement the supervised finetuning of PEGASUS (§5). Both automatic and human evaluations are performed (§6). In particular, we show that the T5-based entailment model can be integrated into summarization models to produce summaries that are entailed in source articles.

2 Related Work

Traditional MDS. DUC (Paul and James, 2004; Dang, 2005) and TAC (Owczarzak and Dang, 2011) MDS data are among the first high-quality relevant datasets. These datasets are human-curated, but tiny in terms of the number of examples. Recent works have explored creative methods for obtaining low-cost MDS datasets. Liu et al. (2018) use Wikipedia articles as summaries and the cited articles as inputs. Antognini and Faltings (2020) use Wikipedia in a similar way, in the video games domain. Fabbri et al. (2019) rely on the website Newser with lengthy human-aggregated extractive summaries. Gholipour Ghalandari et al. (2020), also based on WCEP, is especially relevant.

However, our dataset is different in the following ways. First, all of our articles in the same cluster are about the same event. Next, a large part of our dataset is annotated with article-summary entailment information (i.e., in each of the clusters, for each article in the cluster, whether the article entails the summary; see Section 3). Further, among the annotated article-summary pairs, about half of the articles entail the summary, and half of the articles do not entail the summary. This property makes a realistic and difficult setting for AgreeSum tasks.

In terms of recent MDS neural methods, Chu and Liu (2019) summarize opinions using an autoencoder, in which case the input is much shorter than a typical article. Liu et al. (2019a) improve the model by encoding articles and summaries in the same space. Other novel approaches include using sentence compression in the seq2seq framework (Baziotis et al., 2019), jointly learning sentence fusion and paraphrasing (Nayeem et al., 2018), using graph neural networks to help extraction (Wang et al., 2020b), using spectral methods (Wang et al., 2020c), using transfer learning based on a novel pretraining method called gap-sentence prediction (Zhang et al., 2020a) on a news-specific corpus, among a few others (Li et al., 2020; Gu et al., 2020; Mao et al., 2020).

For MDS tasks that summarize the intersection of articles, a few past works have discussed the helpfulness of models that identify common infor-

---

[3] The RTE datasets (Dagan et al., 2005; Haim et al., 2006; Giampiccolo et al., 2007) correspond to the following two-class classification task: given a premise and a hypothesis, a model would decide if the premise entails the hypothesis.

mation "centroids" among multiple related documents, so as to allow internet users to more efficiently understand events (Radev et al., 2000; Barzilay and McKeown, 2005). The attempted non-neural models rely heavily on topic/theme detection and tracking, and are more extractive than abstractive (Radev et al., 2004). The AgreeSum idea has not been fully explored by researchers since much stronger text generation technologies became available. It is timely to revisit the problem also because recent stronger neural abstractive summarization models are prone to hallucination, as are neural text generation in general (Wiseman et al., 2017; Tian et al., 2019; Wang and Sennrich, 2020; Pang and He, 2020).

Summarization hallucination and evaluation. Non-hallucination is a necessary but not sufficient condition for performing well in AgreeSum: the summary not only needs to be entailed in the union of the articles, but also must be entailed in each of the articles. Unfortunately, recent works have shown the difficulty of identifying and mitigating hallucination (Maynez et al., 2020).

Evaluation-wise, researchers have found that metrics like ROUGE (Lin, 2004) and BERTScore (Zhang et al., 2020b) are only weakly correlated with factuality. Durmus et al. (2020) and Wang et al. (2020a) have therefore proposed using question-answering systems for evaluating summarizers. Recently, Zhou et al. (2021) have made progress in creating token-level hallucination detectors which rely on negative (i.e., hallucination) data augmentation to train.

In terms of improving faithfulness and factuality, researchers did not find natural language inference (NLI)[4] models trained on standard NLI datasets to be robust enough for summarization-related downstream tasks (Falke et al., 2019). Contemporaneously, entity chains are used to explicitly ground the generations so that they become more faithful (Narayan et al., 2021). More broadly, there have been other recent works striving to develop techniques for high-precision generation (Malmi et al., 2019; Tian et al., 2019; Pang and He, 2020; Parikh et al., 2020; Dušek and Kasner, 2020).

3 AgreeSum Task and Datasets

3.1 Task

Short description of AgreeSum. The input is a cluster of around four articles (refer to Section 3.2 for more details) that describe the same event. However, the articles may have different levels of details and/or different levels of neutrality; e.g., one article in a cluster may be an opinion, while other articles may be neutral news. The expected output is an abstractive summary that represents information common and faithful to all input articles in the cluster. Moreover, the summary needs to be informative.

3.2 English AgreeSum Dataset Based on WCEP

Step 1. Recall that WCEP contains neutral human-written news summaries, each of which is linked to a news article. The first step is to obtain the summaries and 8 on-topic articles[5] for each summary based on WCEP. Specifically, we collect 5564 human-written summaries $\{\boldsymbol{y}_i\}_{i=1}^{5564}$ from WCEP. For each summary, we have one linked article to each summary on WCEP; we call the set of such articles $\{\boldsymbol{x}_i^{(0)}\}_{i=1}^{5564}$. Given that we want to generate abstractive summaries, and to make the dataset challenging, the set of articles $\{\boldsymbol{x}_i^{(0)}\}_{i=1}^{5564}$ will *not* be used in the final dataset, to prevent excessive textual overlaps between the input articles and the target summaries. For each i, we obtain 8 other news articles $\boldsymbol{x}_i^{(1)}, \boldsymbol{x}_i^{(2)}, \ldots, \boldsymbol{x}_i^{(8)}$ that are semantically similar to $\boldsymbol{x}_i^{(0)}$, based on a proprietary BERT-based clustering algorithm.

Step 2. The second step is to annotate entailment relations. Annotators are asked to judge if each of the articles in a cluster entails the summary (i.e., "does the article contain all the information presented in the summary?"). 1025 *cluster*-summary pairs are annotated. We designate $\sim$10% of the annotated clusters to be in the dev set. This step is discussed further in Section 4.

Step 3. To make AgreeSum moderately but not overly difficult, we set the maximum number of articles per cluster to be four, and the next step is to transform the dataset to have four articles per cluster. To take advantage of entailment annotations, we duplicate each annotated cluster in the training

---

[4] The NLI datasets, beginning with SNLI (Bowman et al., 2015), correspond to a three-class (entailment, neutral, contradiction) entailment classification task.

[5] A small amount of clusters (233, or $\sim$4%) have fewer than 8 articles to ensure relevance of all articles in a cluster.

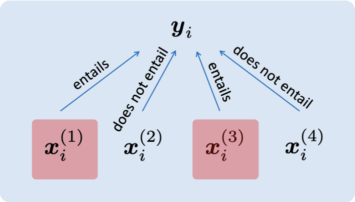

Figure 1: An annotated example (i.e., input-output pair where the input is a cluster of articles and the output is a summary) in the training set. In the figure, two articles in the input cluster entail the summary while the other two do not. An example is either annotated (meaning all article-summary pairs in the cluster-summary pair are annotated) or unannotated (meaning none of the article-summary pairs are annotated). Note that in the dev set, all articles entail the summary given that we would like to compare between generated summaries and the gold summaries.

set $\boldsymbol{c}_i = \{\boldsymbol{x}_i^{(1)}, \boldsymbol{x}_i^{(2)}, \ldots, \boldsymbol{x}_i^{(8)}\}$ ten times so that there is roughly an equal number of annotated and unannotated clusters.[6] Next, for each cluster, we randomly choose four articles to keep in the cluster, and discard the rest.

Dev and test sets. For the development set, we aim to designate the WCEP summaries as gold summaries. Therefore, for each cluster, we only keep the articles that entail the corresponding summary based on human annotation. In the case that a cluster has > 4 articles that entail the summary, we split the cluster into two, such that each newly formed cluster has ≥ 2 articles that entail the summary.

We use WCEP entries corresponding to dates before August 2019 for the training and development sets; for the test set, we sample 150 clusters of articles containing WCEP linked articles published between August 2019 to August 2020 to ensure that the test set does not have overlapping articles or overlapping publication times with the training and development sets.

For each sampled test cluster, we sample four articles from the cluster. Unlike the development set, these four articles are not annotated and are not guaranteed to entail any particular common summary. As a result, the provided WCEP summaries in the test set are **not** gold-standard summaries.

The test set is expected to be challenging due to construction methods, as well as the shift in topics of recent events (e.g., the COVID-19 pandemic). The test set WCEP summaries are not gold-standard summaries, but are nevertheless provided given the potential use to approximate generation informedness (Section 6).

We thus obtain the dataset split shown in Table 1.

	# of cluster-summary pairs			# of article-summary pairs		
	train	dev	test	train	dev	test
all	18208	132	150	70137	423	600
annotated	9130	132	0	33841	423	0
(at least 1) entailed	7610	132	0	17951	423	0
unannotated	9078	0	150	36296	0	600

Table 1: Dataset information. A cluster contains $\leq$ 4 articles. The "(at least 1) entailed" row refers to the number of *annotated* clusters containing at least one article that entails the summary (in the cluster-summary case), or the number of articles that entail the summary *among the annotated pairs* (in the article-summary case).

4 Article-Summary Entailment

4.1 The Entailment Dataset

Workers have annotated the entailment relation of 1025 cluster-summary pairs (a subset of the cluster-summary pairs obtained in Step 1 in Section 3.2), which correspond to 7750 article-summary pairs. For each article-summary pair, we ask *five* professionally trained annotators, randomly chosen from a pool of ~800 raters, whether the summary is semantically entailed in the article; we then take the majority answer. See the appendix for more details.

Our AgreeSum models leverage this entailment dataset, as discussed in Section 5. In addition, this dataset could be seen as a challenging RTE-style (or two-class NLI-style) task.

4.2 Model Performance

To explore how models perform on the article-summary entailment dataset, and to see whether we can have a good entailment-classification model to guide the learning of our summarizer that encourages faithfulness to all input articles in the same cluster, we treat the dataset as a two-class NLI task where the label is either "entailed" or "not entailed," and examine the classification accuracy. Specifically, we evaluated the following three models. RoBERTa-large (Liu et al., 2019b) fine-tuned on MNLI fails on our entailment data[7], likely in

---

[6] A side effect is that such choices could allow for more supervised cross-entropy updates.

[7] In this case, the majority of the predictions are "not entailed."

part because the premises in MNLI are sentences but are articles in our article-summary entailment task. It is also worth noting that unlike T5 (Raffel et al., 2020), RoBERTa-large is not pretrained on a multi-task mixture of many tasks, with each task converted into the text-to-text format.

We also attempt a model that integrates the PEGASUS-encoder which is pretrained in the news domain using the HugeNews corpus which contains around 1.5 billion articles. Given that pretrained PEGASUS does not include `[CLS]` tokens and it is very expensive to re-pretrain, we use a CNN-based classifier (Kim, 2014) whose input is the PEGASUS-encoder-outputs; more specifically, the convolutional layers pool over the sequence of encoder outputs. Based on the architecture by Kim (2014), our CNNs use filter n-gram sizes of 2, 3, 4, and 5, with 256 filters each. The resulting classifier achieves $\sim$68% accuracy on our entailment dataset.[8]

In comparison, T5 (Raffel et al., 2020) shows encouraging results. The multi-task-trained T5-large fine-tuned on our training set achieves 81.3% accuracy (79.1% for vanilla T5-large). T5-small fine-tuned on our training set achieves 79.5% accuracy (76.4% for vanilla T5-small).

We aim to see if using an entailment signal from a moderately good article-summary entailment classification model would help produce summaries that satisfy the AgreeSum criteria.

5 AgreeSum Baselines and Approaches

5.1 Notations and Baselines

We first provide some notations so as to allow easier discussion. Suppose the clusters of articles in the training set are denoted by $\{\boldsymbol{c}_i\}_{i \in N}$. Each cluster contains at most four articles: $\boldsymbol{c}_i = \{\boldsymbol{x}_i^{(j)}\}_{j \leq 4}$, with the summary $\boldsymbol{y}_i$.

For cluster i, let $\boldsymbol{e}_i$ be the set of indices that correspond to articles that entail the summary. For example, in Figure 1 which corresponds to the ith cluster, we have $\boldsymbol{e}_i = \{1, 3\}$. Let E and D denote the encoder and the decoder of PEGASUS, respectively.

The following baselines are based on PEGASUS pretrained using gap-sentence prediction on HugeNews with 1.5 billion articles (3.8 terabytes). Note that despite being an SDS model, PEGASUS also achieves near-SoTA results on the Multi-News MDS dataset (Fabbri et al., 2019), so it is a competitive baseline for MDS as well.

B1: finetuning on $(\boldsymbol{x}_i^{(0)}, \boldsymbol{y}_i)$ pairs. Recall that for each summary $\boldsymbol{y}_i$, we drop the WCEP-linked article $\boldsymbol{x}_i^{(0)}$ to prevent excessive textual overlaps between the input cluster and the output summary. In this baseline, however, we use $\boldsymbol{y}_i$'s in the training set and its corresponding $\boldsymbol{x}_i^{(0)}$'s (5452 pairs) for supervised finetuning.

Why can we use $\boldsymbol{x}_i^{(0)}$ as gold targets? On WCEP, it is reasonable to assume that the summaries are directly connected to the linked articles, and therefore, $\boldsymbol{x}_i^{(0)}$ entails $\boldsymbol{y}_i$. Moreover, these summaries also inform the model of the style of the WCEP summaries. However, the downside is that the model could potentially prioritize extractions from the articles over entailment (i.e., the property that the generated summary is entailed in each article), as we would see in Section 6.

B2: concatenating truncated inputs. We finetune PEGASUS on the following: for each cluster $\boldsymbol{c}_i$, we truncate $\{\boldsymbol{x}_i^{(j)}\}_j$ for each $j \in \boldsymbol{e}_i$ and concatenate them such that the concatenated sequence has length ≤ 1024, given hardware constraints. We use a special symbol to delineate article boundaries.

B3: B1+B2. We first train using B1 and then finetune using B2, which may improve over B1 or B2 alone.

B4: merging encodings and decode. Inspired by Chu and Liu (2019), we first encode $\boldsymbol{x}_i^{(j)}$ separately for each $j \in \boldsymbol{e}_i$, and pass the average of the encodings to the decoder (i.e., $\frac{1}{|\boldsymbol{e}_i|}\sum_{j \in \boldsymbol{e}_i} E(\boldsymbol{x}_i^{(j)})$). Next, we do supervised learning based on the WCEP summaries.

B5: best lead-1 sentence by entailment score. We first extract the first sentence of each article in the cluster. Next, we rerank the sentences using an entailment score, which is the mean of the binary entailment labels, predicted by fine-tuned T5-large (Section 4), between each article in the cluster and the given sentence. We choose the summary corresponding to the highest score, breaking ties randomly.

---

[8] Doing intermediate training on MNLI (Pruksachatkun et al., 2020) and then training on our entailment dataset, unfortunately, does not strengthen performance.

5.2 AgreeSum Model (ASM): Leveraging Unannotated Data

We introduce another baseline model called ASM. The distinguishing feature is that to target cluster-summary entailment (meaning the summary is entailed in each article in the cluster), we attempt to use the T5-entailment-classification results (discussed in Section 4) as a training signal.

Supervised pretraining and training. Given pretrained PEGASUS, we first fine-tune according to B1. Next, for each cluster, we concatenate all elements of $\boldsymbol{c}_i$ similar to B2, and mask out the articles that do not entail $\boldsymbol{y}_i$ by the padding symbol; effectively, we use $\{\boldsymbol{x}_i^{(j)}\}_{j \in \boldsymbol{e}_i}$ as input to the transformer. Then, we use the standard cross-entropy loss L_{ce} to train the summarizer. However, only a small number of clusters are annotated, providing a very limited supervised signal.

Unsupervised entailment loss. We complement L_{ce} with the entailment loss L_e to learn entailment behavior. We fine-tune T5-small on our training dataset to predict entailment, and use this as our entailment classifier F_e. In practice, we obtain T5-outputs using remote procedure calls (RPCs).

F_e takes in an article $\boldsymbol{x}$ and a summary $\boldsymbol{y}$ as inputs, and outputs 1 if $\boldsymbol{x}$ entails $\boldsymbol{y}$ and -1 otherwise. The loss L_e is based on policy gradients (Williams, 1992; Sutton et al., 2000); we aim to maximize a sequence-level metric of a summary decoded from the model during training: $\mathbb{E}_{\tilde{\boldsymbol{y}} \sim p_\phi} \sum_{k=1}^{4} F_e(\boldsymbol{x}_i^{(k)}, \tilde{\boldsymbol{y}})$ where ϕ stands for the parameters of the encoder E and the decoder D. We thus have the following gradient:

$$\nabla_\theta L_e(\phi) = -\mathbb{E}_{\tilde{\boldsymbol{y}} \sim p_\phi} \nabla_\phi \log p_\phi(\tilde{\boldsymbol{y}}) \hat{Q}(\tilde{\boldsymbol{y}}),$$

where

$$\hat{Q}(\tilde{\boldsymbol{y}}) = \sum_{k=1}^{4} F_e(\boldsymbol{x}_i^{(k)}, \tilde{\boldsymbol{y}})$$

is the sequence-level return. Intuitively, during training, we sample a summary $\tilde{\boldsymbol{y}}$ from our model, and run it through the T5 entailment classifier (which is separate from our summarizer) to obtain $\hat{Q}(\tilde{\boldsymbol{y}})$. We then weight the MLE gradient (taking $\tilde{\boldsymbol{y}}$ as the target) by $\hat{Q}(\tilde{\boldsymbol{y}})$. L_e thus aims to guide our summarizer to generate summaries that entail in all or most of the articles.

Unsupervised language loss. Only using the entailment loss L_e may result in degenerations. One way to encourage the model to generate fluent summaries and summaries that look like WCEP summaries is by using GAN-style (Goodfellow et al., 2014) objectives, which have achieved good performance in some conditional generation tasks like textual style transfer and machine translation (Shen et al., 2017; Wu et al., 2018; Pang and Gimpel, 2019). We thus use F_l, a "language classifier" (i.e., discriminator) that distinguishes model generations from real dataset summaries (no matter annotated or not), to force our summarizer to generate sentences that look like the human-written summaries. F_l is based on the CNN settings by Kim (2014) identical to the setting introduced in Section 4, while the inputs to CNNs are sentence representations obtained using PEGASUS.

Specifically, suppose there are k examples in a minibatch, then

$$L_l = -\frac{1}{k} \sum_{i=1}^{k} \left[\log F_l(\boldsymbol{h}_i) + \log(1 - F_l(\tilde{\boldsymbol{h}}_i)) \right],$$

where $\boldsymbol{h}_i$ is the decoder hidden states of WCEP summaries, and $\tilde{\boldsymbol{h}}_i$ is the decoder hidden states of model generations, by professor forcing (Lamb et al., 2016). In the professor forcing algorithm, the input to F_l is the hidden states instead of hard tokens so as to address the mismatch between training-time sequence prefix and test-time sequence prefix.

Summary. We alternate updates among the following:

(1) supervised training: updating E, D to minimize the loss L_{ce};

(2) unsupervised training: updating E, D to minimize the loss $L_e - \lambda L_l$;

(3) language classifier training: updating F_l to minimize the loss L_l.

5.3 Implementation

We implement our model as a fork of the open-source 568M-parameter PEGASUS model (Zhang et al., 2020a).[9] We initialize PEGASUS from the "mixed & stochastic" checkpoint, which was pretrained for 1.5M steps.

All baseline models are fine-tuned with a learning rate of 1e-4. All of the ASM models use 5e-5

Table 2: Results (on test set if not specified). ¶: the first number corresponds to T5-large-evaluated results, and the second number corresponds to human-evaluated results. For each row, human raters annotated the entire test set; each article-generation pair is annotated by three raters, and we take the majority answer. The best result in each column is in blue; the worst in red. n-gram overlap: the proportion of generation n-grams that are also in the source. ‡: the test set WCEP summaries should not be treated as references, given that there is no guarantee that the WCEP summary is entailed in each of the articles; the test set WCEP summaries are provided as an approximate measure of informedness. Note: B4 results in extensive hallucinations and very low ROUGE ($\sim$10), and the ablation study of ASM without L_l produces heavy degenerations, so they are omitted.

(tuned in {1e-5, 5e-5, 1e-4, 2e-4}). All models use beam search for decoding (beam size 8, beam alpha 0.8). Given hardware constraints, all models use a max input length of 1024. The max output decoding length is set to be 128. In addition, we tune $\lambda \in \{0.05, 0.1, 0.3, 0.5, 1, 2\}$ and choose $\lambda = 0.1$ for all reported experiments that include the L_l. We do not change any other default hyperparameter settings adopted from PEGASUS. Please refer to the appendix for more details.

6 Results

The following two models are not included in the table given their poor performance. (1) The ablation study of ASM without language loss does not produce meaningful outputs. In this case, given that the T5 entailment classifier does not encourage language quality, the summaries in fact degenerate heavily. (2) Model B4 (merging encodings and decode) is omitted from the table given very poor ROUGE performance ($\sim$10) and extensive hallucination. Our conjecture is that the mean of the encodings of articles does not correspond to a meaningful encoding in the case of PEGASUS.

6.1 Agreement and Hallucination

First, we claim that ASM achieves better agreement. There are two types of agreement: *article-summary* agreement which is the proportion of summaries entailed in the articles, and *cluster-summary* agreement which is the proportion of clusters in which *all* articles entail the summary. Table 2 reports both the T5-automatic evaluation and the human evaluation results on agreement.

(Preliminary) automatic metrics. Given an article-summary pair, we use T5-large fine-tuned on our entailment dataset (Section 4) to predict whether the summary is entailed in the article. For article-summary agreement, we compute the percentage of "entailed" classifications. For cluster-summary agreement, we compute the percentage of clusters where all article-summary pairs lead to "entailed" classifications. We see that the T5-evaluation results for ASM models perform better than the respective results for baseline models.

Human evaluation. For each row of Table 2, human raters annotated the entire test set (150 clusters, which corresponds to 600 article-generation pairs), on whether the generated summaries are entailed in the article. Workers were asked:

> *Does the article contain all the information presented in the summary?*

The full prompt is available in the appendix. One design choice is that we merge all article-summary pairs for each cluster together into one task/HIT. Therefore, each task/HIT corresponds to four article-summary annotations. To reduce the inherent variance in human evaluation, each article-generation pair is annotated by three different raters, and we take the majority answer. Please see the appendix for more details.

For article-summary agreement, we see that the human evaluation for the ASM models performs a little better than the extractive results (B5). ASM models perform more than 10 points better than the best abstractive baseline results (B1), which is in turn $\sim$5 points better than the other abstractive baseline results (B2, B3). For cluster-summary agreement, this improvement is even clearer, with ASM models performing more than 10 points better than any baseline.

In addition, we see that ASM reduces hallucination compared to B2 and B3. One way to approximate hallucination is by the number of clusters in which none of the articles entail the generated summary. Using both automatic and human evaluation results, we see that our model does better than B2 and B3, but a little worse than B1 which copies extensively from the source articles.

6.2 Discussion on ROUGE

In SDS tasks, Durmus et al. (2020) and Wang et al. (2020a) observe that ROUGE and BERTScore have a small correlation with summary factuality.

A hallucination or non-entailment[10] can have major text-span overlaps with the reference, thereby having a large ROUGE score. Given the nature of AgreeSum, and by Table 2, we confirm that high ROUGE does not imply entailment and should not be considered heavily in evaluation.

On the other hand, intuitively, we do recognize that an overly small ROUGE may indicate bad generations (e.g., extremely short generations, off-topic generations, and other degenerations like repetitions), which is the case for B4 generations as well as ASM-minus-L_l generations.

Thus, practitioners need to rely on and determine the desired tradeoff between the following two automatic metrics: (1) ROUGE as a coarse proxy for summary quality and informedness, and (2) entailment-related and hallucination-related metrics (Section 6.1).

As a reminder, the development set summaries can be treated as gold-standard summaries. However, the test set summaries are not gold-standard summaries; they are only provided so as to allow one way to measure generation quality and informedness. Unlike the development set, none of the test-set input articles are filtered out through the summary-article entailment annotation procedure, given that we do not want to introduce potential bias through too much manipulation and filtering on raw test clusters.

6.3 More Observations

Language. We also asked workers to judge the language of the generations:

> *Is this summary coherent and well-written with no self-contradictions or capitalization, spelling, punctuation, or grammar errors?*

The full prompt is in the appendix. We see that the ASM-generated summaries are marginally better at the above. However, ASM without language loss results in heavy degenerations. On a separate note, we see that ASM generations tend to copy more than B2 and B3, but less than B1.

Examples. The appendix contains a few examples that compare generations from different models. For example, in Table 5, given four articles, we see the different generations that the systems produce. Article 4 is an opinion piece. ASM model correctly abstractively summarizes Article 2 and 4 in a way that agrees with 1 and 3. B1 copies from Article 1, while B2 and B3 have hallucinations. Given space constraints, please refer to the appendix.

6.4 Extension: Post-hoc Entailment Reranking after Decoding a Beam

To generate summaries that achieve better agreement, we also attempted a decoding trick which we name as entailment-oriented decoding, denoted by entdec in Table 3.

We first define an entailment score used in this case. Given a cluster of articles and a generated summary, the entailment score is the mean of the T5-large-predicted binary labels (1 corresponds to "entailed" and 0 corresponds to "not entailed").

A model is suffixed as X-entdec$k$ if we decode from X using beam search with beam size k; and after obtaining the size-k beam, we select the generation that corresponds to the largest T5 entailment score. We pick the beam with the largest score, using the original beam probabilities to break ties. Intuitively, this trick picks the best-entailment summary locally given that the generations in the same beam are usually similar.

Table 3 shows that the entdec-trick generations indeed achieve higher article-summary agreement and human-summary agreement. We see that ASM still maintains the advantage in agreement, even if compared to entdec-decoded generations from other baselines.

6.5 Discussion: Improving Entailment Using T5-Based NLI-Style Models

Falke et al. (2019) find that NLI models trained on

---

[10] Non-entailed summaries are not necessarily hallucinations, given that the non-entailed summaries could correspond to some articles in the cluster but not the rest of the articles.

Table 3: Results using the entdec decoding strategy. The results correspond to the test set performance, if not specified. ¶: the first number in each cell corresponds to T5-evaluated results, and the second corresponds to human-evaluated results. Given that B5 relies on pure extraction, the entdec methods are not applicable. ‡: the test set WCEP summaries should not be treated as references, given that there is no guarantee that the WCEP summary is entailed in each of the articles; the test set WCEP summaries are provided as an approximate measure of informedness.

standard NLI datasets do not offer robust benefits to improving summarization factuality. Maynez et al. (2020), on the other hand, rerank four summaries generated by four different models using BERT-based MNLI models, and find small improvements in faithfulness and factuality. However, these works rank different summaries after decoding assuming an existing summarizer (similar to our entdec trick), instead of updating the model parameters directly. Our contribution lies in the fact that we successfully use entailment models to improve the model during training time.

The major feature of our T5-based NLI model is that (1) our NLI model is based on multi-task-pretrained T5, implying that pretrained T5 can already handle article-length inputs well in certain tasks, and (2) our model is obtained after finetuning on our article-summary entailment dataset. Therefore, our T5-based NLI model is much better adjusted to the length of the premises (given that traditional NLI tasks correspond to sentence-level entailment, but our case corresponds to article-summary entailment). We thus see that using simple T5-based binary signals can successfully improve entailment. However, more complicated modeling may be necessary if the AgreeSum cluster size becomes much larger.

7 Conclusion

We discuss the AgreeSum task with its dataset, and a range of baseline models. AgreeSum is timely given the recent focus on summarization faithfulness. In fact, we show that the summaries produced by several powerful pretraining-based baseline models are not able to follow AgreeSum's requirements satisfactorily. We welcome the community to contribute more advanced methods that work well on AgreeSum, especially when only a small subset of the dataset is labeled with article-summary entailment information.

Within the AgreeSum dataset, we also provide article-summary entailment annotations on a subset of clusters, which we hope can contribute to the recent effort in improving abstractive summarization faithfulness.

Moreover, while there is contemporaneous development of complex approaches to encourage generated abstractive summaries to be entailed in the source articles, we show that it is feasible to improve the entailment behavior of generated summaries based on a binary article-summary entailment classifier.

A Appendix

A.1 Human Evaluation

Recall that human evaluation results are reported in Table 2 and Table 3. Specifically, we asked human raters to annotate the entailment relationship of each article-generation pair. Each row in the table corresponds to a model, and for each model, human raters annotated the entire test set that contains 150 clusters (which corresponds to 600 article-generation pairs). Moreover, to reduce the variance of human evaluation and to improve the confidence to our claims, each article-generation pair is annotated by three different raters, and we take the majority answer.

Our prompts to human raters are described as follows. We merge all article-summary pairs for each cluster together into one task/HIT. Therefore, each task/HIT corresponds to four article-summary annotations.

Instruction at the top of the annotation page: "In this task you will be given one summary of a news story and the text of four news articles. You will be asked to evaluate whether the summary is coherent and well written with no self-contradictions or capitalization, spelling, punctuation, or grammatical errors. Furthermore, for each news article, you will be asked to evaluate: whether the article contains ALL the information presented in the summary. This is equivalent to asking, 'Using only the text of this news article, would it be possible for someone to write this summary?"'

Language: "Is this summary coherent and well-written with no self-contradictions or capitalization, spelling, punctuation or grammar errors? Select "Yes" if this is a coherent summary written in fluent English with perfect grammar and style. Select "No" if the summary contains one or more capitalization, spelling, punctuation, or grammatical errors, or is incoherent, self-contradictory, or otherwise badly written."

Entailment: "Does the article contain all the information presented in the summary?"

A.2 Entailment Annotation in Dataset Creation

We used the same entailment prompt described in Section A.1 to obtain entailment information for a subset of the clusters. The difference is that we used five annotators per article-summary pair instead of three, to ensure the quality of the supervised split of the training set as well as the entire development set.

A.3 More on Reproducibility

We implement our model as a fork of the open-source 568M parameter PEGASUS model.[11]

Baseline models were trained for 20k steps, with the best checkpoint selected based on dev-R2. Final selections are B1 at 3k steps, B2 at 6k steps, and B3 at 4k steps. Proposed model was trained until convergence based on T5-small entailment scores reported during the sampling steps in the policy gradients REINFORCE algorithm. Final selection of this model was at 43k steps.

Runtime details. Given the chosen PEGASUS implementation, our models are trained on TPUs. Given hardware constraints, F_e, implemented via T5-small fine-tuned on our annotated entailment dataset, is served on CPU on a separate machine. In fact, we run 80 replicas of this machine to improve throughput. We make RPC calls (Nelson, 1981) to this cluster of T5-serving machines during policy gradients training (using the f.contrib.rpc module). Baseline models took approximately 24 hours each to train, with the proposed model taking approximately 4 days. Our conjecture is that for the latter, most of the time is spent on the communication between PEGASUS and T5, as well as the expensive computation of T5 on CPU.

A.4 Examples

We now provide some example generations of the AgreeSum task. Given that the input articles are long, we comment out parts of the articles in the tables. Please refer to Table 4, Table 6, and their captions.

For example, in Table 5, Article 4 is an opinion piece. ASM model correctly abstractively summarizes Article 2 and 4 in a way that agrees with 1 and 3. B1 copies from Article 1, while B2 and B3 have hallucinations. In Table 4, all models except for B1 perform well here. B1 entails Article 1 and 2, but not 3 and 4. Similar comparisons can be made in Table 6.

BERT Busters: Outlier Dimensions that Disrupt Transformers

Olga Kovaleva[*1], **Saurabh Kulshreshtha**[*1], **Anna Rogers**[2] **and Anna Rumshisky**[1]

Abstract

Multiple studies have shown that Transformers are remarkably robust to pruning. Contrary to this received wisdom, we demonstrate that pre-trained Transformer encoders are surprisingly fragile to the removal of a very small number of features in the layer outputs (<0.0001% of model weights). In case of BERT and other pre-trained encoder Transformers, the affected component is the scaling factors and biases in the LayerNorm. The outliers are high-magnitude normalization parameters that emerge early in pre-training and show up consistently in the same dimensional position throughout the model. We show that disabling them significantly degrades both the MLM loss and the downstream task performance. This effect is observed across several BERT-family models and other popular pre-trained Transformer architectures, including BART, XLNet and ELECTRA; we also show a similar effect in GPT-2.

1 Introduction

Pre-trained Transformer-based models (Vaswani et al., 2017) have become widely popular in a variety of NLP applications. Multiple studies of BERT-family models (Devlin et al., 2019) showed that Transformers are remarkably robust to pruning (Gordon et al., 2020; Prasanna et al., 2020; Chen et al., 2020; Michel et al., 2019). This work presents a different and unexpected result: it is possible to dramatically disrupt the performance of BERT and other Transformer-based architectures by modifying very few weights (less than 0.0001% for BERT).

In particular, we show that there is a very small number of outlier dimensions that regularly appear in the same position in the pre-trained encoder layers of a given Transformer model. We demonstrate that this effect holds for different Transformer-family architectures, including multiple variants of BERT, as well as ELECTRA (Clark et al., 2020), BART (Lewis et al., 2020), and XLNet (Yang et al., 2019). A similar phenomenon is also present in the decoder layers of GPT-2 (Radford et al.). When these dimensions are disabled throughout the model in the concluding transformation of each layer, they can drastically reduce the overall model performance. With the exception of GPT-2, the last transformation in each layer of these models is normalization (LayerNorm), which is what we mainly focus on in this study.

The contributions of this work are as follows:

- We identify certain outlier dimensions in Transformer layer outputs and show that they play a crucial role in both language modeling and downstream task performance. Disabling the weights for these output dimensions drastically degrades performance (up to 44 points).
- We show that this effect holds for the encoder layers of six different models of the BERT family, as well as other popular pre-trained Transformer-based models including ELECTRA, BART, and XLNet. In GPT-2, a similar phenomenon is observed in the output dense transformation of the decoder layers.
- We demonstrate that outlier weights emerge gradually and begin to emerge early in pre-training, causing abnormal spikes at select dimensions in the output embedding vectors.

To our knowledge, this is the first work to establish the presence of very few regular outliers in the output Transformer representations and their importance for the model performance. It is not clear why these features emerge, but the final transformations clearly play a larger role in the Transformer layers than is usually assumed, and this needs further investigation.

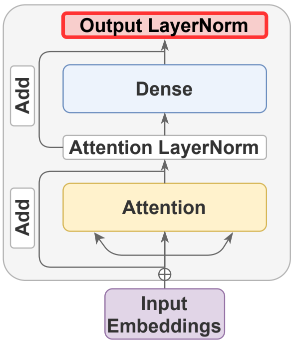

Figure 1: Transformer encoder layer, adapted from (Vaswani et al., 2017).

This paper is organized as follows. After a brief overview of related work (§2), we introduce the methodology for defining, locating, and disabling the BERT outlier weights in §3. In §4.1 and §4.2, we quantify the effect of disabling these weights both in pre-training and in downstream tasks. In §4.3, we demonstrate that other Transformers (BART, ELECTRA, XLNet, and GPT-2) also exhibit similar behavior. §5.1 evaluates magnitude- and position-based criteria for identifying the outlier dimensions and compares them with our proposed criteria. In §5.2, we replicate the outlier effect in a BERT model during pretraining and study its dynamics.

2 Related work

Transformer layer outputs. At a high level, Transformer encoder layers consist of multi-head self-attention followed by a dense layer Vaswani et al. (2017). Most contemporary Transformers use normalization to improve the speed and stability of training.

Usually, the outputs of both self-attention and linear layers undergo the layer normalization transformation (LayerNorm, Ba et al. (2016)). Each LayerNorm transformation is parameterized by a separate set of learned weights (*scaling factors* and *biases*). Xiong et al. (2020) refer to this configuration as *post-LN*. In the *pre-LN* variant adopted by the GPT-2 model, LayerNorm is applied prior to the self-attention or linear transformations instead.

We will refer to the outputs of the final transformation in the encoder layer as *features* and the parameters of this transformation as *weights*. The final transformation is LayerNorm for all models considered in this study except GPT-2, where the last component is a MLP.

Like other normalization techniques, LayerNorm operates in two steps. For a given input x_i of the i-th layer with a hidden dimension m, LayerNorm computes mean and variance across the features:

$$\mu_i = \frac{1}{m}\sum_{j=1}^{m} x_{ij},\ \sigma_i^2 = \frac{1}{m}\sum_{j=1}^{m}(x_{ij}-\mu_i)^2 \quad (1)$$

The inputs are then normalized and a learnable scale-shift transformation is applied to produce the normalized output embedding:

$$\hat{x}_{ij} = \frac{x_{ij}-\mu_i}{\sqrt{\sigma_i^2+\epsilon}},\ y_i = \gamma \odot \hat{x}_i + \beta \quad (2)$$

where $\gamma \in \mathbb{R}^m$ and $\beta \in \mathbb{R}^m$ are trainable parameters referred to as *scaling factor* and *bias* (shift).

So far there have been few studies of normalization strategies in Transformer architectures and they focused mostly on the description of the training process. Xiong et al. (2020) show that the location of LayerNorm in Transformer affects the gradient flow and demonstrate the need of the warmup stage. Nguyen and Salazar (2019) inject multiple normalization blocks in specific network submodules to improve model performance. More recently, LayerNorm alternatives have been proposed and shown to have better gradient propagation through the network (Xu et al., 2019; Shen et al., 2020).

Overparametrization. After the initial reports of redundancy in the BERT model (Michel et al., 2019; Kovaleva et al., 2019), compressing Transformers quickly became a subfield of its own (Jiao et al., 2020; Zafrir et al., 2019; Fan et al., 2019; Guo et al., 2020). See overviews by Ganesh et al. (2020) and Rogers et al. (2020).

Pruning is a class of methods for model compression which involves setting some of its weights to zeros with minimal performance loss. Much pruning work focuses on compression for the sake of efficiency, but it is also used for model analysis, and that is our goal as well. The most common approach is selecting the weights to be pruned by magnitude (Han et al., 2015).

Some of the recent findings are that the lottery ticket hypothesis (Frankle and Carbin, 2019) holds for BERT: its largest weights do form subnetworks that can be retrained alone to reach the performance close to that of the full model (Prasanna et al., 2020; Chen et al., 2020; Gordon et al., 2020). In structured pruning, the best subnets of BERT's heads and MLPs (selected by importance scores) do not quite reach the full model performance, but the worst ones are still much better than the worst magnitude-based subnets (Prasanna et al., 2020), presumably because they retain a lot of high-magnitude weights.

3 Outlier weights in BERT models

In this section, we introduce the methodology for identifying outlier dimensions and describe our method for disabling these outlier features.

3.1 Identification

To identify the outlier weights in BERT-like models, we consider all the output components in each encoder layer. We compute the mean and standard deviation of the bias and scaling factors of the output LayerNorm. We identify the dimensions where both of these weights are at least 3σ from the mean. Figure 2 illustrates this heuristic. Further, we select the dimensions where this is consistently the case for at least half of the model layers. We refer to these dimensions as outliers.

The described heuristic was used to identify the outlier dimensions in four out of six BERT models we considered: BERT-base, BERT-medium, BERT-small and mBERT.[1] For BERT-large, the deepest model we considered, the frequency constraint was relaxed to 1/3 of the layers. In RoBERTa (Liu et al., 2019), the distribution of the scaling factors was a little different from BERTs, and we relaxed the standard deviation constraint down to 2 sigmas to detect the outliers. In Section 10.1 of Appendix, we report positions of outlier weights identified for all models.

3.2 Disabling

To quantify the effect of the outlier weights on BERT, we disable them and examine how this affects model performance. We set the outlier weights to zeros across all layers and report model performance on a) masked language modeling and b) downstream GLUE tasks (Wang et al., 2018).

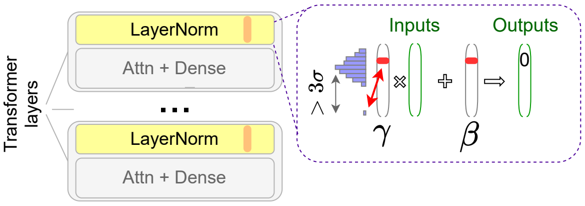

Figure 2: Simplified illustration of our approach to disabling LayerNorm weights. We consistently set the outlier weights γ and β of the output LayerNorm to zeroes, which results in masking of the corresponding features in the output vectors. We repeat the procedure for all of the Transformer layers of the encoder.

Since different model components may affect performance, we also looked at all the parameter vectors and matrices in BERT that have the same dimensionality as the output embeddings. These included key, query and value transformations[2], output LayerNorm, attention LayerNorm, and input embedding layers. In order to examine the effect of these components on model performance, we masked the identified outlier weights of a given component simultaneously across all layers at the same dimensional position. When working with the matrices, we set to zeros the entire row of weights corresponding to the outlier positions across all Transformer layers. Similarly, for LayerNorm, we set the scaling factor and the bias at the outlier position across all Transformer layers to zero. In both cases, this results in "masking" of the output vector's feature at the specified dimension after a forward pass through that layer.

Although the same dimensions repeatedly show up as outliers across different model components, in the preliminary experiments, we found that disabling the weights of the input embedding layers and of the linear layers produced no significant change in performance or in the output embedding space, so we did not pursue this direction further. However, the outlier weights of the output LayerNorm had an unexpectedly large effect on the model, and this is what we focus on in most of our experiments.

3.3 Visualization

As an example, let us consider the two outlier dimensions that the above method identifies for BERT-base-uncased model: `308` [3] and `381`. Fig-

---

[1] BERT-medium and BERT-small come from the official Google repository (https://github.com/google-research/bert), and the other models from the HuggingFace (https://github.com/huggingface/transformers). Interestingly, we discover that the checkpoints of the same BERT-base configuration provided by different repositories (Huggingface vs. Google) have the outliers in different locations; the outliers also have different values: positive vs. negative.

[2] To find outliers in weight matrices, we compute the L_1 norm for each row. The total number of rows is the same as the dimensionality of the layer output embedding (e.g. 768 for BERT-base). From this distribution of row-norms, we select those row indices for which the magnitude is 3σ away from the mean of the distribution.

[3] All dimensions in the paper are zero-indexed.

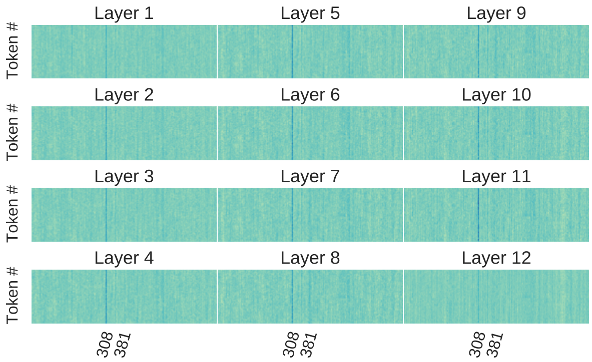

Figure 3: Outlier LayerNorm features `308`, `381` in BERT-base-uncased (randomly sampled input).

ure 3 shows a heatmap of the output embedding of each layer (one pixel per row) for a random passage from WikiText (Merity et al., 2016). Since the output embeddings are produced by LayerNorm, the outlier dimensions with unusually high or low-magnitude weights should be visible in the heatmap.

As seen in Figure 3, dimension `308` consistently produces high-magnitude weights in the output embeddings in most BERT layers; feature `381` shows visibly high values in layers 7-10. The magnitude of a given feature depends both on the LayerNorm scaling factor and the bias (Equation 2). We find that both contribute to the outlier effect, to various degrees in different layers. See Table 13 in the Appendix for statistics on all scaling factors and biases in BERT-base.

Features that show high magnitude throughout the model are expected to distort the resulting embedding space. In a brief experiment, we found that the vector representations of up to 95% of the input tokens from the WikiText corpus have abnormally high magnitudes at the dimensions corresponding to the outlier weights we identified. We found that this embedding distortion is not attributable to the input embedding layer (Layer 0). We did this by manually setting select embedding weights of the three channels of the input embedding layer (token, token type, and position) to zero (along with the weights of the following normalization layer).

The fact that the embedding distribution we observed is not uniform is in line with observations by Ethayarajh (2019) who concluded that BERT embeddings are highly anisotropic and form a cone-like shape in the hidden space. The outlier weights we identify are likely the cause of this, since after they are removed, the embedding space becomes relatively uniform.

Table 1: Input masked tokens (blue) are given in brackets. RoBERTa correctly reconstructs 4 out of 6 masked tokens (green), and fills in plausible (brown) predictions for the remaining 2 tokens. RoBERTa with 2 randomly disabled LayerNorm dimensions works almost the same as the base model. However, RoBERTa with 2 outlier LayerNorm dimensions makes incorrect and implausible (red) predictions, and changes the hidden token states significantly enough to map the unmasked input tokens to other, often non-sensical words. In this example, we do not show the special tokenizer tokens.

4 Effects of Disabling Outlier Weights

In this section, we consider the effects of disabling outlier weights in BERT on language modeling (§4.1) and on downstream tasks (§4.2). We also investigate whether other Transformers exhibit a similar phenomenon (§4.3).

4.1 Masked Language Modeling

Our key finding is that disabling the outlier dimensions significantly degrades the quality of the language model, even though fewer than 0.001% weights of the model are affected. Table 1 shows a sample output before and after the LayerNorm outliers are disabled in RoBERTa[4]. It is clear that the quality of the language model degrades dramatically, while disabling an equal number of randomly selected non-outliers has almost no effect.

To quantify this effect, we measure the cross-entropy loss before and after disabling each dimension of the LayerNorm on at a time. We do this on the validation subset of the WikiText corpus

---

[4] More sample outputs are given in the Appendix.

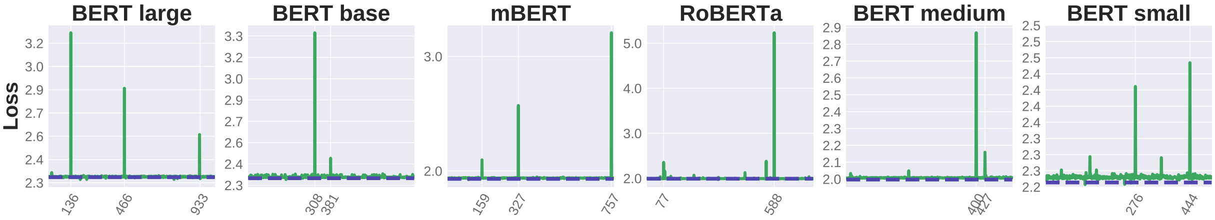

Figure 4: Language model cross-entropy loss (green) after the scaling factor and bias for a given dimension are set to zero, one at a time. The dashed blue line shows the loss achieved by the full model.

Table 2: Cross-entropy (*CE*) on the validation set of WikiText when the LayerNorm weights are zeroed. *Single* shows the performance when the most damaging outlier is disabled vs. disabling one non-outlier feature (averaged over all non-outliers disabled one at a time). *All* shows performance for when all outliers in a given model are disabled vs. disabling an equal number of randomly selected non-outliers (averaged over 1000 runs). *#w* indicates the total number of modified weights in a given model.

(Merity et al., 2016). We use the standard maximum sequence length of 256 and the token masking probability of 0.15.

All tested models show surprising sensitivity to zeroing out the weights at the outlier positions across all layers of the model (Figure 4). For example, removing only 24 parameters (the scaling factor and the bias of a specific LayerNorm dimension across all 12 layers) increases RoBERTa's loss by almost a factor of 4.

Table 2 shows even more drastic effects when scaling factors and biases for all the outlier dimensions are disabled simultaneously. For comparison, we randomly sample an equal number of non-outlier dimensions and disable the corresponding LayerNorm weights throughout the model. We report the loss averaged over 1000 runs.

4.2 BERT Downstream Tasks

In order to investigate the effect of outlier weights on downstream performance, we evaluate BERT-base on the GLUE benchmark tasks (Wang et al., 2018), with the exclusion of Winograd Schema Challenge, which BERT generally fails to learn (Prasanna et al., 2020). We use the evaluation split of the GLUE benchmark for which the labels are publicly available. As described above, BERT has two outlier dimensions, `308` and `381`. We consider the following two sets of experiments:

1. Disable post fine-tuning. We fine-tune BERT on every GLUE task, then disable the outlier LayerNorm parameters (scaling factor and bias pair) across all layers as described in subsection 3.2. We experiment with disabling each of the two detected outliers both individually and simultaneously in pre-trained BERT-base. We compare the resulting performance to (a) removing the LayerNorm weights for all other hidden dimensions one-by-one, and (b) randomly sampling pairs of non-outlier dimensions so as to disable them simultaneously.

2. Disable pre-fine-tuning. We disable the layer norm parameters for the outlier dimensions *prior* to fine-tuning. Our goal is to check whether the fine-tuning allows the transformers to recover the information from rest of the parameters.

For all the fine-tuning runs, we set the learning rate to 5e-5, batch size to 64 and train for 4 epochs across all the experiments. Since BERT performance varies a lot due to task-specific initialization (Dodge et al., 2020), we use the same initialization across all experiments.

Figure 5 shows model performance when LayerNorm outliers are disabled one at a time. Table 3 compares task-specific performance of the outlier-disabled and the full model for each task.

The main takeaway from the *post fine-tuning* experiments is that disabling one or the other of the

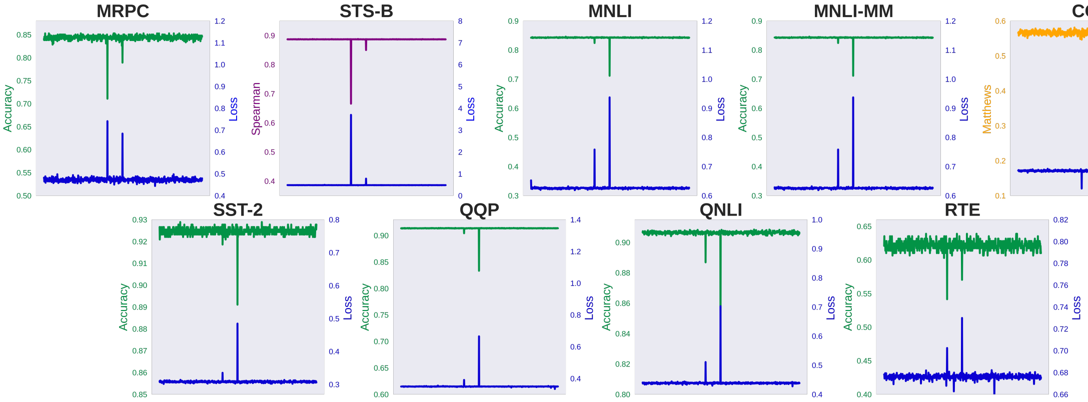

Figure 5: Performance of BERT-base on GLUE tasks when one LayerNorm weight at a time is disabled throughout the model. Dimensions are shown on the X axis. Loss (blue) and accuracy, or correlation coefficients, where applicable (other colors) are shown.

Table 3: Performance of the pretrained BERT-base model vs. different configurations with disabled outlier weights: post fine-tuning (*post-ft*) and pre-fine-tuning (*pre-ft*). [†]We disable each of non-outlier dimension parameters one at a time and average over them. [‡]For the random sampling of the pairs of non-outlier dimensions, we report averages over 1000 runs. *For the pre-finetuning experiment where random non-outlier parameters are disabled, we sample 10 non-outlier dimensions randomly and disable LayerNorm weights and biases for them across the entire model.

outlier dimensions (or both) drastically degrades model performance on downstream tasks. Which of them affect downstream performance the most is highly task-dependent. For example, the outlier dimension `308` has little effect on CoLA(-2.16) but a large effect on STS-B(-23.4), and for `381` it's the opposite. On SST-2, QNLI, RTE neither outlier drops the performance by over 10 points individually, but disabling them both has a strong adverse effect.

In general, disabling two outliers together causes more severe damage across the board than disabling a single outlier. The overall performance drop is task-specific. The most adversely affected tasks are STS-B (-44.1) and CoLA (-32.3), which are the regression tasks that also suffered the most in pruning experiments by Prasanna et al. (2020). However, MNLI and SST-2 are classification tasks, and both of them also lose over 20 points. Note that disabling random non-outlier dimensions (either alone, or in pairs) has negligible effect on performance across tasks. Disabling one outlier and one random non-outlier has the same effect as disabling a single outlier.

In *pre-fine-tuning* experiments, the question we ask is whether the model can recover from the handicap we introduce, and still learn the task. We expect it to mostly recover, since even randomly initialized BERT without any pre-training can be fine-tuned to solve GLUE tasks fairly well (Kovaleva et al., 2019). In this case, since most of the pretrained sub-networks are still accessible to the classifier, we expect to see a strong recovery close to the baseline. We find this to be the case, however, the model is more adversely affected: -1.1 on average when two outliers are disabled, compared to disabling 10 non-outliers (-0.31 on average).

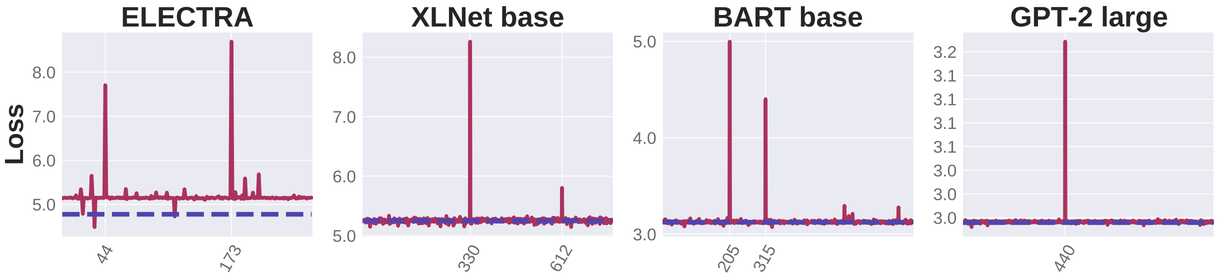

Figure 6: Performance (loss) of other Transformer models after a given LayerNorm scaling factor and bias are set to zero, one at a time. For GPT-2, the dense layer weights and biases are disabled, as it is an instance of a pre-LN model. The dashed blue line shows the loss for the full model.

Model	**Task**	**Data**	**#Params**	**Disabled** # dims	 weight %	**Performance** Baseline	 Disabled
ELECTRA	MLM	WikiText	110M	2	4×10^{-5}	4.8	**8.1**
XLNet	PLM	WikiText	120M	2	4×10^{-5}	5.2	**8.4**
BART	Summ.	CNN/Daily Mail	140M	2	9×10^{-6}	3.1	**4.4**
GPT2	CLM	WikiText	770M	1	0.024	3.0	**3.2**

Table 4: Loss increase in other Transformer models after layer normalization scaling factors and biases highlighted in Figure 6 are set to zero, compared to the baseline configuration. For GPT-2, the dense layer weights and biases are disabled instead, since it is a pre-LN model. *MLM*, *PLM*, and *CLM* stand for masked, permutation, and causal language modeling objectives, respectively. *Summ.* stands for the summarization task. *#dims* denotes the total number of dimensions modified.

4.3 Outliers in Other Transformers

Above, we described our methodology for identifying outliers in BERT models and studied how they affect model performance. In this section, we show that a similar phenomenon is observed in other popular Transformers: BART-base, ELECTRA-base generator, XLNet-base, and GPT-2 large.

Since our goal here was merely to confirm the existence of outlier dimensions, in these experiments, we simply disabled individual LayerNorm dimensions of the encoder part of the model across all Transformer layers. For GPT-2, we modify the weights of the dense output layer instead of the LayerNorm weights, since it uses the pre-LayerNorm (pre-LN) configuration (i.e., LayerNorm is placed before the output feature-producing feed-forward layer).

We perform this experiment for all models, measuring how this affects the loss function in the native pre-training tasks of three models: permutation language modeling task for XLNet, causal language modeling for GPT-2, and masked language modeling for the generator component of ELECTRA. For BART, we found that the pre-trained model had unusually high perplexity out of the box, and we substituted the modeling task with summarization on the CNN/Daily Mail dataset (Hermann et al., 2015).

As with BERT, our results (Figure 6) suggest that for each model, there are a few distinct dimensions which disrupt performance significantly more than the rest. We identify a few most impactful dimensions and also disable them at once, as reported in Table 4. The effect on perplexity is the least pronounced for GPT2, which we attribute to the fact that the model is significantly larger than the others, which may make it more robust to the disabling of individual weights. However, we found that when six dimensions are disabled simultaneously, the perplexity increases by over 300 times.

5 What Makes Outlier Weights Special

5.1 Magnitude or Location?

In this section, we conduct two experiments to validate our proposed criteria for selecting BERT weights to be disabled. Specifically, we want to understand if the same effects would be observed (1) with magnitude-based selection of LayerNorm parameters to be disabled, or (2) using our selection method, but disabling the outlier dimensions only in the first (input) layer or in the later layers (which may have a more direct effect on the output). We use the drop in the loss value for this comparison.

First, we compare the effect of disabling the

	CE	#w	CE	#w
baseline (full model)	2.30	0	2.30	0
Random	2.31	24	2.32	48
LSF	2.72	24	2.74	48
LB	3.21	24	3.42	48
Outlier-`308`	3.32	24	**4.53**	48
Outlier-`381`	2.44	24		

Table 5: BERT-base cross-entropy loss (*CE*) on the WikiText validation data when one (left) or two (right) outlier dimensions are disabled at a time, compared to magnitude-based pruning approaches (LSF and LSB). *#w* denotes the total number of modified weights.

selected dimensions (`308` and `381` in BERT-base, disabled individually or together – i.e. disabling either 12 or 24 LayerNorm scaling factor and bias pairs) to disabling of the following alternatives:

- **Random**: disable 12 or 24 randomly selected pairs of LayerNorm scaling factor and bias pairs in the entire model;
- **Largest Scaling Factor (LSF)**: sort the LayerNorm scaling factors in the model by magnitude and disable the top 12 (or 24) scaling factors and the corresponding biases;
- **Largest Bias (LB)**: repeat the above using the LayerNorm biases instead, i.e. select the top 12 (or 24) LayerNorm biases and disable the corresponding scaling factor / bias pairs.

Table 5 suggests that simple magnitude-based pruning of the output LayerNorm results in a much smaller degradation. As compared to disabling both BERT outliers, the magnitude-driven pruning of the same number of weights results in the value of cross-entropy that is 1.3x smaller.

Looking at the effects of disabling the outlier dimensions only in a subset of layers, Table 6 shows that modifications made to the input layer have little to no effect. Interestingly, switching off the weights in the last Transformer layer, which is used for computing inputs for task-specific classifiers, also does not disrupt the model. However, as we begin to disable earlier layers and the number of layers with disabled weights increases, we observe progressively larger loss values.

We conclude that both the magnitude and the consistent emergence of outlier weights in the same locations across the model are responsible for the emergence of distinct embedding features that BERT heavily relies on.

	1	12	11–12	9–12	7–12	1–12
CE	2.33	2.40	2.67	2.81	2.87	**4.53**
#w	4	4	8	16	24	48

Table 6: BERT-base language modeling cross-entropy loss (*CE*) on the validation set of WikiText corpus, shown by location and number of modified Transformer layers. *#w* denotes the total number of modified weights.

5.2 How Do Outlier Weights Emerge?

In this section, we examine the emergence of outlier dimensions during pre-training. To the best of our knowledge, there are no publicly available BERT pre-training checkpoints available to study these effects. We pre-train[5] a BERT-medium model (chosen due to computational constraints) from scratch on the BookCorpus data (Zhu et al., 2015) and track statistics of the LayerNorm scaling factors and biases. We start from a randomly initialized BERT-medium configuration that has 8 layers with the hidden dimensionality of 512 units. We save checkpoints of the model every 2000 steps, and we track the output LayerNorm weights across all of the model's layers as the training progresses.

Figure 7 shows that both scaling factors and biases begin to diverge from their initialization values quite early (after approximately 50k steps) in the training process. At roughly the same point, both training loss and evaluation perplexity begin to fall off. An interesting question for future work is to clarify whether there is a causal relationship here.

Although the published BERT-medium model had two outlier dimensions, our model had only one dimension for which *both* the scaling factor and the bias exceed their corresponding means by more than three standard deviations.

Due to the gradual emergence of these outliers during pre-training, there is a possibility that thresholding their distance from the rest of the parameters can be used as a litmus test for when the pre-training is complete. We leave the investigation of this hypothesis to future work.

6 Implications and Future Work

The outlier dimension effect we identified may enable **attacks on Transformer-based encoders** that could be used to degrade the model quality while modifying very few weights. Further, since these perturbations to the model do not cause the

---

[5] We used two RTX-3090 GPUs for pre-training.

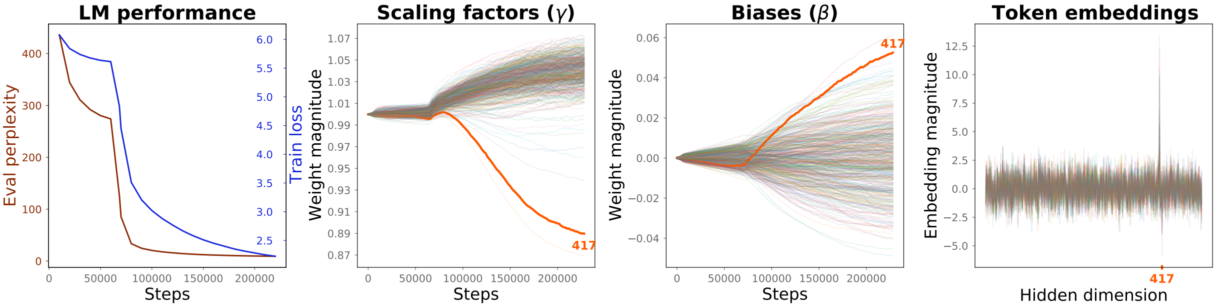

Figure 7: BERT-medium pre-training on the BookCorpus dataset. *(left)* Evaluation perplexity (brown) and train loss (blue) as the training progresses. *(middle)* The changes in the scaling factors and the biases of the output normalization layer. Each line corresponds to one of the 512 dimensions. We highlight (in orange) the `417`-th dimension, for which both the scaling factor and the bias fall out of the three sigma range at the end of pretraining. *(right)* Token embeddings computed for an input sequence that was randomly sampled from the data. Each line corresponds to one input token. The outlier embedding values are marked at the same `417`-th dimension. All the plots are presented for the middle Transformer layer (4).

model to break completely, this may lead to late detection of this attack. To curtail the risks of this attack from affecting deployed Transformer models, we would suggest simple measures such as storing the file checksums for the trained models at a secure location and verifying that the deployed model file matches the checksums.

Another direction for exploiting the phenomenon of outlier dimensions is **pruning**. The studies of model compression using unstructured pruning typically do not consider whether the pruned weights were in the same position throughout the model. Our work suggests that if the outliers were disabled consistently, the drop in performance could be expected to be larger than for random or magnitude-based pruning.

Finally, future work could consider outlier dimensions in the context of **weight initialization**. Our experiments suggest that these dimensions are a normal emergent property of Transformer pretraining. It is possible that higher performance or faster convergence could be achieved by manipulating the initialization to encourage such outliers and experimenting with their number.

7 Conclusion

The main contribution of our work is isolating the phenomenon of a small number of outlier dimensions in Transformer layer outputs which significantly disrupt performance while modifying less than 0.0001% of all parameters of the model. We attribute this phenomenon to an interaction of high-magnitude scaling factors and biases in the same dimension throughout the model, rather than magnitude alone. It emerges early in the training and consistently warps the embedding space.

In case of BERT, the layer output component is LayerNorm. We introduce a method to isolate these outlier dimensions for BERT, and we show that the phenomenon is present in six models of BERT family that we examine. It is also present in four other Transformer-based models (ELECTRA, XLNet, BART, and GPT-2), although the effect of their disabling varies.

8 Acknowledgments

We would like to thank the anonymous reviewers for their insightful comments. This work is funded in part by the NSF award number IIS-1844740 to Anna Rumshisky.

We would like to note that in an independent study concurrent to ours, Luo et al. (2021) report a similar effect of outlier values in the embedding space of BERT and RoBERTa. We invite the reader to look into their study for more details on the outlier features from the perspective of word embeddings.

9 Impact statement

This work analyzes the behavior of layer normalization in the popular BERT family of models, using standard benchmarks. No new models are presented, and no data was collected.

We estimate that experiments presented in this paper consumed 436.8 kWh of energy which resulted in a 108 Kilograms of CO2 emissions computed using the regional average of power generation to carbon emissions.

10 Appendix

10.1 Candidate outlier dimensions of the models.

For each of the BERT-like models we experimented with we present the outlier candidate weights, detected as described in section 3.

Model component	**Outliers**
output.dense.weight	275, 276, 444
attention.output.dense.bias	193
attention.output.LayerNorm.weight	275, 276, 444
attention.output.LayerNorm.bias	276, 444
output.LayerNorm.weight	121, 262, 444, 276
output.LayerNorm.bias	276, 444

Table 7: BERT-small outlier dimension candidates across model components.

Model component	**Outliers**
attention.output.dense.bias	92, 400, 476, 17
output.dense.weight	400
output.dense.bias	400
attention.output.LayerNorm.weight	17, 400, 430
attention.output.LayerNorm.bias	192, 400
output.LayerNorm.weight	11, 193, 393, 427, 400
output.LayerNorm.bias	400, 427

Table 8: BERT-medium outlier dimension candidates across model components.

Model component	**Outliers**
output.dense.weight	308, 381
output.dense.bias	308
attention.output.dense.bias	308
attention.output.LayerNorm.weight	308, 381
attention.output.LayerNorm.bias	145, 308, 381
output.LayerNorm.weight	92, 145, 308, 381, 225
output.LayerNorm.bias	308, 381

Table 9: BERT-base outlier dimension candidates across model components.

10.2 Scaling factor and bias statistics for BERT-base.

For the BERT-base configuration, we present the detailed statistics on per-layer scaling factors and biases of the output LayerNorm (see Table 13). We report per-layer means, standard deviations and counts of the weights falling out of the three sigma range. We also show the values of the outlier weights (`308` and `381`) along with their ranks, where the ranks are computed for the corresponding sorted arrays of weight magnitudes. Note that the outlier weights consistently appear to be *among* the top largest or top smallest LayerNorm weights throughout the model, but are not necessarily the top-1 largest/smallest values.

10.3 Sample language model outputs after disabling outlier LayerNorm weights.

For RoBERTa and BERT, we randomly sample a set of sentences from Wikipedia and BookCorpus, mask multiple input tokens, and use the models for token prediction. We compare the baseline (full) models with the models where select LayerNorm weights are zeroed out across all of the Transformer layers. In particular, we compare the setups where the outlier dimensions (two per model) are disabled as opposed to random dimensions (two per model).

Model component	**Outliers**
attention.output.dense.bias	757, 327
output.dense.weight	757, 159
output.dense.bias	159, 757
attention.output.LayerNorm.weight	159, 757, 327
attention.output.LayerNorm.bias	159, 757, 327
output.LayerNorm.weight	159, 757, 327
output.LayerNorm.bias	159, 757, 327

Table 10: Multilingual BERT (mBERT) outlier dimension candidates across model components.

Model component	**Outliers**
output.dense.weight	588
output.dense.bias	588, 494
attention.output.dense.bias	588
attention.output.LayerNorm.bias	77, 217, 453, 551, 588, 496, 731, 494
output.LayerNorm.bias	77, 453, 551, 588, 217, 240, 496, 61, 494

Table 11: Base RoBERTa outlier dimensions across model components.

Model component	**Outliers**
attention.output.dense.bias	466, 18
output.dense.bias	466, 750, 18, 933
attention.output.LayerNorm.weight	234, 466, 933
attention.output.LayerNorm.bias	9, 71, 136, 234, 327, 706, 466, 474, 929, 933, 18, 143
output.LayerNorm.weight	80, 136, 232, 234, 331, 466, 639, 665, 702, 724, 750, 763, 968, 315, 428, 933, 18, 506, 314
output.LayerNorm.bias	136, 466, 706, 327, 9, 929, 18, 143, 933

Table 12: BERT-large outlier dimension candidates across model components.

	Scaling factors				**Biases**			
Transf. layer	mean / std	#$>3\sigma$	308 value / rank	381 value / rank	mean / std	#$>3\sigma$	308 value / rank	381 value/rank
1	0.756 / 0.056	12	0.343 / 764	0.404 / 762	-0.037 / 0.099	6	-1.325 / 0	0.144 / 78
