While benchmarks exist to validate the performance of ML in such scenarios, albeit the degree to which data annotators affect ML outcomes for such nuanced language patterns is unclear, nor certain is the presence of a systematic framework to discover implicit biases among the annotators that might have been responsible. For instance, in (Sap et al., 2019) authors investigated the presence of racial bias in automatic hate speech detection models, racial bias in an algorithm used to manage the health of populations was discovered in (Obermeyer et al., 2019; Caliskan et al., 2017). Besides, there exists several documented evidences of how machine learning-driven automation has resulted in catastrophic dangers to human security (Brown et al., 2006; West et al., 2019; Buolamwini and Gebru, 2018; Hamidi et al., 2018; Noble, 2018), infrastructure resiliency (Osoba and Welser, 2017; Vladeck, 2014), education (Pedro et al., 2019), and economy (Anderson, 2019; Furman and Seamans, 2019). Several approaches are proposed to counter them, including the development of guidelines and policies surrounding the ethical use of machine learning (Wiens et al., 2019), platforms and toolboxes for diagnosing biases (Brundage et al., 2020), recommended practices, and frameworks for evaluating the fairness and explainability (Hardt et al., 2016; Beutel et al., 2019; Pleiss et al., 2017; Gunning, 2017). In (Sheng et al., 2008) authors suggested when labeling is not perfect, selective acquisition of multiple labels is a strategy that data miners should consider. The purpose of this research is to model the extent to which professional background and mental biases affect analytic results from ML algorithms that are specifically applied to complex social media analysis.

We propose *Mixed-Method Design (MMD)* as a new approach towards selecting unbiased data annotators. Broadly, MMD is a method that focuses on collecting, analyzing, and mixing both quantitative and qualitative data in a single study or series of studies. Its central premise is that the use of quantitative and qualitative approaches, in combination, provides a better understanding of research problems than either approach alone (Creswell and Clark, 2017; Shorten and Smith, 2017). In this work, the qualitative work involves conducting surveys and questionnaires on modern racism, moral foundation, demographics among 100 participants who will also label the data. Using Subject Matter Expert (SME) as a baseline, we built a suite of supervised machine learning models from the labeled data and compared the performance of all participants against the SME. Finally, using statistical analysis, we identified key profile characteristics of data labelers that played an important role in how they labeled the data. Our main contributions are:

- Develop a generalized framework for selecting unbiased data annotators for problems surrounding inflammatory language, hate speech, and others, and requiring labeled data.
- Develop an open-source web-based platform[1] and deploy it to perform mixed-method design.
- Design and develop privacy-preserving and problem-agnostic qualitative surveys and questionnaire towards discovering implicit biases among potential data labelers.
- Identify a subset of key profile characteristics that plays a critical role identifying reliable annotators.

2 Mixed Method Design

The Mixed-method design workflow is shown in Figure 1 to selecting data labelers for complex tasks that involve risks of bias and ethics violation. The rest of the section discusses each step in more detail.

2.1 Labeling Task (Study)

This study focuses on Brexit 2016 referendum as a narrative to investigate implicit biases among the data labelers. Since Britain split from the European Union and changed its relationship to the bloc on trade, security and migration was both welcomed and denigrated and polarized the UK/EU. In the past, several opinion polls and surveys revealed a remarkable divide between generations and demographics within and outside of UK and EU countries.

For our study, we selected a set of 10,000 English tweets related to Brexit between January 2019 and October 2019 which was narrowed down to 2,000 tweets for ground truth annotation and to 250 tweets for annotation by Amazon Mechanical

---

[1] `https://thirdeye.ornl.gov`

Figure 1: Mixed-Method Design Workflow

Turk workers.The labeling task primarily focused on identifying whether a given tweet contains inflammatory language, i.e., language that is intended to arouse anger, create and encourage disorder, provoke violent feelings, or excite strong feelings for or against something or someone. Additionally, the participants were asked to answer the following questions about each tweet: 1) Does this text attempt to advocate for violence, hatred, discrimination, or a specific policy? 2) Does this text express a problem with a specific characteristic of an 'other'? 3) Does this text contain a propaganda device? Before starting the labeling assignment all participants were asked to take a short training that provided definitions and explanations for all four label categories.

2.2 Ground Truth Label Generation

First, a Brexit Subject Matter Expert (SME) was hired to generate ground truth labels for the collected tweets. In addition to Brexit knowledge, the SME has previous experiences examining online communication. The study also assessed SME's geo-political and demographic background. The hired SME spent a significant amount of time in Britain and was well versed with the geo-political polarization in the region. However, the SME was not a British citizen allowing an unbiased perspective. In addition to the SME, each tweet was labeled by a social scientist with expertise in inflammatory language and online propaganda. Obtaining labels from two experts was done to allow us to assess the general difficulty of the labeling task.

2.3 Participant Selection

Next, Amazon Mechanical Turk was used to hire over 100 data annotators from selected countries around the world. Figure 2 shows the distribution of participants. On average each participant took three weeks to complete the study and data labeling process. By analyzing time to label each tweet and the generated labels we detected several participants who were providing random labels or who always provided the same answer. These were removed from the study.

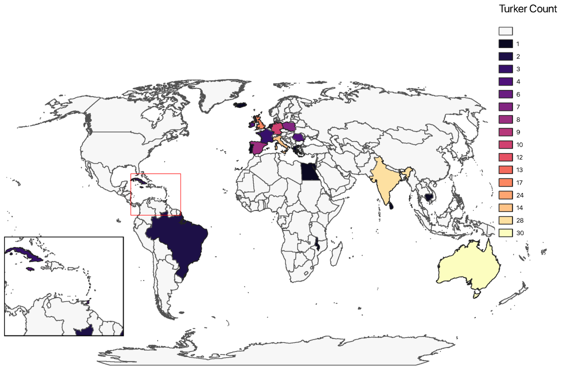

Figure 2: Data annotators were hired from all over the world from majority of the English speaking countries.

2.4 Survey

Both SME and the participants have to complete the following surveys before beginning the data labeling process. The surveys are designed to capture implicit biases.

2.4.1 Symbolic Racism 2000 Scale

Racist viewpoints are a key demographic of inflammatory hate speech. The SR2K is a widely used tool and is considered a reliable method for measuring an individual's racism (Sears and Henry, 2005). The questions within this scale measure contemporary attitudes (Henry and Sears, 2002). The SR2K was incorporated in this research because the participants are labeling data associated with racial ideologies and understanding how they feel about those ideologies is key to explaining their classification choices.

2.4.2 Moral Foundations Questionnaire

The Moral Foundations Questionnaire (MFQ) is considered to be a reliable measure of moral interests (Graham et al., 2011). The MFQ was developed based on the Moral Foundation Theory in 2008 and we used the 2011 version in this research. The MFQ was selected for use in this research because it allows us to assess participants' political leanings and their general moral preferences.

2.4.3 Knowledge Survey

The participants were given a 10 question knowledge survey that was designed to test participants' previous awareness of history associated with inflammatory speech and the Civil Rights Movement. This information is key to understanding participants' prior awareness of historic issues. The insights gained from this section will be used to compare participants' ability to identify inflammatory speech.

2.4.4 Demographics Survey

The demographic survey explored general information about the participants. The demographics collected included age, ethnicity, gender, education, marital status, employment, income, nationality, and political affiliation.

2.4.5 Social Media Background Survey

To better understand the participants' prior experience with social media the final section of the pre-survey had ten questions to address those experiences. The first four question of this section were meant to test their awareness of the most popular social media platforms. The following four questions were meant to generate a deeper understanding of the participants' personal interactions with social media platforms. The final two questions were open ended and focused on participants' profession/career, so that an understanding of their domain expertise may be gained without directly asking, as responses to a direct question on expertise may result in unreliable and exaggerated or understated responses.

2.5 Platform Development for Annotation

A interactive web-based application[2] is developed to help with the data labeling process of tweets related to Brexit. Besides, a training video with set of instructions are designed to guide users to label the data properly.

The remainder of the paper discusses the qualitative and quantitative analysis, as well as identification and ranking of characteristics indicative of a reliable data annotator.

3 Data Analysis

In this section we present the analysis of the collected data. We measure the agreement of each annotator with the SME and study the relation between the agreement and the annotator characteristics measured by the surveys. Table 1 shows the distribution of ground truth labels provided by the SME.

Table 1: Statistics of our ground truth dataset.

	True	**False**
Inflammatory	128	122
Problematization	49	201
Advocation	66	184
Propaganda	150	100

3.1 Agreement with Ground Truth

To measure the agreement of each annotator with the SME, we use Matthews Correlation Coefficient (MCC)MCC ranges from -1 (perfect disagreement) to 1 (perfect agreement) and can be calculated from confusion matrix using the following equation:

$$\mathrm{MCC} = \frac{\mathrm{TP} \times \mathrm{TN} - \mathrm{FP} \times \mathrm{FN}}{\sqrt{\mathrm{R}_{+} \times \mathrm{R}_{-} \times \mathrm{P}_{+} \times \mathrm{P}_{-}}}, \tag{1}$$

where R+ represents the sum of true positives and false negatives, R- represents the sum of false positives and true negatives, P+ represents the sum of true positives and false positives, and P- represents the sum of false negatives and true negatives. Figure 3 shows the range of MCC values for each label category. In the figure, each bar represents one annotator and the y-axis represents the MCC score. The orange bars represent labels generated by the social scientist with expertise in online inflammatory language.

In all four plots the y-axis range is -0.2 to 0.9 to allow easier comparison of results between the different categories. An interesting observation is that some label categories seem to have a higher disagreement with the ground truth. For example, this is the case for advocates violence category in the bottom left corner which tends to have lower MCC values than the other three categories. A possible explanation is that different people perceive this specific narrative category differently, while the other categories tend to be perceived more similarly.

3.2 Analysis of Survey Results

We used box plots to compare each individual survey with GT agreement. Specifically, annotators

---

[2] `https://thirdeye.ornl.gov`

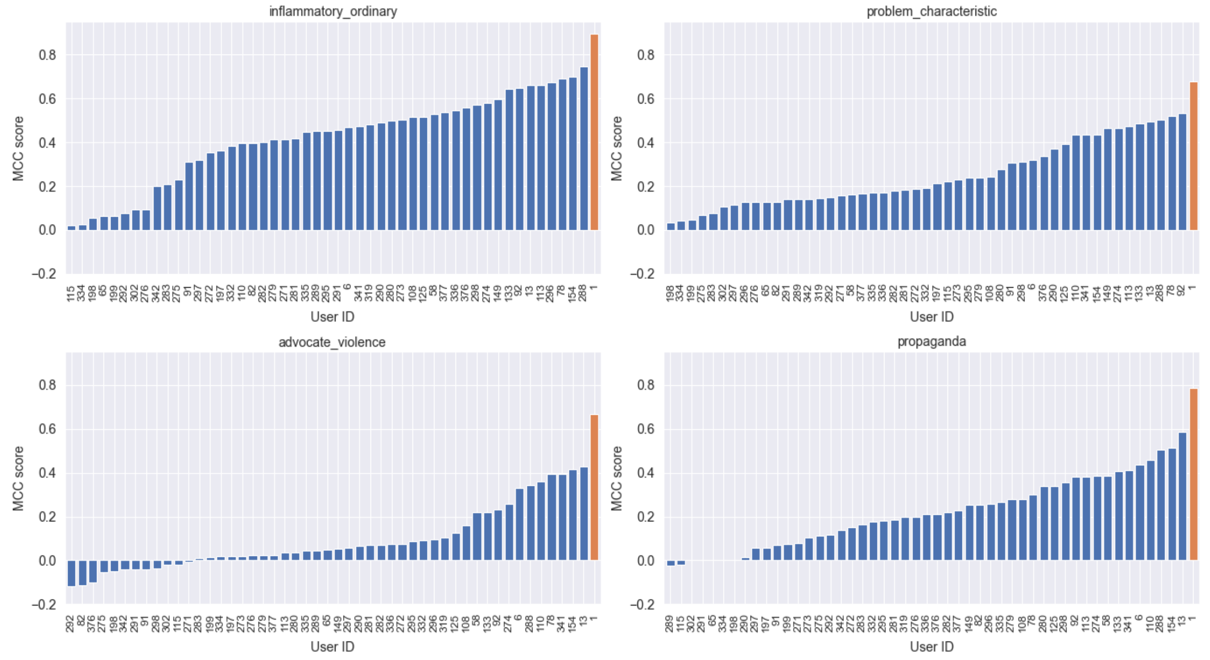

Figure 3: Annotator agreement with the ground truth (SME labels) for each of the four label categories. Each blue bar represents one annotator, while the orange bars represent annotations generated by a social scientist with expertise in online inflammatory language.

were divided into two groups according to their survey scores: group with a score lower than the median score and individuals with higher or equal to the median score. This was done for each survey separately. We plotted statistics of agreement with the GT for each of these two groups using boxplots. We also compare the groups using two-sample t-test with significance threshold of 5%. The results are snown in Figures 5, 7, and 9.

Figure 4 shows SR2K results for all annotators, and Figure 5 shows differences in agreement with the subject matter expert (SME) for individuals with low and high SR2K score. The figures are color-coded to match, i.e., the light blue bars in Figure 4 indicate which annotators belong to the light blue colored bars in Figure 5. Specifically, annotators were divided into two groups according to their SR2K score: group with a score lower than the median score (19) and individuals with higher or equal to the median score. There are 24 annotators in the former group and 25 annotators in the latter group. The figure shows there are significant differences between groups with high and low SR2K score in terms of agreement with the SME (GT), particularly when identifying tweets containing a problem characteristic and tweets advocating violence. Individuals with a higher SR2K tend to agree with the SME, on average, much less than individuals with a lower score when identifying such tweets. We compared the groups using two-sample t-test and in all cases but the first (inflammatory/ordinary) the differences in terms of MCC between the two groups are statistically significant (p-value was lower than 5%).

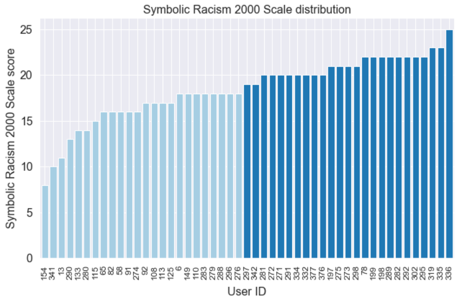

Figure 4: SR2K results for all annotators. Each bar in the figure represents one annotator. The bars are color-coded to indicate which annotators scored lower than median SR2K score, and which score higher or equal to median score.

Figure 6 shows MFQ results for all annotators. Similarly as in the case of the SR2K score, we compared the MFQ score (also called “progressivism” score) with the annotators’ MCC score (Figure 7). The results show that individuals with higher progressivism score tend to, on average, agree with the SME more than individuals with lower progres-

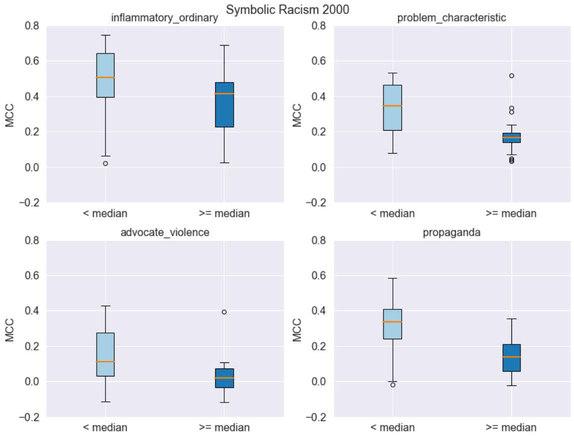

Figure 5: Comparison of the Symbolic Racism 2000 Scale results and agreement with the GT. The lighter colored bar represents the group with the lower than median SR2K score and the darker blue represents the group with higher or equal to median score.

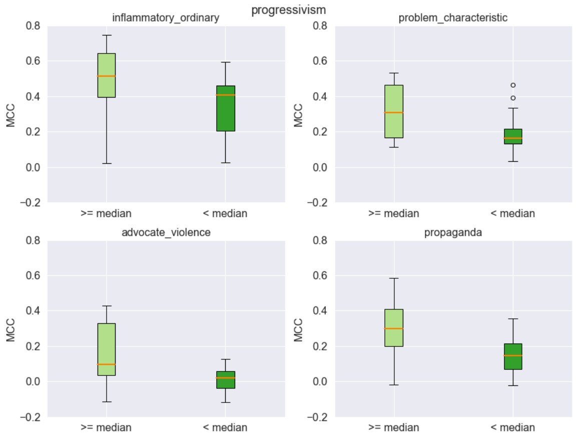

Figure 7: Comparison of the Moral Foundations Questionnaire results and agreement with the GT. The lighter colored bar represents the group with the higher or equal to median MFQ (progressivism) score and the darker bar represents the group with lower than median score.

sivism score. We compared the two groups using independent two sample t-test. The differences in MCC between the two groups statistically significant for all four narrative categories (p-value lower than 5% in all cases).

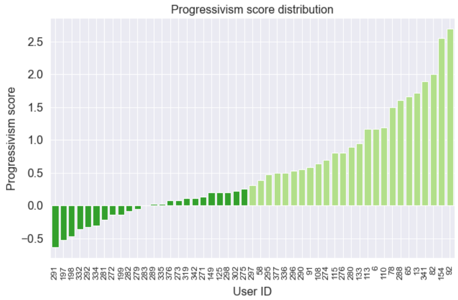

Figure 6: MFQ results for all annotators. Each bar in the figure represents one annotator. The bars are color-coded to indicate which annotators scored lower than median MFQ score, and which score higher or equal to median score.

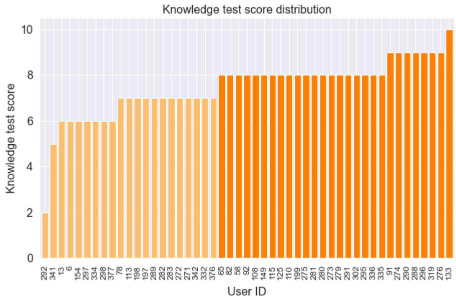

Figure 8: Knowledge Test results for all annotators. Each bar in the figure represents one annotator. The bars are color-coded to indicate which annotators scored lower than median Knowledge Test score, and which score higher or equal to median score.

Figure 8 shows Knowledge Test results for all annotators. Finally, we compared the knowledge test scores with the annotators' agreement with GT (Figure 9). In this case, we can see that there are no differences between the two groups of annotators, which was also confirmed by t-test (p-values for all four narrative categories range from 77-98%).

4 Discussion

The qualitative surveys captured a number of profile characteristics of both SME and other data annotators. As our final question, we aimed to rank the collected characteristics according to their importance towards indicating higher or lower agreement with the ground truth (SME). To do this, we calculated the following three statistics to capture the relation between each profile characteristic and agreement with the ground truth: mutual information score statistic, recursive feature elimination, and univariate linear regression test. All profile characteristics were ranked using each of these three statistics. A final rank for each profile characteristic was produced as a sum of all three individual ranks.

In Figure 10, we show the ranked characteristic from the least (Residence) to the most (purity_sanctity – a component of the MFQ) important. Thus, the results show the location of residence is the least important factor in indicating

possible agreement with the ground truth, while socio-demographic attributes such as purity, progressiveness, etc., are much more important for identifying more reliable annotators.

In Figure 11, we show top five characteristics and their average values that substantially influence the evidentiary based selection of unbiased annotators.

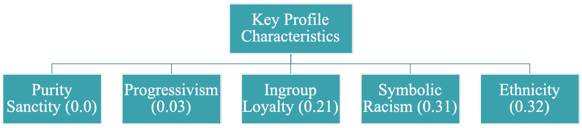

Figure 11: Key attributes and their measured average values.

Specifically, this research has strongly indicated that data reviewers morals, prejudices, and prior knowledge of the narrative in question significantly impact the quality of labeled data and consequently, the performance of ML models. ML projects that rely on labeled text data to understand narratives must qualitatively assess their data reviewers worldviews if they are to make definitive statements about their results.

For the automated detection of complex narratives, it is important that models built should be free from any implicit biases of any kind. We hope this work contributes to the broad research presently taking place across the field of machine learning to analyze and understand massive amounts of electronic communications (i.e. social media posts, news, blogs, etc.) in complex scenarios involving issues related to ethics, race, gender, and biases surrounding them.

5 Conclusion

The discipline of natural language processing and machine learning has tremendously improved in the last decade. However, it still suffers from biases surrounding complex narratives related to education, health, climate, gender, race, and ethics; especially, it unfairly penalizes certain segments of the population, e.g. women and minorities. Societal, cultural, and demographic phenomena play a pivotal role in how the population conceptualizes policy decisions and complex events. Thus, it is critical for societal good that narratives should be carefully crafted for maximum impact. It is our collective responsibility that any automation (classification, prediction, etc.) surrounding these narratives must be free of any preconceived notions or predilections of any kind. One way to achieve this is by producing high-quality input labeled data curated by annotators aware of such biases. Inspired by this, we have proposed a new framework based on mixed-method design to improve the odds of selecting annotators, who can curate unbiased and high-quality labeled data. In doing so, we identified and ranked personal and professional traits critical to selecting a diverse pool of data annotators, so the resulting labeled data and the models built using those data best matched the ground-truth. In the future, we would like to extend our study to cater to multi-lingual narratives and expand beyond existing issues of culture, region, and geopolitical dynamics.

An Evaluation of Disentangled Representation Learning for Texts

Krishnapriya Vishnubhotla[1,2], **Graeme Hirst**[1], and **Frank Rudzicz**[1,2,3]
[1]Department of Computer Science, University of Toronto
[2]Vector Institute for Artificial Intelligence

Abstract

Learning disentangled representations of texts, which encode information pertaining to different aspects of the text in separate representations, is an active area of research in NLP for controllable and interpretable text generation. These methods have, for the most part, been developed in the context of text style transfer, but are limited in their evaluation. In this work, we look at the motivation behind learning disentangled representations of content and style for texts and at the potential use-cases when compared to end-to-end methods. We then propose evaluation metrics that correspond to these use-cases. We conduct a systematic investigation of previously proposed loss functions for such models and we evaluate them on a highly-structured and synthetic natural language dataset that is well-suited for the task of disentangled representation learning, as well as two other parallel style transfer datasets. Our results demonstrate that current models still require considerable amounts of supervision in order to achieve good performance.

1 Introduction

The similarity of texts can be assessed along multiple dimensions. They could contain the same topics, as identified by semantic similarity. They could belong to the same genre or be written by the same author, in which case we might identify stylistic similarity. Texts that present a positive sentiment may be considered similar to one another when compared to those that express a negative sentiment, even if they talk about different topics. The similarity of texts, therefore, must be defined together with a frame of reference or a pre-specified dimension of variation.

Text representations obtained by current representation learning methods combine all of these different aspects of a text into a single vector embedding (Conneau et al., 2017; Reimers and Gurevych, 2019). This results in only a fuzzy measure of text similarity when it is calculated using methods such as the cosine distance between vector embeddings. Recently, some research in NLP has focused on learning *disentangled* representations for texts, which aim to capture the different dimensions of variation of a text in separate vector embeddings. These methods have been investigated for style transfer to obtain disentangled representations of content and style (John et al., 2019; Romanov et al., 2019; Cheng et al., 2020), and paraphrase generation for disentangling syntax and semantics (Chen et al., 2019; Balasubramanian et al., 2020). Inspired by parallel developments on style transfer and disentanglement in computer vision, many of them operate within the variational autoencoder framework, where the autoencoder is modified to now encode a text into two latent vectors: one capturing the style (the aspect of variation), and the other capturing the content. Style transfer is then achieved by combining the content vector of the input with a style vector of the target style.

Disentanglement-based models offer two main advantages when compared to end-to-end style transfer methods:

1. Sampling from the latent space of the style embeddings allows for more diverse and controlled stylistic generation.
2. Similarity of documents can now be calculated for each aspect of variation, allowing for finer-grained retrieval.

In this work, we focus on models that aim to disentangle **content** from **form**, or meaning from style, for texts. Thus, style transfer is viewed as a form of paraphrasing, where the paraphrase demonstrates certain stylistic properties. It is important to make this distinction between what constitutes style versus meaning for a text, more so when for-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1939–1951
August 1–6, 2021.

Meaning Representation	**name[nameVariable], food[Indian], customerRating[average]**
EXTROVERT	nameVariable is an Indian place, also nameVariable has an average rating, you know.
UNCONSCIENTIOUSNESS	Yeah, mmhm... I don't know. nameVariable is an Indian place with a damn average rating.
CONSCIENTIOUSNESS	Did you say nameVariable? I see, well it is an Indian restaurant with an average rating.
DISAGREEABLE	Actually, basically, everybody knows that nameVariable is an Indian restaurant, also it has an average rating.
AGREEABLE	Let's see what we can find on nameVariable. Well, right, it is an Indian restaurant with a quite average rating.

Table 1: The same meaning representation mapped to different stylistic surface realisations in the PersonageNLG dataset.

mulating style transfer problems, in order to have measurable definitions of what information may and may not be changed by the model. Parallel paraphrase datasets, therefore, are a much-needed resource for the effective evaluation of these models. However, few works on disentangled representation learning actually evaluate their models on such datasets, testing instead only on the non-parallel datasets used for training. Further, some works evaluate exclusively on metrics from the style transfer task, ignoring the retrieval aspect.

The goal of this study is to conduct a systematic and grounded evaluation of various disentangled representation learning models. We first use, as a testbed for our evaluation strategy, a highly-structured Natural Language Generation dataset, PersonageNLG (Oraby et al., 2018), which maps a meaning representation to a set of stylistically different surface realisations corresponding to five personality types (Table 1). This dataset provides us with textual variation and gold-standard annotations for the two dimensions of interest, content and form. The structured and somewhat synthetic nature of this dataset allows us to systematically investigate the quality of the disentangled representations for metrics of aspect-specific retrieval as well as style transfer.

We then extend our experiments to two other parallel style transfer datasets: the GYAFC formality corpus (Rao and Tetreault, 2018), and the Bible dataset (Carlson et al., 2018). Although parallel, they are not annotated for semantic content as the PersonageNLG dataset is; however, they are arguably more representative of the kinds of data we expect to obtain in the real world. Despite testing our models with loss functions that do not require parallel data, we limit ourselves to such datasets for the ease and consistency of evaluation. Our code is publicly available at `github.com/priya22/drl-nlg-eval`.

2 Background

Works on style transfer in NLP operate with varying definitions of what constitutes style. Many choose to define this as a factor of variation in data that can be manipulated, including aspects such as topic and sentiment. This approach has been contested by others who maintain that the semantic content of a text should not be modified when manipulating style. The latter definition fits with what stylometric analysis and linguistics consider to be the style of a text. Thus, the output of a style transfer system should be a paraphrase of the input text.

2.1 Model Architectures

The models used to achieve style transfer fall into a few broad categories. End-to-end sequence transformation models are inspired by machine translation seq-2-seq models, where the translation is done from style A to style B. These sometimes require parallel data, but methods such as backtranslation circumvent that (Prabhumoye et al., 2018; He et al., 2020). Some others look at this as a controlled text generation problem, where the control is generally a categorical variable indicating the desired stylistic class of the output, and is passed along with the input to a text generation module such as an LSTM (Hu et al., 2017; Ficler and Goldberg, 2017).

The focus of this work is on a third class of models that first learn disentangled latent representations of style and not-style (henceforth referred to as content) for a text, and train a generator that takes both vectors as input. To transform a text A into the style of text B, we extract the content vector of the former, the style vector of the latter, and pass them through the generator. Note that here, the style vectors of each text are not the same categorical variable, but rather a vector embedding that encodes the style-specific properties of the text. One can also obtain a single style vector representation by averaging the style vectors of all texts belonging to that class, as Fu et al. (2018) did; however, we are more interested in disentangling information at the individual text level rather than in corpus-level indicators.

2.2 Relevant Literature

Disentanglement of latent spaces has been widely studied and very successful in computer vision applications, but less so in NLP. This can be attributed to the vague nature of what actually constitutes style as opposed to content for a text, and uncertainty as to whether they can actually be disentangled at all (Lample et al., 2019; Yamshchikov et al., 2019). However, by using some supervision with respect to these two dimensions, researchers have attempted to obtain representations that *for the most part* encode information relating to only style or only semantics.

Romanov et al. (2019) first proposed obtaining separate embeddings of form and meaning of texts. Starting with an encoder-decoder setup, they added adversarial and motivational losses based on style labels that encourage the form vector to encode information relevant to the label. Their models were evaluated on non-parallel datasets with two types of stylistic variation: diachronic language shift and newspaper titles versus scientific paper titles. In parallel work, John et al. (2019) proposed a disentanglement model that appends additional content-based losses, where content is approximated by a bag-of-words representation of the text. Their approach was applied to sentiment transfer for Yelp and Amazon reviews.

Other work has looked at disentangling syntax from the semantics of a text. Chen et al. (2019) proposed a VAE-based model that used parallel paraphrase corpora; this was also the focus of Bao et al. (2019) and Balasubramanian et al. (2020).

All of these works are very similar in the base model architecture and the kinds of loss functions used to guide disentanglement. In the following sections, we consolidate and propose a broad categorization of these losses that we hope will guide future work in this area. We then evaluate these models on parallel style transfer datasets, with ablation studies on the PersonageNLG dataset.

Note on unsupervised disentanglement: While unsupervised approaches such as the β-VAE have been very successful at disentangling factors of variation in visual data (Higgins et al., 2017), we are still far from achieving such a clean separation of the data generating factors for text. A recent promising approach in this direction was presented by Xu et al. (2020), who use pretrained models along with a novel constraint over the latent space of a VAE to control the sentiment and topic of a text.

3 Methodology

3.1 Autoencoder Model

Following previous literature, our encoder module takes as input a text, and computes latent vector embeddings for each aspect: content and form. The decoder takes as input both vectors, and generates output text. The entire autoencoder model is trained to reconstruct the input text.

Let us denote our content and form encoders by E_c and E_f, the decoder by G, and their model parameters by θ_{E_f}, θ_{E_c} and θ_G respectively. Our base loss can thus be written as:

$$L_{AE} = L_{rec} + \beta L_{reg} \tag{1}$$

where

$$L_{rec}(\theta_{E_c}, \theta_{E_f}, \theta_G) = \mathop{\mathbb{E}}_{x}[-\log\, p_g(x \,|\, E_f(x), E_c(x))] \tag{2}$$

is the reconstruction loss of the autoencoder given input x, p_g is the decoder distribution, and L_{reg} is an additional regularization term. For a Variational Autoencoder (VAE) model, this is the Kullback-Leibler divergence between the latent posterior distributions q of the encoders and the latent prior $p(z)$:

$$L_{reg}(\theta_E) = D_{KL}(q(z \,|\, x) \,\|\, p(z)) \tag{3}$$

An alternative regularization for text autoencoders was proposed by Shen et al. (2020), where the AE loss is augmented with a denoising objective. The input text is perturbed with small amounts of "noise" in the form of word deletions or substitutions; the autoencoder is still trained to reconstruct the original text. Here,

$$L_{reg}(\theta_E, \theta_G) = \mathop{\mathbb{E}}_{(x,\tilde{x})}[-\log\, p_g(x \,|\, E(\tilde{x}))] \tag{4}$$

where $\tilde{x}$ is the noisy version of the input text x. These denoising autoencoders (DAEs) were shown to be more stable than VAEs for text modeling.

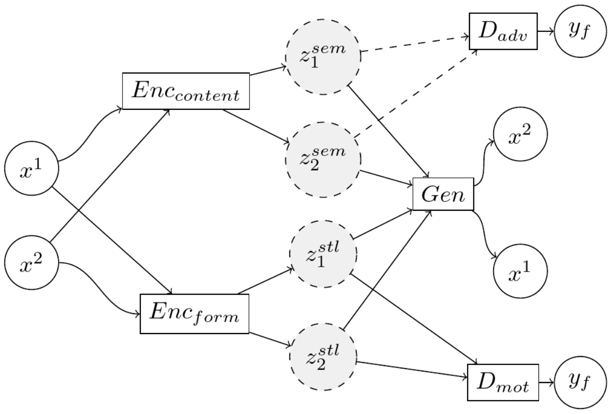

Figure 1: The main components of a Disentangled Representation Learning model. z^{sem} and z^{stl} denote the content and form vectors respectively; each is input to a motivational and an adversarial network. The generator is trained to reconstruct the original input as well as paraphrases.

3.2 Losses for Disentanglement

With our base autoencoder in hand, we can now start adding losses that encourage each latent vector to encode information relevant to the corresponding aspect, i.e, content (semantics) and form (style).

3.3 Proxy-based Losses

Supervised losses are usually based on some form of proxy information present for a specific aspect.

For the form dimension, the most common proxy is class labels that indicate the style of a particular datapoint, such as formal or informal. A stronger proxy could include a list of linguistic attributes of the sentence that are highly indicative of and inform its style. These usually have to be manually defined and extracted, as by John et al. (2019), who use high-polarity sentiment words as a proxy for the sentiment aspect.

An attribute-based proxy for content can be found by looking at the information present in, say, the meaning representation of a sentence (as provided in NLG datasets), or extracting semantics-predictive information such as semantic role labels. John et al. (2019), for example, use the bag-of-words representation of a text as a proxy for semantic information.

These additional losses are usually combined with the autoencoder objective in two ways: as a **motivational** loss, which *encourages* a latent vector to encode the proxy information, and as an **adversarial** loss, which *discourages* a latent vector from encoding the proxy information. Thus, once we define a proxy loss for, say, content, we would append a motivational loss to the content encoder and a corresponding adversarial loss to the form encoder.

Below, we use z_c and z_f to denote the content and form vectors of a text x.

3.3.1 Loss Functions for Form

Motivational: For the datasets that we consider here, and in most real-world applications, we have the stylistic class of a text as a proxy for the form aspect. The motivational and adversarial networks are implemented as classifiers that are trained to predict this label from the corresponding latent representation. The loss function of the former is simply the cross-entropy loss of the classifier:

$$L_{mot}(\theta_D, \theta_{E_f}) = \underset{z_f}{\mathbb{E}}[-\log\ D(z_f)] \tag{5}$$

D and θ_D represent the classifier and its parameters respectively.

Adversarial: We now want to ensure that the content vector does not contain any information about the form class of the text. Thus, we aim to *maximize* the entropy of the adversarial classifier. This is the approach followed by many prior works (John et al., 2019; Fu et al., 2018), which we also adopt here, as it can be nicely extended to multi-label classification, which will prove useful in the content-based losses.

Adversarial training occurs in two steps. First, the classifier is trained to predict the form label given the content representation. Then, the content encoder's parameters are updated based on the entropy loss:

$$L_{adv}(\theta_D) = \underset{z_c}{\mathbb{E}}[-\log\ D(z_c)] \tag{6}$$

$$L_{adv}(\theta_{E_c}) = \underset{z_c}{\mathbb{E}}[\mathbb{H}(D(z_c))] \tag{7}$$

where $\mathbb{H}(D(z_c))$ is the entropy calculated over the classifier-predicted label distribution.

3.3.2 Loss Functions for Content

Proxy information for content is generally rare, and needs to be formulated by means of some heuristic measure. In the case of NLG datasets, we have annotated meaning representations that serve as a good proxy. However, such structured representations of meaning are difficult to obtain for general texts.

Let us assume we have a list of k key-value pairs that represent content, as in the MR from Table 1.

We represent the content proxy as a k-dimensional multi-hot vector y_c, where each dimension y_c^i is a binary indicator of whether key k_i is present in the MR.

Motivational: The motivational loss is thus defined as the multi-label cross-entropy loss over the classifier prediction, similar in form to Eq. 6, but now taking the content vector as input.

Adversarial: In turn, the adversarial content loss is found by first training a multi-label classifier that takes the form vector as input and predicts the content attribute vector, and then training the form encoder to maximize the entropy of this classifier.

3.4 Parallel Losses

These losses require as input a pair of paraphrases, say x^1 and x^2. We obtain the latent vectors for content and form for each of these: $z_c^1, z_f^1, z_c^2, z_f^2$ respectively.

Paraphrase reconstruction loss: Here, we swap the content vectors of the paraphrases, retain the form vectors, and attempt to reconstruct the original inputs. This was used by Chen et al. (2019) to disentangle syntax and semantics in paraphrase corpora.

$$\begin{aligned} L_{para}(\theta_{E_c}, \theta_{E_f}, \theta_G) = & \mathop{\mathbb{E}}_{x_1,x_2}[-\log\ p_g(x^1 \mid z_f^1, z_c^2)] \\ & + \mathop{\mathbb{E}}_{x_1,x_2}[-\log\ p_g(x^2 \mid z_f^2, z_c^1)] \end{aligned} \tag{8}$$

Distance-based loss: This takes the form of a max-margin loss that aims to keep the cosine similarity between the content embeddings of paraphrases higher than that between a random selection of negative example pairs. This particular loss is used by Chen et al. (2019) and Balasubramanian et al. (2020) to disentangle syntax and semantics, although they differ slightly in the criteria to select positive and negative pairs.

4 Datasets

PersonageNLG Dataset: The PersonageNLG corpus (Oraby et al., 2018) is a set of 88,000 pairs of meaning representations and natural language utterances, based on the E2E challenge dataset. Each utterance is associated with a unique style, which corresponds to one of five personality types: Agreeable, Disagreeable, Conscientious, Unconscientious, and Extrovert. The utterances are obtained by means of a statistical NLG system, and by varying a set of 36 predefined stylistic parameters that specify certain phrase aggregation and pragmatic markers (Table 1). The dataset essentially provides us with a structured and synthetic corpus of textual variation, with each utterance annotated for both content (a meaning representation) and form (the stylistic personality class). This makes it ideal for evaluating the quality of disentangled representations.

GYAFC Dataset: Introduced by Rao and Tetreault (2018), the GYAFC corpus consists of 120,000 parallel sentence pairs that are paraphrased in two styles: formal and informal. See section A.1 for details. GYAFC is one of the very few parallel datasets available for style transfer research in NLP.

Bible dataset: This dataset, compiled by Carlson et al. (2018), consists of eight verse-aligned public domain versions of the Bible; see section A.2 for details. These versions are spread out across different decades, and thus belong to their own unique stylistic class. The natural parallel alignment between verses, as well as the relatively stable nature of their semantic content across time, makes this dataset ideal for studies in style transfer (although surprisingly few works on style transfer use it).

5 Evaluation

The goal of our model is to encode in separate vectors the style-specific and content-specific features of a text. The following metrics guide our similarity measures for content and form:

- **Content (C_{sim}):** For the PersonageNLG dataset, content similarity between two sentences is measured as fraction overlap between content labels (Section 3.3.2). For generated sentences, we use all possible slot values for each field of the Meaning Representation (Table 1) to approximate a bag-of-words content representation, and calculate fraction overlap of content terms in both sentences. For the other two datasets, we use the BLEU scores between the generated text and the target paraphrase as a measure of content preservation.

- **Form (F_{class}, F_{sim}):** For all three datasets, we first train a fasttext[1] classifier on their respective training sets to predict stylistic class given the input text (F_1 scores on the test sets

---

[1] https://fasttext.cc/

are shown in Table 2). This classifier is then used to predict the style class of a generated text. F_{class} is the F_1 score of the predicted labels for generated texts, using the target labels as ground truth.

Additionally, for the NLG dataset, we use an F_{sim} measure that measures the fraction overlap of non-content words of the two texts, where "non-content" is defined as all words that are not associated with content as defined above.

We divide our evaluation metrics into three groups, based on the capabilities and use-cases of learning disentangled representations.

5.1 Autoencoder Capabilities

Reconstruction: One of the basic functions of our model is as an autoencoder, i.e., a model that can reconstruct the input text from its latent encoding. We use the self-BLEU score between the input (reference) and the generated text to measure reconstruction quality.

5.2 Disentanglement

The quality of disentanglement of representations is assessed in two main ways.

Classification: The first is a classification task that aims to predict the proxy information for each text using the latent vectors. For each of our dimensions of content and form, this gives us four measures corresponding to the accuracy of a classifier trained to predict content (form) information from the content (form) vectors, and that of a classifier trained to predict form (content) information from the content (form) vectors. Ideally, we want the former numbers to be high and the latter to be close to random chance.

Retrieval: As stated, one of the advantages of having disentangled representations for each aspect is that we can now obtain aspect-specific similarity scores. Since all our datasets are parallel paraphrase corpora, we can measure how well the content vectors perform at retrieving paraphrases. For each sentence in our test set, we obtain the cosine similarity scores of its content vector with that of every other sentence, and look at how many of the top-k matches are paraphrases of the input. We evaluate this for $k = 5$ for the GYAFC and Bible datasets, and $k = 1$ for the NLG corpus.

Similarly for form, we find the top-k neighbours for the form vector of each sentence and report the precision@k of retrieving texts from the same stylistic class. This metric is particularly informative for PersonageNLG, where we look at the F_{sim} between the input and the closest match.

Dataset	**F_1 score**
PersonageNLG	0.99
GYAFC	0.87
Bible	0.72

Table 2: Performance of the external fasttext classifier on test sets.

5.3 Style Transfer

Finally, we evaluate the effectiveness of our model for the task of style transfer, by testing with paraphrase pairs. Thus, for each pair of paraphrases in the test set, we obtain the content vector of the first and the form vector of the second, and pass them to the decoder module (and vice-versa). The **content preservation** and **transfer quality** of generated sentences are measured using C_{sim} and F_{class} respectively. We also measure the **fluency** of the generated text by measuring the perplexity of generated sentences with a trigram Kneser-Ney language model trained on the training set of each dataset.

6 Experiments

6.1 Setup

The encoder and decoder of our base model are 2-layer LSTM networks with a hidden size of 64. Both the content and form vectors are of the same size for each dataset: 16 for PersonageNLG and 32 for the others. At each decoder timestep, the concatenated latent vector $z = [z_c, z_f]$ is added to the input to obtain the next prediction. During training, teacher forcing with probability 0.4 is used; we use greedy decoding for the PersonageNLG dataset and and beam search with a beam size of 5 otherwise. Motivational and adversarial classifiers are single-layer linear networks trained with RMSprop.

The GYAFC and NLG datasets come with predefined training and test splits. For the Bible dataset, we use a random stratified split with 65–15–20 split for training, validation, and test respectively.

6.2 Experimental Method

Our goal is to methodologically evaluate the effectiveness of each of these losses for disentangling content from form. We start with our vanilla autoencoder model (L_{ae}), and at each step, add additional losses based on incorporating some supervised information into our model. The terms we add are guided by some intuition on the kinds of supervision we would expect to see in the real world.

1. **Form losses L_{form}:** This assumes that each text is labeled with a class that indicates its stylistic category, such formal / informal, Shakespearean / modern, positive / negative, etc. This enables us to append two of our losses to the base loss: the motivational and adversarial form losses (Section 3.3.1).
2. **Motivational only L_{mot}:** We now add our proxy information for content. We first keep only the motivational losses and remove the adversarial losses for each aspect.
3. **Combined proxy losses L_{proxy}:** We add adversarial losses for form and content to the model above, giving us our full proxy-loss–based model.
4. **Paraphrase losses:** Finally, we add the parallel losses detailed in Section 3.4, taking advantage of our parallel datasets. The alignment of two paraphrases essentially acts as a proxy for the equivalence of semantic content between two texts. Accordingly, we test the following loss combinations:
   - Parallel losses only (Section 3.4) (L_{para});
   - Parallel losses + form losses from point 1 above (L_{para_f}).

Baseline: We additionally compare the effectiveness of these models when compared to a categorical conditional generation model. Here, the form vector is simply an 8-dimensional encoding of the style class label, rather than derived from the input text. The model is trained using the F_{adv} and C_{mot} losses to ensure the content embedding doesn't encode style information, along with the reconstruction loss L_{rec}.

All of these loss combinations are tested on the PersonageNLG dataset, since it is annotated with proxies of both content and form.

7 Results and Discussion

We experimented with both the VAE and the DAE models for our base architecture, and found that the latter was more stable during training. Training the VAE with multiple latent vectors and additional losses often resulted in the model completely ignoring one of the latent vectors; stable modeling of such architectures is still an active area for text data and is left to future work.

7.1 Disentanglement

We first examine how well our models are able to disentangle information pertaining to form and content into the respective latent vectors. Table 3 reports the performances of each model for the metrics discussed in Section 5.2. For conciseness, we only report cross-aspect classification scores in the Classification column, where a lower number indicates better disentanglement. More detailed results with same-aspect scores are presented in Appendix C.1.

In the absence of parallel data, we see that directly adding supervised losses along each dimension is the most effective strategy of disentangling information. Accordingly, the largest performance drops on cross-aspect classification are achieved with the addition of motivation losses L_{form} and L_{mot} for form and content. Adversarial losses do help the overall performance of the model as demonstrated by the drop in cross-aspect classification metrics, especially in the form domain. The maximal supervision afforded by the paraphrase losses L_{para} demonstrates a significant improvement over the best proxy-based model here, indicating that proxy information is generally not complete enough to capture semantic content. However, the lack of similar supervision along the form dimension is reflected in the higher cross-aspect classification scores across all models.

We show t-SNE plots of the form and content vectors computed by each model in Appendix B. The paraphrase model gives us neat clusters of the content vectors corresponding to the different meaning representations.

However, classification numbers alone don't present the whole picture. Our measures of retrieval quality help to isolate the effects of classifier effectiveness from the goodness of the representations alone. For the NLG dataset in particular, the retrieval scores tell us whether the form vector of a text actually encodes information about the linguistic features informing its style, rather than simply encoding enough to be classified in the right stylistic class. Are sentences with similar

	Autoencoder	**Disentanglement**			
	BLEU	Classification: $F_1 \downarrow$		Retrieval $\uparrow$	
Target →		Form	Content	Form	Content
Input →		z_c	z_f	z_f	z_c
$L_{ae}*$	43.4	0.96	0.73	0.57	0.85
L_{form}	−0.07	−0.67	−0.11	0.13	0.08
L_{mot}	0.01	−0.31	**−0.14**	0.08	0.13
L_{proxy}	−0.05	−0.73	−0.13	**0.13**	**0.14**
L_{para}	0.06	−0.68	−0.03	0.11	0.13
L_{para_f}	−0.03	**−0.75**	−0.10	0.12	0.12
$L_{baseline}$	−0.03	−0.65	–	–	0.09

Table 3: Results on reconstruction and disentanglement quality for the PersonageNLG dataset. The first row reports the absolute metric for the base autoencoder model L_{ae}; subsequent rows report the difference from this base score. The first column reports the self-BLEU score between the reconstructed and input text. For classification, we report the cross-aspect F_1 scores of a classifier trained to predict the target aspect from the input. For retrieval, we report the C_{sim} and F_{sim} scores between the input text and its nearest neighbour in the latent space.

textual stylistic or content features closer to each other in the embedding space when compared to other sentences from the same style/content class? The relatively low delta scores when compared to classification performance indicate that this is not the case. While there are marginal improvements, proxy-based losses don't seem to be informative enough to enforce fine-grained structure in the latent space. Our experiments on style transfer in the next section reinforce this conclusion.

7.2 Style Transfer

We swap the form and content vectors of paraphrases from our test set, and evaluate the generated sentences using the metrics defined in Section 5.3. For the NLG dataset, as before, we use term-overlap measures of the similarity for the content and style terms between the generated text and the target paraphrase (C_{sim} and F_{sim}); results are shown in Table 4. Both of these measures are far from their ideal values of 1.0.

The full proxy model L_{proxy} achieves the best performance across all metrics (sample outputs are shown in Appendix C.2). The paraphrase models tend to perform worse than the baseline, especially on the transfer strength metric, F_{sim}. This points to the form vector not being informative enough, especially when no motivational losses are used. It also indicates that the adversarial losses from the proxy-based models were indeed helpful in disentanglement.

We see similar trends in both disentanglement quality and style transfer for the GYAFC and Bible datasets. The quality of text generated was significantly worse when compared to the NLG dataset, but we are still able to encode the style and content-related information in separate vectors with some success, as evidenced by the retrieval scores.

	$C_{sim} \uparrow$	$F_{sim} \uparrow$	Fluency $\downarrow$
L_{ae}	0.29	0.46	1.11
L_{form}	0.28	0.58	1.08
L_{mot}	0.36	0.48	1.09
L_{proxy}	**0.39**	**0.72**	1.10
L_{para}	0.33	0.45	1.11
L_{para_f}	0.35	0.55	1.09
$L_{baseline}$	0.30	0.60	1.06

Table 4: Evaluation of style transfer on the PersonageNLG dataset. Arrows denote desired direction of change.

7.2.1 Does Disentanglement Help?

Our comparison with the categorical baseline $L_{baseline}$ tells us whether learning disentangled representations indeed provides an advantage for the style transfer task. From Table 4, we see that it does quite well on the C_{sim} metric, but is notably lower than L_{proxy} for F_{sim}. This demonstrates the advantage of having a separate vector representation of the form of a text, as opposed to the stylistic class.

7.3 Discussion

Our experiments all demonstrate that direct supervision along each aspect is crucial for learning good aspect-specific representations. This is the case even for the synthetic PersonageNLG dataset,

		Disentanglement		Style Transfer	
		Clf. ↓	Ret. ↑	C_{sim} ↑	F_{class} ↑
GYAFC	L_{base}	0.43	0.20	1.5	0.50
	L_{para_f}	0.35	0.49	3.6	0.83
Bible	L_{base}	0.64	0.25	1.3	0.11
	L_{para_f}	0.12	0.72	3.4	0.39

Table 5: Results on disentanglement quality and style transfer for the GYAFC and Bible datasets. The Clf. column reports the F_1 score of a classifier trained to predict the stylistic class label from the content vector; Ret. reports the P@5 for retrieving paraphrases using the content vectors.

which is by design constrained to have two separable aspects of variation (meaning and style); this is quite rare in real-world data. Indeed, the best performing style transfer model on this dataset, from Harrison et al. (2019), is a heavily supervised one that conditions a seq-2-seq model with annotations for each type of variation in the surface realisations (i.e., the presence of certain tokens).

In the absence of parallel datasets, proxy information is widely used to encourage disentanglement. However, our results show that such supervision is not sufficient to ensure that the embeddings actually encode the linguistic properties that are characteristic of a text's stylistic class (or meaning). With the retrieval experiments on the NLG dataset, we can see that the F_{sim} scores do not significantly differ between the different models. This indicates the difficulty of learning linguistic properties from class labels alone. This also explains the rather high F_1 scores for content classification from form embeddings.

The poor performance of these models on the style transfer task in particular indicates that the decoder, and hence the reconstruction objective itself, is somewhat lacking. This is reflected in the high classification scores of content information from form vectors, especially for the paraphrase model L_{para}. Additional constraints such as the backtranslation loss (Prabhumoye et al., 2018) go some way towards mitigating this issue. On the style transfer task, the baseline model $L_{baseline}$ shows performance comparable to the disentanglement models. One explanation for their poor performance is the inherent defects of variational models of text, such as the latent space vacancy issue, as demonstrated by other works (Xu et al., 2020; Shen et al., 2020).

For evaluation of such disentangled representations, traditional metrics of style transfer, such as the accuracy of an external classifier, are not the best indicators of disentanglement, nor a good demonstration of the usefulness of such embeddings. Most works on disentangled representations for style transfer do end up using a single, averaged vector embedding to inform the decoder of the desired target style. If the goal of learning disentangled representations is to perform style transfer between two classes, then a conditioned language model such as that of Ficler and Goldberg (2017) would suffice.

A more useful use-case for disentangled representations is for calculating aspect-specific similarity and retrieval between texts. However, it is not clear whether we can achieve such disentanglement with current models without fine-grained supervision along each aspect. While the NLG dataset provides us with the necessary supervision to introduce such constraints (via adversarial losses), and also evaluate them, such supervision is not available for real-world datasets.

8 Conclusion

Encoding the different factors of variation in data in separate embeddings is a desirable goal for learning robust and interpretable text representations, as well as for controllable text generation. While style transfer, and sentiment transfer in particular, has guided most of the prior research in this area, we have shown that the associated metrics and datasets are not entirely representative of the goals of learning disentangled text representations. We re-purposed an existing NLG dataset for this task instead, and performed a stronger evaluation of current models for disentangled representation learning. We have also shown that heavy supervision is needed along each aspect to obtain useful representations. Improvements in variational generative models that can overcome issues of posterior collapse and the use of decoding constraints stronger than the reconstruction loss would greatly benefit such models.

Appendices

A Parallel Style Datasets

A.1 GYAFC Corpus

The *Grammarly's Yahoo Answers Formality Corpus*, or GYAFC for short, is a benchmark corpus for formality style transfer in NLP[2]. It consists of a total of 120,000 informal / formal sentence pairs, split into training, validation, and test sets.

Sentences were initially sampled from the Yahoo Answers L6 corpus, and formal and informal rewrites from each were collected from workers on Amazon Mechanical Turk (Rao and Tetreault, 2018). Table 6 shows example paraphrases from this corpus.

A.2 Bible Dataset

More than 30 English translations of the Bible have been published over the course of four centuries, the earliest being the King James Version of 1611. These versions are all highly parallel, aligned by verse, and are high-quality translations due to the importance of the source. Carlson et al. (2018) identified 8 of these versions that are in the public domain and released aligned corpora for each[3]. Table 7 shows a sample verse paraphrased in each of the 8 versions we consider. Each version consists of 31,096 verses, giving us close to 870,000 paraphrase pairs. We first split this into an 80–20 development–test split; the development set is further split into training and validation sets with the same ratio.

Formal	I'd say it is punk though.
Informal	However, I do believe it to be punk.
Informal	Gotta see both sides of the story.
Formal	You have to consider both sides of the story.

Table 6: Sample paraphrases from the GYAFC dataset.

B t-SNE Visualization

t-Distributed Stochastic Neighbor Embedding is a non-linear dimensionality reduction technique useful for visualizing high-dimensional data. Figure 2 shows t-SNE plots of the form vectors (left column) and content vectors (right column) for sentences in the test set of the PersonageNLG dataset, for each of the loss function combinations we tested. Adding the supervised losses for form successfully groups the form vectors together into five clusters for each of the personality classes. While content vectors also show some clustering with the adversarial and motivational losses, paraphrase losses here are the most effective at grouping them into neat clusters for each of the unique meaning representations in our test set.

C More Results

C.1 Detailed Disentanglement Evaluation

In Table 8, we present a more detailed evaluation on the disentanglement metrics for our models. Here, the Classification column presents both same-aspect and cross-aspect F_1 scores. Higher scores for the former and lower scores for the latter indicate better disentanglement.

We notice that form information is not effectively removed from the content representations, as evidenced by the higher F_{sim} scores for the content vectors z_c. This is a consequence of the weaker label-based proxy used for style, as opposed to the Meaning Representation-based attribute proxy for content.

C.2 Style Transfer Outputs

Table 9 shows sample outputs from the style transfer experiments on PersonageNLG. The model used is the best performing proxy-based model L_{proxy}, with motivational and adversarial losses for both style and content. Two paraphrases with different styles are first encoded into their form and content vectors. The output is generated by passing the form vector of the first sentence and the content vector of the second to the decoder. We see that the model transfers the form attributes quite well across the inputs, but content attributes are not retained perfectly.

Abstract

We consider a joint information extraction (IE) model, solving named entity recognition, coreference resolution and relation extraction jointly over the whole document. In particular, we study how to inject information from a knowledge base (KB) in such IE model, based on unsupervised entity linking. The used KB entity representations are learned from either (i) hyperlinked text documents (Wikipedia), or (ii) a knowledge graph (Wikidata), and appear complementary in raising IE performance. Representations of corresponding entity linking (EL) candidates are added to text span representations of the input document, and we experiment with (i) taking a weighted average of the EL candidate representations based on their prior (in Wikipedia), and (ii) using an attention scheme over the EL candidate list. Results demonstrate an increase of up to 5% F1-score for the evaluated IE tasks on two datasets. Despite a strong performance of the prior-based model, our quantitative and qualitative analysis reveals the advantage of using the attention-based approach.

1 Introduction

Information extraction (IE) comprises several subtasks, e.g., named entity recognition (NER), coreference resolution (coref), relation extraction (RE). State-of-the-art results mainly report performance on single tasks, usually solving them on a sentence level (especially NER, RE). However, in practice, IE system decisions should be consistent on the document level, e.g., when processing news articles to automatically link entities (aside from potentially learning, e.g., new relations). Yet, the challenge of solving the tasks jointly on a document level has not received as much attention and remains hard (Durrett and Klein, 2014; Yao et al., 2019; Zaporojets et al., 2021).

On the other hand, it is well established that IE models benefit from incorporating background information of knowledge bases (KBs). Still, so far this has been shown from the perspective of solving individual tasks such as relation classification or entity typing (e.g., Peters et al. (2019); Liu et al. (2020)). Integrating KBs in joint models, realizing and analyzing the more complex end-to-end setting, has been left unexplored.

In terms of the nature of KBs adopted in IE, current approaches use either (i) structured knowledge *graphs* comprising `(subj,rel,obj)` triples, e.g., Wikidata (Yang and Mitchell, 2017; Han et al., 2018; Zhang et al., 2019), or (ii) *textual* descriptions, usually in hyperlinked documents, e.g., Wikipedia (Martins et al., 2019; Yamada et al., 2020). It has not been established to what extent KB-text and KB-graph entity representations complement each other in boosting IE performance.

We address both research gaps of (a) integrating KB information into a joint end-to-end IE model for solving named entity recognition, coreference resolution and relation extraction, and (b) analyzing what KB representation is more beneficial for IE, either *KB-graph* trained on Wikidata, or *KB–text* trained directly on Wikipedia. We particularly contribute: (i) a first span-based end-to-end architecture incorporating KB knowledge in a joint entity-centric setting, exploiting unsupervised entity linking (EL) to select KB entity candidates, (ii) exploration of prior- and attention-based mechanisms to combine the EL candidate representations into the model, (iii) assessment of the complementarity of KB-graph and KB-text representations, and (iv) consistent gains of up to 5% F1-score when incorporating KB knowledge in 3 document-level IE tasks evaluated on 2 different datasets.

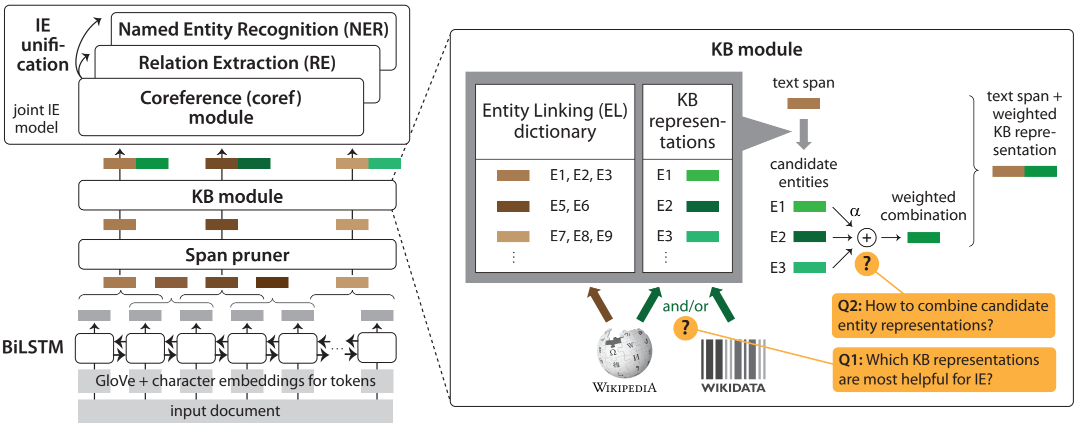

Figure 1: Joint information extraction (IE) model with addition of a knowledge base (KB) module.

2 Model

Figure 1 illustrates our model architecture. Input document tokens are represented using concatenated GloVe (Pennington et al., 2014) and character embeddings (Ma and Hovy, 2016) and pushed through a BiLSTM to obtain contextualized token representations, which are combined into spans. Similar to Luan et al. (2019); Zaporojets et al. (2021), a span pruner limits the number of spans for downstream modules. The *KB module* (§2.2) combines span representations with KB entity representations (§2.1), trained either on Wikidata (*KB-graph*) or Wikipedia (*KB-text*). The KB-enriched span representations then serve as input for joint predictions on downstream IE tasks (§2.3).

2.1 Entity Representations

We experiment with 3 possible entity representations: *KB-text*, *KB-graph*, and concatenating *both*.

KB-text: We follow Yamada et al. (2016) to obtain the entity representations using a skip-gram architecture (Mikolov et al., 2013a,b), training to jointly predict (i) the linked entities (through Wikipedia hyperlinks) given the target entity, and (ii) the neighboring words for a given entity hyperlink.

KB-graph: We adopt Joulin et al. (2017) to train the entity embeddings directly on Wikidata triples `(subj,rel,obj)` by optimizing a linear classifier to predict the `obj` entity from the `subj` entity and the relation type `rel`.

2.2 KB module

For a span s_i from token l to r, we obtain the representation $\mathbf{g}_i$ as input to the KB module by concatenating the respective hidden LSTM states $\mathbf{h}_l$ and $\mathbf{h}_r$, and an embedding $\boldsymbol{\psi}_{r-l}$ for the corresponding span width $r-l$:

$$\mathbf{g}_i = [\mathbf{h}_l; \mathbf{h}_r; \boldsymbol{\psi}_{r-l}]. \tag{1}$$

We look up a given span s_i in a dictionary built from Wikipedia, to determine its candidate entities set[1] C_i, as well as the prior probability p_{ij} for each $c_{ij} \in C_i$, as per Yamada et al. (2016, §3).

To combine the KB candidates c_{ij}, we either use (i) a uniform average (*Uniform*), (ii) the prior weights p_{ij} (*Prior*), (iii) an attention scheme (*Attention*), or (iv) attention with prior information (*AttPrior*). The unnormalized attention scores for *Attention* and *AttPrior* are:

$$\Phi_{\mathit{Attention}}(s_i, c_{ij}, \mathrm{K}) = \mathcal{F}_A\left([\mathbf{g}_i; \boldsymbol{\xi}_{\mathrm{K}}(c_{ij})]\right) \tag{2}$$

$$\Phi_{\mathit{AttPrior}}(s_i, c_{ij}, \mathrm{K}) = \mathcal{F}_{AP}\big([\mathbf{g}_i; \boldsymbol{\xi}_{\mathrm{K}}(c_{ij}); p_{ij}]\big) \tag{3}$$

where $\mathrm{K} \in \{\mathit{KB\text{-}text}, \mathit{KB\text{-}graph}, \mathit{both}\}$ refers to the entity representations from §2.1, $\boldsymbol{\xi}_{\mathrm{K}}$ returns such representation for c_{ij}, and $\mathcal{F}_*$ is a feed-forward neural network (FFNN). The KB representation for span s_i is a weighted average of its candidates C_i:

$$\mathbf{e}_i^{\mathrm{K}} = \sum_{c_{ij} \in C_i} \alpha_{ij} \cdot \boldsymbol{\xi}_{\mathrm{K}}(c_{ij}) \tag{4}$$

where weights α_{ij} either are uniform ($1/\left|C_i\right|$), the prior p_{ij}, or softmax-normalized attention scores (softmax over Φ from eq. (2) or eq. (3)). The concatenation $[\mathbf{g}_i; \mathbf{e}_i^{\mathrm{K}}]$ forms the KB-enriched representation for span s_i, as input for IE modules (§2.3).

2.3 Joint IE model

The joint IE model comprises 3 modules (Fig. 1) using the same KB-enriched representations $[\mathbf{g}_i; \mathbf{e}_i^{\mathrm{K}}]$,

---

[1] We limit this to the 16 most frequent ones.

Dataset	# Entity clusters	# Entity types	# Relations	# Relation types
DWIE	23,130	311	21,749	65
DocRED	98,610	6	50,503	96

Table 1: Dataset statistics.

and using a weighted combination of the 3 module losses to minimize during training. Note that NER and RE are framed as multi-label classification.

NER module: We use a FFNN on each span s_i to produce scores $\mathbf{\Phi}_{\text{NER}}(s_i) \in \mathbb{R}^{|L_E|}$, with L_E the set of possible entity types. At inference, we accept type $l \in L_E$ for span s_i if $\mathbf{\Phi}_{\text{NER}}(s_i)_l > 0$.

Coref module: We use the coreference scheme proposed by Lee et al. (2017), using a FFNN to produce scores $\Phi_{\text{coref}}(s_i, s_j)$: at inference time, the highest scoring antecedent of span s_j is then chosen (potentially s_j itself). Indeed, to allow for singletons we accept self-references (s_j, s_j) if NER predicts the span s_j to be an entity.

RE module: Similar to Luan et al. (2019, 2018), we use a FFNN to produce scores $\mathbf{\Phi}_{\text{RE}}(s_i, s_j) \in \mathbb{R}^{|L_R|}$ for each pair of spans (s_i, s_j), with L_R the set of relation types. We accept relation $l \in L_R$ for pair (s_i, s_j) if $\mathbf{\Phi}_{\text{RE}}(s_i, s_j)_l > 0$.

IE unification: Above modules make span level predictions. We obtain entity-centric predictions using the coref clusters, by assigning the union of predicted entity/relation types within a coref cluster to all its members, as do Zaporojets et al. (2021).

3 Experimental Setup

We evaluate our proposed models[2] on entity-centric multi-task datasets, summarized in Table 1: DWIE (Zaporojets et al., 2021) and DocRED (Yao et al., 2019). We report on coreference resolution (coref), NER and relation extraction (RE). For coref, we report the average of 3 common F1 scores, as implemented by Pradhan et al. (2014): MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998) and CEAF_e (Luo, 2005). Since we focus on entity-centric, document-level IE, for NER and RE we use *hard* metrics (Zaporojets et al., 2021) on the level of entity clusters (i.e., aforementioned coref clusters): predictions are counted as correct only if (i) all mentions (with exact boundary match) are present in the entity cluster, and (ii) the predicted entity type (for NER) or relation type between two clusters (for RE) is correct.

Our experiments address 2 main questions (see Fig. 1): **(Q1)** Which type of KB representation is most helpful for IE (*KB-text*, *KB-graph*, or *both*; see §2.1)? **(Q2)** Which weighting scheme to use for α (*Uniform*, *Prior*, *Attention*, *AttPrior*; see §2.2)?

4 Results

We summarize the comparison of various model choices for both DWIE and DocRED datasets in Table 2. First, looking into **(Q1)**, we note that including background information from *KB-graph* and *KB-text* significantly boosts performance compared to the *Baseline* without any KB. Additionally, our model outperforms the results from Zaporojets et al. (2021) (not listed in the table) by about 2 percentage points F1, using the same input (GloVe) representations. Furthermore, we observe a general improvement in results when combining *both* representations, suggesting that a (hyper)text corpus (Wikipedia) and a knowledge graph (Wikidata) embed complementary information for raising IE performance.

Deeper analysis reveals that adding KB representations mainly benefits performance for "rare" entity types: e.g., limiting the test set to entity types that occur ≤50 times in the training set for DWIE, compared to *Baseline*, F1 for NER goes up by +13.9 for *KB-both* with *AttPrior*, while the benefit gradually decreases for more frequently occurring entity types. For RE, we note that overall we also see a clear performance gain from adding KB information (e.g., +5.1% F1 for *both* KB sources with *AttProp* compared to *Baseline* for DWIE), yet the boost is not as clear for relations with fewer training instances. (The latter makes sense, since we inject KB representations of entities rather than explicitly also for relations; we leave studying adding relation embedding information for future work.)

Second, for **(Q2)**, we note that the *AttPrior* scheme is the overall winner among the different EL candidate weigthing schemes. We observed that in terms of ranking EL candidates, *Prior* performs quite well on DWIE — for 86.5% of entity mentions it assigns the highest score to the correct EL candidate, while *Attention* and *AttPrior* achieve it for 46.2%, resp. 77.2% of the mentions — which basically confirms that DWIE has a similar entity distribution as Wikipedia.[3] Yet, it seems necessary to include alternative candidates, and

Table 2: Main results of the experiments in F1 scores grouped by the background KB source. We report Avg. F1 scores of MUC, B^3 and $CEAF_e$ for Coref, and hard F1 metrics for NER and RE. **Bold** font indicates the best results for each of the different *KB source* types. Additionally, the best overall results are underlined.

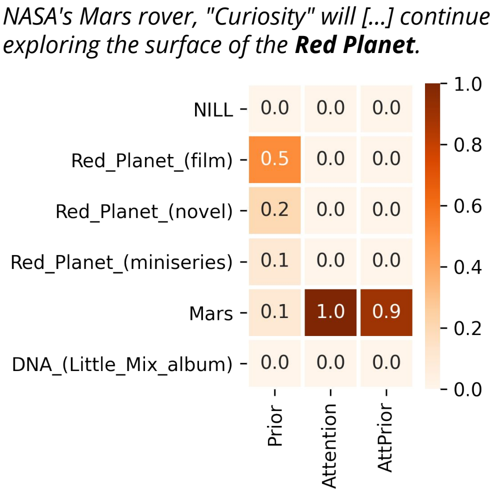

Figure 2: Illustration of EL candidate weighting: the α weights for top candidates for "Red Planet" from the example sentence at the top. Attention-based weighting (*Attention*, *AttPrior*) correctly identify the "Mars" entity, while the Wikipedia-based *Prior* fails, as most of Wikipedia's "Red Planet" links refer to the film.

the attention-based schemes thus can correct EL mistakes of *Prior*, as illustrated in Fig. 2. This correction leads to a resulting boost for the IE tasks as reported in Table 2. E.g., we found that for DWIE, looking at clusters with entity mentions for which *Prior* makes wrong EL predictions, the *AttPrior* weighting scheme retrieves +3.7% more of the gold standard annotated named entities (as opposed to just +0.6% in the clusters with correct *Prior* EL candidates). Perfecting the EL prediction would potentially boost IE performance even more.

5 Related Work

As stated earlier, we studied how to integrate (i) knowledge base information into IE, and particularly (ii) end-to-end IE combining multiple tasks (NER, relation extraction, coreference resolution), while (iii) taking an entity-centric perspective, i.e., focus on making consistent decisions on the document level. For (i), integrating KB into IE has been applied for individual tasks: relation classification (Poerner et al., 2020; Zhang et al., 2019; Yang and Mitchell, 2017), entity typing (Peters et al., 2019) and NER (Yamada et al., 2020). For (ii), recently span-based architectures (Lee et al., 2017; Luan et al., 2019; Wadden et al., 2019; Fei et al., 2020) have been proposed. Our work unifies the KB integration concept into such span-based IE system, in particular an entity-centric one (as per (iii)), building on Jia et al. (2019); Zaporojets et al. (2021). For the KB integration approach, we exploit entity representations trained on a hypertext corpus, as in (Yamada et al., 2016; Ganea and Hofmann, 2017; Yamada et al., 2020) or learnt from a knowledge graph (Yang and Mitchell, 2017; Han et al., 2018; Zhang et al., 2019). Our results show that both offer complementary value for IE. Similarly to our work, Yamada and Shindo (2019) also explore using an attention-weighted combination of entity representations, but they use it to build a full document representation (with mentions having the entities as candidates) for a text classification task. In contrast, our span-based attention model is able to "inject" knowledge in each of the mentions separately, for more fine-grained downstream IE tasks that are mention-dependent, e.g., coreference resolution, relation extraction and NER.

6 Conclusion

We propose an end-to-end model for joint IE (NER + relation extraction + coreference resolution) incorporating entity representations from a background knowledge base (KB), using a span-based system. We find that representations built from a knowledge graph and a hypertext corpus are complementary in boosting IE performance. To combine candidate entity representations for text spans, we explore various weighting schemes: an attention-based combination is successful in combining prior frequency information from a hypertext corpus with contextual information to identify the relevant entity, and achieves highest IE performance.

Knowing More About Questions Can Help: Improving Calibration in Question Answering

Shujian Zhang **Chengyue Gong** **Eunsol Choi**

`szhang19@utexas.edu, {cygong,eunsol}@cs.utexas.edu`

Abstract

We study calibration in question answering, estimating whether model correctly predicts answer for each question. Unlike prior work which mainly rely on the model's confidence score, our calibrator incorporates information about the input example (e.g., question and the evidence context). Together with data augmentation via back translation, our simple approach achieves 5-10% gains in calibration accuracy on reading comprehension benchmarks. Furthermore, we present the first calibration study in the open retrieval setting, comparing the calibration accuracy of retrieval-based span prediction models and answer generation models. Here again, our approach shows consistent gains over calibrators relying on the model confidence. Our simple and efficient calibrator can be easily adapted to many tasks and model architectures, showing robust gains in all settings.[1]

1 Introduction

Despite rapid progress in AI models, building a question answering (QA) system that can always correctly answer any given query is beyond our reach. Thus, questioners have to interpret the model prediction, deciding whether to trust it. We study providing an accurate estimate of the correctness of model prediction for each example at test time. As making incorrect predictions can be much more costly than making no prediction (e.g., missing diagnosis is much more costly than querying human experts), calibrators can bring practical benefits (Kamath et al., 2020).

Existing work on calibration focuses on mdoel confidence, such as the max probability of the predicted class (Guo et al., 2017; Desai and Durrett, 2020). Unlike classification tasks, question answering explores large output space, either through answer generation (Raffel et al., 2020; Lewis et al., 2020) or selecting a span from provided documents (Rajpurkar et al., 2016). In both settings, optimal decoding is often prohibitively expensive, and heuristic decoding is a standard practice (Seo et al., 2017). Thus, relying on the model's confidence score alone is not sufficient for calibration (Kumar and Sarawagi, 2019).

Nonetheless, prior work (Kamath et al., 2020; Jagannatha and Yu, 2020) relied heavily on model confidence, such as the max probability of the predicted answer, together with a handful of manually crafted features containing little information about the input, such as the length of the question. We empower the calibrator by introducing an input example embedding from a pre-trained language model (Alberti et al., 2019; Liu et al., 2019) fine-tuned on QA supervision data as additional features. With this simple and general feature, calibrator can identify questions regarding rare entities or examples with little lexical overlap between the question and the context. We bring further gains by paraphrasing questions or contexts respectively through back translation (Sennrich et al., 2016), providing lexical variations of the question and the context and enriching the feature space.

We evaluate our calibrator with internal metrics (i.e., calibration accuracy) and external metrics (i.e., impact on QA performance). We first evaluate calibrators in reading comprehension settings introduced in Kamath et al. (2020) – in-domain (Rajpurkar et al., 2016; Kwiatkowski et al., 2019), out of domain (Fisch et al., 2019), and adversarial (Jia and Liang, 2017). Then, we expand calibration study to more challenging open retrieval QA setting (Voorhees and Tice, 2000; Chen et al., 2017), where a system is not provided with an evidence document. We adapt our calibrator for state-of-the-art generation based (Raffel et al., 2020) and extractive (retrieve-and-predict) QA models (Karpukhin

et al., 2020), showing gains in both models. While calibration accuracy is higher in the generation based model, the extractive method provides better answer coverage above fixed accuracy. Lastly, we use calibrator as a reranker for the answer span candidates in an extractive open retrieval QA model (Karpukhin et al., 2020), showing modest gains. We provide rich ablation studies on design choices for our calibrator, such as the choice of base model to derive input example encoding. Our simple input example embedding from pretrained language models shows consistent gains in all settings and datasets. Without any manual engineering specific to the question answering task, our calibrator could be easily adapted to other tasks with rich output space.

2 Problem Definition

We estimate how the models' prediction confidence aligns with the empirical likelihood of correctness (Brier, 1950). Formally, a calibrator f takes the input example x_i and the trained model M_θ and identifies whether the model's prediction is correct or not. We treat the correctness as binary (i.e., answer string exact match) for simplicity, instead of partial credit (e.g., token level F1 score). We study two settings: reading comprehension (RC) and open retrieval QA. In RC, an input example x_i will be a context c_i and the question q_i, and in open domain QA, an input example will be a corpus C and the question q_i.

We use the same metrics to evaluate the performance of the calibrator f in the two settings.

2.1 Metric: Calibrator performance

Accuracy: Given evaluation data $D_{\text{eval}} = \{(x_1, y_1), (x_2, y_2) \dots (x_N, y_N)\}$ and a learned model M_θ, we define the accuracy of the calibrator f as:

$$\text{acc}(f) = \sum_{i=1}^{N} \mathbb{I}\left\{ f(x_i, M_\theta) = \mathbb{I}[M_\theta(x_i) = y_i] \right\}.$$

AUROC: Based on the above definition of the accuracy of the calibrator f, we computes the coverage – fraction of evaluation data D_{eval} that model makes prediction on – and risk, the error at that coverage. We plot risk versus coverage graph, and measure the area under the curve, i.e., AUROC (Area Under the Receiver Operating Characteristic Curve) (Hanley and McNeil, 1982).

2.2 Metric: End task performance

We measure how the calibrator performance impacts QA performances. First, we study selective QA setting – where we use calibrator score to decide which examples from D_{eval} to make predictions.

For the extractive model for open retrieval QA (Karpukhin et al., 2020), where multiple answer candidates are given, we further evaluate the performance of calibrator as a reranker and measure the answer span exact match (EM) score.

Selective QA (coverage at fixed accuracy): We use the calibrator score to rank the *examples* in the evaluation data. Specifically, we use the calibrator's confidence for the top answer candidate instead of model score to decide which examples in D_{eval} the model answers most confidently. Then, we report the percentage of evaluation data that can be predicted while maintaining threshold accuracy (80%), following prior work (Kamath et al., 2020).

Open Retrieval QA (top-N accuracy): We use the calibrator score to rank the *answer candidates* for each evaluation example, similar to how candidate translations are reranked in machine translation (Shen et al., 2004). We first retrieve answer candidates from multiple paragraphs and utilize the calibrator to override the model's prediction. The calibrator scores the top N answer candidates and outputs the answer with the highest confidence score instead of the answer with the highest model score. Our calibrator can be added as last step for any open retrieval QA systems which generates multiple answer candidates without retraining the model. We evaluate the top 1 exact match accuracy and the top 5 exact match accuracy after re ranking with our calibrator score.

3 Methods

We propose two general approaches to improve binary calibrator: new feature vector, a dense representation of the input example (Section 3.2) and data augmentation with backtranslation which further improves the new feature vector (Section 3.3). While both are simple, well-established formula for improving end tasks in NLP, neither has been explored in the context of calibration, as prior work assumed model confidence score is the most prominent signal. We follow prior work (Kamath et al., 2020) for calibrator architecture and focus on improving its feature space.

3.1 Calibrator Architecture

A binary classifier is trained using the gradient boosting library XGBoost (Chen and Guestrin, 2016), which classifies each test example as correctly answered by the base QA model or not. This calibrator does not share its weights with the base QA models. We finetune the following hyperparameters on the development set: colsample by level, colsample by node, colsample by tree, learning rate, and the number of estimators. All calibrators are trained five times, each with different data partitions and random seeds. We report the variances in the results.

3.2 Input Example Embedding Feature From Base QA Model

Prior work uses manually designed features based on the scores to the predicted answer (details in Section 4.2.1). Such features retain little information about input example – e.g, question and the evidence context. Inspired by the recent works in machine learning (e.g. Song et al., 2019; Hendrycks et al., 2019), which use hidden vectors to classify in-domain and out-of-domain data, we introduce an input example embedding, a new feature vector that represent question and (optionally) evidence context to a calibrator.

Our input example embedding is a fixed dimensional vector representing an input example, similar to sentence embeddings (Conneau et al., 2017). It differs in that the representation is taken from the final layer of base QA model, which is trained with supervision from question answering data and it encodes question and (optional) evidence context simultaneously. In Section 6.1, we report minor performance degradation from using embeddings from generic pretrained language model instead.

Each base model processes input example, either query q_i or query, context pair (q_i, c_i) to generate a sequence of hidden vectors, which will be compressed into a fixed dimensional vector to be used as calibrator feature.[2] We denote the input example as a sequence of tokens $\mathbf{t} = (t_0, t_1, \cdots, t_n)$ where n is the length of the input. We pass the sequence $\mathbf{t}$ through base QA model and get $(\mathbf{h}_0, \mathbf{h}_1, \cdots, \mathbf{h}_n)$ where $\mathbf{h}_i$ is the corresponding final-layer hidden state of t_i, and $\mathbf{h}_i = (\mathbf{h}_{i,0}, \cdots, \mathbf{h}_{i,m})$ where m is the number of hidden dimensions. Then, we get the m-dimensional feature vector

$$\phi(q_i, c_i) = [\frac{1}{n}\sum_{i=1}^{n}\mathbf{h}_{i,0}; \cdots ; \frac{1}{n}\sum_{i=1}^{n}\mathbf{h}_{i,m})], \quad (1)$$

where each dimension is an average across the length n. We then train a binary classifier using these features as a calibrator. We now describe our base QA models to get this hidden representations.

3.2.1 Base QA Model

We use standard span prediction architecture for RC, and a generation based model and an extractive model for open retrieval QA.

For RC and extractive open retrieval QA model, we use a standard span prediction architecture based on a pretrained language model (Devlin et al., 2018), which predicts start and end index of the answer span separately with softmax layer. The output hidden vector sequence will equal the sum of the length of question and the length of evidence context. For the open retrieval QA setting, the extractive model first retrieves a passage from the corpus and predicts an answer span from it. We use the best model from dense passage retrieval (DPR)(Karpukhin et al., 2020).[3] Specifically, this model retrieves the top 100 retrieved passages as input and trains a span prediction model, which optimizes a softmax cross-entropy loss to select the correct passage among the candidates, and the answer span prediction loss. The model then selects the answer span with the highest answer span score (sum of the start and end logit score) from the passage with the highest passage score. In this setting, $\mathbf{t}$ is a concatenation of question q_i and the context c_i.

For generation based model, we use a sequence-to-sequence (seq2seq) model, specifically T5-small (Raffel et al., 2020), which takes the question as an input and generates answer tokens. For this base QA model, $\mathbf{t}$ only consists of the query since the context is not provided.

Data For all experiments in RC, we train the model on the SQuAD 1.1 dataset. For open retrieval QA, models are trained on the Natural Questions (NQ) dataset (Kwiatkowski et al., 2019) following the data split from Lee et al. (2019).

3.3 Data Augmentation Via Paraphrasing

Paraphrase generation can improve QA models (Yu et al., 2018) by handling language vari-

---

[2] For simplicity, we write equations with (q_i, c_i) pair as an input, when only query is provided (e.g., generation based open retrieval QA method) c_i is empty.

Table 1: Experiment Configuration. In domain / Out of domain distinguishes whether the training data for calibrator is different from the test data.

ation. Compared to sentence retrieval (Du et al., 2020) and language model based example generation (Anaby-Tavor et al., 2020), backtranslation can capture the ambiguity of questions and answer(Singh et al., 2019). Given a (q_i, c_i) pair, we use back translation (Sennrich et al., 2016) to generate paraphrases of the question q'_i from q_i and the evidence context c'_i from c_i.

We use standard transformer-based neural machine translation models (Junczys-Dowmunt et al., 2018) trained on WMT dataset.[4] We first translate the original sentences to a pivot language and then translate them back to the source language. To guarantee translation quality, French and German are used as the pivot languages. We use beam search decoding with beam size as 4 and truncate the context length to 512, as the reading comprehension model truncates the context anyway. We analyze the quality of backtranslation in Section 6.2.

We denote (q'_i, c_i) as $\mathbf{t}^q = (t^q_0, \cdots, t^q_{n_q})$ and (q_i, c'_i) as $\mathbf{t}^c = (t^c_0, \cdots, t^c_{n_c})$. Here, n_q and n_c denote the length after backtranslating the question and context, respectively. For $\mathbf{t}^q$ and $\mathbf{t}^c$, we pass them through the base QA model, get $\mathbf{h}^q$ and $\mathbf{h}^c$, and extract the m-dimensional feature vector as in Eqn (1),

$$\begin{aligned}\phi(q'_i, c_i) &= [\frac{1}{n_q}\sum_{i=1}^{n_q}\mathbf{h}^q_{i,0}, \cdots, \frac{1}{n_q}\sum_{i=1}^{n_q}\mathbf{h}^q_{i,m}],\\ \phi(q_i, c'_i) &= [\frac{1}{n_c}\sum_{i=1}^{n_c}\mathbf{h}^c_{i,0}, \cdots, \frac{1}{n_c}\sum_{i=1}^{n_c}\mathbf{h}^c_{i,m})].\end{aligned} \tag{2}$$

We use the concatenation of the original input example embedding and backtranslated one, $[\phi(q_i, c_i); \phi(q'_i, c_i)]$ and $[\phi(q_i, c_i); \phi(q_i, c'_i)]$ as features. Backtranslating both context and question did not bring further gains, thus the results from such a feature set are not presented. We hypothesize that backtranslating context and question together might introduce too severe noise. We do not use data augmentation for open retrieval QA experiments.

4 Experimental Settings

In this section, we describe the experimental setting, dataset setups and baseline systems. Table 1 summarizes the evaluation scheme. A separate calibrator is trained for each calibrator train data configuration.

4.1 Data

For all in-domain reading comprehension experiments, we randomly split the data into training, development, and test (40%,10%,50%), following regression and classification benchmarks (Asuncion and Newman, 2007). Further, we assume only limited supervised data is available for calibrators, simulating a set up where we have a general QA model and small number of annotated data reserved for calibration.

Standard RC We test two in domain settings and two out of domain settings. We randomly sample 4K examples from each of the datasets included in the training portion of the MRQA shared task (Fisch et al., 2019) (SQuAD (Rajpurkar et al., 2016), NewsQA (Trischler et al., 2017), TriviaQA (Joshi et al., 2017), SearchQA (Dunn et al., 2017), HotpotQA (Yang et al., 2018), Natural Questions (Kwiatkowski et al., 2019)). We train two calibrators, one with the SQuAD1.1 + HotpotQA datasets and another with the SQuAD1.1 + NQ datasets. For out of domain evaluation, we use four remaining datasets from MRQA shared task training set.

---

[4] `https://huggingface.co/transformers/model_doc/marian.html`

Adversarial RC (SQuAD 1.1 Adversarial) The adversarial examples manipulate the evidence paragraph to change the model prediction but not the gold answer. We sample 2K examples from the development portion of the SQuAD 1.1 (Jia and Liang, 2017) AddSent dataset, which appends an additional sentence that looks similar to the question at the end of the paragraph. For the out-of-domain case, we train the calibrator on 6K examples (1K each sampled from MRQA datasets) and test on adversarial examples.

Unanswerable RC (SQuAD 2.0) We sampled 2K examples from the development portion of the SQuAD 2.0 dataset (Rajpurkar et al., 2018), which contains examples where the answer to the question cannot be derived from the provided context. Crowdworkers posed questions that were impossible to answer based on the paragraph alone while referencing entities in the paragraph and ensuring that a plausible answer is present. For out of domain setting, we train the calibrator on 6K examples (1K each sampled from MRQA datasets) and test on SQuAD 2.0 dataset (same as adversarial RC setting).

Open Retrieval QA We use the open retrieval version of the NQ (Lee et al., 2019). We split its training data 60% and 40% for calibrator training and validation and use the NQ test set for testing.

4.2 Comparison Systems

We summarize the calibrators used in our study in Table 2. All calibrators are trained with the same gradient boosting library XGBoost (Chen and Guestrin, 2016), and they only differ in the feature sets. These calibrators are efficient, trained within a few minutes even with our new feature space.

4.2.1 Reading Comprehension

MaxProb is the simplest baseline that relies on the model's confidence score. The model score is the sum of the logit scores of the start and end of the answer span for reading comprehension. For open retrieval question answering, the model first determines the passage with the highest passage-match score and then extracts the answer span from this passage.

Formally, given the set of answer spans Y, MaxProb with model M_θ estimates confidence on input x_i as:

$$\textit{MaxProb} = \max_{y \in Y} M_\theta \left(y \mid x_i \right),$$

where $M_\theta(y \mid x_i)$ refers to the model score for candidate answer y.

QA model	Calibrator Feature Set	# Features
RC	MaxProb	1
	features: Kamath et al. (2020)	17
	Ours	m
	+ features	$17 + m$
	+ features + $\phi(q_i, c_i')$	$17 + 2m$
	+ features + $\phi(q_i', c_i)$	$17 + 2m$
Extractive (DPR)	Unnormalized Scores	2
	Normalized Scores	2
	Ours + Normalized Score	$2 + 2m$
Generation (T5)	Likelihood	1
	Ours + Likelihood	$1 + m$

Table 2: Comparison Systems: different calibrators explored for three base QA models. The last two QA models are for open retrieval QA task. The dimension of question context embedding is m defined in Eqn (1) (eg. m is 768 for reading comprehension).

Kamath et al. (2020) uses a calibrator based on the following general features: passage length, the predicted answer length, and the top-5 largest softmax probabilities generated by the model. They also use test time dropout (Gal and Ghahramani, 2016): given an input x_i and model M_θ, compute $M_\theta(x_i)$ with K different dropout masks, obtaining prediction distributions $\hat{p}_1, ..., \hat{p}_k$, where each $\hat{p}_i$ is a probability distribution over Y. Two options are used as confidence estimates. First, taking the mean of $\hat{p}_i$ (Lakshminarayanan et al., 2017)

$$\textit{Dropout Mean} = \frac{1}{K} \sum_{i=1}^{K} \hat{p}_i.$$

Second, taking the variance of the $\hat{p}_i$ (Feinman et al., 2017; Smith and Gal, 2018)

$$\textit{Dropout Variance} = \mathrm{Var}\left[\hat{p}_1, \ldots, \hat{p}_K\right].$$

The dimension of *MaxProb*, 2th-5th probability, *Dropout Mean*, *Dropout Variance*, context length and prediction length are 1, 4, 5, 5, 1, 1, respectively. In total, this feature set contains 17 features.

Ours represents a calibrator that is trained with the question context embedding, $\phi(q_i, c_i)$ in Eqn (1). '+ features' refers to augmenting features from (Kamath et al., 2020), described above. Augmenting the feature sets with question context embeddings from backtranslated questions is denoted as '+$\phi(q_i', c_i)$', and augmenting the feature sets with question context embeddings from backtranslated contexts is denoted as '+$\phi(q_i, c_i')$' from Eqn. (2).

4.2.2 Open Retrieval QA

We consider separate calibrators for two different approaches (Karpukhin et al., 2020; Raffel et al., 2020).

Extractive (Retrieve-And-Predict) We consider two baseline calibrators: one takes the product of normalized passage score (normalized across all passage candidates) and answer score (normalized across the top 10 answer spans for each passage), and another takes the product of unnormalized passage and answer scores.

Then, we introduce calibrator augmented with our input example embedding. We include two example embeddings as features: one is the question context embedding as used in the reading comprehension setting (from Eqn 1), and another is the average of the answer span start token representation and the answer span end token representation.

Generation based (Seq2Seq) For seq2seq models (Raffel et al., 2020), the output answer space includes all sentences that can be generated with conditional language model. Thus, instead of MaxProb, we use the likelihood of the generated answer (i.e., the product of the conditional probabilities for each token in the generated answer) as a baseline. Then, we introduce calibrator with our input example embedding (from Eqn 1).

5 Results

Calibration Table 3 reports calibration results on standard reading comprehension datasets. The top block displays the performance of calibrators trained on the SQuAD and HotpotQA datasets, and the bottom block shows the results of calibrators trained on the SQuAD and NQ datasets. In both settings, the our input example embedding works better than the manual feature set. However, two approaches are complementary in all settings. Interestingly, paraphrasing questions shows gains in Natural Questions but not in other datasets. We hypothesize that organically collected search queries contain more ambiguous and ill-defined queries than crowdsourced questions where questions were based directly on the context. Adding paraphrased context embeddings, on the other hand, shows a modest gain across all settings. Unlike QA models have access to millions of parameters, calibrators, even with our feature set, are provided with very limited information. We hypothesize that augmenting the feature set with paraphrased context enabled the calibrator to gain more information about the example, facilitating higher performance.

Table 4 shows the results in more challenging settings: one with adversarial attacks and another containing unanswerable questions. In both settings, we observe sizable gains (5-10% increase in calibration accuracy) for the in domain setting, but the gains are smaller in out of domain settings. Similar to the Natural Questions dataset, in SQuAD 2.0, which includes adversarially designed questions without an answer, paraphrasing the question is more helpful than paraphrasing the context. On the other hand, in the adversarial setting where contexts are manipulated, paraphrasing contexts is more effective. Overall, our new feature vector shows consistent gain across all datasets and settings.

We present the calibration in open retrieval QA in Table 5. Overall, calibrator accuracy is higher

Table 4: Calibration results on adversarial and unanswerable SQuAD datasets. In the out of domain setting, we first list the training dataset of calibrator, then the test dataset.

Model	Answer Acc	Calibrator	Calib. Accu	Calib. AUROC	Cov@Acc=80%
Extractive (DPR)	41.0	Unnormalized scores	65.9±0.2	65.2±0.2	10.4%
(Karpukhin et al., 2020)		Normalized scores	72.2±0.4	74.5±0.3	28.9%
		Ours (+ Normalized Scores)	**77.3±0.3**	**78.7±0.2**	**30.5%**
Generation (T5)	25.5	Likelihood	89.3±0.1	86.6±0.1	10.4%
(Raffel et al., 2020)		Ours (+ Likelihood)	**91.6±0.3**	**92.9±0.1**	**11.3%**

Table 5: Calibration results on NQ open retrieval test set for different base QA models and calibration features.

compared to RC, partially because the answer accuracy is substantially lower. For example, with generation based model (T5)'s answer accuracy of 25.5, simply predicting incorrectly for every example will give 74.5 calibration accuracy. In both models, internal confidence scores (Likelihood and Normalized scores) provide reasonable calibrator performance, yet adding our feature set improves the performance. In particular, our calibrator shows a larger gain in the DPR setting. Encouraged by this result, we test our calibrator as an answer candidate reranker for top answer candidates from DPR. Despite high calibration accuracy of generation based approach, selective QA performance (Cov@Acc=80%) is higher with the extractive approach, suggesting comparing calibration performance across models of different accuracy is challenging.

Answer Reranking Table 6 shows the results of our calibrator as an answer candidate reranker. The calibrator considers the top 1,000 answer candidates (100 retrieved passages, each with top 10 answer spans) and outputs top candidates based on the calibrator score instead of the model score. We show negligible gains in top 1 accuracy but bigger gains in top 5 accuracy. These small but noticeable gains show potential for using calibrators to improve open retrieval QA performances, where multiple answer candidates are considered.

	Top 1 EM	Top 5 EM
DPR	41.0	57.8
Unnormalized scores	10.3±0.2	23.1±0.3
Normalized scores	41.2±0.1	58.6±0.1
Ours (+ Normalized scores)	**41.4±0.1**	**59.0±0.1**

Table 6: Results on open domain question answering in NQ. The calibrator is used as a reranker for selecting the top answer span out of 1,000 answer spans (10 answer spans per each of 100 retrieved passages).

6 Analysis

6.1 Task-Agnostic Representation vs. Representation from QA Model

Our study has shown that input example embedding is very useful, adding complementary power to model confidence features. Based on this result, we further ask the question, is it possible to build a calibrator without accessing the model parameters, but only a small amount of calibration training data (which consists of questions, context, and whether the model's prediction is correct or incorrect)? We train a calibrator that does not have any access to the QA model parameters and only takes the model's predictions on a small set of training data (a couple thousand of QA examples). This cali-

	In Domain	Out of Domain
	SQuAD1.1 + Hotpot QA	Other MRQA datasets
CLS	63.5±0.4	62.3±0.5
Ours	65.8±0.3	63.7±0.3
Diff.	2.3%	1.4%

Table 7: CLS token ablation results, all numbers refer to calibration accuracy. Using CLS token as a feature shows a strong calibration performance, lagging behind question context encoding from the RC model only by a few points. The gap is even smaller in out of domain setting.

brator uses a standard pretrained language model (BERT) to encode [CLS; (q_i, c_i)] and takes the final layer hidden representation of the [CLS] token as a feature. Table 7 shows the performance of the [CLS] token classifier. Surprisingly, this calibrator outperforms the MaxProb baseline (in Table 3) in all settings and outperforms Kamath et al. (2020) (in Table 3) in most settings, indicating information about the question and context might be more useful than the QA model's confidence. Using the input example embedding from the QA model shows only 1-3 point gains than using the CLS token embedding. This trend holds for across various settings (more results in Table 11 in Appendix).

6.2 Quality of Back Translation

Question paraphrasing (Dong et al., 2017) can improve performances of QA models. Similarly, both question and context paraphrasing improves calibration performance. In this section, we investigate the quality of backtranslation used in our study. We manually inspect 100 question paraphrasing from SQuAD 2.0 dataset. 71 examples maintain the original meaning, 12 examples change its meanings, and 17 examples are hard to distinguish. One common pattern for meaning change is when proper nouns in the original sentences are missing and incorrectly translated (e.g. John Calvin → Jean Calvin).

We study how much variability is introduced during paraphrasing by studying divergence between the original sentence and the paraphrased sentence. We calculate the sentence BLEU score with *NLTK* (Bird et al., 2009), using the original text as source and the back-translated text as target for both question paraphrasing and context paraphrasing. The average sentence BLEU score is larger than 0.55 for all datasets, indicating back-translation introduces relatively minor changes in phrasing.

q	In what country is Normandy located?
q'	What country is Normandy in?
q	When did Edward return?
q'	When did Edward come back?
q	How would one write T(n) = 7n2 + 15n + 40 in big O notation?
q'	How do you write T(n) = 7n2 + 15n + 40?
q	What kind of arches does Norman architecture have?
q'	What kind of arches does Norman's building have?

Table 8: Question back translation samples from SQuAD 2.0 dataset. The first row (q) refers to the original question, and the second row (q') refers to back-translated question. In the third example, back translation introduces an error.

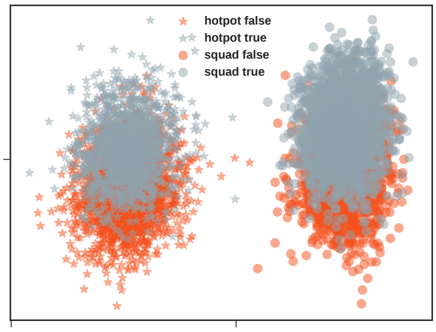

Figure 1: A visualization for the input example embedding from HotPotQA and SQuAD datasets. We denote the data domain by markers with different shapes and denote the correctness with different colors. The X-axis and Y-axis denote the first and second dimensions extracted by linear discriminant analysis, respectively.

Visualization Figure 1 shows a visualization of the question context embeddings from HotpotQA and SQuAD. We use linear discriminant analysis (Pedregosa et al., 2011) to plot input example embeddings and observe that embeddings from the same dataset are closer to each other. It demonstrates that embeddings are almost linearly separable between domains, but it is much harder to distinguish correct answers from incorrect ones.

Choice of Calibrator Architecture We test if our results are sensitive to the choice of classifiers: XGBoost, logistic regression (LR), and k-nearest

	In Domain	Out of Domain
	SQuAD1.1 + NQ	Other MRQA datasts
Xgboost	67.4±0.5	65.4±0.3
LR	66.6±0.3	64.7±0.3
KNN	66.3±0.2	64.6±0.3

$\phi(q_i, c_i')$	DE	73.0±0.4	66.5±0.5
$\phi(q_i', c_i)$	FR	72.5±0.4	65.8±0.5
$\phi(q_i', c_i)$	DE	72.8±0.3	66.1±0.4

Table 10: Calibration accuracy for different pivot languages: French vs. German, using calibrator with features (Ours + features).

neighbors (KNN). Table 9 indicates our gains hold across different classifiers. Full experimental results can be found in Appendix.

Choice of Pivot Language We test whether the choice of pivot language in backtranslation impacts performances. We find little difference between pivoting through German or French (See Table 10).

7 Related Work

Calibration in NLP Calibration has become an important topic in NLP as well as general machine learning (Guo et al., 2018; Pleiss et al., 2017; FAN et al., 2021) as confidence scores from calibrators can be useful for the error correction process (Feng and Sears, 2004). Calibration has been studied in natural language inference, commonsense reasoning (Desai and Durrett, 2020; Varshney et al., 2020), dialogue systems (Mielke et al., 2020), semantic parsing (Dong et al., 2018), coreference resolution (Nguyen and O'Connor, 2015) and sequence labeling (Jagannatha and Yu, 2020).

In question answering, Kamath et al. (2020)'s study on selective question answering inspired our work. We measure the calibration performance with calibrator accuracy, AUROC, and coverage at accuracy. Expected Calibration Error (ECE) (Guo et al., 2017) is another commonly used metric for calibration performance, but we consider calibrator as a binary classifier at here. Jagannatha and Yu (2020) also studies calibration in reading comprehension, using language model perplexity and model's confidence as features. Language model perplexity coarsely and indirectly captures information about the question and context. We propose an improved feature space and thoroughly test it in challenging settings, e.g., adversarial RC, unanswerable RC, and open retrieval QA.

Calibration During Training Recent work in QA introduces an answer verification step (Tan et al., 2018; Hu et al., 2019; Wang et al., 2020) at the end of the pipeline. During the training, this verifier module takes the questions, answers, or MRC model's state as inputs and determines the answers' validity. Then, the validity score is used to update the model parameters during training. Thus, the validator is jointly trained with the MRC model. While this is conceptually similar to our set up, instead of tying the calibrator into the model, we design a universal post-hoc calibrator that can be easily applied to any model architecture.

Calibration with Ensembles Ensemble diversity has been used to improve uncertainty estimation and calibration (e.g. Raftery et al., 2005; Stickland and Murray, 2020). While it is effective, calibration with model ensembling is usually expensive and time consuming (Zhou et al., 2002, 2018). Our calibrator is an offline postprocessing step that does not require further training of the original model.

8 Conclusion

We introduce a richer feature space for question answering calibrators with question and context embeddings and paraphrase-augmented inputs. Our work suggests deciding the correctness of a QA system depends on both the semantics of the question-context and the confidence of the model. We thoroughly test our calibrator in domain shift, adversarial, and open domain QA settings. The experiments show noticeable gains in performance across all settings. We further demonstrate our calibrator's general applicability by using it as a reranker in extractive open domain QA. To summarize, our calibrator is simple, effective and general, with potential to be incorporated into existing models or extended for other NLP tasks.

B Hyperparameters and Training Details

A binary classifier is trained using the gradient boosting library XGBoost (Chen and Guestrin, 2016). We finetune the following hyper-parameters, colsample by level, colsample by node, colsample by tree, learning rate, and the number of estimators on the development set. We use the following search space: colsample by level/mode/tree is set to the same value and selected from $\{0.0, 0.1, 0.2, 0.3, 0.4, 0.5\}$, the learning rate and number of estimators are selected from $\{0.01, 0.1, 0.2, 0.5\}$ and $\{5, 25, 50, 100\}$, respectively. These hyper-parameters are chosen based on the performance on the validation set.

For base QA models, we mostly following the hyperparameters used in the original work (e.g., batch size 32 & learning rate of 5×10^{-5} for BERT-base SQuAD 1.1 model). All calibrators are trained five times, each with different data partitions and random seeds. We report the variances in the results. Our calibrator does not share its weights with the base QA models.

Enhancing Metaphor Detection by Gloss-based Interpretations

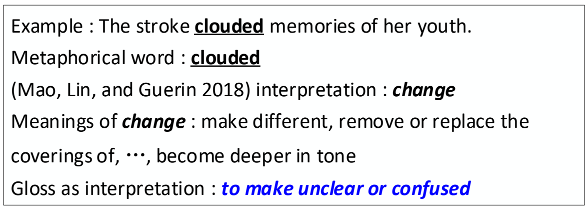
Abstract

This paper focuses on utilizing *metaphor interpretation* to enhance *metaphor detection*. Considering that existing approaches to metaphor interpretation are limited by ambiguous meanings of the metaphorical substitute words, this paper proposes a novel interpretation mechanism that utilizes *glosses* to interpret metaphorical words. Since there is no dataset annotated for both metaphor detection and metaphor interpretation, we enhance three datasets TroFi, VUA, and PSUCMC from the field of metaphor detection with gloss annotations. Accordingly, we develop a model for jointly conducting metaphor detection and gloss-based interpretation (named MDGI-Joint for short). Experimental results demonstrate that MDGI-Joint outperforms state-of-the-art models on all the three enhanced datasets and that gloss-based metaphor interpretation benefits metaphor detection.[1]

1 Introduction

Metaphor has been defined as words or other linguistic expressions representing another concept with the language from a more concrete conceptual domain (Kövecses and Zoltán, 2002; Lagerwerf and Meijers, 2008). According to existing studies on metaphor (Kövecses and Zoltán, 2002; Steen, 2010), metaphor has been used so frequently in daily language that it almost occurs in one out of three natural language sentences.

Metaphor detection aims to identify all *metaphorical words* in given texts and has been demonstrated to be of great value in many Natural Language Processing (NLP) tasks, such as machine translation (Mao et al., 2018), machine reading comprehension (Shutova et al., 2013), *etc*. Therefore, metaphor detection has drawn increasing interests in recent years. There have emerged a number of methods for metaphor detection, including SEQ (Gao et al., 2018), RNN_HG (Mao et al., 2019), RNN_MHCA (Mao et al., 2019), MUL_GCN (Le et al., 2020), DeepMet (Su et al., 2020), *etc.*



Example : The stroke **<u>clouded</u>** memories of her youth.
Metaphorical word : **<u>clouded</u>**
(Mao, Lin, and Guerin 2018) interpretation : ***change***
Meanings of ***change*** : make different, remove or replace the coverings of, ⋯, become deeper in tone
Gloss as interpretation : ***to make unclear or confused***

Figure 1: An example for metaphor detection, where the word **<u>clouded</u>** is a metaphorical word (highlighted in bold and underline). Interpretation by a substitute word (highlighted in **bold**) is computed by (Mao et al., 2018). Gloss as interpretation (highlighted in ***blue bold italics***) is picked from the Merriam Webster dictionary.

To capture the meanings of metaphorical words, *metaphor interpretation* has also been studied, which paraphrases metaphorical expressions into literal expressions that maintain the intended meanings of given texts (Mao et al., 2018). Existing approaches have treated metaphor interpretation as extraction of transferred properties, identification of the underlying conceptual mapping, or generation of a literal substitute paraphrase (Rai and Chakraverty, 2020). All of them are yet limited by ambiguous meanings of the metaphorical substitute words. Consider the example shown in Figure 1. The metaphorical word **<u>clouded</u>** is interpreted as **change** in (Mao et al., 2018), where **change** has 10 diverse meanings according to WordNet (Miller, 1995). Due to multiple meanings of **change**, it is difficult to precisely capture the intended meaning of the metaphorical word **<u>clouded</u>**.

It has been pointed out by Group (2007) that, metaphors have a clear distinction between their

basic meanings and contextual meanings. Consider the example shown in Figure 1 again. The gloss-based interpretation for **clouded** gives the meaning "*to make unclear or confused*", which is evidently different from the basic meaning "*to grow cloudy*" of **clouded**. In other words, different from the substitute word, the *gloss* extracted from dictionaries can provide an unambiguous interpretation of **clouded** which exhibits a clear distinction to its basic meaning. Therefore, we can utilize gloss-based metaphor interpretation to enhance the metaphor detection task.

Based on the above observations, we propose to use glosses to interpret metaphorical words. Specifically, we formulate metaphor interpretation as a task of predicting the best gloss among a set of candidate glosses. Considering that *Word Sense Disambiguation* (WSD) (Kilgarriff, 2004) is a popular technique for identifying the correct meaning of a target word, modern WSD methods can be adapted to metaphor interpretation.

By now there is a lack of dataset annotated for both metaphor detection and metaphor interpretation. In order to study whether gloss-based interpretation benefits metaphor detection, we enhance three benchmark datasets in the field of metaphor detection, including two English datasets (TroFi and VUA) and one Chinese dataset (PSUCMC). For each dataset, we construct a set of candidate words and annotate these words with glosses extracted from a dictionary.

Accordingly we develop a joint model for **M**etaphor **D**etection and **G**loss-based **I**nterpretation (named MDGI-Joint for short). To be specific, our joint model encodes contexts and glosses independently for every given word. Based on both the contextual word embedding and gloss embeddings, a probability distribution for all glosses of the given word is computed and then used to predict the best gloss, in a similar way as the state-of-the-art WSD method (Blevins and Zettlemoyer, 2020), Afterwards, an attention mechanism is employed to compute an integrated representation of all glosses. This integrated representation is then concatenated with the contextual word embedding to determine whether the given word is metaphorical through a classical prediction layer. The joint model is trained by minimizing a combined loss from both the metaphor detection task and the metaphor interpretation task.

We conduct experiments on the aforementioned three enhanced datasets. Experimental results demonstrate that gloss-based metaphor interpretation does benefit metaphor detection. On one hand, the proposed model achieves state-of-the-art performance on all three enhanced datasets in the metaphor detection task. On the other hand, it also achieves comparable performance with the outstanding WSD method in the metaphor interpretation task.

The main contributions of this paper can be summarized as follows.

- We provide a novel interpretation mechanism that utilizes glosses to interpret metaphorical words.
- We enhance three metaphor detection datasets (TroFi, VUA, and PSUCMC) with annotations of glosses for metaphorical words.
- We develop a joint model for metaphor detection and gloss-based interpretation and empirically show that metaphor interpretation with glosses benefits metaphor detection.

2 Related Work

2.1 Metaphor Detection

Early studies on metaphor detection (Shutova et al., 2010; Rei et al., 2017) usually follow the linguistics theory (Lakoff and Johnson, 1980) and construct mappings from the source domain to the target domain.

Subsequent studies focus on metaphor detection over subject-verb-objects, adjective-noun tuples, or metaphorical phrases. Among these studies, a lot of semantic features including the degree of abstractness, the degree of concreteness, the degree of imageability, semantic super-senses (namely coarse semantic categories originating in WordNet), lemma unigrams, and grammatical dependencies are added to improve performance of metaphor detection (Turney et al., 2011; Tsvetkov et al., 2014; Klebanov et al., 2016; Özbal et al., 2016; Jang et al., 2015). Jang et al. (2015) took topic distribution into consideration. Jang et al. (2016) explored topic transition between a metaphor and its context. For handing multi-modal information, Shutova et al. (2016) considered both word embeddings and visual embeddings whereas Bulat et al. (2017) introduced a cross-modal method to integrate linguistic representations and property-based representations. A broader context of discourse was considered by (Jang et al., 2015) and (Mu et al., 2019).

Regarding word-level metaphor detection, metaphor detection can be treated as a sequence tagging task. Wu et al. (2018) proposed a neural model, which uses Word2Vec (Mikolov et al., 2013) as text representation and encodes part-of-speech (POS) tags, word clusters with Convolutional Neural Network (CNN) and Bidirectional Long Short-Term Memory (Bi-LSTM) network. Gao et al. (2018) and Mao et al. (2019) respectively utilized GloVe (Pennington et al., 2014) and ELMo (Peters et al., 2018) embeddings. Le et al. (2020) proposed to construct a graph CNN guided by dependency trees of sentences for metaphor detection and to construct a multi-task learning framework for the WSD task, utilizing the knowledge from WSD to improve metaphor detection. Instead of treating metaphor detection as a sequence tagging task, Su et al. (2020) proposed a novel reading comprehension paradigm based on a pre-trained language model, using features from POS tags and local texts.

2.2 Metaphor Interpretation

Metaphor interpretation is an intricate task, having a challenge in deciphering the meaning conveyed by a metaphorical expression (Rai and Chakraverty, 2020). Existing approaches to metaphor interpretation can be grouped into three categories. For the first category, the problem of metaphor interpretation is treated as a problem of extraction of transferred properties. It is often assumed that a metaphor is essentially a projection of a specific set of salient concept properties from the source domain, known as *property matching* (Su et al., 2016; Ortony, 1980). Su et al. (2016) extracted perceptual properties from the source domain and the target domain, and then searched for metaphor interpretation by expanding the extracted properties with synonymy relationships from WordNet. In contrast to property matching, the second category defines the problem of metaphor interpretation as a problem of identifying the underlying conceptual mapping, usually focusing on re-conceptualization of the target domain (Marmolejo-Ramos et al., 2013; Semino, 2010). Martin (2006) empirically found that metaphor interpretation has certain contextual clues (*e.g.*, the appearance of a concept from the target domain) and related metaphorical expressions. For the last category, the problem of metaphor interpretation is treated as the generation of a literal substitute paraphrase (Mao et al., 2018; Shutova et al., 2012). Mao et al. (2018) used hypernyms and synonyms as candidate substitutes and computed the best substitute word by the cosine similarity between the embedding of the given word and the embedding of a candidate substitute.

All the above methods for metaphor interpretation fail to capture the contextual meaning of a metaphorical word due to ambiguous interpretation of the metaphor. To tackle this issue, in this work we provide a novel interpretation mechanism that utilizes glosses to interpret metaphorical words.

2.3 Word Sense Disambiguation

Word sense disambiguation (WSD) aims to predict a specific meaning of a word that occurs in a particular context (Navigli, 2009). Understanding the meaning of a word in context is critical to many NLP tasks, such as machine translation (Vickrey et al., 2005; Neale et al., 2016; Gonzales et al., 2017) and information extraction (Ciaramita and Altun, 2006; Bovi et al., 2015). One category of WSD is class-based, which provides coarse-grained labels that are shared among different words. The other category of WSD is word-based, aiming to disambiguate every word in texts (Palmer et al., 2001; Moro and Navigli, 2015; Blevins and Zettlemoyer, 2020). Our proposed metaphor interpretation scheme belongs to this category. Some neural models for word-based WSD exploit encoders for better feature extraction. Based on an encoder, they either train classifiers on top of extracted features (Kågebäck and Salomonsson, 2016) or introduce a shared output space to label words (Raganato et al., 2017). Other neural models augment word representations with additional data by semi-supervised learning (Melamud et al., 2016; Yuan et al., 2016). BEM (Blevins and Zettlemoyer, 2020), which inspires our model, is a state-of-the-art method for word-based WSD. It introduces a bi-encoder model to embed the target word with its surrounding context and its glosses.

3 The Proposed MDGI-Joint Model

Given a sentence s consisting of n words $\{w_0, w_1, \dots, w_i, \dots, w_{n-1}\}$ and a list of all m_i candidate glosses $G_i = \{g_i^0, g_i^1, \cdots, g_i^j, \dots, g_i^{m_i-1}\}$ for the target word w_i, the task of metaphor interpretation aims to select a gloss from G_i to interpret the intended meaning of w_i, whereas the task of

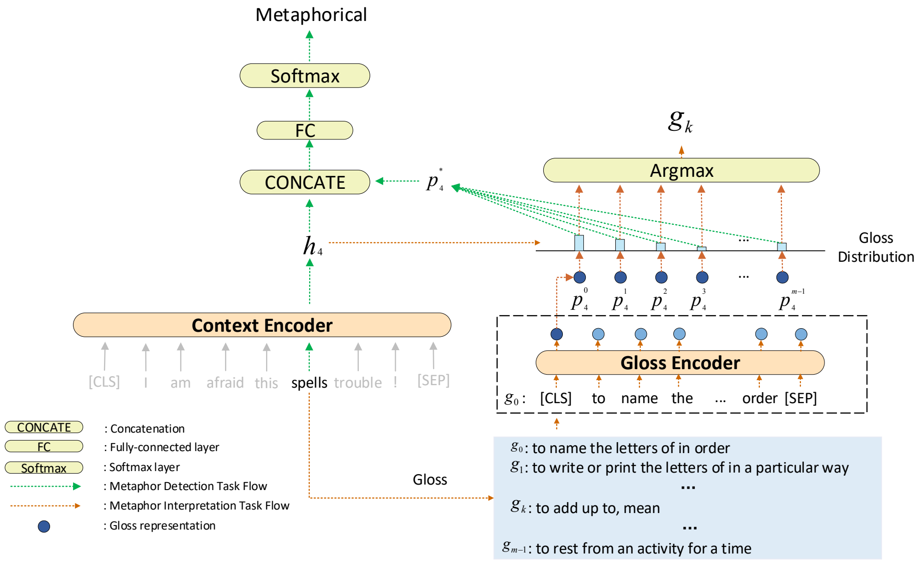

Figure 2: The architecture of our proposed joint model for **M**etaphor **D**etection and **G**loss-based **I**nterpretation.

metaphor detection focuses on predicting whether the word w_i is metaphorical or literal. Since gloss-based metaphor interpretation provides a rich representation for the contextual meaning of the target word, it is appropriate to construct a joint model to incorporate gloss-based metaphor interpretation and metaphor detection. Therefore, we propose a model named MDGI-Joint to incorporate metaphor detection and metaphor interpretation.

The architecture of MDGI-Joint is given by Figure 2. MDGI-Joint employs two encoders to generate respectively the contextual representation and the gloss representation for a target word. The probability distribution over all candidate glosses is computed by an attention mechanism. The gloss with the highest probability is predicted as the interpretation of the target word. Afterwards, an integrated representation of all candidate glosses is computed and then concatenated with the contextual representation. The concatenated representation is finally used to determine whether the target word is metaphorical, through a fully-connected layer followed by the softmax classifier.

3.1 Encoding Module for Sentences

Given a sentence s consisting of n words $\{w_0, w_1, \ldots, w_i, \ldots, w_{n-1}\}$ as well as a target word w_i, the contextual representation of w_i will be encoded into a vector. Considering that the pre-trained language model BERT (Devlin et al., 2019) has been proved to be effective in transfer learning, contributing to state-of-the-art performance in many NLP tasks, we fine-tune a BERT model to be the context encoder. Initially, we construct a token sequence "[CLS], $w_0, w_1, \cdots, w_{n-1}$,[SEP]", where [CLS] and [SEP] are special tokens introduced in BERT. Then this token sequence is taken as input to BERT, yielding a sequence of 768-dimensional vectors "$h_{[CLS]}, h_0, h_1, \ldots, h_{n-1}, h_{[SEP]}$" as the output of BERT. The corresponding vector h_i for the target word w_i is treated as the contextual representation of w_i.

3.2 Encoding Module for Glosses

For the target word w_i, we collect the set of candidate glosses $G_i = \{g_i^0, g_i^1, ..., g_i^{m_i-1}\}$ from an existing dictionary. We fine-tune another BERT model to be the gloss encoder. Similar to the encoding module for sentences, we also construct a token sequence for each gloss and feed it into BERT. For each gloss $g_i^j \in G_i$ where $0 \leq j \leq m_i - 1$, we use the output 768-dimensional vector corresponding to the first token "[CLS]" as the gloss representation, which is written as p_i^j.

3.3 Prediction for Metaphor Interpretation

Based on the contextual representation h_i of w_i and the gloss representation p_i^j of each gloss $g_i^j \in G_i$ where $0 \leq j \leq m_i - 1$, the probability α_i^j for a gloss g_i^j to represent the intended meaning of the word w_i is computed by an attention mechanism, formally defined as follow:

$$\alpha_i^j = \frac{\exp(h_i^T p_i^j)}{\sum_{k=0}^{m_i-1} \exp(h_i^T p_i^k)} \qquad (1)$$

3.4 Prediction for Metaphor Detection

We define the joint representation q_i of the target word w_i as the concatenation of the contextual representation h_i and the weighted sum p_i^* of gloss representations $p_i^0, \ldots, p_i^{m_i-1}$, which is formally defined below:

$$\begin{aligned} p_i^* &= \sum_{j=0}^{m_i-1} \alpha_i^j p_i^j, & (2) \\ q_i &= [h_i; p_i^*] & (3) \end{aligned}$$

where $[;]$ denotes the concatenation of two vectors.

By transforming the joint representation q_i through a fully connected layer followed by the softmax classifier, the probability distribution l_i that the target word w_i is metaphorical or literal is formally defined below:

$$l_i = \mathsf{softmax}(W_1 q_i + b_1) \tag{4}$$

where $W_1 \in \mathbb{R}^{2\times1536}$ and $b_1 \in \mathbb{R}^2$ are learnable parameters. The probability distribution l_i is of the form $[l_i^0, l_i^1]$, where l_i^0 is the predicted probability that w_i is literal, and l_i^1 is the predicted probability that w_i is metaphorical.

3.5 Training Objective Function

Based on predicted probabilities $\alpha_i^0, \ldots, \alpha_i^{m_i-1}$ over glosses, the loss value for metaphor interpretation about the target word w_i is defined as:

$$\text{loss}_i^{\text{MI}} = -\sum_{j=0}^{m_i-1} I(f_i = g_i^j)\log(\alpha_i^j) \tag{5}$$

where f_i is the correct gloss for w_i in sentence s, $I(X) = 1$ if X is true and $I(X) = 0$ otherwise.

As for the task of metaphor detection, we employ the binary cross entropy loss for predicting the target word w_i to be literal or metaphorical, defined as follow:

$$\text{loss}_i^{\text{MD}} = -(1-y_i)\log(l_i^0) - y_i \log(l_i^1) \tag{6}$$

where y_i is the correct label, $y_i = 0$ if the label is literal or $y_i = 1$ if the label is metaphorical.

The proposed joint model is trained by minimizing the following combined loss for every training sentence.

$$\text{loss} = \sum_{i=0}^{n-1} \text{loss}_i^{\text{MD}} + I(w_i \in \mathcal{C}) * \text{loss}_i^{\text{MI}} \tag{7}$$

where n is the number of words in the considering sentence, and $\mathcal{C}$ is a predefined set of candidate words required to be interpreted, which is collected from all metaphorical words in our experiments.

4 Experiments

4.1 Three Enhanced Datasets

We enhance three datasets TroFi, VUA and PSUCMC from the field of metaphor detection, where TroFi and VUA are in English and PSUCMC is in Chinese.

- TroFi (Birke and Sarkar, 2006). This is a benchmark metaphor dataset with verb metaphors annotated. Following the work (Mao et al., 2019), we treat unlabeled words as literal in the training phase.

- VUA (Steen, 2010). The VU Amsterdam Metaphor Corpus (VUA) samples fragments from the British National Corpus. All words in the corpus are labeled. We evaluate on both the VUA ALL POS track and the VUA-Verb track.

- PSUCMC (Lu and Wang, 2017; Nacey et al., 2019). The PSU Chinese Metaphor Corpus

Table 3: Data splits of PSUCMC for different POS tags, including NOWN, VERT, ADJ and ADV.

Dataset	NOUN	VERB	ADJ	ADV
all	929	2,547	390	19
train	760	1,988	334	13
val	105	244	31	4
test	64	315	25	2

Table 4: Accuracy on the metaphor interpretation task. All numbers are in %.

Model	VUA	PSUCMC	TroFi
BEM	45.5	**82.3**	71.9
MDGI-Joint-S	**46.4**	**82.3**	**72.2**
MDGI-Joint	44.3	80.8	70.9

consists of text samples from the Lancaster Corpus of Mandarin Chinese where are annotated for metaphor-related words following MIPVU (Steen, 2010). All words in PSUCMC are labeled. Following the experimental setting of VUA, we evaluate on both the PSUCMC ALL POS track and the PSUCMC-Verb track.

All these datasets are enhanced to support the gloss-based metaphor interpretation task. We refer to the set of words that need to be interpreted as the *candidate set*. For TroFi, the candidate set includes all labeled verbs. For VUA, the words in the candidate set are randomly selected from verbs. As for PSUCMC, we randomly choose a set of words and filter the meaningless words to construct a candidate set. Words in the candidate set are annotated by human annotators.

For English datasets, when given a word in the candidate set, the annotators are asked to look up the Merriam-Webster dictionary[2] to fetch its glosses. For the Chinese dataset, word glosses are extracted from the Baidu Dictionary[3].

For every dataset, four annotators are recruited to annotate the dataset independently. All annotators need to select the most appropriate gloss that expresses the contextual meaning of the target word, by comparing all glosses with the given context of the target word. They also need to discuss and determine the final labels after generating their own annotations.

To verify the reliability of the annotations, we use kappa-score to measure inter-annotator agreements for the annotations. Kappa-score (Siegel, 1956) has been widely used in computational linguistics to measure the reliability of an annotation scheme. Table 1 shows the kappa-score for annotations in every dataset, which demonstrates that the annotations have a high degree of reliability.

For PSUCMC and TroFi, we randomly split the samples into a training set, a validation set, and a test set according to the proportion of $8:1:1$. For VUA, the data splits provided by (Mao et al., 2019) are reused. Table 2 reports the statistics of all experimental datasets, whereas Table 3 gives more details about PSUCMC.

4.2 Experimental Setup

In our experiments, BERT[4] is used as both the context encoder and the gloss encoder, where the uncased BERT base model is used for TroFi and VUA, and the Chinese BERT base model is used for PSUCMC.

There are two variants for our proposed model. The first variant, named MDGI-Joint-S, shares parameters between the context encoder and the gloss encoder. The second one, named MDGI-Joint, implements two independent encoders for context and gloss, respectively.

To train these two models, we set the learning rate as 2e-5. The maximum number of epochs is set to 20. We set the dropout probability to 0.2 for the fully connected layer. The max sequence length is set to 128 for TroFi and VUA, and 256 for PSUCMC. The batch sizes for the two tasks are all set to 8 for VUA and TroFi, and 16 for PSUCMC. We keep the best model that maximizes the F1 score on the validation set for the metaphor detection task. This model is then used to evaluate the test set.

4.3 Compared Methods

We compare our method with the following methods.

- SEQ (Gao et al., 2018). SEQ is a neural model taking ELMo embeddings and GloVe embeddings as input. It uses a Bi-LSTM encoder to capture the contextual information of the target word, and then employs a fully connected layer followed by the softmax classifier to predict whether a word is metaphorical or not.

- RNN_HG (Mao et al., 2019). RNN_HG also takes ELMo embeddings and GloVe embeddings as input. Different from SEQ (Gao et al., 2018), RNN_HG concatenates the encoded representation with the GloVe embedding to capture the contextual information of the target word.

- RNN_MHCA (Mao et al., 2019). RNN_MHCA has a similar architecture as RNN_HG. But it adopts a multi-head contextual attention mechanism to capture the contextual information of the target word.

- MUL_GCN (Le et al., 2020). MUL_GCN is a multi-task learning framework. It exploits the similarity between word sense disambiguation and metaphor detection, by employing a graph convolutional neural network (GCN) to connect the words of interest with context words for metaphor detection.

- DeepMet (Su et al., 2020). DeepMet is a RoBERTa (Ott et al., 2019) based model with an ensemble strategy. It also takes features including POS tags and local texts as input. For fairness, we only compare our models with the single model of DeepMet.

- BEM (Blevins and Zettlemoyer, 2020). BEM is a model for the WSD task. It consists of two independent encoders. One is the context encoder, which embeds the target word and its surrounding context. The other encoder is the gloss encoder, which embeds the gloss for each word sense. Both encoders are deep transformer networks initialized from BERT.

For the evaluation on PSUCMC and TroFi, we use the publicly released code for all the compared methods except for MUL_GCN whose code is unavailable. Thus we cannot obtain results for MUL_GCN on both PSUCMC and TroFi. For VUA, we present results that are reported in the published papers of the compared methods.

It should be noted that all compared methods target the English domain only in their published papers. Since PSUCMC is a dataset in the Chinese domain, to evaluate the compared methods on PSUCMC, we use ELMo embeddings trained on the Xinhua proportion of Chinese gigawords[5], which is a Chinese corpus released by Che et al. (2018) and Fares et al. (2017); moreover, we place the GloVe embeddings with word embeddings trained on the zh-wiki corpus[6] based on Word2Vec (Mikolov et al., 2013).

4.4 Experimental Results

We use P (precision), R (recall), F1 (F1 score) and Acc (accuracy) as the evaluation metrics for the metaphor detection task, and Acc (accuracy) for the metaphor interpretation task. All the reported numbers are in percent. For the metaphor detection task, all words in the test set are evaluated. For the metaphor interpretation task, although corresponding glosses can be computed for all words, only the words with annotations in the test set are evaluated.

4.4.1 Results for Metaphor Interpretation

It can be seen from Table 4 that, no matter whether the two encoders share parameters or not, the proposed model achieves similar results comparable with BEM. MDGI-Joint-S is even slightly superior to BEM. The implemented BEM model does not share parameters between the two encoders. Therefore, it can be confirmed that the improved performance of MDGI-Joint-S comes from capturing the interaction between the two tasks, rather than from inheriting parameters from BEM.

4.4.2 Results for Metaphor Detection

From Table 5, it is evident that MDGI-Joint outperforms other methods over all three datasets except for the VUA-Verb track. Although DeepMet achieves the best performance on the VUA-Verb track, it exhibits lower performance than our proposed model on other datasets and the VUA ALL POS track. There results indicate that joint training for metaphor detection and metaphor interpretation does improve the performance of metaphor

Table 8: Ablation study for the gloss-based metaphor interpretation task. The measure is accuracy in %.

Model	VUA	PSUCMC	TroFi
MDGI-Joint-S	**46.4**	**82.3**	**72.2**
MDGI-Joint	44.3	80.8	70.9
MD-MGI	44.8	80.8	70.3

detection. It can also be seen that all the compared methods perform poorly on the Chinese dataset PSUCMC. This is probably due to that these methods are strongly language sensitive. The reason why DeepMet outperforms our model on the VUA-Verb track is due to extra information such as subclasses of POS tags being taken as input in DeepMet. It is interesting to see whether our proposed model can be further improved by exploiting extra information. But this question is out of the scope of this work. It will be explored in our future work.

4.5 Case Study

As shown in Table 6, we use two cases to exemplify the superiority of our model in the metaphor detection task, demonstrating that gloss-based interpretation improves performance of metaphor detection.

The first example is picked from the TroFi dataset (see Row 2 in Table 6). In this example the detected word **rained** is a metaphorical word, but DeepMet predicts it as literal. The reason could be that the word **rained** commonly occurs in the given context. In contrast, MDGI-Joint correctly predicts it as metaphorical according to its gloss-based interpretation ***to fall like rain*** since a gloss of the form *do like some behavior* is commonly used as the gloss of a metaphorical word.

The second example is selected from the VUA dataset (see Row 3 in Table 6). In this example the detected word **stand** has a literal meaning in its context. DeepMet wrongly predicts it as metaphorical, while MDGI-Joint gives a correct prediction based on its predicted gloss-based interpretation which has an expression style as that of general glosses of literal words.

4.6 Ablation Study

To investigate the effect of joint training for the two tasks, we further conduct experiments on the following weakened models.

- MD-MGI. In this model we only use the context representation to predict whether a target word is metaphorical. In other words, the weighted sum of gloss representations is not considered in the metaphor detection task, although the two tasks are still jointly trained without sharing parameters between the context encoder and the gloss encoder.
- MD (only). This model addresses the metaphor detection task only and neglects the metaphor interpretation task. It detects metaphors based on the contextual representation of words only.

From Table 7 we observe that the performance of MD-MGI drops slightly on the metaphor detection task compared to the proposed model. The reason is probable that, in MD-MGI the two tasks only interact through the context encoder, leading to limited benefits for metaphor detection. From Table 8 we can see that all the three compared variants are comparable in the metaphor interpretation task, where MDGI-Joint-S is slightly better than others. These results show that whether the metaphor detection task uses the weighted sum of gloss representations or not has few impacts on the metaphor interpretation task. It can be seen

Table 9: Performance on the VUA ALL POS track for metaphor detection, separated by different POS tags. In-vocabulary words are annotated words whereas out-of-vocabulary words have no annotations. Only a portion of verbs in VUA are annotated.

POS	P	R	F1	Acc
ADJ	78.6	57.1	66.2	92
ADV	81.5	65.2	72.4	96.4
NOUN	78.3	60.8	68.8	91.6
VERB(in-vocabulary)	79.2	75.5	77.3	82.0
VERB(out-of-vocabulary)	78.1	70.2	73.9	91.6
Other POS	88.3	84.6	86.4	97.5

from Table 7 that the weakest variant namely MD (only) performs worse than all the other variants, indicating that joint training for metaphor detection and metaphor interpretation leads to performance improvement in metaphor detection.

4.7 Error Analysis on VUA

Taking the VUA dataset as example, there are more false negatives than false positives generated by MDGI-Joint; *i.e.*, the recall is lower than the precision, as shown in Table 9. Especially, adjectives, adverbs and nouns have a significantly lower recall than verbs. The reason for this phenomenon is two-fold. On one hand, only a partial set of verbs has annotations in the VUA dataset, so the detection of metaphorical adjectives, adverbs or nouns can only gain limited benefits from the metaphor interpretation task. On the other hand, in VUA a number of metaphors appear at the phrase level, but MDGI-Joint is only able to detect metaphors at the word level, thus it is more likely to predict false negatives. Consider the following example picked from VUA id:a7w-fragment01#41: *But only two million out of the 20 million journeys which ambulance crews carry out each year are emergency calls.* MDGI-Joint only detects the word *carry* as metaphorical. It treats words separately and cannot predict the preposition *out* in the phrase *carry out* as metaphorical. It also wrongly predicts *crews* as literal possibly due to that the word is a noun.

5 Discussion

Out-of-vocabulary words are treated differently in the training phase and in the test phase. In the training phase, the loss of metaphor interpretation over out-of-vocabulary words is not computed according to Equation (7). In the test phase, the evaluation on metaphor detection involves all words, but the evaluation on metaphor interpretation only targets in-vocabulary words. For the metaphor detection task, in-vocabulary words and out-of-vocabulary words have no different treatments. We have conducted extra experiments for metaphor detection on the VUA ALL POS track. The results reported in Table 9 show that MDGI-Joint achieves significantly higher performance on in-vocabulary verbs (77.3%) than on out-of-vocabulary verbs (73.9%), but on all out-of-vocabulary words, MDGI-Joint achieves similar performance (77.2%).

Due to the limited glosses extracted from existing dictionaries, there will be correct glosses for novel metaphors that do not appear in the training set. It has been shown (Rai and Chakraverty, 2020) that interpreting novel metaphors in general situations is difficult. Hence our proposed gloss-based interpretations are definitely more suitable for conventional or lexical metaphors. Nevertheless, by considering that we can expand glosses with more external resources, the effectiveness of our proposed approach is not limited to a fixed set of metaphors.

6 Conclusion and Future Work

Metaphor detection is of great value in many natural language processing tasks. In this paper we have utilized gloss-based metaphor interpretation to enhance metaphor detection. The novelty mainly lies in the interpretation mechanism, *i.e.*, utilizing glosses to interpret metaphorical words. Accordingly, we propose a joint model for metaphor detection and gloss-based interpretation. We enhance three datasets in the field of metaphor detection to evaluate the joint model. Experimental results confirm that metaphor interpretation in gloss improves the performance of metaphor detection. Future work will extend our approach to other rhetoric identification tasks.

Evaluating Word Embeddings with Categorical Modularity

Abstract

We introduce categorical modularity, a novel low-resource intrinsic metric to evaluate word embedding quality. Categorical modularity is a graph modularity metric based on the k-nearest neighbor graph constructed with embedding vectors of words from a fixed set of semantic categories, in which the goal is to measure the proportion of words that have nearest neighbors within the same categories. We use a core set of 500 words belonging to 59 neurobiologically motivated semantic categories in 29 languages and analyze three word embedding models per language (FastText, MUSE, and subs2vec). We find moderate to strong positive correlations between categorical modularity and performance on the monolingual tasks of sentiment analysis and word similarity calculation and on the cross-lingual task of bilingual lexicon induction both to and from English. Overall, we suggest that categorical modularity provides non-trivial predictive information about downstream task performance, with breakdowns of correlations by model suggesting some meta-predictive properties about semantic information loss as well.

1 Introduction

Word embeddings represent words and phrases in continuous low-dimensional vector spaces. They are usually trained with neural language models or word collocations (Bengio et al., 2003; Collobert and Weston, 2008; Mikolov et al., 2013b; Levy et al., 2015), such that similar assignments in a space reflect similar usage patterns. The rise of monolingual embeddings such as Word2Vec (Mikolov et al., 2013b), GloVe (Pennington et al., 2014), and FastText (Bojanowski et al., 2017), coupled with the need to transfer lexical knowledge across languages, has also led to the development of cross-lingual word embeddings, in which different languages share a single distributed representation and are mapped into the same vector space. Such methods use different bilingual supervision signals (at the level of words, sentences, or documents) with varying levels of strength (Ruder et al., 2019).

A central task in the study of word embeddings is finding metrics to evaluate their quality. These metrics can either be *extrinsic*, where embeddings are used as input features for downstream NLP tasks and evaluated on their performance, or *intrinsic*, where embeddings are directly tested for how well they capture syntactic or semantic properties in their own right (Qiu et al., 2018). Extrinsic methods are not always feasible for low-resource languages due to a lack of annotated data. Moreover, downstream model components can be fine-tuned to achieve higher performance on certain tasks without necessarily indicating improvement in the semantic representation of words in an embedding space (Leszczynski et al., 2020).

This paper presents *categorical modularity*, a low-resource intrinsic evaluation metric for both monolingual and cross-lingual word embeddings based on the notion of graph modularity. The underlying principle is that *in good embeddings, words in the same semantic category should be closer to each other than to words in different categories*. We quantify this by building the k-nearest neighbor graph with a fixed set of words' semantic categories and computing the graph's modularity for a given embedding space. *Modularity* measures the strength of division of a graph with densely connected groups of vertices, with sparser connections between groups (Newman, 2006).

We source our semantic categories from Binder et al. (2016). In contrast to other semantic and ontological categories in the literature, these have been motivated by a set of experiential attributes with neurobiological consistency, covering sensory, motor, spatial, temporal, affective, social, and cog-

nitive dimensions. We refer to these attributes collectively as *Binder categories*. The resulting dataset consists of 500 English words, each labeled with three categories at three levels of semantic granularity. For example, the word *chair* belongs to *Concrete Objects* (Level 1), *Artifacts* (Level 2), and *Furniture* (Level 3). 442 words are pulled from Binder, on top of which we add a few words to even out distributions of categories and replace a few English-specific words with words that are more easily translated to non-English languages.

We then translate these 500 English words into 28 more languages, selected based on their availability in the form of pre-trained vectors from the MUSE library (Conneau et al., 2018). We produce 300-dimensional embeddings for these words using three popular embedding models: the monolingual FastText (Bojanowski et al., 2017) and subs2vec (Paridon and Thompson, 2020) models and the cross-lingual MUSE (Conneau et al., 2018) model. Using these embeddings, we obtain the nearest-neighbor sets among the 500 words within each (language, model) pair and use those relationships to calculate a modularity score for the pair. We compare modularity scores to performance on three downstream tasks: sentiment analysis (monolingual classification), word similarity (monolingual regression), and word-level bilingual lexicon induction (BLI, cross-lingual regression) both to and from English. We obtain moderate to strong positive correlations on all three tasks, with slightly stronger results on the monolingual tasks. We also provide an analysis of correlations broken down by individual model and explore potential meta-predictive properties of categorical modularity.

We further show that estimating modularity on Binder categories yields relevant information that cannot simply be derived from naturally occurring distributions of word clusters in embedding spaces. We show this by replicating all three downstream task correlation analyses with modularity scores based on clusters obtained with unsupervised community detection methods (Clauset et al., 2004), which we henceforth refer to as *unsupervised clusters*. After establishing the utility of categorical modularity, we show some of its use cases for comparing and selecting models for specific NLP problems, and we discuss preliminary results about the individual categories we find to be most predictive of downstream task performance.

Our code and data are available to the public.[1]

2.1 Word Embedding Evaluation Metrics

While word embeddings have become crucial tools in NLP, there is still little consensus on how to best evaluate them. Evaluation methods commonly fall into two categories: those motivated by an *extrinsic* downstream task and those motivated by the *intrinsic* study of the nature of semantics and the cognitive sciences (Bakarov, 2018). Intrinsic and extrinsic metrics do not always align, as some models have high quality as suggested by intrinsic scores but low extrinsic performance, and vice versa (Schnabel et al., 2015; Glavaš et al., 2019).

Some commonly used methods of extrinsic evaluation include named entity recognition (Collobert et al., 2011) —including the datasets *CoNLL-2002* and *CoNLL-2003* (Tjong Kim Sang and De Meulder, 2003)—, sentiment analysis (Schnabel et al., 2015), semantic role labeling, and part-of-speech tagging (Collobert et al., 2011). Intrinsic evaluation methods include word semantic similarity (Baroni et al., 2014), concept categorization (Baroni et al., 2014), and experiments on neural activation patterns (Søgaard, 2016).

Our categorical modularity metric is inspired by Fujinuma et al. (2019). They study the modularity of cross-lingual embeddings based on the premise that different languages are well-mixed in good cross-lingual embeddings and thus have low modularity with respect to language. Our metric improves upon the modularity proposed in Fujinuma et al. (2019) by overcoming the problem caused by low modularity potentially occurring with a purely random distribution of word vectors and being mistaken for high embedding quality, as it is unlikely for a random distribution to coincidentally have highly modular clusters corresponding to Binder categories. Moreover, our metric is able to evaluate both monolingual and cross-lingual word embeddings and allow for comparisons between these types of embeddings (e.g., FastText and MUSE), and it incorporates cognitive information through the use of brain-based semantic categories.

2.2 Cognitive Approaches to NLP

Recent work on word embeddings has explored the connections between NLP word representations

---

[1] `https://github.com/enscma2/categorical-modularity`

and cognitively grounded representations of words. Such connections enrich both computational and neuroscientific research: external cognitive signals can enhance the capacity of artificial neural networks to understand language, while language processing in neural networks can shed light on how the human brain stores, categorizes, and processes words (Muttenthaler et al., 2020).

Cognitive approaches to lexical semantics propose a model in which words are defined by how they are organized in the brain (Lakoff, 1988). Based on this premise, Hollenstein et al. (2019) propose *CogniVal*, a framework for word embedding evaluation with cognitive language processing data. They evaluate six different word embeddings against a combination of 15 cognitive data sources acquired via eye-tracking, electroencephalography (EEG), and functional magnetic resonance imaging (fMRI). In a similar line of work, both Søgaard (2016) and Beinborn et al. (2019) evaluate word embeddings using fMRI datasets.

The use of cognitive data in NLP goes well beyond the evaluation of word embeddings. Utsumi (2020) uses the neurosemantically inspired categories from Binder et al. (2016) to identify the knowledge encoded in word vectors. Among other conclusions, they find that the prediction accuracy of cognitive and social information is higher than that of perceptual and spatiotemporal information.

3 Modularity and k-NN Graphs

The concept of modularity has origins in the field of network science, as first introduced by Newman (Newman, 2006). The goal of the modularity measure is to quantify the strength of the division of a network into clusters. Usually, such networks are represented with graphs. Intuitively, the modularity of a graph measures the difference between the fraction of edges in the graph that connect two nodes of the same category and the expected corresponding fraction if the graph's edges were distributed at random. Thus, the higher the proportion of edges between nodes that belong to the same category, the higher the modularity.

In our case, we construct the pertinent graph with the k-nearest neighbors algorithm. Given a set S_w of N words and a set S_c of categories such that each of the N words belongs to exactly one of the categories in S_c, we map each of the N words into a d-dimensional word embedding vector space and obtain a d-dimensional vector for each word. For each pair (w_i, w_j), where $w_i, w_j \in S_w$ and $1 \leq i, j \leq |S_w|$, with corresponding d-dimensional vectors v_i and v_j, we compute their cosine similarity (the cosine of the angle between them), which we denote by $\texttt{similarity}(i, j)$.

We create a matrix M_D of dimensions $|S_w| \times |S_w|$, where entry $(M_D)_{i,j}$ is $\texttt{similarity}(i, j)$. For a given $k \in \mathbb{Z}_{>0}$, we build the $|S_w| \times |S_w|$ k-nearest neighbor matrix (denoted k-NNM) as follows: entry (i, j) of k-NNM is equal to 1 if and only if word j is one of the k nearest neighbors of word i (i.e., if $\texttt{similarity}(i, j)$ is among the k largest cosine similarities between i and all other words in S_w). We note that M_D and k-NNM are not necessarily symmetric, as word i being the k-th nearest neighbor of word j does not imply the reverse. Finally, we define the k-NN graph of S_w as the graph defined by k-NNM viewed as an adjacency matrix. We can now describe how to compute the modularity score following the schema in Fujinuma et al. (2019).

Let d_i denote the degree of node i, that is, $d_i = \sum_j (k\text{-NNM})_{i,j}$, and let g_i denote the category of word i. For each category $c \in S_c$, the expected number of edges within c is

$$a_c = \frac{1}{2m} \sum_i d_i \, I[g_i = c], \tag{1}$$

where m is the total number of edges in the k-NN graph and I is the indicator function that evaluates to 1 if the argument is true and to 0 otherwise.

The fraction of edges e_c that connect words of the same semantic category c is

$$e_c = \frac{1}{2m} \sum_{i,j} (k\text{-NNM})_{i,j} \, I[g_i = c] \, I[g_j = c]. \tag{2}$$

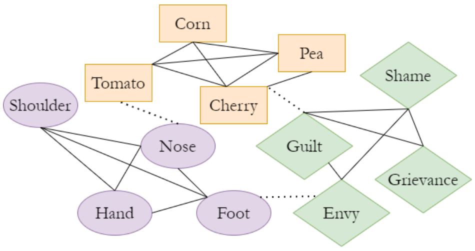
By weighting the $|S_c|$ different semantic categories together, we calculate the overall modularity Q as follows:

$$Q = \sum_{c=1}^{|S_c|} (e_c - a_c^2). \tag{3}$$

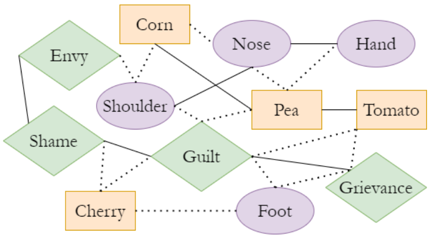
Finally, we normalize Q by setting

$$Q_{max} = 1 - \sum_{c=1}^{N} a_c^2, \quad Q_{norm} = \frac{Q}{Q_{max}}. \tag{4}$$

In our setting, Q_{norm} indicates the modularity score of one (language, model) pair overall, but



(a) A high-modularity semantic k-NN graph.



(b) A low-modularity semantic k-NN graph.

Figure 1: A toy visualization of the meaning of categorical modularity with some words pertaining to the Binder categories *Body Parts* (purple ovals), *Plants* (peach rectangles), and *Emotions* (green rhombi). Dotted edges connect nodes of different categories, while solid edges connect nodes of the same category.

we denote by Q_c the modularity of said (language, model) pair with respect to category $c \in S_c$. The definition of Q_c (normalized) is deduced from Equation 4:

$$Q_c = \frac{e_c - a_c^2}{Q_{max}}. \tag{5}$$

A higher value of Q_{norm} indicates that a higher number of words that belong to the same categories appear connected in the k-NN graph. In Sections 5 and 6, we analyze the values Q_{norm} for each of the languages, and in Section 8, we make some observations about the different values of Q_c.

In our conclusions about how our categorical modularity scores correlate with downstream task performance, we also want to prove that our selected neurosemantic-based categories are nontrivial and are better predictors than the unsupervised clusters that emerge from the embeddings. To find these clusters, we use the Clauset-Newman-Moore greedy modularity method (Clauset et al., 2004). This algorithm iteratively joins the pair of communities that most increases modularity until no such pair exists. For each value of k, we obtain the unsupervised communities in this manner and compute their modularity scores. In Section 6, we show that Binder categories are significantly better predictors than the unsupervised clusters using the same set of 500 words.

4 Dataset

In this section, we define the sets S_N and S_c of words and their semantic categories, respectively, that we use to compute categorical modularity scores for 29 languages.[2] As outlined in Section 1, our motivation to take a cognitive approach in the study of word embeddings prompts us to use words and categories that reflect a brain-based computational model of semantic representation as in Binder et al. (2016). We have 500 words (comprised of nouns, adjectives, and verbs) with 3 levels of categories, from most general (Level 1) to most specific (Level 3). Each word is tagged with 3 categories (one per level), which are listed in Table 1. After lifting 442 English words from Binder and adjusting the word set to optimize evenness of distribution across categories and translatability of concepts across languages, we manually translate the words to the 28 non-English languages[3] mentioned in footnote 2.

Level 1. Concrete Objects, Concrete Events, Abstract Entities, Concrete Actions, Abstract Actions, States, Abstract Properties, Physical Properties.
Level 2. Living Things, Other Natural Objects, Artifacts, Social Events, Nonverbal Sound Events, Weather Events, Miscellaneous, Concrete Events, Abstract Constructs, Cognitive Entities, Emotions, Social Constructs, Time Periods, Body Actions, Locative Change Actions, Social Actions, Miscellaneous Actions, Abstract Actions, States, Abstract Properties, Physical Properties.
Level 3. Animals, Body Parts, Humans, Human Groups, Plants, Natural Scenes, Miscellaneous Natural Objects, Furniture, Hand Tools, Manufactured Foods, Musical Instruments, Places/Buildings, Vehicles, Miscellaneous Artifacts, Social Events, Nonverbal Sound Events, Weather, Events, Miscellaneous Concrete Events, Abstract Constructs, Cognitive Entities, Emotions, Social Constructs, Time Periods, Body Actions, Locative Change Actions, Social Actions, Miscellaneous Actions, Abstract Actions, States, Abstract Properties, Physical Properties.

Table 1: Three levels of Binder categories.

---

[2] The 29 languages are: Arabic, Bulgarian, Catalan, Croatian, Czech, Danish, Dutch, English, Estonian, Finnish, French, Greek, Hebrew, Hungarian, Indonesian, Italian, Macedonian, Norwegian, Polish, Portuguese, Romanian, Russian, Slovak, Slovenian, Spanish, Swedish, Turkish, Ukrainian, and Vietnamese.

[3] For languages with which we were not familiar, we solicited translations from colleagues, whom we compensated fairly for this work.

5 General Categorical Modularity

With the dataset of 500 words that belong to three levels of semantic categories, we compute the modularity scores of each of the 29 languages for each of the three word embedding models (which we refer to as 87 (language, model) pairs): FastText,[4] MUSE,[5] and subs2vec.[6] We briefly summarize the properties of each of these embeddings.

FastText. Monolingual embeddings for 157 languages trained on Common Crawl and Wikipedia that use CBOW with position-weights and character n-grams (Bojanowski et al., 2017).

MUSE. Cross-lingual embeddings resulting from the alignment of 30 FastText embeddings into a common space under the supervision of ground-truth bilingual dictionaries (Conneau et al., 2018).

subs2vec. Monolingual embeddings for 55 languages trained on the OpenSubtitles corpus of speech transcriptions from television shows and movies using the FastText implementation of the skipgram algorithm (Paridon and Thompson, 2020). The authors claim that subtitles are closer to the human linguistic experience (Paridon and Thompson, 2020).

Information about the sizes of each (language, model) pair can be found in Appendix B. For each pair, we build the k-NN graph and compute modularity for different values of k and different levels of categories, which we treat as our 2 hyperparameters. We consider small values for k (namely $k \in \{2, 3, 4\}$) due to the fact that categories such as *States* have as few as 4 words.

6 Downstream Task Experiments

We test the reliability of categorical modularity by running a few downstream tasks and computing the Spearman rank correlations between categorical modularity scores and performance on these tasks.

After determining the optimal set of hyperparameters (k and level of semantic categories) for each task, we then compare the correlation produced by that set of hyperparameters with the correlation produced by the corresponding value of k with the modularity of the unsupervised clusters constructed by the community detection algorithm described in Section 3 to establish the non-triviality of the predictive properties of these chosen semantic categories. Table 2 provides a summary of correlation values for four tasks: movie review sentiment analysis (Sentiment), word similarity (WordSim), bilingual lexicon induction from English (BLI from), and bilingual lexicon induction to English (BLI to). Appendix A contains full tables with the correlation results. A visual summary of the results can be found in Figure 2.

Task	ρ	$\rho_{\mathbf{ft}}$	$\rho_{\mathbf{m}}$	$\rho_{\mathbf{s}}$
Sentiment	0.54	0.44	0.68	0.46
WordSim	0.71	0.59	0.34	0.80
BLI from	0.55	0.40	0.54	0.76
BLI to	0.50	0.29	0.56	0.82

Table 2: Summary of Spearman correlations of categorical modularity with downstream task performance for Binder categories, aggregated across all models (ρ) and broken down within FastText ($\rho_{\mathbf{ft}}$), MUSE ($\rho_{\mathbf{m}}$), and subs2vec ($\rho_{\mathbf{s}}$).

6.1 Sentiment Analysis

We first test our modularity scores through correlations with performance on the binary classification task of sentiment analysis, where the input is a movie review and the output is a binary label that corresponds to either positive or negative sentiment for that review. For this task, our data consists of 5,000 randomly selected positive movie reviews and 5,000 randomly selected negative reviews from the IMDB Movie Reviews dataset (Maas et al., 2011). We randomly partition these 10,000 reviews into 80% training and 20% testing data. Because this dataset is only available in English, we use the Google Translate API[7] to translate the data to 15 more languages (Arabic, Bulgarian, Catalan, Croatian, Czech, Danish, Dutch, Estonian, Finnish, French, Greek, Hebrew, Hungarian, Indonesian, and Italian) for a total of $n = 48$ observations. The languages and the dataset size of 10,000 are chosen due to Google Translate API rate limits.

For each (language, model) pair, we convert the raw text of each review to a 300-dimensional embedding vector. We use the built-in black-box position-weighted continuous bag-of-words embedding model for FastText and subs2vec (Bojanowski et al., 2017), and we use a simple mean of individual word embeddings for MUSE, as the MUSE

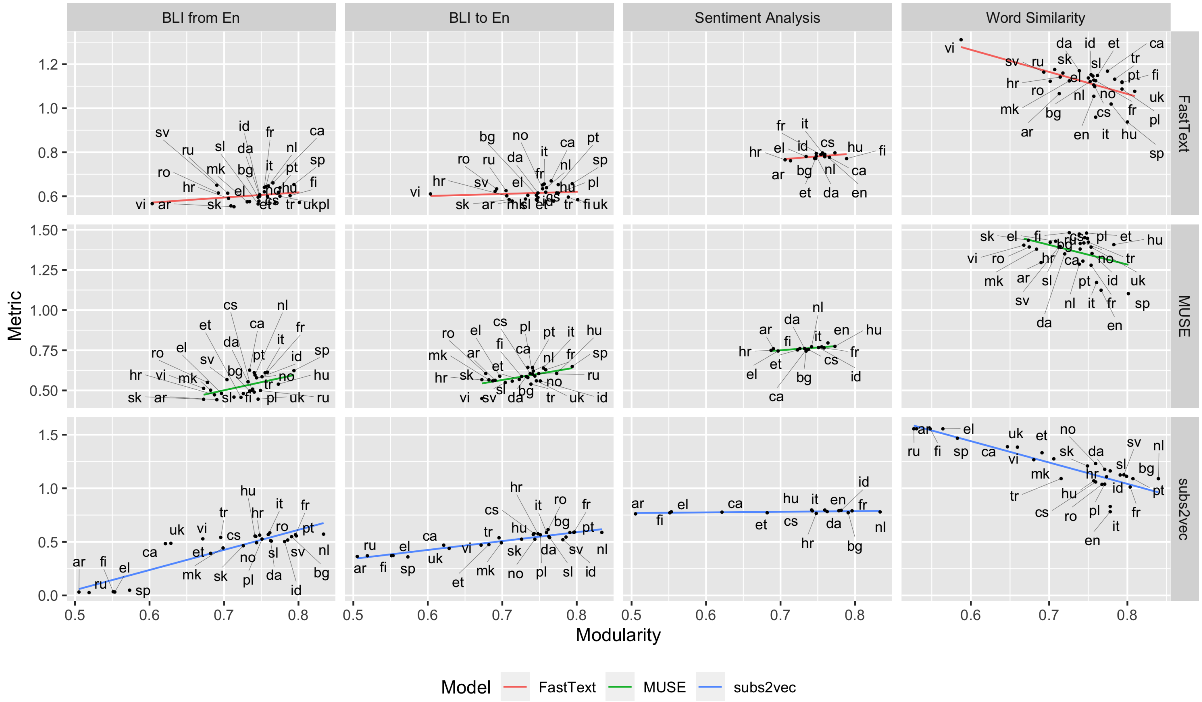

Figure 2: Summary of modularity vs performance metrics across tasks. Each language is represented with its 2-letter ISO 639-1 code. Hebrew, an outlier on the low end, is not included in this plot. Full modularity and performance data is included in our public GitHub repository.

library does not have multi-word phrase embeddings built into its functionality. Using a vanilla linear support vector machine model with scikit learn's default settings,[8] we run the task on each language-model pair 30 times and record the mean accuracy and precision scores for each pair. We then calculate the Spearman correlations of each of the 9 modularity scores with both the accuracy and precision values. Furthermore, we analyze the overall merged correlations (taking all 48 data points for a given modularity score and performance metric) as well as the correlations within models (taking only the 16 data points within each single model), giving us a total of 72 Spearman correlation values.

We find that the optimal set of hyperparameters is Level 3 categories with $k = 2$, which gives a Spearman correlation of $\rho = 0.54$ with the accuracy metric. Breaking it down by individual model, we have $\rho_{\mathbf{ft}} = 0.44$ for FastText, $\rho_{\mathbf{m}} = 0.68$ for MUSE, and $\rho_{\mathbf{s}} = 0.46$ for subs2vec. For $k = 2$, the correlations of unsupervised clusters with accuracy are $\rho = 0.09$ for all 48 observations merged, $\rho_{\mathbf{ft}} = 0.1$, $\rho_{\mathbf{m}} = 0.4$, and $\rho_{\mathbf{s}} = 0.35$, providing evidence that Binder categories contain non-trivial predictive information that is not present in naturally emerging clusters.

6.2 Word Similarity

Our next downstream task is the monolingual regression task of word similarity, in which the input is two words in one language and the output is a real number between 0 and 4 representing how similar the two words are (a higher score represents a greater degree of similarity). We use the English, Italian, and Spanish word pair datasets from SemEval-2017 (Camacho et al., 2017), and we use the same Google Translate API from Section 6.1 to translate the English dataset into the remaining 26 languages. Each language's dataset then has 500 word pairs, which we randomly split into 400 training pairs and 100 testing pairs for each trial.

Given a language and a model, we take each word pair, compute the 300-dimensional embeddings of both words, and calculate the Euclidean distance, Manhattan distance, and cosine similarity between the embeddings. We then feed these three scalars as a vector of inputs into a standard linear regression model from Python's scikit-learn package with default settings,[9] whose output is the

---

[8] `https://scikit-learn.org/stable/modules/svm.html`

[9] `https://scikit-learn.org/stable/modules/linear_model.html`

similarity score given in the dataset. To evaluate task performance, we compute the Mean Squared Error (MSE) loss for each run and record the mean MSE loss over 30 trials per (language, model) pair.

We then calculate the Spearman correlations of each of the 9 modularity scores with the negatives of the losses (such that positive correlation means that high modularity predicts high performance), both merged (87 data points) and within individual models (29 data points per model), for a total of 36 correlation values.

We find that all of the merged correlations are moderately to strongly positive. In particular, with the optimal hyperparameters of Level 2, $k = 2$, we have $\rho = 0.71$ overall, $\rho_{\mathbf{ft}} = 0.59$ for FastText, $\rho_{\mathbf{m}} = 0.34$ for MUSE, and $\rho_{\mathbf{s}} = 0.8$ for subs2vec. In comparison, the correlations of the unsupervised cluster modularities with mean MSE loss for $k = 2$ are $\rho = 0.27$, $\rho_{\mathbf{ft}} = 0.36$, $\rho_{\mathbf{m}} = 0.3$, and $\rho_{\mathbf{s}} = 0.42$, all weaker than their Binder counterparts.

6.3 Word-Level Bilingual Lexicon Induction

In addition to both monolingual classification and monolingual regression tasks, we also test our modularity metric on the cross-lingual regression task of bilingual lexicon induction. Using the ground-truth bilingual dictionaries provided by the publishers of MUSE (Conneau et al., 2018), we run this task with the 28 non-English languages listed in footnote 2 in two directions: translation to and from English. We use the 5,000-1,500 train-test split provided in the MUSE dictionary dataset and formulate the tasks as multivariate, multi-output regression tasks: for each observation in each (language, model) pair, we convert the English source word to its 300-dimensional embedding specified by the English version of the model and feed this vector as input to the same scikit-learn linear regression model as in Section 6.2, of which the output is a 300-dimensional vector in the target language model space representing the embedding of the target word.

We follow this procedure in the other direction as well by converting source non-English words to embeddings in the appropriate non-English model spaces, feeding those embeddings into the linear regression model, and computing 300-dimensional predictions for the target English word vectors in the English model spaces. To measure task performance in the "from English" direction, we convert the ground-truth non-English target words into vectors in the corresponding non-English embedding model space, compute the cosine similarities between each ground-truth vector and its corresponding predicted vector, and record the mean of those cosine similarities as a measure of how close we are to the ground truth on average. We run 30 trials per (language, model) pair and record the mean of the mean cosine similarities.

In the "to English" direction, we similarly convert the ground-truth English target words into vectors and compute the mean cosine similarity over the prediction-ground-truth pairs. We calculate the Spearman correlations of each of the 9 modularity scores with the 30-trial means of mean cosine similarities in both directions. Once again, we calculate the correlations both across all models and within each individual model, yielding 72 total correlation values.

The optimal set of hyperparameters for the merged correlation in the "from English" direction is Level 3, $k = 2$, giving a moderate $\rho = 0.55$ overall, $\rho_{\mathbf{ft}} = 0.4$ for FastText, $\rho_{\mathbf{m}} = 0.54$ for MUSE, and a strong $\rho_{\mathbf{s}} = 0.76$ for subs2vec. For comparison, the corresponding $k = 2$ correlations for unsupervised cluster modularities are $\rho = 0.35$, $\rho_{\mathbf{ft}} = 0.04$, $\rho_{\mathbf{m}} = 0.27$, and $\rho_{\mathbf{s}} = 0.65$ — all weaker than their Binder counterparts.

The optimal set of hyperparameters for the merged correlation in the "to English" direction is also Level 3, $k = 2$, giving a moderate $\rho = 0.5$ overall, a weak $\rho_{\mathbf{ft}} = 0.29$, a moderate $\rho_{\mathbf{m}} = 0.56$, and a very strong $\rho_{\mathbf{s}} = 0.82$. The corresponding unsupervised cluster correlations for $k = 2$ are $\rho = 0.35$, $\rho_{\mathbf{ft}} = 0.04$, $\rho_{\mathbf{m}} = 0.27$, and $\rho_{\mathbf{s}} = 0.65$.

Notably, in both the word similarity and BLI tasks, $\rho_{\mathbf{s}}$ is significantly stronger than $\rho_{\mathbf{ft}}$ and $\rho_{\mathbf{m}}$. This may be due to the fact that compared to sources such as Wikipedia and Common Crawl, the subtitles used as training data for subs2vec are more representative of how the human brain semantically maps language, as suggested by the model's creators (Paridon and Thompson, 2020).

Overall, these downstream task experiments suggest that categorical modularity is a non-trivially significant predictor of performance on both monolingual and cross-lingual NLP tasks (though it is stronger on monolingual tasks) and that it may have potential to be a meta-predictor of how well a particular model matches the information encoded in the human brain.

7 Use Cases: Comparing and Selecting Models

After having established substantial evidence of the predictive properties of categorical modularity, we present some examples of how the research community can make use of the metric for model evaluation and selection.

7.1 Comparing Models within a Language

The best hyperparameters for the tasks described in Section 6 are Level 3 with $k = 2$ along with Level 2 with $k = 2$. Across the 29 languages at the latter, FastText has the highest modularity 9 times (Arabic, Catalan, Estonian, Finnish, Greek, Macedonian, Polish, Turkish, Ukrainian), while MUSE has the highest modularity 3 times (Hungarian, Russian, Spanish), and subs2vec has the highest modularity 17 times. For Level 3 with $k = 2$, FastText has the highest modularity 13 times, while MUSE has the highest modularity 2 times (Russian, Vietnamese), and subs2vec has the highest modularity 15 times. Though individual choices should be made with each language, this suggests that subs2vec may be a strong choice for monolingual tasks overall.

7.2 Comparing Languages within a Model

We also present some evidence that categorical modularity predicts bilingual lexicon induction performance moderately well, and predictive properties are especially strong within subs2vec. For the optimal set of hyperparameters found in that task within subs2vec (Level 2, $k = 2$, $\rho_{\mathbf{s}} = 0.77$ from English and $\rho_{\mathbf{s}} = 0.81$ to English), the languages with the highest modularities in subs2vec are Dutch (0.84), Portuguese (0.81), French (0.80), Bulgarian (0.80), Swedish (0.80), Indonesian (0.79), and English (0.78), while the languages with the lowest modularities are Catalan (0.65), Spanish (0.58), Hebrew (0.58), Greek (0.56), Finnish (0.55), Arabic (0.53), and Russian (0.53). This may suggest which languages have lower amounts of resources at this time and hence deserve more data collection efforts on the part of the NLP community, particularly within subs2vec's domain of subtitle and conversational data.

7.3 Categorical Modularity as a Potential Meta-Predictor

We find evidence that categorical modularity reveals some information about how well models map to the human brain, as suggested by subs2vec's significantly stronger correlations. This is particularly true with regression tasks. Given a new or existing embedding model, calculating its categorical modularities and assessing their correlations with regression tasks such as word similarity may reveal if the model space is representative of how linguistic information is encoded in the brain.

8 Discussion and Future Work

Categorical modularity shows promise as an intrinsic word embedding evaluation metric based on our preliminary experiments. We can envision extending this work in several directions. For one, we can calculate single-category modularities (denoted by Q_c as defined in Equation 5) and test which individual categories contain the most predictive properties. Our limited experiments in this direction with the movie sentiment analysis task suggest that concrete and non-living categories have better predictive capabilities than abstract and living ones: for the sentiment analysis task, the 5 most strongly correlated categories are *Nonverbal Sounds*, *Artifacts*, *Concrete Objects*, *Vehicles*, and *Manufactured Foods*, while the 5 least correlated categories are *Abstract Properties*, *Abstract Constructs*, *Miscellaneous Actions*, *Humans*, and *Abstract Actions*.

We may also extend our work to more models and languages to see if the predictive properties truly hold across all languages and models. Additionally, as more multilingual research and data becomes available in this space, we may probe different sets of semantic categories, further downstream tasks (particularly multi-class classification, monolingual text generation, and sentence-level bilingual lexicon induction), and further variations of models used in downstream tasks (e.g., deeper neural networks instead of vanilla SVMs and linear regressions). We can also envision improvements upon the categorical modularity metric itself, perhaps by way of a lower-resource metric or a metric that works well on contextualized word embeddings for which the word-vector mappings may have more complex geometries. Our code and data, which are available to the public,[10] can also enable researchers and practitioners to replicate our results and experiment with different models, words, languages, and categories.

---

[10] `https://github.com/enscma2/categorical-modularity`

9 Conclusion

In this paper, we introduce categorical modularity, a novel low-resource metric that may serve as a tool to evaluate word embeddings intrinsically. We present evidence that categorical modularity has strong non-trivial predictive properties with respect to overall monolingual task performance, moderate predictive properties with respect to cross-lingual task performance, and potential meta-predictive properties of model space similarity to cognitive encodings of language.

Impact Statement

Ethical Concerns

All of the data used in this paper is either our own or from publicly released and licensed sources. Our data is mainly aimed towards researchers and developers who wish to assess the qualities of word embedding models and gain some intuition for embedding model selection for downstream tasks. In particular, our conclusions would be suited for researchers working among the 29 functioning languages given in the MUSE library, which are heavily skewed towards Indo-European languages. Though we do not directly introduce novel NLP applications, we provide resources that may be useful in selecting technologies to deploy and informing the development of word embedding systems.

Categorical modularity is intended to be an informational tool that sheds light on semantic representation of natural language information in computational word embeddings, and there are many aspects of its capabilities that can be improved upon, extended, or further explored. We would also like to emphasize that we have only tested our metric on three specific downstream tasks with basic downstream models, and these may not be representative of all NLP tasks in general. Categorical modularity also has not yet been shown to reveal information on representational harms inherent in word embedding spaces, so evidence of good downstream task performance should not be misconstrued as indicative of strong and beneficial performance across all NLP domains.

Environmental Impact

We acknowledge the pressing threat of climate change and therefore record some statistics on the computational costs of our experiments. All of our experiments are run with a 13-inch 2019 MacBook Pro with a 1.7 GHz Quad-Core Intel Core i7 processor running Python 3.8.3 in Terminal Version 2.11 on MacOS Big Sur Version 11.1. For the English language, generating FastText embeddings for our 500 core words took 20.31 seconds, generating the 500×500 k-NNM took 1 hour and 25.72 seconds, generating MUSE embeddings for the 500 words took 23.13 seconds, and generating the 500×500 k-NNM took 7 minutes and 39.32 seconds. For the downstream task of movie review sentiment analysis, it took 42.03 seconds to generate FastText sentence embeddings for 10,000 English reviews and 6 minutes and 38.32 seconds to generate these embeddings with MUSE. It took 0.35 seconds per review to translate from English to Spanish using the Google Translate API, and it took 2.6 seconds to run 30 trials of the sentiment analysis task for English FastText using scikit-learn's LinearSVC. For the task of word similarity calculation, English FastText embeddings and 3-dimensional input data took 21.25 seconds to generate for 500 word pairs, English MUSE-based embedding data took 33.47 seconds to generate, and the word similarity task using scikit-learn's LinearRegression took 0.09 seconds on the generated English FastText-based inputs. For bilingual lexicon induction, FastText English-Spanish embedding data took 55.87 seconds to generate, MUSE English-Spanish embedding data took 27 minutes and 29.56 seconds to generate, and the BLI task took a combined 4.35 seconds for both directions of English-Spanish using FastText. All other tasks took less than one second per language/model pair.

A Appendix: Full Results for Correlations of Categorical Modularities with Downstream Tasks

This section contains full tables of correlations of general categorical modularities and unsupervised cluster modularities with downstream tasks. As above, ρ is overall correlation, ρ_{ft} is the correlation within FastText, ρ_m is the correlation within MUSE, and ρ_s is the correlation within subs2vec. On notation: in the "Model" columns, a, b represents the hyperparameters of Level a Binder categories with $k = b$ neighbors, while "C, a" represents "control" unsupervised clusters with the hyperparameter of $k = a$ neighbors.

Abstract

Language modeling (LM) for automatic speech recognition (ASR) does not usually incorporate utterance level contextual information. For some domains like voice assistants, however, additional context, such as time at which an utterance was spoken, provides a rich input signal. We introduce an attention mechanism for training neural speech recognition language models on both text and non-linguistic contextual data [1]. When applied to a large de-identified dataset of utterances collected by a popular voice assistant platform, our method reduces perplexity by 7.0% relative over a standard LM that does not incorporate contextual information. When evaluated on utterances extracted from the long tail of the dataset, our method improves perplexity by 9.0% relative over a standard LM and by over 2.8% relative when compared to a state-of-the-art model for contextual LM.

1 Introduction

Conventional automatic speech recognition (ASR) systems include a language model (LM) and an acoustic model (AM). The LM component is trained separately, typically on large amounts of transcribed utterances that have been collected by an existing speech recognition system.

Voice assistants have become ubiquitous and crucially rely on ASR systems to convert user inputs to text. They often collect utterances spoken by users, along with associated de-identified contextual information. We hypothesize that these additional data, such as the time at which an utterance was spoken, provide a useful input signal for a LM. As an example, knowing that an utterance was spoken on December 25th, a LM should learn that the word "christmas" rather than "easter" is more likely to follow the phrase "lookup cookie recipes for".

To-date, some voice assistants have leveraged coarse geographic information for improving location search queries (Bocchieri and Caseiro, 2010; Lloyd and Kristjansson, 2012). These past efforts, however, have largely focused on improving a particular skill of an ASR system, and not the system's speech recognition in general.

In this paper, we focus on adapting recurrent neural network language models (RNN-LMs) to use both text and non-linguistic contextual data for speech recognition in general. While, outside of ASR, transformer-based (Vaswani et al., 2017) language models have largely replaced RNN-LMs, RNNs remain dominant in ASR architectures such as connectionist temporal classification (Graves et al., 2006), and RNN-T (Graves, 2012; He et al., 2019).

The most common method for incorporating non-linguistic information into a RNN-LM is to learn a representation of the context that is concatenated with word embeddings as input to the model. This concatenation-based approach has been used in a variety of domains including text classification (Yogatama et al., 2017), personalized conversational agents (Wen et al., 2013), and voice search queries (Ma et al., 2018).

Recently, attention mechanisms, initially developed for machine translation (Bahdanau et al., 2014; Luong et al., 2015), have been used by neural LMs to adaptively condition their predictions on certain non-linguistic contexts. Tang et al. (2016) use an attention module that attends to word-location information to predict the polarity of a sentence. Similarly, Zheng et al. (2019) use an attention mechanism over learned personality trait embeddings, in order to generate personalized dialogue responses.

The aforementioned approaches learn a representation of the context that is directly used as input to a neural LM. In contrast to these methods, Jaech and Ostendorf (2018a) adapt the weight-

---

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1994–2003
August 1–6, 2021.

matrix used in an RNN model to a given contextual input. The authors propose decomposing the weight-matrix into a set of left and right basis tensors which are then multiplied by a learned context embedding to produce a new weight-matrix. Factorizing the weight-matrix enables a larger fraction of a model's parameters to adjust to a given contextual signal. This factorization-based approach has proven effective in generating automatic completions of sentences that are personalized for particular users (Jaech and Ostendorf, 2018b).

We introduce an attention mechanism that augments both the concatenation-based and factorization-based approaches to condition a neural LM on context. The attention mechanism that we propose builds up a dynamic context representation over the course of processing an utterance. The resulting embedding can be used as an additional input to either the concatenation-based or factorization-based model.

Our experiments focus primarily on conditioning neural LMs on datetime context. We concentrate on datetime information because of its widespread availability in many ASR systems. Our approach, however, can generalized to any type of context. To underscore this point we also provide results for conditioning LMs on geolocation information and dialogue prompts that are commonly available in ASR systems.

We evaluate our method on a large de-identified dataset of transcribed utterances. Compared to a standard model that does not include contextual information, using our method to contextualize a neural LM on datetime information achieves a relative reduction in perplexity of 7.0%, and a relative reduction in perplexity of 9.0% when evaluated on the tail of this dataset. Moreover, our attention mechanism can improve state-of-the-art methods for conditional LMs by over 2.8% relative in terms of perplexity.

2 Data

We use a corpus of over 5,000 hours of de-identified, transcribed English utterances, collected over several years. Each utterance also contains associated information about the year, month, day, and hour that the utterance was spoken. The datetime information is reported according to the local time zone of each given user. Any information about the device or the speaker from which an utterance originates has been removed. We randomly split our dataset into a training set, development set and test set, using a partition ratio of 90/5/5 and we ensure that each partition contains more than 500 hours worth of data.

3 Context Representation

A typical utterance in our dataset might look like this:

2020-12-23 07:00 play christmas music.

In the example above, we can infer that the utterance "play christmas music" was spoken on December 23, 2020 at 7 in the morning local time. In order to condition a LM on this datetime information, we consider two methods for transforming the contextual information into a continuous vector representation:

1. **Learned embeddings:** We first consider creating tokens for the month number, week number, day of the week and hour that an utterance was spoken. In the example above, we would transform the datetime information into tokens representing: month-12, week-52, wednesday, 7am. These tokens are subsequently used as input to the model, where they are passed through an embedding layer to generate context embeddings. These embeddings are initialized as random vectors, and trained along with the rest of the model. We experiment with different ways of parsing the information, such as encoding weekday versus weekend, or morning versus evening, but find this information is largely entailed within our method for processing datetime information.

2. **Feature-engineered representation:** Additionally, we consider transforming the datetime information into a single 8-dimensional feature-engineered vector, where the dimensions of the vector are defined as

$$\begin{bmatrix} sin(\frac{2\pi \cdot hour}{24}) & cos(\frac{2\pi \cdot hour}{24}) \\ sin(\frac{2\pi \cdot day}{7}) & cos(\frac{2\pi \cdot day}{7}) \\ sin(\frac{2\pi \cdot week}{53}) & cos(\frac{2\pi \cdot week}{53}) \\ sin(\frac{2\pi \cdot month}{12}) & cos(\frac{2\pi \cdot month}{12}) \end{bmatrix}$$

Since the datetime context is continuous and cyclical, this approach explicitly encodes temporal proximity in the date and time information.

3.1 Input Representation

We assume as input to a model a sequence of either word or subword tokens, w_i for $i \in \{1, \dots, n\}$, that are converted by an embedding layer into embeddings $x_i \in \mathcal{R}^e$ for $i \in \{1, \dots, n\}$, where n is the length of the input sequence and e is the dimensionality of the word embeddings.

We additionally represent the contextual information as either:

1. A set, M, of four learned context embeddings $M = \{m_1, m_2, m_3, m_4\}$, where m_1 is an encoding of the month information, m_2 is an encoding of the week information, m_3 is an encoding of the day of the week information, and m_4 is an encoding of the hour of the day information. When using the concatenation-based or factorization-based approaches without attention, we first concatenate the embeddings together, $m = [m_1; m_2; m_3; m_4]$, and use the resulting vector as input to the model.
2. A set, M, containing a single embedding $M = \{m\}$, where m represents an 8-dimensional feature-engineered contextual datetime representation, as described in the previous section.

4 Model

In this section, we first describe the architecture of the concatenation-based and factorization-based approaches. We then introduce our attention-mechanism that can be used to augment both of these approaches. The notation we use to describe architectures assumes a 1-layer RNN model. The methods we discuss, however, can be applied to each layer of a multi-layer RNN model.

4.1 Concatenation-based LM Adaptation

The concatenation-based approach learns a weight matrix $\mathbf{W_m}$ of dimensionality $\mathcal{R}^{f \times d}$, where f represents the size of the context representation and d represents the hidden-dimensionality of the RNN model. In practice, f is either a hyperparameter when datetime context is represented as learned embeddings, or $f = 8$ when this context is represented as a feature-engineered vector. When representing contextual information as learned embeddings, recall that we first concatenate the embeddings together before passing these into the model. In this case, f is four-times the size of each individual context embedding.

A standard RNN model without contextual information keeps track of a hidden-state at time-step t, h_t, that is calculated as

$$h_t = \sigma(\mathbf{W_x} x_t + \mathbf{W_h} h_{t-1} + b),$$

where x_t represents the word embedding at time-step t, b is a bias vector, $\mathbf{W_x} \in \mathcal{R}^{e \times d}$, and $\mathbf{W_h} \in \mathcal{R}^{d \times d}$.

In the concatenation-based approach, this hidden-state is adapted in the following manner

$$h_t = \sigma(\mathbf{W_m} m + \mathbf{W_x} x_t + \mathbf{W_h} h_{t-1} + b).$$

Notice that the expression above can be equivalently calculated by concatenating the matrices $\mathbf{W_m}$ and $\mathbf{W_x}$, as well as the vectors m and x_t

$$h_t = \sigma([\mathbf{W_x}; \mathbf{W_m}][x_t; m] + \mathbf{W_h} h_{t-1} + b).$$

To generate a prediction, $\hat{y}_t$ for a word at time-step t, h_t is passed through a projection layer, $W_v \in \mathcal{R}^{d \times |V|}$ to match the dimension of the vocabulary size $|V|$, before applying a softmax layer

$$\hat{y}_t = softmax(W_v h_t).$$

4.2 Factorization-based LM Adaptation

Unlike the concatenation-based approach, which directly inserts contextual information into the RNN cell, the factorization-based method adapts the weight matrices $\mathbf{W_x}, \mathbf{W_h}$ of the RNN model. Compared to the concatenation-based architecture, this approach adapts a larger fraction of the RNN model's parameters.

The adaption process involves learning basis tensors $\mathbf{W_{x'}^{(L)}}, \mathbf{W_{x'}^{(R)}}$ and $\mathbf{W_{h'}^{(L)}}, \mathbf{W_{h'}^{(R)}}$. These basis tensors are of fixed rank r, where r is a tuned hyperparameter. The left adaptation tensors, $\mathbf{W_{x'}^{(L)}}, \mathbf{W_{h'}^{(L)}}$, are of dimensionality $\mathcal{R}^{f \times e \times r}$, and $\mathcal{R}^{f \times d \times r}$, respectively. The right adaptation tensors, $\mathbf{W_{x'}^{(R)}}, \mathbf{W_{h'}^{(R)}}$ are both of dimensionality $\mathcal{R}^{r \times d \times f}$. We can now use the contextual representation to interpolate the two sets of basis tensors to produce two new weight matrices, $\mathbf{W'_x}$ and $\mathbf{W'_h}$, where

$$\mathbf{W'_x} = \mathbf{W_x} + (\mathbf{W_{x'}^{(L)}}^T m)^T (\mathbf{W_{x'}^{(R)}}^T m)$$

$$\mathbf{W'_h} = \mathbf{W_h} + (\mathbf{W_{h'}^{(L)}}^T m)^T (\mathbf{W_{h'}^{(R)}}^T m).$$

The resulting matrices $\mathbf{W'_x}, \mathbf{W'_h}$ are now used as the weights in the RNN cell. A prediction, $\hat{y}_t$, is generated in the same manner as in the concatenation-based model.

4.3 Attention Mechanism

We propose an attention mechanism that augments both the concatenation-based and factorization-based approaches. We apply this mechanism to the context embeddings at each time-step of the RNN model, in order to adapt the context representation dynamically. We hypothesize that at certain time-steps within an utterance, attending to particular datetime information will facilitate the model's predictions more than other information.

For instance, assume a LM is given the phrase "what temperature will it be on friday". By the time the model has observed the words "what temperature will", we would expect the model to condition the predictions of the remaining words primarily on the hour and day information. Using an attention mechanism enables us to dynamically weight the importance that the model places on particular datetime context as the model processes an utterance.

We assume as input to the attention mechanism the same set M of context representations. However, in the case where datetime information is represented as a feature-engineered vector, we augment M to include an 8-dimensional vector of all 0s: $M = \{m, \mathbf{0}\}$. We do so because our attention mechanism builds a dynamic representation of the context by interpolating over multiple context embeddings. Thus, the attention mechanism can act as a learnable gate to limit the non-linguistic context passed into the model. We also experiment with adding a similar vector of all 0s in the case where context embeddings are learned, but find no improvement.

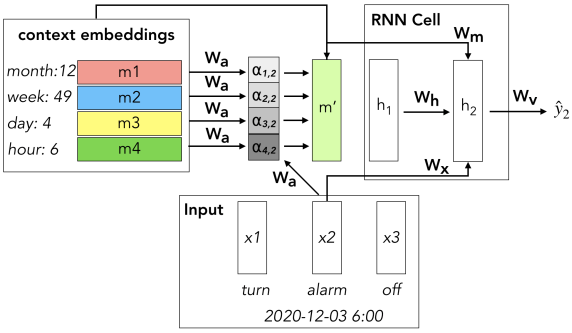

Figure 1: Model architecture of the concatenation-based model using attention. Datetime context is encoded as learned embeddings, and the input word embedding at time-step *t* is used as the query vector at *t*.

In addition to the set M, the attention mechanism takes in a query vector, q_t, for each time-step *t*. We propose two methods for defining this query vector

1. Let $q_t = x_t$, where x_t is the embedding for the input word at time-step *t*.
2. Let $q_t = h_t$, where h_t is the hidden state of the RNN model at time-step *t*.

Importantly, when q_t is chosen such that $q_t = x_t$, we can parallelize the computation of the attention mechanism for all time-steps before running a forward pass through the model. This cannot be done when $q_t = h_t$, as the attention mechanism can only be computed sequentially for each hidden state of the model.

Regardless of the choice of q_t, the attention mechanism first computes a score for each context embedding $m_i \in M$ for a given q_t. To compute this score, we learn a weight matrix W_a. The size of W_a is $\mathcal{R}^{f \times e}$ if $q_t = x_t$, or $\mathcal{R}^{f \times d}$ if $q_t = h_t$.

For a given $m_i \in M$ and q_t, we calculate a score as

$$score(m_i, q_t) = m_i^T \mathbf{W_a} q_t.$$

We then define the alignment score as

$$\alpha_{i,t} = softmax(score(m_i, q_t))$$

The alignment scores are finally used to build up a dynamic representation of the context, m'_t, for a given time-step.

$$m'_t = \sum_{i=1}^{|M|} \alpha_{i,t} m_i$$

We can now use this constructed context, as the context input to either the concatenation-based or the factorization-based approach.

In Figure 1 we illustrate how the attention mechanism augments the concatenation-based approach. For an utterance like "turn alarm off", we showcase how the model builds a dynamic representation of the datetime context, at a given time-step *t* (*t* = 2 in the figure).

5 Experimental Setup

We used a 1-recurrent-layer LSTM model (Hochreiter and Schmidhuber, 1997) as the base model in all of our experiments. Both the concatenation-based and factorization-based methods can be easily adapted to use an LSTM cell. Models were trained using the Adam optimizer with an initial learning rate of 0.001, and a standard cross entropy loss function. Each of the LMs was trained for

Method	Context Approach	Attention Query	Relative Perplexity Reduction		
			Full	Head	Tail

Table 1: Test set perplexities of contextual LMs based on datetime information, with relative reductions compared to the *Default* LSTM model that does not use contextual datetime information. We bold best results within each type of method, and underline best results overall. Improvements in perplexity from using our attention mechanism are statistically significant.

400,000 batch update steps, using a batch-size of 256. The training of each model was conducted on a single V100 GPU, with 16GB of memory on a Linux cluster, and took roughly 6 hours to train. Implementation of the model and training procedure was written in PyTorch and native PyTorch libraries. We used a fixed dimensionality of 512 for word, context and hidden state embeddings. We initially experimented with smaller and larger embedding sizes (50, 100, 1024), but found that 512 generally provided a good tradeoff between model performance and compute resources required to train a model. We set the rank of the basis tensors in the factorization-approach to 5, after experimenting with rank sizes 2, 3, 10, 15, 20. In practice, we found that the larger the rank size the less stable the training procedure became. Other hyperparameters, such as the initial learning rate, were selected via random search. We initialized random weights using Xavier-He weight initialization (He et al., 2015).

6 Results

6.1 Datetime

We evaluated our models on a heldout set of utterances that were randomly sampled from the full dataset. The utterances in our training and evaluation set were collected in the same time-range. We also defined the head and tail subsets of our development set, representing, respectively, the top 5% most frequently occurring utterances, and utterances occurring only once.

We used two metrics for our evaluations: perplexity and word error rate. Perplexity is a common statistic widely used in language modeling and speech recognition to measure how well a language model predicts a sample of text (Jelinek et al., 1977). Word error rate, on the other hand, measures the Levenshtein (minimum edit) distance between a recognized word sequence and a reference word sequence. In practice, these two statistics have been shown to be correlated by a power law relationship (Klakow and Peters, 2002).

In Table 1, we report the relative decrease in perplexity of models that leveraged datetime context compared to a baseline LSTM model that did not use any contextual information. We additionally trained a simple baseline, *Prepend*, which was comprised of a standard LSTM model that treated datetime context as input tokens that were prepended to the input texts.

In reporting our results, we distinguish between

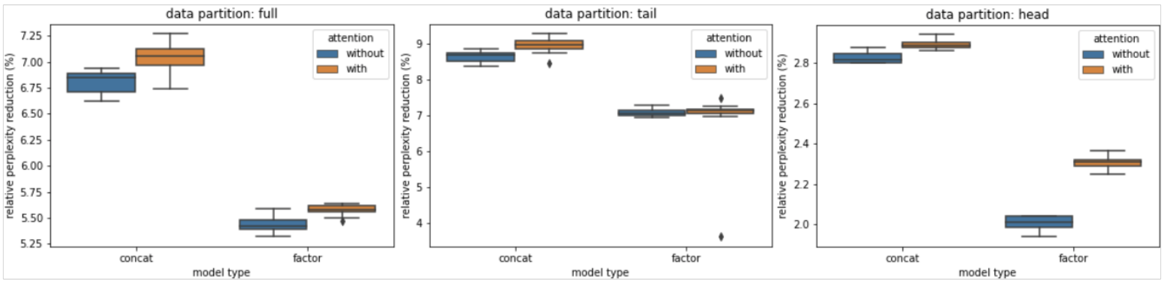

Figure 2: Perplexity confidence bounds at a 95% confidence level for the best-performing concatenation-based and factorization-based models with and without attention. Bounds are evaluated on the full, head and tail partitions of the evaluation set. Perplexity reductions are relative to the *Default* LSTM model that does not use contextual datetime information.

the two forms of representing contextual information: either as learned embeddings or as a feature-engineered representation. We also differentiate between the two variants of encoding the query vector used by the attention mechanism: either by using the hidden state vector, or the input embedding at a given time-step.

For the concatenation-based model, we found that adding our attention mechanism led to further reductions in perplexity, regardless of the type of query vector or context representation used. We obtained the best results when representing datetime information as learned embeddings and using the input embedding at a given time-step as the query vector.

We corroborated these results by computing 95% confidence intervals for the best-performing concatenation-based models with and without attention. Confidence intervals were calculated by running the training algorithm 10 times for each model type. Figure 2 visualizes the intervals.

In the case of the factorization-based approach, we achieved the lowest perplexity when the attention mechanism used the hidden state of the RNN model as the query vector and datetime information was represented as a feature-engineered vector. Again, we found that on the full dataset the improvement in perplexity by using our attention mechanism was statistically significant.

In nearly every experiment we ran, we found that our attention mechanism further reduced perplexity. The use of attention led to the largest relative improvement in the factorization-based approach when using learned context embeddings. In this instance, perplexity was reduced by 2.8% on the tail of our evaluation set, and by 2.1% on the full dataset.

Method	Context Approach	Attention Query	WERR (%)	
			Full	Tail
Default	NA	NA	0.0	0.0
Prepend	FE	NA	0.0	0.0
Concat	Emb	Word	**1.1**	**1.2**
Factor	FE	Hidden	0.8	0.8

Table 2: We report relative improvement (decrease) in WER compared to the *Default* LSTM model that does not use contextual information. Context representation approaches are feature-engineered (FE) or embeddings (Emb).

In addition to evaluating the models on relative reductions in perplexity, we also validated the downstream performance of a hybrid CTC-HMM (Graves et al., 2006) ASR system that incorporated contextual information in its LM component. As the LM component of this system, we used the best-performing models within each category of method that we report in Table 1. Table 2 summarizes the results. We evaluated the relative WER reduction(WERR) on a large test set of de-identified, transcribed utterances representative of general user interactions with Alexa, as well as on the tail of this dataset. As in Table 1, the concatenation-based model with attention mechanism achieved the largest reductions in WER.

6.2 Other Non-Linguistic Context

So far, our experiments have focused exclusively on conditioning neural LMs on datetime context. We underscore, however, that the contextual mechanism we introduce can be applied to any type of contextual information that can be represented as embeddings. To illustrate this point we train two neural LMs using two other types of context: geolocation information and dialogue prompts.

Context Type	Relative PPL Reduction (%)		WERR (%)	
	Full	Tail	Full	Tail
Default	0.0	0.0	0.0	0.0
Datetime	11.4	11.6	<u>1.6</u>	<u>1.7</u>
Geo-hash	12.4	12.5	0.5	1.0
Dialogue Prompt	<u>13.9</u>	<u>14.1</u>	0.3	0.6

Table 3: We report relative improvement (decrease) in WER and (decrease) in perplexity (PPL) compared to the *Default* LSTM model that does not use contextual information. We report results on both the full test dataset as well as utterances from the tail of the dataset. The best results are underlined.

We train the LMs on a subset of the utterances of the initial dataset which also contain utterance-level geo-hash information and dialogue prompt information. The geo-hash information [2] associated with each utterance encodes a very rough estimate of the geolocation of a user's device. Dialogue prompts indicate whether a transcribed utterance was an initial query to the dialog system or if it was a follow-up turn.

We learn embeddings to represent both the geo-hash and the dialogue prompt information. We ingest both types of contexts via the concatenation-based approach, using word-embeddings as the attention queries. We evaluate these models on a test set of de-identified utterances representative of user interactions with Alexa. Table 3 summarizes the results. In general, we find that conditioning neural LMs on each of the different types of context reduces perplexity and WER.

7 Analysis

In this section, we focus once again on datetime information to better understand how contextual LMs use datetime signal.

7.1 Datetime Context Signal

The first question we hope to answer is: to what extent can the relative improvements in perplexity and WER in the models that incorporate datetime context be explained by the additional signal from the context versus the additional parameters that these models contain?

To answer this question, we randomly shuffled the datetime information associated with each utterance in our training and test sets. For each of our best-performing models in a given category of method (prepend, concat, or factor), we retrained and evaluated those models on the dataset containing shuffled datetime information.

In Table 4, we report the relative degradation (i.e., a negative reduction) in perplexity resulting from evaluating these models on the shuffled datetime contexts. In general, if a model uses datetime information as an additional signal, we would expect the performance of the model to decrease when the datetime context is shuffled.

Method	Context Approach	Attention Query	Relative PPL Reduction (%)	
			Full	Tail
Prepend	FE	NA	-1.5	-1.2
Concat	Emb	Word	-1.6	-1.2
Factor	FE	Hidden	-1.4	-1.0

Table 4: Relative degradation in perplexity (PPL) of models that incorporate datetime information when that context is randomly shuffled. Context representations are feature-engineered (FE) or embeddings (Emb).

We observed the overall largest relative degradation in perplexity, when using the concatenation-based model. Recall that when trained on correct datetime information this was our best-performing model overall in terms of both perplexity and WER, indicating that the performance of this model can be attributed in part to its use of contextual information.

7.1.1 Visual Analysis

In addition to these results, we visualize how the contextual LMs leverage datetime contexts. For a given utterance, we can evaluate the probability of the words in the utterance as we vary the datetime information associated with the utterance. In Figure 3, we evaluate the conditional probability of the word "snooze" in an utterance following the start-of-sentence token, as we vary the hour of day information associated with this utterance. As we would expect, the probability of this "snooze" is highest in the morning (between 5 and 6 am), as users are waking up and snoozing their alarms. As we move away from the morning hours, the conditional probability of the word "snooze" decreases substantially, reaching a low-point by the afternoon and evening. The horizontal blue dashed line

---

[2] We use a two integer precision geo-hash.

indicates the conditional probability of the word 'snooze' following the start-of-sentence token when evaluated with a LM that does not ingest datetime information. This analysis further corroborates that the trained contextual LMs successfully condition their predictions on datetime information.

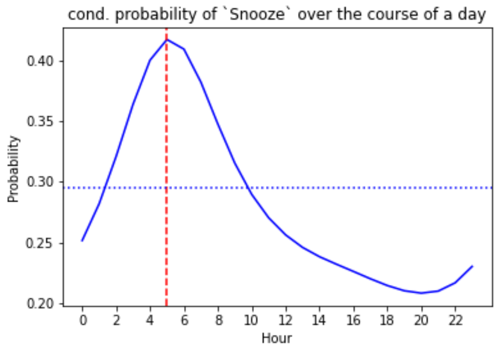

Figure 3: Changing conditional probability of the word "snooze" as the associated hour of day information varies.

7.2 Attention Weights

We next seek to understand how the attention mechanism constructs a dynamic representations of datetime context. To do so, we visualize the weights of the attention mechanism as an utterance is processed by the model. For a given utterance like "play me best christmas songs" spoken in December, we highlight the changing weight placed on each of the datetime information. Figure 4 shows this analysis.

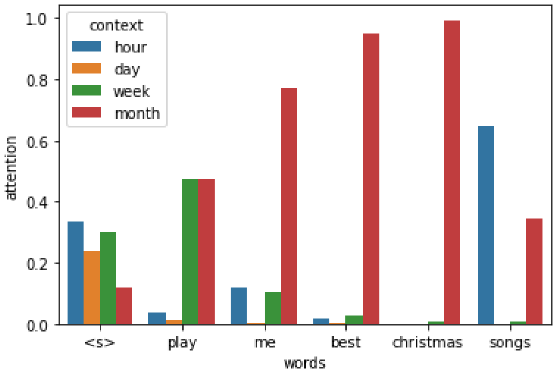

Figure 4: Changing attention weights placed on particular context embeddings over the course of an utterance.

When the model processes the start-of-sentence token, the attention mechanism weights each of the datetime information roughly equally. However as the model processes the subsequent words "play me best", the attention begins to shift towards using more of the month information (i.e., that this utterance was spoken in December), and away from hour and day information. This would suggest that conditioning on the fact that the utterance was spoken in December can help the model predict the type of media to play.

Once the model observes the word "christmas", it places all of the attention on the month information, indicating the model has successfully learned that "christmas" is a word strongly associated with a particular month (i.e., December). Finally when the word "songs" is ingested, the model substantially reduces the weight placed on month information and in turn increases the weight on hour information. This shift might indicate that the model has learned to condition the type of music users listen to to the hour of the day. Overall, the behavior of the attention mechanism is consistent with our initial hypothesis that certain types of datetime information can benefit a contextual LM model more than others over the course of an utterance.

8 Related Work

Within the domain of ASR, Biadsy et al. (2017) have explored using an adaptive-training approach to incorporate non-linguistic features into a maximum entropy LM. They propose first training the parameters of a LM that are associated with text data, then freezing those parameter and learning parameters associated with multiple types of non-linguistic features.

Zhang et al. (2019) and Yoon et al. (2017) propose a similar two-pronged approach for personalizing conversational neural LMs. They propose first pretraining a RNN-LM on a large dataset of conversational data, then finetuning the model on data associated with a particular user.

More recently, Jain et al. (2020) and Liu et al. (2020) propose attention mechanisms for conditioning RNN-T and hybrid ASR systems on words that are likely to occur in an utterance.

Another related line of research has explored learning utterance embeddings for dialogue systems using Gaussian mixture models that are enhanced with utterance-level context, such as intent (Yan et al., 2020).

Outside of ASR, our work directly builds upon the concatenation-based (Mikolov and Zweig, 2012) and factorization-based (Jaech and Ostendorf, 2018a) approaches to condition RNN-LMs on sentence context. The concatenation-based approach has been adopted as a common method for incorporating non-linguistic context into a neural LM (Yogatama et al., 2017; Wen et al., 2013; Ma et al., 2018; Ghosh et al., 2016). Methods that apply low-rank matrix factorization to RNNs are somewhat newer, and were first explored by Kuchaiev and Ginsburg (2017).

Our contribution lies first in the application of these models to ASR, and secondly their extension with an attention mechanism. The attention mechanism we propose builds on the global attention model proposed by Luong et al. (2015). While attention-based models have been used to condition neural models on particular aspects or traits (Zheng et al., 2019; Tang et al., 2016), we focus on contextual information that benefits ASR systems.

9 Conclusion

In this paper, we introduce an attention-based mechanism to condition neural LMs for ASR on non-linguistic contextual information. The proposed model dynamically builds up a representation of contextual information that can be ingested into a RNN-LM via a concatenation-based or factorization-based approach. We find that incorporating datetime context into a LM can yield a relative reduction in perplexity of 9.0% over a model that does not incorporate context. Moreover, the attention mechanism we propose can improve state-of-the-art contextual LM models by over 2.8% relative in terms of perplexity. While we focus on datetime information, we demonstrate that our approach can be applied to any type of non-linguistic context, such as geolocation and dialogue prompts.

Annotation and Evaluation of Coreference Resolution in Screenplays

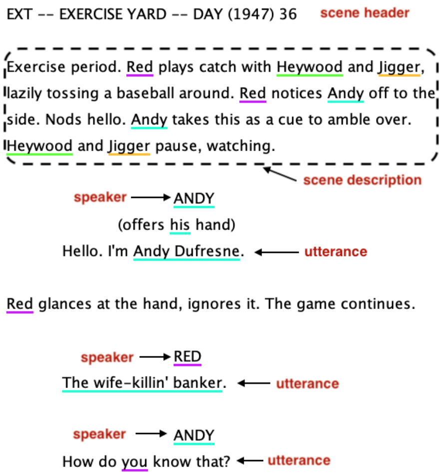
Abstract

Screenplays refer to characters using different names, pronouns, and nominal expressions. We need to resolve these mentions to the correct referent character for better story understanding and holistic research in computational narratology. Coreference resolution of character mentions in screenplays becomes challenging because of the large document lengths, unique structural features like scene headers, interleaving of action and speech passages, and reliance on the accompanying video. In this work, we first adapt widely-used annotation guidelines to address domain-specific issues in screenplays. We develop an automatic screenplay parser to extract the structural information and design coreference rules based upon the structure. Our model exploits these structural features and outperforms a benchmark coreference model on the screenplay coreference resolution task.

1 Introduction

Screenplays are semi-structured text documents containing the dialogue and directions of a film. Automated screenplay analysis provides an opportunity early in the creative process to offer insights into character representations and portrayals (of who interacts with whom, about what, and how), including from a diversity, inclusion, and social impact perspective (Ramakrishna et al., 2017; Shafaei et al., 2020; Martinez et al., 2020). A typical screenplay contains indented blocks of text that can be classified into scene headers, scene descriptions, speakers, and utterances, as shown in Figure 1 (Agarwal et al., 2014). A scene header starts a new scene and provides location and temporal information. Scene descriptions describe the characters and their actions, and the speaker and utterance blocks contain the characters' names and speech.



EXT -- EXERCISE YARD -- DAY (1947) 36

Exercise period. Red plays catch with Heywood and Jigger, lazily tossing a baseball around. Red notices Andy off to the side. Nods hello. Andy takes this as a cue to amble over. Heywood and Jigger pause, watching.

ANDY
(offers his hand)
Hello. I'm Andy Dufresne.

Red glances at the hand, ignores it. The game continues.

RED
The wife-killin' banker.

ANDY
How do you know that?

Figure 1: Coreference-annotated screenplay excerpt from the movie *The Shawshank Redemption (1994)*. Mentions of the same character are underlined with the same color.

Screenplays can refer to a character by different names, pronouns, and nominal expressions. For example, the screenplay excerpt shown in Figure 1 refers to the character *Andy* by the mentions – *Andy Dufresne* (name), *The wife-killin' banker* (nominal), and *his* (pronoun). Many downstream tasks need to find and map all such mentions to the correct *referent*. For example, Gorinski and Lapata (2015) resolved pronominal mentions to their correct antecedent (prior co-referring mention) to find speaker-listener and semantic relations between characters for the movie-summarization task. Chen and Choi (2016) crowdsourced character-mention labels in TV show transcripts for automatic character identification. Deleris et al. (2018) used direct and indirect character references in utterances to study social relationships between characters. Thus, resolving character mentions in screenplays is an essential subtask in many applications. In NLP literature, this task is formally called coreference resolution (Jurafsky and Martin, 2009) and has been studied extensively (Sukthanker et al., 2020; Stylianou and Vlahavas, 2021).

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2004–2010
August 1–6, 2021. ©2021 Association for Computational Linguistics

Most existing coreference datasets focus on news and web text (Pradhan et al., 2012; Webster et al., 2018), but do not include screenplays that have distinct content and structure. First, the document lengths of screenplays are much larger than news articles (Gorinski and Lapata, 2015), increasing the computational complexity of antecedent scoring (Lee et al., 2017). Second, scene headers alter the story's context affecting coreference between mentions of different scenes. Lastly, coreference annotation of some mentions requires the knowledge of the accompanying movie or TV clip because textual descriptions may not capture all the post-production visual details of a scene. Thus, two main challenges for coreference resolution in screenplays are: (1) the lack of suitable annotation rules to handle domain-specific issues and (2) finding methods to leverage the unique screenplay structure to improve coreference resolution.

Our objective in this work is to address the coreference resolution of characters in screenplays. We only focus on characters because most modern narrative studies are centered around their role as agents driving the plot (Bamman et al., 2013; Labatut and Bost, 2019). Our contributions are 1) we establish coreference annotation guidelines for screenplays and use them to label screenplay excerpts, 2) we develop a screenplay parser to convert the semi-structured text into a machine-readable format, and 3) we use the structural information of screenplays to design coreference rules, which improves the performance of coreference resolution when combined with a benchmark coreference resolution model (Lee et al., 2018).

2 Related Work

Screenplay Parsing: Weng et al. (2009) motivated the need for screenplay parsing for social network analysis. Agarwal et al. (2014) formalized the screenplay parsing task and developed an SVM-based parser. Winer and Young (2017) extended it to extract fine-grained information from scene headers. Our parser uses a rule-based algorithm to achieve comparable performance.

Coreference Resolution: OntoNotes 5 is the benchmark dataset for English coreference resolution, containing documents from newswire, broadcast news, telephone conversations, and weblogs (Pradhan et al., 2012). However, it does not contain screenplay texts. The closest work to screenplay coreference is the *LitBank* dataset (Bamman et al., 2020), which contains coreference annotations of 100 works of fiction taken from Project Gutenberg (Lahiri, 2014).

Few previous works address coreference annotation in screenplays. Chen and Choi (2016) labeled character mentions for two TV shows: *Friends* and *The Big Bang Theory*. Zhou and Choi (2018) later extended this dataset by including plural mentions, but mainly focused on character utterances and did not consider action notes. Ramanathan et al. (2014) created a dataset of 19 TV episodes for joint coreference resolution in visual and textual media content. Gorinski and Lapata (2015) created the *ScriptBase* corpus of movie screenplays, which included coreference labels. However, they found the labels using the Stanford CoreNLP system (Lee et al., 2011), which has not been evaluated for screenplay coreference.

3 Annotation

We annotate screenplays with character mentions for coreference resolution (see Figure 1). Following OntoNotes 5 annotation guidelines, we mark the maximal extent of noun phrases, pronouns, and possessives that refer to some character (Pradhan et al., 2012). Characters do not have to be persons; consider for example, the spider *Aragog* in the *Harry Potter* movies. We include singleton character entities. We do not label mentions that refer to multiple characters because finding the correct antecedent of plural mentions often requires the accompanying video clip's aid (Zhou and Choi, 2018). For example, it is difficult to decide whether *They* refers to *Vosen and agents*, *Others*, or both in the following lines without watching the movie.

> [Vosen and agents]$_x$ come running out of the front door. [Others]$_y$ leave through a side entrance. [They] jump in sedans. (*Bourne Ultimatum, 2007*)

We follow OntoNotes 5 annotation guidelines to handle appositions (adjacent noun phrases separated by comma, colon, or parentheses), copula (noun phrases connected by linking verbs, for example, *is*, *look*, etc.), and generic *you* mentions (Pradhan et al., 2012). If a mention's referent is revealed to be identical with another character as the story progresses, we tag the mention with the latter character (Bamman et al., 2020). The screenplay sometimes contains references to the reader or the camera's point of view. We tag such instances with a special READER entity, for example:

Movie	Tokens	Characters	Names	Pronouns	Nominals
The Shawshank Redemption (1994)	7,734	44	329	448	111
Bourne Ultimatum (2007)	7,722	39	491	344	76
Inglourious Basterds (2009)	7,284	23	426	458	124
TOTAL	22,740	106	1,246	1,250	311

Table 1: Statistics of the coreference annotated data.

> In the background, [we]$_{READER}$ see, [our]$_{READER}$ three counterfeit German Officers, Hicox, Wicki, and Stiglitz, enter the basement tavern. They obviously see the five German soldiers, but their too far away for [us (the audience)]$_{READER}$ to read their face. (*Inglourious Basterds, 2009*)

Screenplay Coreference Dataset: We annotated screenplay excerpts of three movies: *The Shawshank Redemption*, *Bourne Ultimatum*, and *Inglourious Basterds*. We downloaded the screenplay documents from IMSDb [1]. We chose these movies because the annotators were familiar with them, and they cover a wide range of genres (drama, action, thriller, and war). Three doctoral students were each assigned one screenplay, which they annotated for coreference according to the guidelines of section 3. The lead author checked the annotations independently for labeling errors. Less than 1% of the mentions required correction, suggesting high overall agreement. Table 1 describes some statistics of the labeled data. The corpus contains $2,807$ mentions in total, covering 106 characters. More than 44% of the mentions are pronouns, and about 11% are nominal mentions.

4 Model

Our coreference model consists of two parts: 1) a screenplay parser to extract structural information, and 2) coreference rules to resolve mentions occurring in speaker blocks.

4.1 Screenplay Parser

The screenplay parser reads raw screenplay text documents and assigns a structural tag – scene header, scene description, speaker, utterance or *other* (see Figure 1) to each line, following the tagset of Agarwal et al. (2014). The parser uses regular expressions to assign the structural tags. Thus, it is a rule-based 5-way multiclass classifier. The *other* tag includes all lines that do not fall in the other four categories, for example, camera transitions (*CUT TO*, *FADE IN*, etc.), dialogue metadata expressions (*O.S.*, *V.O.*, *(shouting)*, etc.), etc. The parser removes blank lines and whitespace indents.

4.2 Coreference Resolution

We use the following strategy to find the coreference clusters of characters in screenplays.

Add *says*: Given a screenplay, we parse it using our screenplay parser and collect all lines tagged as scene header, scene description, speaker, or utterance. We add the word *says* after speaker-tagged lines and concatenate all lines, separated by a newline delimiter. This lexical addition tells the model that the character mentioned in the speaker-tagged line speaks the succeeding utterance-tagged lines.

Keep speakers: We apply a coreference resolution model, pre-trained on OntoNotes 5, to the concatenated text to find coreference clusters. Since OntoNotes 5 annotates for unrestricted coreference (find coreference clusters of all ACE entities and events), we need to prune the clusters to keep only those containing character mentions. We keep clusters that contain any mention which appears in a speaker-tagged line.

Merge clusters: Due to the large document size (see Table 1), long coreference chains, like those of main characters, sometimes get segmented and occur as separate clusters. We merge the segmented clusters using speaker information. Screenplays usually refer to a character by a unique name in the speaker-tagged lines. If two speaker-tagged lines belonging to separate clusters contain identical names, we merge the corresponding clusters.

5 Experiments and Results

5.1 Screenplay Parser Evaluation

We annotated lines of 39 movie screenplay excerpts for the structural tags. These movies were different from the ones annotated for coreference. Three annotators, all doctoral students, labeled 9,758 lines, with a Krippendorff's inter-rater reliability score of 0.983 (strong agreement). We parsed the annotated excerpts using our rule-based parser and evaluated its classification performance. Table 3 shows the

Speaker	1833	95.4	96.1	95.7
Utterance	3754	90.5	94.5	92.5

Table 3: Screenplay parser's classification performance

5.2 Screenplay Coreference Evaluation

We evaluated our coreference model on the labeled screenplay data collected in section 3. We used the model of Lee et al. (2018), a widely used benchmark for coreference resolution, as the pre-trained model for our method. Lee et al. (2018) calculates mention scores for each span, retains the top-scoring ones and finds antecedent scores of mention pairs. We replaced the model's original GloVe vectors with SpanBERT (large) embeddings. Joshi et al. (2020) showed that the SpanBERT-adapted model obtains 79.6 avg. F1 on the OntoNotes 5 test set for the unrestricted coreference task.

Baseline: Given a screenplay, we find the structural tags for each line using our parser and retain the lines tagged as scene header, scene description, speaker, or utterance. We input the text to the coreference resolution model of Lee et al. (2018), pre-trained on OntoNotes 5. We keep clusters that contain any mention whose named entity tag is *PERSON*. We use spaCy (Honnibal et al., 2020) for named entity recognition.

Metrics: Following the official evaluation framework of CoNLL-2012 multilingual coreference task (Pradhan et al., 2014), we used the MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998) and $CEAF_e$ (Luo, 2005) measures to evaluate our model. We also used the NEC score (Agarwal et al., 2019) to evaluate coreference resolution by mention-type – name, pronoun and nominal. Tables 2 and 5 show the performance of our model and baseline in coreference resolution and character mention identification respectively. Table 4 shows the NEC scores for different mention types.

	Name	Pronoun	Nominal
Baseline	39.1	39.8	48.8
Our Model	**47.6**	**62.1**	**55.4**

Table 4: NEC F1 by mention type

	P	R	F1
Baseline	86.5	63.9	73.1
Our Model	**88.7**	**80.8**	**84.5**

Table 5: Mention identification performance.

Ablation Study: We study how each coreference rule – *Add says*, *Keep speakers*, and *Merge clusters* – described in section 4.2, contributes to the model's performance. Table 2 shows the results of the ablation experiments. *-Add says* means that we do not add *says* after speaker-tagged lines, *-Keep speakers* implies that we retain clusters that contain any mention whose named entity tag is *PERSON* instead of those that contain any mention appearing in speaker-tagged lines, and *-Merge clusters* denotes that we do not merge clusters.

6 Discussion

The results of Table 2 suggests that inputting the raw screenplay directly to the pre-trained coreference model performs poorly. The performance substantially improves when we use the coreference rules (+17.3 avg. F1). The improvement is largest for pronouns (+22.3 NEC F1), as shown in Table 4, possibly because of the *Add says* rule that helps the model to find the antecedent of personal pronouns in utterance-tagged lines. The rule adds

6.3 avg. F1 towards the overall performance (Table 2). Coreference resolution of named mentions also improves greatly (+8.5 NEC F1), probably because of the *Merge clusters* rule that joins clusters if they contain mentions in speaker-tagged lines that have identical names. It contributes 3.6 avg. F1 to the final score (Table 2). The *Keep speakers* rule adds 3.7 avg. F1, which suggests that retaining clusters containing speaker-tagged mentions is better than keeping those containing *PERSON*-tagged (NER) mentions to retrieve character references.

7 Applications

We show two applications of coreference resolution in computational narratology: finding mention-type interactions and character actions.

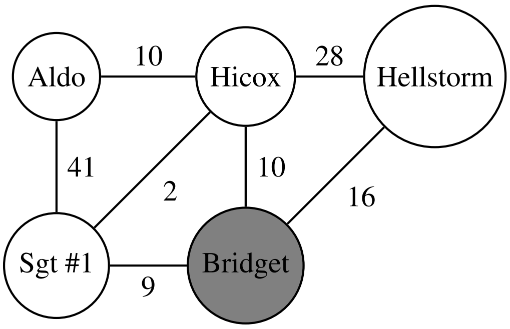

Figure 2: Character network of speech interactions. Edge weight is the number of interactions. Bridget has the **lowest** weighted degree.

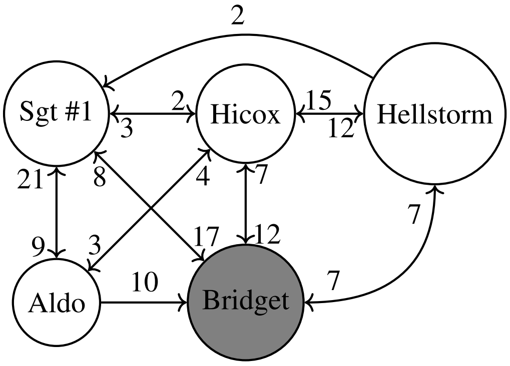

Figure 3: Character network of mention interactions. Edge weight is the number of mentions. Bridget has the **highest** weighted in-degree.

Mention-type Interactions: Figures 2 and 3 show character networks of the top five speaking characters from the movie *Inglourious Basterds (2009)*, capturing speech and mention-type interactions respectively. The edge weight between characters A and B in the speech network (Fig 2) is the number of times A speaks right after B or vice versa (Ramakrishna et al., 2017). The directed edge weight from character A to character B in the mention network (Fig 3) is the number of times A mentions B in their speech. We used the structural tags and coreference annotations to create these networks.

We observe that the two character networks provide different insights. Using degree centrality, *Bridget* is the least 'important' character in terms of speech interactions, but is most mentioned by other characters. This supports the movie plot which contains a scene where the Basterds discuss their plans of meeting *Bridget*, without her being there.

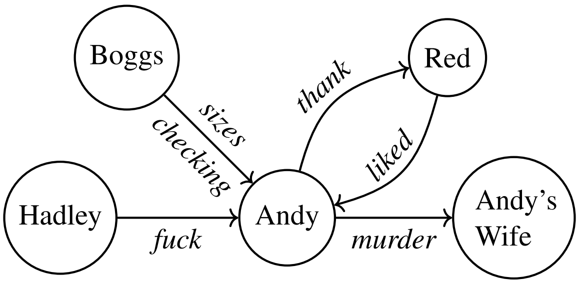

Figure 4: Character network of action interactions. Edge labels are actions. Head node of edge is the agent, and tail node of edge is the patient of the action.

Character Actions: We can use semantic role labeling and coreference resolution to find character actions. Figure 4 shows a subgraph of the character action network of *The Shawshank Redemption (1994)* movie. The directed edge label is the action, the head node is the agent (ARG0), and the tail node is the patient (ARG1) of the action. We applied the SRL model of Shi and Lin (2019) to the sreenplay's sentences, and then substituted the semantic roles with their referred character, wherever possible. From figure 4, we observe that *Andy* had positive interactions with *Red*, but was negatively treated by *Boggs* and *Hadley*, which is in line with the movie plot.

8 Summary and Future Work

We presented a coreference annotation guideline for screenplays and developed rules based on the screenplay's structure to improve coreference resolution performance. Our work can facilitate future annotation and modeling of coreference resolution in screenplays to support computational narratology studies. We plan to label more screenplays to train an end-to-end coreference model and study character interactions using coreference clusters. The data is available in the supplementary material.

Abstract

In Natural Language Understanding (NLU), to facilitate Cross-Lingual Transfer Learning (CLTL), especially CLTL between distant languages, we integrate CLTL with Machine Translation (MT), and thereby propose a novel CLTL model named Translation Aided Language Learner (TALL). TALL is constructed as a standard transformer, where the encoder is a pre-trained multilingual language model. The training of TALL includes an MT-oriented pre-training and an NLU-oriented fine-tuning. To make use of unannotated data, we implement the recently proposed Unsupervised Machine Translation (UMT) technique in the MT-oriented pre-training of TALL. The experimental results show that the application of UMT enables TALL to consistently achieve better CLTL performance than our baseline model, which is the pre-trained multilingual language model serving as the encoder of TALL, without using more annotated data, and the performance gain is relatively prominent in the case of distant languages.

1 Introduction

Virtual assistants, such as Amazon Alexa, Apple Siri, and Google Assistant, are increasingly popular due to the convenience they bring to customers. A core function of virtual assistants is Natural Language Understanding (NLU), which is a combo of slot filling and intent classification. NLU models behind virtual assistants are generally trained in a supervised manner, which requires a large amount of annotated data. Collecting annotated data is not a big deal for high-resource languages, but difficult or even impossible for low-resource languages. As a result, when ported to a low-resource language, an NLU model may suffer from the so-called "data hungriness" (van der Ploeg et al., 2014). This problem can be alleviated by conducting Cross-Lingual Transfer Learning (CLTL) (Yarowsky et al., 2001), where annotated data in a high-resource source language is used to bootstrap an NLU model aimed at a low-resource target language.

The key to CLTL is to learn a shared representation space for the given source-target language pair. A traditional way to achieve this goal is to leverage cross-lingual word embeddings, which are obtained by mapping the words in both languages to a shared word embedding space (Zhang et al., 2017; Conneau et al., 2017; Artetxe et al., 2018a; Chen et al., 2018; Chen and Cardie, 2018; Chen et al., 2019). However, most studies on this topic only consider similar languages (e.g. English-German) but ignore distant languages (e.g. English-Japanese), since it is more challenging to conduct CLTL between distant languages than between similar languages. Recently, contextualized word embeddings generated by pre-trained language models have shown significant advantages over ordinary word embeddings (Peters et al., 2018; Devlin et al., 2019; Liu et al., 2019). For the purpose of CLTL, many efforts have been made to develop multilingual variants of pre-trained language models. These efforts have in turn brought about pre-trained multilingual language models, each of which is pre-trained on a multilingual corpus so that the learned representation space is not only rich in contextual clues but also shared by all the involved languages (Mulcaire et al., 2019; Conneau and Lample, 2019; Conneau et al., 2020). However, in this pre-training, the collection of the

---

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2011–2020
August 1–6, 2021.

multilingual corpus is not obviously biased to any language, thus in the learned representation space, similar languages are still similar to each other, and distant languages are still distant from each other. As a result, although pre-trained multilingual language models have greatly promoted CLTL, it is still more challenging to conduct CLTL between distant languages than between similar languages. This opinion has been verified by several empirical studies on a popular pre-trained multilingual language model named Multilingual BERT (M-BERT) (Devlin et al., 2019), where the CLTL performance of M-BERT between similar languages is decent, but that between distant languages is still far from satisfactory (Pires et al., 2019; Wu and Dredze, 2019; Karthikeyan et al., 2020).

From our point of view, CLTL can be analogized to the process of a human being learning a foreign language, where the prior knowledge on the native language plays an important role. Language educators believe that a foreign language learner can benefit a lot from translation, since translation not only involves all aspects of foreign language learning but also helps to enhance the correlation between the native language and the foreign language (Witte et al., 2009). According to our observation and experience, this is especially the case when the native language and the foreign language are distant from each other. Inspired by these thoughts, to facilitate CLTL, especially CLTL between distant languages, we propose a novel CLTL model named Translation Aided Language Learner (TALL), where CLTL is integrated with Machine Translation (MT). Specifically, we adopt a pre-trained multilingual language model, which is now recognized as the state of the art in CLTL, as our baseline model, and construct TALL by appending a decoder to it. On this basis, we directly fine-tune the baseline model as an NLU model to conduct CLTL, but put TALL through an MT-oriented pre-training before its NLU-oriented fine-tuning. We believe that the MT-oriented pre-training can help TALL to enhance the correlation between the given source-target language pair in its representation space, and thus can make CLTL easier to conduct in its NLU-oriented fine-tuning, especially in the case of distant languages. To make use of unannotated data, which is not only large in amount but also available for every language, we implement the recently proposed Unsupervised Machine Translation (UMT) (Artetxe et al., 2018b; Lample et al., 2018a; Yang et al., 2018; Lample et al., 2018b; Liu et al., 2020) technique in the MT-oriented pre-training of TALL.

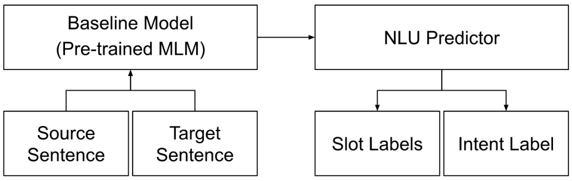

Figure 1: The NLU-oriented fine-tuning of our baseline model. MLM means multilingual language model.

To verify the effectiveness of TALL, we carry out a series of experiments to compare the CLTL performance of TALL with that of the baseline model. In these experiments, we address not only CLTL tasks between similar languages but also those between distant languages. For each given CLTL task, we separately use two popular pre-trained multilingual language models for model construction. To implement UMT, we collect unannotated sentences from Wikipedia dumps. To conduct CLTL, we separately collect annotated sentences from two multilingual NLU datasets. The experimental results show that the application of UMT enables TALL to consistently achieve better CLTL performance than the baseline model without using more annotated data, and the performance gain is relatively prominent in the case of distant languages.

2 Translation Aided Language Learner

2.1 Task Definition

NLU is a combo of slot filling and intent classification. Given a sentence x consisting of m words $\{w_1, \ldots, w_m\}$, slot filling is to predict a slot label y_i^σ for each word w_i, and intent classification is to predict an intent label y^ι for x. In this paper, NLU models are required to be trained under a zero-shot CLTL scenario, where annotated sentences in the given source language are used for model optimization, while those in the given target language are used for model evaluation.

2.2 Baseline Model

A transformer (Vaswani et al., 2017) is a sequence-to-sequence model consisting of an encoder and a decoder. A main feature of transformers is that they use multi-head self-attention and multi-head cross-attention to model dependencies in sequential data. These attention mechanisms enable transformers to extract long-term contextual clues from text. As a result, transformers have been intensively used in transfer learning to develop pre-trained language models, which generate contextualized word embeddings. For example, some pre-trained language models, such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), are implemented as transformer encoders, and some other ones, such as the GPT family (Radford et al., 2018, 2019), are implemented as transformer decoders.

As a sub-field of transfer learning, CLTL has witnessed the wide application of transformers in developing pre-trained multilingual language models. Most of the existing pre-trained multilingual language models, such as M-BERT, XLM (Conneau and Lample, 2019), and XLM-RoBERTa (XLM-R) (Conneau et al., 2020), are implemented as transformer encoders. Actually, these pre-trained multilingual language models are the multilingual variants of BERT and RoBERTa, since each of them is identical to either BERT or RoBERTa except being pre-trained on a multilingual corpus. The representation space learned through this pre-training is not only rich in contextual clues but also shared by all the involved languages. Therefore, in theory, each of these pre-trained multilingual language models can be simply fine-tuned to address any CLTL task between its involved languages.

The pre-trained multilingual language models mentioned above are now recognized as the state of the art in CLTL. To push the state of the art, we adopt one of them as our baseline model, and fine-tune it as an NLU model to conduct CLTL. As shown in Figure 1, in this NLU-oriented fine-tuning, we feed each given sentence to the baseline model, and feed the final hidden states of the baseline model to an NLU predictor. Since the baseline model is fitted with a sub-word tokenizer, a given sentence x consisting of m words $\{w_1, \ldots, w_m\}$ is tokenized into n tokens ($n \geqslant m$) such that the baseline model generates n final hidden states $\{h_1, \ldots, h_n\}$. For slot filling, the NLU predictor first performs an average pooling on the final hidden states related to each word w_i, and then uses a dense layer with a softmax normalization to map the pooling result to a slot distribution for w_i:

$$\mathrm{p}(y_i^\sigma \mid x) = \mathrm{softmax}\big(W^\sigma \mathrm{f_a}(h_{k_i}, \ldots, h_{l_i}) + b^\sigma\big)$$

where W^σ is a trainable weight, b^σ is a trainable bias, k_i and l_i separately represent the start position and end position of the final hidden states related to w_i, and $\mathrm{f_a}(\cdot)$ represents average pooling. For intent classification, the NLU predictor first performs an average pooling on all the final hidden states, and then uses another dense layer with another softmax normalization to map the pooling result to an intent distribution for x:

$$\mathrm{p}(y^\iota \mid x) = \mathrm{softmax}\big(W^\iota \mathrm{f_a}(h_1, \ldots, h_n) + b^\iota\big)$$

where W^ι is a trainable weight, and b^ι is a trainable bias. On this basis, for model optimization, we minimize the following joint loss through stochastic gradient descent on annotated sentences in the given source language:

$$\mathcal{L}_{nlu} = -\log\Big(\prod_{i=1}^{m} \mathrm{p}(y_i^\sigma \mid x) \cdot \mathrm{p}(y^\iota \mid x)\Big)$$

For model evaluation, we infer the baseline model on annotated sentences in the given target language to measure three evaluation metrics, namely Slot F1, Intent Accuracy, and Semantic Accuracy (i.e. sentence-level joint accuracy).

2.3 Proposed Model

Since the baseline model is pre-trained on a multilingual corpus, all its involved languages are correlated with each other in its representation space. Normally, the larger such correlation between languages, the easier it is to conduct CLTL. To equally treat all possible CLTL tasks, the multilingual corpus used in the pre-training of the baseline model is collected in a subtle way that is not obviously biased to any language. However, there are two side effects of doing so. On the one hand, instead of focusing on a specific CLTL task, the baseline model pays equal attention to all possible CLTL tasks. On the other hand, in the representation space of the baseline model, the correlation between languages is proportional to their linguistic similarity, or in other words, similar languages are still similar to each other, and distant languages are still distant from each other. This implies that the CLTL ability of the baseline model can be pertinently improved for each given CLTL task, and the room for improvement is relatively large when the CLTL task is between distant languages.

To pertinently improve the CLTL ability of the baseline model for each given CLTL task, we would like to transform its representation space, which is used for all possible CLTL tasks, into a specialized one, where the correlation between the given source-target language pair is expressly enhanced. This goal can be achieved by resorting to MT, since

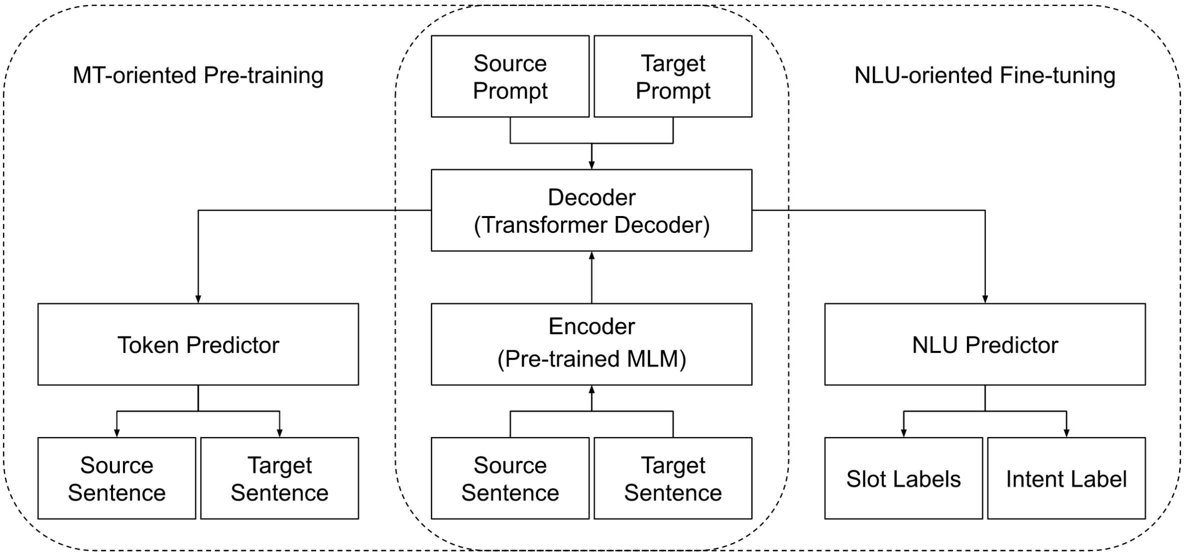

Figure 2: The MT-oriented pre-training and NLU-oriented fine-tuning of our proposed Translation Aided Language Learner (TALL).

translation is the most direct way to correlate languages with each other. As shown in Figure 2, for MT to be workable, we treat the baseline model as an encoder and append a decoder to it. Considering that the encoder is implemented as a transformer encoder, we implement the decoder as a transformer decoder to keep the model architecture consistent. Besides, as in Vaswani et al. (2017), we also share the token embeddings between the encoder and the decoder. The resulting new model can be seen as a standard transformer, where the encoder is a pre-trained multilingual language model. We expect this model to learn the correlation between the given source-target language pair by addressing a two-way MT task, and thus name it Translation Aided Language Learner (TALL).

Before conducting CLTL with TALL, we need to pre-train it as a two-way MT model that translates between the given source-target language pair. As shown in Figure 2, in this MT-oriented pre-training, we feed each given sentence to the encoder, feed a prompt for the translated sentence to the decoder, and feed the final hidden states of the decoder to a token predictor. Given a sentence x and a prompt x' for the translated sentence, suppose the decoder generates a final hidden state h'_i for the i-th token in x', then h'_i can be seen as a memory of both x and the first i tokens in x'. The token predictor uses a dense layer with a softmax normalization to map this memory to a token distribution for the position i in the translated sentence:

$$\mathrm{p}(y_i^\tau \mid x, x') = \mathrm{softmax}(W^\tau h'_i + b^\tau)$$

where W^τ is a trainable weight tied to the token embeddings, and b^τ is a trainable bias. Since two-way MT requires the translated sentence to be in either the source language or the target language, which depends on the current direction, we extend the token vocabulary with two language identifiers, which separately represent the two languages, and thereby inform the decoder about the currently required language by setting the first token of x' to the corresponding language identifier. By the way, since the token vocabulary is highly multilingual, most probabilities in the above token distribution are for the tokens beyond the given source-target language pair and thus make no sense. Therefore, we ignore these probabilities when inferring TALL to generate translated sentences.

By convention, the training of MT models is supervised and thus requires parallel corpora. However, parallel corpora are generally expensive to collect, which makes them scarce or even unavailable for many source-target language pairs. Since TALL is designed to be a general-purpose CLTL model, a supervised training on parallel corpora is not applicable to its MT-oriented pre-training. Recently, an unsupervised training technique for MT models, which is named Unsupervised Machine Translation (UMT), has been proposed. Instead of relying on parallel corpora, UMT relies on monolingual corpora of unannotated sentences. This is attractive to us, since a large amount of unannotated sentences are always available for every language. Therefore, we implement the UMT training recipe proposed by Lampe et al. (2018b) in the MT-oriented pre-training of TALL. Specifically, for model optimization, we collect a source-language corpus S and a target-language corpus T, each of which is a set of unannotated sentences. On this basis, we measure the following two losses:

- **Denoising auto-encoding loss.** As in Lample et al. (2018a), we implement a noise injector $\mathrm{f_n}(\cdot)$, which injects noise to each given sentence by randomly dropping and swapping its tokens. For each source-language sentence $s \in S$, we first run the noise injector to obtain a noise-injected sentence $\mathrm{f_n}(s)$, which can be seen as a sentence in a different language, and then use TALL to translate $\mathrm{f_n}(s)$ to the source language, the expected result of which is s. Besides, we also perform this process on each target-language sentence $t \in T$. This is the so-called "denoising auto-encoding", whose loss is defined as the cross-entropy loss on recovering the original sentences from the noise-injected sentences:

$$\begin{aligned}\mathcal{L}_{dae} =& \mathbb{E}_{s\in S}\big[-\log \mathrm{p}\big(s \mid \mathrm{f_n}(s)\big)\big]+\\ & \mathbb{E}_{t\in T}\big[-\log \mathrm{p}\big(t \mid \mathrm{f_n}(t)\big)\big]\end{aligned}$$

- **Back-translation loss.** Let us use $\mathrm{f_m}(\cdot)$ to represent the inference of TALL, which translates each given sentence to its opposite language in the given source-target language pair. For each source-language sentence $s \in S$, we first infer TALL to obtain a TALL-translated sentence $\mathrm{f_m}(s)$, which is in the target language, and then use TALL to translate $\mathrm{f_m}(s)$ to the source language, the expected result of which is s. Besides, we also perform this process on each target-language sentence $t \in T$. This is the so-called "back-translation", whose loss is defined as the cross-entropy loss on recovering the original sentences from the TALL-translated sentences:

$$\begin{aligned}\mathcal{L}_{bt} =& \mathbb{E}_{s\in S}\big[-\log \mathrm{p}\big(s \mid \mathrm{f_m}(s)\big)\big]+\\ & \mathbb{E}_{t\in T}\big[-\log \mathrm{p}\big(t \mid \mathrm{f_m}(t)\big)\big]\end{aligned}$$

We sum up the above two losses to obtain a joint loss, and thereby minimize the joint loss through stochastic gradient descent. For model evaluation, we collect another source-language corpus and another target-language corpus, each of which is also a set of unannotated sentences. On this basis, we implement the round-trip translation trick proposed by Lample et al. (2018a), where we first translate each given sentence to its opposite language in the current source-target language pair, and then translate the resulting sentence to the original language. By inferring TALL, we perform this process on all the sentences in the above two corpora to obtain two reconstructed corpora. Thereby, we measure the BLEU score between the two original corpora and the two reconstructed corpora to evaluate the translation performance of TALL.

The above MT-oriented pre-training guarantees that TALL can learn a representation space, where the given source-target language pair are expressly correlated with each other. As a result, it will be easier to conduct CLTL with the pre-trained TALL than with the baseline model. This is especially the case when the given source-target language pair are distant from each other, since translating between distant languages reveals more knowledge than translating between similar languages. However, considering that the representation space of TALL is co-carried by the encoder and the decoder, we have to fine-tune them together as an NLU model when we conduct CLTL with the pre-trained TALL. To this end, we implement the fine-tuning approach of BART (Lewis et al., 2020) in the NLU-oriented fine-tuning of TALL. Specifically, as shown in Figure 2, we feed each given sentence to the encoder, feed this sentence again as a prompt to the decoder with the corresponding language identifier prefixed to it, and feed the final hidden states of the decoder except the last one to the NLU predictor. On this basis, both the model optimization and the model evaluation remain the same as in the NLU-oriented fine-tuning of the baseline model.

3 Related Works

Cross-lingual word embeddings. A traditional way to conduct CLTL is to leverage cross-lingual word embeddings, which are usually learned in an unsupervised manner. For example, Zhang et al. (2017) formulate the learning of cross-lingual word embeddings as an adversarial game, and explore several adversarial training methods to implement it. Conneau et al. (2017) first use adversarial training to learn a linear mapping from the word embeddings of a source language to those of a target language, and then use a Procrustes solution to refine it. Artetxe et al. (2018a) first use an unsupervised initialization scheme to create an initial mapping, and then use a self-learning procedure to iteratively improve it. Chen et al. (2018) propose a language-adversarial training method, and use it to address cross-lingual sentiment classification. Besides, there are also several studies on multilingual word embeddings. For example, Chen and Cardie (2018) propose an unsupervised approach to learning multilingual word embeddings, which directly exploits the relations between all the involved languages. On this basis, Chen et al. (2019) propose a multi-source CLTL model, which not only uses adversarial training to learn language-invariant features, but also uses a mixture-of-experts method to dynamically exploit the similarity between a target language and multiple source languages.

Pre-trained multilingual language models. The currently dominant way to conduct CLTL is to fine-tune pre-trained multilingual language models, which are multilingual variants of pre-trained language models, and are each pre-trained on a multilingual corpus. For example, Mulcaire et al. (2019) propose Rosita as a multilingual variant of ELMo, and pre-train it on a multilingual corpus covering 3 languages. Devlin et al. (2019) propose M-BERT as a multilingual variant of BERT, and pre-train it on a multilingual corpus covering 104 languages. Conneau and Lample (2019) propose XLM as a multilingual variant of BERT, and pre-train it on a multilingual corpus covering 15 languages. Conneau et al. (2020) propose XLM-R as a multilingual variant of RoBERTa, and pre-train it on a multilingual corpus covering 100 languages. Besides, there are also several empirical studies on M-BERT. For example, Pires et al. (2019) carry out a large number of probing experiments to verify and interpret the zero-shot CLTL performance of M-BERT. Wu and Dredze (2019) explore the zero-shot CLTL potential of M-BERT on 5 downstream tasks covering 39 languages. Karthikeyan et al. (2020) provide a comprehensive study on the contribution of each component of M-BERT to its CLTL ability, which focuses on the impact of linguistic properties of the languages, the architecture of the model, and the learning objectives.

UMT technique. The UMT technique is aimed at reducing the reliance of MT models on parallel corpora. For example, Artetxe et al. (2018b) construct an MT model consisting of a language-invariant encoder and two language-specific decoders, and train it on a non-parallel corpus through denoising auto-encoding and back-translation. Lample et al. (2018a) construct an MT model consisting of a language-invariant pair of encoder and decoder, and train it on a non-parallel corpus not only through denoising auto-encoding and back-translation but also through adversarial training. Yang et al. (2018) construct an MT model consisting of two pairs of encoder and decoder, which partially share their parameters, and train it on a non-parallel corpus not only through denoising auto-encoding and back-translation but also through adversarial training. Lample et al. (2018b) propose a simple but effective approach based on the above works, where the constructed MT model only consists of a language-invariant pair of encoder and decoder, and its training on a non-parallel corpus only requires denoising auto-encoding and back-translation. Liu et al. (2020) first pre-train BART on a non-parallel multilingual corpus through denoising auto-encoding, and then fine-tune the pre-trained BART for downstream MT tasks.

4 Verification Experiments

4.1 Experimental Settings

CLTL tasks. For generality, we address not only CLTL tasks between distant languages but also those between similar languages. Specifically, we separately conduct CLTL between three source-target language pairs, which include two distant language pairs, namely English-Japanese and German-Japanese, and one similar language pair, namely English-German.

Pre-trained multilingual language models. For compatibility, we use different pre-trained multilingual language models for model construction. Specifically, for each given CLTL task, we separately use two popular pre-trained multilingual language models, namely M-BERT (base and cased) and XLM-R (base), to construct both the baseline model and TALL.

Training data. For practicality, we adopt large-scale corpora and real-world datasets as training data. Specifically, to implement UMT, we collect a source-language corpus of 1M unannotated sentences and a target-language corpus of 1M unannotated sentences from Wikipedia dumps for model optimization, and also collect a source-language corpus of 10K unannotated sentences and a target-language corpus of 10K unannotated sentences from Wikipedia dumps for model evaluation. To conduct CLTL, we collect annotated sentences in real-world domains from two multilingual NLU

CLTL Task	Pre-trained MLM	BLEU Score	Slot F1			Intent Accuracy			Semantic Accuracy		
			BSL	TALL	Gain	BSL	TALL	Gain	BSL	TALL	Gain
EN-JA (distant)	M-BERT	41.19	56.78	60.87	7.20%	80.37	83.21	3.53%	14.56	16.39	12.57%
	XLM-R	39.83	58.21	63.19	8.56%	81.19	83.92	3.36%	16.58	18.47	11.40%

Table 1: The translation performance of TALL on Wikipedia and the CLTL performance of both the baseline model and TALL on MultiATIS++. EN means English. JA means Japanese. DE means German. BSL means the baseline model. Gain means the CLTL performance gain of TALL over the baseline model. The gain numbers are in percentage and calculated as $(\text{TALL} - \text{BSL}) \div \text{BSL}$.

CLTL Task	Pre-trained MLM	Slot F1 Gain	Intent Accuracy Gain	Semantic Accuracy Gain
EN-JA (distant)	M-BERT	53.61%	36.75%	59.45%
	XLM-R	50.96%	31.60%	71.86%
DE-JA (distant)	M-BERT	47.75%	31.46%	55.55%
	XLM-R	58.49%	34.45%	69.19%
EN-DE (similar)	M-BERT	10.42%	9.69%	18.00%
	XLM-R	12.75%	7.81%	23.87%

Table 2: The CLTL performance gain of TALL over the baseline model on the multi-domain multilingual NLU dataset.

datasets. The first multilingual NLU dataset is MultiATIS++ (Xu et al., 2020), which is an extension to Multilingual ATIS (Upadhyay et al., 2018). It provides 5K annotated sentences for each language, which are all in the domain of airline travel. The second multilingual NLU dataset is a multi-domain dataset collected from a virtual assistant. It provides 100K annotated sentences for each language, which are evenly distributed in five domains, namely music, notifications, smart home, weather, and books. By the way, in the above two multilingual NLU datasets, each word is annotated with a slot label in the B-I-O format, and each sentence is annotated with an intent label.

4.2 Implementation details.

We use WikiExtractor (Attardi, 2015) to extract paragraphs from Wikipedia dumps, use Stanza (Qi et al., 2020) to split paragraphs into sentences, use HuggingFace's Transformers (Wolf et al., 2019) to tokenize sentences into tokens and load pre-trained multilingual language models, and use PyTorch (Paszke et al., 2019) to implement both the baseline model and TALL. For model optimization, we apply an AdamW optimizer (Loshchilov and Hutter, 2019) with an initial learning rate of 0.0001, a weight decay factor of 0.01, and a batch size of 64 in the MT-oriented pre-training of TALL, and apply another AdamW optimizer with an initial learning rate of 0.00005, a weight decay factor of 0.01, and a batch size of 256 in the NLU-oriented fine-tuning of both the baseline model and TALL. After each epoch, we evaluate the validation performance, which refers to BLEU score in the MT-oriented pre-training of TALL and Semantic Accuracy in the NLU-oriented fine-tuning of both the baseline model and TALL. If the obtained performance number is improved, we save the model, otherwise we cancel the finished epoch by restoring the model to the last saved version. We decay the learning rate by 0.5 after each cancelled epoch, and terminate the model optimization after the 5th cancelled epoch. For model evaluation, we use NLTK (Loper and Bird, 2004) to measure BLEU score, and use the evaluation script for the CoNLL-2000 shared task to measure Slot F1.

4.3 Experimental Results

As shown in Table 1, we carry out a series of experiments on the unannotated sentences collected from Wikipedia and the annotated sentences collected from MultiATIS++. Each of these experiments is aimed at a different combination of CLTL task and pre-trained multilingual language model, and includes the corresponding MT-oriented pre-training of TALL and the corresponding NLU-oriented fine-tuning of both the baseline model and TALL. On this basis, we first evaluate the translation performance of TALL in its MT-oriented pre-training, then evaluate the CLTL performance of both the baseline model and TALL in their NLU-oriented fine-tuning, and finally calculate the CLTL performance gain of TALL over the baseline model in percentage. Besides, as shown in Table 2, we also repeat the NLU-oriented fine-tuning of both the baseline model and TALL on the annotated sentences collected from the multi-domain multilingual NLU dataset, and thereby obtain another CLTL performance gain of TALL over the baseline model. The experimental results show that due to the application of UMT in the MT-oriented pre-training, TALL consistently achieves better CLTL performance than the baseline model in the NLU-oriented fine-tuning without using more annotated data, and the performance gain is relatively prominent in the case of distant languages.

4.4 Ablation Study

Denoising auto-encoding. In the MT-oriented pre-training of TALL, we try to discard the denoising auto-encoding loss and only minimize the back-translation loss in the UMT training. As a result, we observe that TALL achieves a very poor translation performance and a very poor CLTL performance. This implies that TALL learns little cross-lingual knowledge through the UMT training without denoising auto-encoding.

Back-translation. In the MT-oriented pre-training of TALL, we also try to discard the back-translation loss and only minimize the denoising auto-encoding loss in the UMT training. As a result, we observe that TALL achieves an almost perfect translation performance but a very poor CLTL performance. This is because the UMT training without back-translation makes TALL a copying model instead of an MT model, and a copying model can work perfectly in the model evaluation based on round-trip translation.

BART-style fine-tuning. In the NLU-oriented fine-tuning of TALL, instead of following the fine-tuning approach of BART, we try to discard the decoder and only fine-tune the encoder following the way we fine-tune the baseline model. As a result, we observe a very poor CLTL performance. This implies that the decoder of TALL is necessary for its NLU-oriented fine-tuning.

5 Further Discussion

Is a startup supervision necessary for the back-translation? In several existing UMT training recipes, the back-translation is supervised during its startup stage, where the supervision is provided by replacing the inference of TALL with a bilingual dictionary (Lample et al., 2018a; Artetxe et al., 2018b). This startup supervision is aimed at initializing a shared representation space for the given source-target language pair. However, since the encoder of TALL is a pre-trained multilingual language model, TALL already possesses a properly initialized representation space, which is shared by all the involved languages, and thus does not need a startup supervision. Actually, we tried to use a parallel corpus generated by a naive MT model to provide a startup supervision, which is equivalent to using a bilingual dictionary, but did not observe any translation performance gain.

How does the UMT training affect the CLTL performance? The UMT training uses the denoising auto-encoding and the back-translation to enhance the correlation between the given source-target language pair in the representation space of TALL. Since the encoder of TALL is a pre-trained multilingual language model, the representation space of TALL can be seen as an extension to that of the pre-trained multilingual language model. In the representation space of the pre-trained multilingual language model, similar languages have been more correlated with each other than distant languages. That is to say, in the representation space of TALL, there is more potential to enhanced the correlation between distant languages than between similar languages. As a result, although the CLTL performance between similar languages is better than that between distant languages, the CLTL performance gain between distant languages is larger than that between similar languages.

6 Conclusion

The contribution of this paper is three-fold. First of all, we construct a novel CLTL model TALL based on a pre-trained multilingual language model. In the next place, we train TALL to conduct CLTL through an MT-oriented pre-training and an NLU-oriented fine-tuning. Last but not least, we implement UMT in the MT-oriented pre-training of TALL to make use of unannotated data. Compared with the baseline model, which is the pre-trained multilingual language model used to construct TALL, TALL consistently achieves better CLTL performance without using more annotated data, and the performance gain is relatively prominent in the case of distant languages. In the future, we will collect unannotated corpora that are linguistically compatible with the downstream NLU tasks for the UMT training, which we believe can further boost the CLTL performance of TALL.

Pipeline Signed Japanese Translation Focusing on a Post-positional Particle Complement and Conjugation in a Low-resource Setting

Ken Yano and **Akira Utsumi**

Abstract

Because sign language is a visual language, the translation of it into spoken language is typically performed through an intermediate representation called gloss notation. In sign language, function words, such as particles and determiners, are not explicitly expressed, and there is little or no concept of morphological inflection in sign language. Therefore, gloss notation does not include such linguistic constructs. Because of these factors, we argue that sign language translation is effectively processed by taking advantage of the similarities and differences between sign language and its spoken counterpart. We thus propose a pipeline translation method that clearly focuses on the difference between spoken Japanese and signed Japanese written in gloss notation. Specifically, our method first uses statistical machine translation (SMT) to map glosses to corresponding spoken language words. We then use three transformer-based seq2seq models trained using a large out-of-domain monolingual Japanese corpus to complement postpositional particles and estimate conjugations for the verbs, adjectives, and auxiliary verbs in the first translation. We apply the seq2seq models in sequence until the translation converges. Our experimental results show that the proposed method performs robustly on the low-resource corpus and is +4.4/+4.9 points above the SMT baseline for BLEU-3/4.

1 Introduction

It is essential to build a social infrastructure for hearing-impaired and hearing communities to share sufficient information so that they can quickly obtain information necessary for daily life and disasters and lead a safe and secure life. Sign language used in deaf communities has different vocabulary and grammar from spoken language. There are two variations of sign language in Japan (Chonan, 2001): (1) Japanese Sign Language (JSL) and (2) Manually Coded Japanese (MCJ). JSL is often used by early signers, and syntax, such as word order and language structure, is different from spoken Japanese. By contrast, the syntax of MCJ is similar to that of spoken Japanese in terms of word order. It is used by late signers or acquired hearing-impaired people. However, the two variations are said to be used interchangeably and there is no clear boundary between them. In this work, we consider an intermediate between JSL and MCJ, and denote it Signed Japanese (SJ) in the following discussion.

Translation from sign language to spoken language is typically performed in two steps. First, consecutive signs are recognized from a video signal and transformed into an intermediate representation called a *gloss*, then the gloss is translated into a sentence in spoken language. Current state-of-the-art sign language recognition and translation methods (Camgöz et al. 2020; Yin and Read 2020) require a large amount of data and pay little attention to differences between sign language and the corresponding spoken language. Therefore, the success of these approaches relies heavily on large paired corpora, and resource-poor sign language studies, including SJ, cannot take advantage of such approaches. In sign language, function words, such as pre-positional or post-positional particles and determiners, do not tend to be explicitly signed, and inflectional morphemes associated with verbal predicates that express categories, such as tense, mood, and aspect, are not manually signed, in general. For example, in SJ, post-positional particles ‘助詞’ are generally not explicitly signed, and the signs associated with verbal predicates are not conjugated, whereas in Japanese, verbs, adjectives, and auxiliary verbs are conjugated. Therefore, the gloss does not include such language constructs.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2021–2032
August 1–6, 2021.

Although gloss notation is commonly used by writing a series of spoken words that correspond to each sign in capital letters, because of the lack of sign language resources, its quality and size differ greatly according to the language (Bungeroth et al., 2008). SJ signs are heavily polysemous and their meaning is often context sensitive. Additionally, there is no publicly available corpus for SJ translation studies. Therefore, in this study, we use an in-house corpus that uses our gloss notation method. The details of the corpus and its notation are described in Section 2.

To solve challenging problems, we propose a novel pipeline method to translate from SJ written in gloss to Japanese. In particular, we focus on the linguistic differences between SJ and Japanese and estimate the post-positional particles that are missing and the appropriate forms of morphological inflection of words. Our method assumes that the ground truth gloss of the signed sentence is available. This assumption does not limit the availability of the above two-step sign language translation method. Our method first uses phrase-based statistical machine translation to match the SJ gloss to Japanese words. Then we refine the results further using transformer-based seq2seq (Sutskever et al., 2014) models, which are trained using a large out-of-domain parallel corpus. Specifically, we use three different seq2seq models (1) to complement the post-positional particles, (2) to apply morphological inflection by conjugating verbs, adjectives, and auxiliary verbs, and (3) to re-estimate the post-positional particles over the previous output. We repeatedly apply these models sequentially and adjust the translation results until they converge.

The proposed method works robustly, even for small training datasets, which are typically of the order of thousands of pairs in a dataset, and the results show that the state-of-the-art method is inferior to the SMT baseline with the low-resource setting. We found that iterative updates of translations are effective for improving the grammaticality and fluency of the translation output. Our experimental results show that the proposed model provides +4.4/+4.9 higher translation performance for BLEU3/BLEU4 scores compared with the SMT baseline.

2 Materials

We use two corpora: one is a small in-house SJ and Japanese parallel corpus, and the other is a large out-of-domain Japanese monolingual corpus. We describe the details of each corpus as follows.

2.1 SJ and Japanese parallel corpus

The locally organized in-house parallel corpus contains 1,086 sentence pairs with $>$7.5K glosses from a vocabulary of 655 words, and $>$11K Japanese words from a vocabulary of $>$1.2K words. The average length of a gloss sentence is 6.9 words, with a maximum length of 12 words and minimum length of 2 words, and the average length of a Japanese sentence is 10.3 words, with a maximum length of 21 words and minimum length of 5 words. The corpus consists of the ground truth gloss transcriptions of signs and their translations to Japanese sentences. The sentences are various spontaneous conversations that seemingly took place at municipal offices, such as asking for a certified copy of the resident register, pension, and unemployment insurance. In the corpus, a gloss word is written in the form gN, where N corresponds to an arbitrary unique number. We adopt this notation instead of using Japanese words because glosses in SJ are heavily polysemous and a sign maps to different Japanese words depending on the context. Instead, we use an auxiliary dictionary to map each gloss to spoken words or phrases. This notation method also helps the proposed method to select the appropriate Japanese word or phrase within the phrase-based statistical machine translation model that we use in the study.

Because of the sparsity of the parallel corpus, approximately 2.3% of the glosses are singletons, so we add all gloss dictionary items as additional parallel data to reduce OOV issues at test time.

2.2 Out-of-domain Japanese corpus

We use a subset of the Balanced Corpus of Contemporary Written Japanese [1] as an out-of-domain Japanese corpus to manually generate pseudo parallel corpora. The details of the corpus generation procedure are described in Section 3. To select the subsets, we use pattern matching to select sentences that end in a pattern such as [∼か？(question), ∼しました。(admit), ∼ほしいで

Gloss	Definition
g208	年, ため “year,for”
g20	費, お金, 費用 “expense,money”
g28	だから, ついて “about,because”
g17	相談, 会議 “ask,meeting”
g496	する, やる “do”
g2	したい, 欲しい, 好き “want,like”

Figure 1: Overall pipeline translation architecture from a gloss sequence $\mathcal{G}$ to a grammatical Japanese sequence $\mathcal{S}_{+PP+C}$. The green and gray arrows indicate the translations by a statistical machine translation model and three neural machine translation models, respectively. The table in the upper right corner shows an excerpt from the gloss dictionary. (p.pos. = post-positional)

す。(ask), ～います。(confirm), ～します。(intend), ～希望する。(desire)]. These patterns were chosen so that the selected sentences are similar to the target Japanese in the paired corpus. The monolingual corpus contains >195K sentences with >3.9M Japanese words from a vocabulary of >70K Japanese words.

3 Methodology

The overall proposed pipeline translation system is shown in Fig. 1. $\mathcal{G}$ represents a gloss sequence and $\mathcal{S}$ represents a Japanese sequence. We define two subscripts for $\mathcal{S}$, that is, PP, which denotes ‘post-positional particle,’ and C, which denotes ‘conjugation,’ with the prefix $+$ or $-$ for each subscript, which denotes the existence or non-existence, respectively, of post-positional particles and conjugation. The definition of each term is provided in Table 1.

	post-positional particles	conjugation
$\mathcal{S}_{-PP-C}$		
$\mathcal{S}_{+PP-C}$	✓	
$\mathcal{S}_{-PP+C}$		✓
$\mathcal{S}_{+PP+C}$	✓	✓

Table 1: Definitions of terms for the variants of $\mathcal{S}$

3.1 Translation method

The proposed pipeline translation consists of six steps. Algorithm 1 shows the steps applied in sequence to gradually convert from $\mathcal{G}$ to $\mathcal{S}_{+PP+C}$, which is the final translation of this algorithm. The details of each step are as follows:

Step 0: Translate $\mathcal{G}$ into $\mathcal{S}_{-PP-C}$

We use a phrase-based statistical machine translation (pbsmt) (Koehn et al., 2007) to translate $\mathcal{G}$ into $\mathcal{S}_{-PP-C}$. In this step, we map each gloss phrase to the appropriate Japanese phrases without considering the post-positional particles and conjugations of the output Japanese sequence.

Step 1: Translate $\mathcal{S}_{-PP-C}$ into $\mathcal{S}_{+PP-C}$

We use a transformer-based seq2seq model (Vaswani et al., 2017) (s2s_m1) to translate $\mathcal{S}_{-PP-C}$ into $\mathcal{S}_{+PP-C}$. In this step, the model estimates missing post-positional particles in $\mathcal{S}_{-PP-C}$ and inserts them to generate $\mathcal{S}_{+PP-C}$.

Step 2: Translate $\mathcal{S}_{+PP-C}$ into $\mathcal{S}_{+PP+C}$

We use another transformer-based seq2seq model (s2s_m2) to translate $\mathcal{S}_{+PP-C}$ into $\mathcal{S}_{+PP+C}$. In this step, the model estimates the appropriate morphological inflection or conjugated form for verbs, adjectives, and auxiliary verbs in $\mathcal{S}_{+PP-C}$ to generate $\mathcal{S}_{+PP+C}$.

Step 3: Convert $\mathcal{S}_{+PP+C}$ to $\mathcal{S}_{-PP+C}$

In this step, we remove the previously estimated post-positional particles in $\mathcal{S}_{+PP+C}$ from Step 2 to generate $\mathcal{S}_{-PP+C}$.

Step 4: Translate $\mathcal{S}_{-PP+C}$ into $\mathcal{S}_{+PP+C}$

We use the other transformer-based seq2seq model (s2s_m3) to translate $\mathcal{S}_{-PP+C}$ into $\mathcal{S}_{+PP+C}$ by re-estimating missing post-positional particles. In Step 1, we estimated the post-positional particles over a Japanese sequence in the canonical form ($\mathcal{S}_{-PP-C}$); however, in the present step, we estimate them over for the conjugated word sequence ($\mathcal{S}_{-PP+C}$). We assume that this will correct the previous estimation using the conjugated form of the word sequence obtained in the previous steps.

Step 5: Convert $\mathcal{S}_{+PP+C}$ to $\mathcal{S}_{+PP-C}$

In this step, we transform $\mathcal{S}_{+PP+C}$ to $\mathcal{S}_{+PP-C}$ by converting words in $\mathcal{S}_{+PP+C}$ to their canonical form. Steps 3, 4, 5, and 2 are repeated until the translation output converges or the number of iterations reaches the maximum limit (10).

Algorithm 1 Translation of a sign gloss sequence into a Japanese sentence

```
Input: $\mathcal{G}$
Output: $\mathcal{S}_{+PP+C}$
  Step 0: $\mathcal{G} \rightarrow \mathcal{S}_{-PP-C}$
  Step 1: $\mathcal{S}_{-PP-C} \rightarrow \mathcal{S}_{+PP-C}$
  Step 2: $\mathcal{S}_{+PP-C} \rightarrow \mathcal{S}_{+PP+C}$
  $\mathcal{S}_{prev} = \emptyset$
  $\mathcal{S}_{next} = \mathcal{S}_{+PP+C}$
  while $\mathcal{S}_{prev} \neq \mathcal{S}_{next}$ do
      $\mathcal{S}_{prev} = \mathcal{S}_{next}$
      Step 3: $\mathcal{S}_{+PP+C} \rightarrow \mathcal{S}_{-PP+C}$
      Step 4: $\mathcal{S}_{-PP+C} \rightarrow \mathcal{S}_{+PP+C}$
      Step 5: $\mathcal{S}_{+PP+C} \rightarrow \mathcal{S}_{+PP-C}$
      Step 2: $\mathcal{S}_{+PP-C} \rightarrow \mathcal{S}_{+PP+C}$
      $\mathcal{S}_{next} = \mathcal{S}_{+PP+C}$
  end while
  return $\mathcal{S}_{next}$
```

4 Training

4.1 Statistical machine translation model in Step 0

We use Moses (Koehn et al., 2007) to train the phrase-based statistical machine translation model to translate from $\mathcal{G}$ to $\mathcal{S}_{-PP-C}$ in Step 0. To train the model, we use the parallel corpus and preprocess the target Japanese sequences by deleting post-positional particles, and convert conjugated words, such as verbs, adjectives, and auxiliary verbs, to their canonical forms using MeCab [2].

Note that we leave any post-positional particles untouched if gloss words corresponding to them exist. For example, the Japanese word か *ka* which is a post-positional particle bound to the end of an interrogative sentence, has a corresponding gloss word in SJ. The translation model is described by the following noisy-channel model to estimate the best target Japanese word sentence $s \in \mathcal{S}_{-PP-C}$ for a source gloss sentence $g \in \mathcal{G}$ as

$$s_{best} = argmax_s \; p(g|s)p_{LM}(s), \qquad (1)$$

where $p_{LM}(s)$ is a language model based on the n-grams of $\mathcal{S}_{-PP-C}$. $p(g|s)$ is decomposed into a phrase-based formula using a phrase translation table and phrase reordering model (Koehn et al., 2007). For the language model, we use modified 3-gram Kneser–Ney smoothing.

4.2 Encoder-decoder translation models in Steps 1, 2, and 4

For the seq2seq models used in Steps 1, 2, and 4 in Section 3.1, we use a transformer-based encoder-decoder model (Ott et al., 2019). For all models, we use an encoder and decoder with an embedding of size 512, FFN-embedding of size 2048, and six layers with eight attention heads. We use the Adam optimizer with label smoothing cross-entropy loss with a smoothing factor of 0.1. We set the initial learning rate to 5e-4 with a warmup updates of 4,000 and use the inverse sqrt learning rate scheduler. We set the maximum tokens in a batch to 4K. We use tied embedding for the input and output layers. We obtain the hyperparameters from a non-exhaustive parameter search, and the results are shown in Table 9 of the Appendix.

We randomly split the corpus into training, validation, and test sets in an 8:1:1 ratio. For tokenization, we use byte pair encoding (Sennrich et al., 2016), which is trained using the training dataset. We set the number of operations to 10K for each tokenization of the seq2seq models. For the seq2seq model in Step 1, we pre-process the out-of-domain monolingual corpus as follows:

- Source: preprocess Japanese sequences by deleting post-positional particles and converting all conjugated words, such as verbs, adjectives, and auxiliary verbs, to their canonical forms.
- Target: preprocess Japanese sequences by leaving post-positional particles untouched and converting all conjugated words, such as verbs, adjectives, and auxiliary verbs, to their canonical forms.

The pre-processed corpus becomes the pseudo-parallel corpus to train the seq2seq model in Step

---

[2] https://pypi.org/project/mecab-python3/

1 to translate $\mathcal{S}_{-PP-C}$ into $\mathcal{S}_{+PP-C}$. The training corpora of the other seq2seq models, that is, s2s_m2 in Step 2 and s2s_m3 in Step 4, are similarly preprocessed and independently trained using the pseudo-parallel corpus.

We observed that training the seq2seq model in Step 2 took more than a few hundred epochs, whereas training the seq2seq model in Steps 1 and 4 took less than 30 epochs. We used the models with the lowest validation loss for the experiments. The results on the test set demonstrated that the BLEU4 scores were 74.20, 98.75, and 75.06 for s2s_m1, s2s_m2, and s2s_m3, respectively. This indicates that post-positional particle estimation is more uncertain compared with the estimation of morphological inflection.

5 Experiments

To evaluate the proposed method, we conducted 100 experiments and for each test, we randomly selected 10 samples from the parallel corpus for testing and used the remaining samples to retrain the statistical machine translation model in Step 0. For each test, we finetuned the parameters of the seq2seq model (s2s_m1, s2s_m2, s2s_m3) by the training data and we used a beam size of 5 for decoding of the models. We averaged the 100 results to calculate the metrics of the performance.

We denote the proposed method in Section 3.1 by SMT+Iterative_s2s and compared its performance with the following baselines (naive, LSTMs, and SMT), the variants of the proposed method (SMT+1step_s2s and SMT+2step_s2s) and the transformer-based end-to-end Gloss2Text (G2T) model proposed by Yin and Read (2020). The followings are the brief explanations of each model.

- **naive**: This baseline replaces each gloss word with a Japanese word using the gloss dictionary. If more than one Japanese word is defined for a gloss, the first word is used.
- **LSTM**: This baseline uses encoder-decoder LSTM with an attention mechanism (Bahdanau et al., 2015) to directly translate $\mathcal{G}$ into $\mathcal{S}_{+PP+C}$. The model is trained using the parallel corpus without using the out-of-domain corpus and is configured with several different hyperparameter settings.
- **SMT**: This baseline uses only the statistical machine translation model to directly translate $\mathcal{G}$ into $\mathcal{S}_{+PP+C}$. This model is trained using the parallel corpus and without using the out-of-domain corpus.
- **SMT+1step_s2s**: This model is a variant of the proposed model which first executes Step 0 of Algorithm 1 to translate $\mathcal{G}$ into $\mathcal{S}_{-PP-C}$. Then it uses another seq2seq model trained using the out-of-domain corpus to directly translate $\mathcal{S}_{-PP-C}$ into $\mathcal{S}_{+PP+C}$. We compared the performance of this model, which jointly estimates post-positional particles and conjugations, with the model that estimates them separately using different models.
- **SMT+2step_s2s**: This model is another variant of the proposed model which performs Steps 0–2, but does not iteratively update the translation result as it does in Algorithm 1. We examined how the iterative updates of the result with **SMT+Iterative_s2s** contribute to the performance compared with the model without them.

For G2T, we changed the original hyperparameters suggested by Yin and Read (2020) and found that the following parameters were optimal using hyperparameter search on our parallel corpus. Encoder and decoder: embed-size = 256, FFN-embed-size = 1024, num-layer = 1, num-attention-head = 4.

5.1 Results

Table 2 shows the results of the experiment. To evaluate performance, we used the following metrics, BLEU-1/2/3/4 (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and word error rate (WER), and averaged the scores to obtain the results. The results showed that the proposed model (SMT+Iterative_s2s) outperformed the other models. The poor performance of the naive model indicates that the simple lookup method using the gloss dictionary did not produce successful results. LSTMs with different hyperparameters varying in the dimensions of the embedding and the hidden layers (256, 512, 1024) and the number of layers (1, 2) show the baseline performances to directly translate $\mathcal{G}$ into $\mathcal{S}_{+PP+C}$. Among them, the LSTM with the dimensions of the embedding and the hidden layers of 1024 and the number of layers of 1 showed the best performance. The best LSTM and the G2T were inferior

	embed	hidden	layers	BLEU1	BLEU2	BLEU3	BLEU4	METEOR	WER
naive				0.184	0.049	0.007	0.002	0.139	0.801
LSTM	256	256	1	0.628	0.538	0.453	0.365	0.623	0.419
	512	512	1	0.692	0.608	0.527	0.442	0.688	0.349
	1024	1024	1	0.717	0.634	0.552	0.467	0.714	0.320
	256	256	2	0.448	0.314	0.222	0.154	0.408	0.616
	512	512	2	0.558	0.440	0.325	0.225	0.530	0.502
	1024	1024	2	0.590	0.466	0.332	0.209	0.556	0.466
G2T (Yin and Read, 2020)				0.695	0.640	0.592	0.535	0.708	0.305
SMT				0.788	0.724	0.663	0.599	0.800	0.233
SMT+1step_s2s				0.810	0.752	0.697	0.638	0.830	0.301
SMT+2step_s2s				0.811	0.756	0.701	0.642	0.829	0.245
SMT+Iterative_s2s				**0.817**	**0.762**	**0.707**	**0.648**	**0.833**	**0.216**

Table 2: Performance evaluations of naive, LSTMs, G2T (Yin and Read, 2020), SMT, SMT+1step_s2s, SMT+2step_s2s, and SMT+Iterative_s2s on BLEU1/2/3/4↑ and METEOR↑, and word error rate (WER) ↓ by averaging the scores from all experiments. The hyperparameters of LSTMs, the dimensions of the embedding and hidden layers, and the number of layers, are specified in the columns of 'embed', 'hidden', and 'layers', respectively. We use the same parameters for the encoder and the decoder of the LSTMs.

Model	Step	Source	Target	GS	EP
pbsmt	0	$\mathcal{G}$	$\mathcal{S}_{-PP-C}$	38.0	
s2s_m1	1	$\mathcal{S}_{-PP-C}$	$\mathcal{S}_{+PP-C}$	79.5	35.1
s2s_m2	2	$\mathcal{S}_{+PP-C}$	$\mathcal{S}_{+PP+C}$	99.2	35.1
s2s_m3	4	$\mathcal{S}_{-PP+C}$	$\mathcal{S}_{+PP+C}$	86.9	36.1

Table 3: Error propagation analysis of SMT+Iterative_s2s. The score is the exact match for the correct ratio (%) (GS = gold standard, EP = error propagation).

to the SMT because there were insufficient samples to train the neural models with large capacity. All the pipeline models that combined the SMT and seq2seq models outperformed the models that directly translate $\mathcal{G}$ into $\mathcal{S}_{+PP+C}$. This clearly demonstrates the effectiveness of the pipeline approach. Table 8 in Appendix illustrates the translation samples at each step of SMT+Iterative_s2s.

We investigated whether adding the monolingual Japanese corpus in 2.2 to train the target language model improved the performance of the SMT baseline. However, on the contrary, performance was slightly degraded. We believe that this was because of a domain mismatch between the corpora. The statistical significance test results confirmed that the performance of SMT+Iterative_s2s was significantly better than that of SMT, SMT+1step_s2s, and SMT+2step_s2s (see Table 10 in the Appendix).

Table 3 shows the error propagation analysis of SMT+Iterative_s2s. The score was measured using the exact match by counting the outputs that exactly matched the references at each step. Column 'GS' represents the gold standard score when using the ground truth input, and column 'EP' represents the score when using the output from the previous pipeline stage as the input propagating the errors. Clearly, a large portion of the error originated from Step 0 when translating $\mathcal{G}$ into $\mathcal{S}_{-PP-C}$. The GS score of s2s_m2 was much higher than that of s2s_m1 and s2s_m3, which was indicated by its higher BLEU score for the model evaluation on the test set described in Section 4. We verified that the EP score of s2s_m3 was 2.8% greater than that of s2s_m2, thereby illustrating the efficacy of the retrospective complement of post-positional particles. Note that the EP score of s2s_m3 was measured by allowing the output of s2s_m2 in the EP to be set to the input and removing all post-positional particles.

Table 4 shows the frequency of iterative update counts by SMT+Iterative_s2s. Approximately 72% of the results converged at the first iteration, and approximately 26% of the results converged at the second iteration. Counts above 6 were achieved when the same phrase was repeatedly generated, which is a phenomenon known as hallucination (Wang and Sennrich, 2020). If we detected such an error, we removed the repeating phrase to shorten the output.

5.2 Qualitative Evaluation

Table 5 shows the qualitative evaluations of the results using the proposed model and the other models with BLEU4, WER, and perplexity (PPL) scores. PPL in the last column was measured by the transformer-based language model that was pretrained by using the 494M-word Japanese Wikipedia.

We observed that the results of SMT and G2T had more post-positional particle selection errors than the other pipeline models, and the results of SMT+1step_s2s had more verb conjugation errors than SMT+2step_s2s, which suggest the efficacy of the independent estimation of post-positional particles and conjugations. We confirmed that the post-positional particle estimations using SMT+Iterative_s2s were either more natural or less error-prone than those using SMT+2step_s2s, which made the translation results more fluent.

Loop count	Freq.
1	723 (72.3%)
2	258 (25.8%)
3	4 (0.4%)
4	6 (0.6%)
6	1 (0.1%)
7	2 (0.2%)
8 ≥	6 (0.6%)

Table 4: Frequency of the iteration counts of Algorithm 1 until the translation output converged using SMT+Iterative_s2s.

Table 6 shows the average perplexity scores of the results of the SMT and pipeline models. While the perplexities of the pipeline models were much lower than that of SMT, the perplexity of the proposed SMT+Iterative_s2s was not the lowest. This result suggests that word-based perplexity is not suitable for evaluating equally acceptable translation outputs.

6 Discussion

In Table 5, most of the outputs using SMT+2step_s2s and SMT+Iterative_s2s were grammatically acceptable Japanese sentences with slight differences in the post-positional particle selections. As shown in the second and third examples in Table 5, the PPL scores of SMT+2step_s2s were lower than those of SMT+Iterative_s2s, but the BLEU4 and WER scores of SMT+Iterative_s2s were better than that of SMT+2step_s2s, even though the meanings of the sentences were almost the same. By contrast, the sentences of SMT+2step_s2s and SMT+Iterative_s2s in the first and last examples had different meanings, even though the PPL, BLEU4, and WER scores indicated that the results of SMT+Iterative_s2s were better than those of SMT+2step_s2s. However, depending on the context, the results of SMT+2step_s2s may be more appropriate. The main cause of the ambiguity issue is related to the information bottleneck raised by Yin and Read (2020) regarding the gloss notation of sign language. Currently, our parallel corpus does not include any non-manual signals (NMSs), such as facial expression, eye gaze, mouth, and movement of the head and shoulders. However, NMSs act as grammatical markings for syntactic information (Valli et al. 2011; Koizumi et al. 2002). NMSs are not expressed in sequence, but simultaneously with manual signs, and their subtleties make sign recognition and annotation more difficult. Perhaps, this is one of the reasons that most existing sign language corpora do not or only contain partial NMS labels along with glosses. As suggested by Yin and Read (2020), the performance of G2T translation may not impose an upper bound for sign-to-text translation unless the gloss faithfully describes the signed sentences. We are interested in investigating whether incorporating visual features from signs would improve the proposed G2T translation method. Because of the limited space in this paper, we leave this issue for future work.

Table 7 depicts examples of the translation errors by SMT+Iterative_s2s categorized into gloss word translation error, post-positional particle exchange, and conjugation exchange. As shown in Table 3, a large portion of the translation errors originated from gloss word translations. These errors mostly occurred because of the incorrect selection of Japanese wording for gloss phrases. For instance, the phrase 被災地 *hisaichi* ‘disaster area’ in the reference of the 2nd example in Table 7, which is expressed as a sequence of three glosses: 受ける ‘receive’, 災害 ‘disaster’, and 場所 ‘area’, was translated into the un-grammatical phrase, 受けて 災害場所 *ukete saigaibasho*. It is because the correct mapping from glosses to compound nouns cannot be learned by the phrase-based SMT unless they appear in the training set. The second major source of translation errors was the post-positional particle exchanges. These errors possibly change the semantic from the reference as indicated in the 5th example of Table 7, 図書館に本を寄贈する方法 “how to donate books to libr ray” v.s. 図書館の本を贈る方法 “how to give a book from the library”. As we mentioned above, some of these errors are difficult to handle because the system output may be correct in another context. Trans-

Camgöz et al. (2018) proposed end-to-end sign language translation in the framework of neural machine translation, allowing them to jointly learn the spatial sign representation, underlying language model, and mapping between sign and spoken language using PHOENIX-Weather 2014T (Camgöz et al., 2018) corpus. Their later work (Camgöz et al., 2020) further improved the model by introducing a transformer-based architecture that jointly learns sign language recognition and translation while being trainable in an end-to-end manner using connectionist temporal classification loss to bind the recognition and translation problems into a single unified architecture.

In a similar research line, Yin and Read (2020) proposed the G2T model using a transformer-based seq2seq model, and evaluated the performance on PHOENIX-Weather 2014T (Camgöz et al., 2018) and ASLG-PC12 (Othman and Jemni, 2012) in various ways by changing the numbers of encoder-decoder layers and embedding schemes. All the end-to-end state-of-the-art sign language translation methods rely on large datasets and cannot be used for resource-poor datasets. The

pipeline method that we proposed is related to the transfer learning method proposed by Mocialov et al. (2018). They proposed transfer learning to improve British Sign Language modeling at a gloss level by fine-tuning or layer substitution on neural network models pre-trained on the Penn Treebank dataset. Although the purpose of their work was not to translate sign language, their work is similar to ours in that it takes advantage of linguistic commonality between resource-poor sign language and its spoken language. Our approach to converting non-grammatical sentences into grammatical sentences is related to previous work on grammatical error correction (Imamura et al. 2012; Liu et al. 2018; Oyama et al. 2013). They used insert or replace operations to correct particle or morphological inflection errors in a monolithic model, and we believe that the proposed seq2seq-based iterative method using multiple models can be used for similar tasks.

8 Conclusion

We proposed a pipeline machine translation method from SJ to Japanese by assuming that the gloss of the sign is provided. We focused on grammatical differences between SJ and Japanese, particularly post-positional particles and morphological inflections, and proposed a pipeline model by cascading the phrase-based statistical machine translation and three transformer-based seq2seq models, which effectively addressed the resource-poor issue of the sign language corpus. The statistical machine translation model first maps each gloss phrase to a Japanese phrase, then three seq2seq models pre-trained using the monolingual corpus transform the initial translation by complementing post-positional particles, and apply conjugations for verbs, auxiliary verbs, and adjectives. Translation is repeated until the output converges. We confirmed that the proposed method outperformed the SMT baseline by +4.4/+4.9 points for BLEU-3/4.

Language-Mediated, Object-Centric Representation Learning

Abstract

We present Language-mediated, Object-centric Representation Learning (LORL), a paradigm for learning disentangled, object-centric scene representations from vision and language. LORL builds upon recent advances in unsupervised object discovery and segmentation, notably MONet and Slot Attention. While these algorithms learn an object-centric representation just by reconstructing the input image, LORL enables them to further learn to associate the learned representations to concepts, i.e., words for object categories, properties, and spatial relationships, from language input. These object-centric concepts derived from language facilitate the learning of object-centric representations. LORL can be integrated with various unsupervised object discovery algorithms that are language-agnostic. Experiments show that the integration of LORL consistently improves the performance of unsupervised object discovery methods on two datasets via the help of language. We also show that concepts learned by LORL, in conjunction with object discovery methods, aid downstream tasks such as referring expression comprehension.

1 Introduction

Cognitive studies show that human infants develop object individuation skill from diverse sources of information: spatial-temporal information, object property information, and language (Xu, 1999, 2007; Westermann and Mareschal, 2014). Specifically, young infants develop object-based attention that disentangles the motion and location of objects from their visual appearance features. Later on, they can leverage the knowledge acquired through word learning to solve the problem of object individuation: words provide clues about object identity and type. The general picture from cognitive science is that object perception and language co-develop in support of one another (Bloom, 2002).

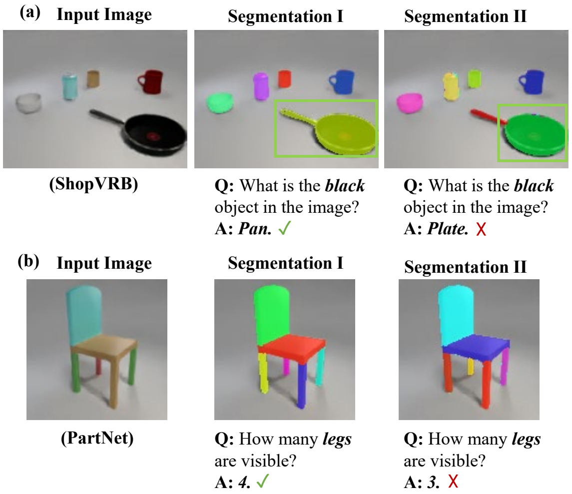

Figure 1: Two illustrative cases of Language-mediated, Object-centric Representation Learning. Different colors in the segmentation masks indicate individual objects recognized by the model. LORL can learn from visual and language inputs to associate various concepts: *black*, *pan*, *leg*, with the visual appearance of individual objects. Furthermore, language provides cues about how an input scene should be segmented into individual objects: (a) segmenting the frying pan and its handle into two parts (Segmentation II) yields an incorrect answer to the question ; (b) an incorrect parsing of the chair image makes the counting result wrong.

Our long-term goal is to endow machines with similar abilities. In this paper, we focus on how language may support object discovery and segmentation. Recent work has studied the problem of unsupervised object representation learning, though without language. As an example, factorized, object-centric scene representations have been used in various kinds of prediction (Goel et al., 2018), reasoning (Yi et al., 2018), and planning tasks (Veerapaneni et al., 2020), but they have not considered the role of language and how it may help object representation learning.

As a concrete example, consider the input images shown in Fig. 1 and the paired questions. From language, we can learn to associate concepts,

---

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2033–2046
August 1–6, 2021.

such as *black, pan*, and *leg*, with the referred object's visual appearance. Further, language provides cues about how an input scene should be segmented into individual objects: a wrong parsing of the input scene will lead to an incorrect answer to the question. We can learn from such failure that the handle belongs to the frying pan (Fig. 1a) and the chair has four legs (Fig. 1b).

Motivated by these observations, we propose a computational learning paradigm, Language-mediated, Object-centric Representation Learning (LORL), associating learned object-centric representations to their visual appearance (masks) in images, and to concepts—words for object properties such as color, shape, and material—as provided in language. Here the language input can be either descriptive sentences or question-answer pairs. LORL requires no annotations on object masks, categories, or properties during the learning process.

In LORL, four modules are jointly trained. The first is an image encoder, learning to encode an image into factorized, object-centric representations. The second is an image decoder, learning to reconstruct masks for individual objects from the learned representations by reconstructing the input. These two modules share the same formulation as recent unsupervised object discovery research: learning to decompose the image into a series of *slot* profiles, comprised of pixel masks and latent embeddings. Each slot profile is expected to represent a single object in the image.

The third module in LORL is a pre-trained semantic parser that translates the input sentence into a semantic, executable program, where each concept (i.e., words for object properties such as *red*) is associated with a vector space embedding. Finally, the last module, a neural-symbolic program executor, takes the object-centric representation from Module 1, intermediate representations from Module 2, and concept embeddings and the semantic program from Module 3 as input, and outputs an answer if the language input is a question, or `TRUE/FALSE` if it's a descriptive sentence. The correctness of the executor's output and the quality of reconstructed images (as output of Module 2) are the two supervisory signals we use to jointly train Modules 1, 2, and 4.

We integrate the proposed LORL with state-of-the-art unsupervised discovery methods, MONet (Burgess et al., 2019) and Slot Attention (Locatello et al., 2020). The evaluation is based on two datasets: ShopVRB (Nazarczuk and Mikolajczyk, 2020) contains images of daily objects and question-answer pairs; PartNet (Mo et al., 2019) contains images of furniture with hierarchical structure, supplemented by descriptive sentences we collected ourselves. We show that LORL consistently improves existing methods on unsupervised object discovery, much more likely to group different parts of a single object into a single mask.

We further analyze the object-centric representations learned by LORL. In LORL, conceptually similar objects (e.g. objects of similar shapes) appear to be clustered in the embedding space. Moreover, experiments demonstrate that the learned concepts can be used in new tasks, such as visual grounding of referring expressions, without any additional fine-tuning.

2 Related Work

Unsupervised object representation learning. Given an input image, unsupervised object representation learning methods segment objects in the scene and build an object-centric representation for them. A mainstream approach has focused on using compositional generative scene models that decompose the scene as a mixture of component images (Greff et al., 2016; Eslami et al., 2016; Greff et al., 2017; Burgess et al., 2019; Engelcke et al., 2020; Greff et al., 2019; Locatello et al., 2020; Goyal et al., 2020). In general, these models use an encoder-decoder architecture: the image encoder encodes the input image into a set of latent object representations, which are fed into the image decoder to reconstruct the image. Specifically, (Greff et al., 2019; Burgess et al., 2019; Engelcke et al., 2020) use recurrent encoders that iteratively localize and encode objects in the scene. Another line of research (Eslami et al., 2016; Crawford and Pineau, 2019; Kosiorek et al., 2018; Stelzner et al., 2019; Lin et al., 2020) leverages object locality to attend to different local patches of the image. These models often use a pixel-level reconstruction loss. In contrast, we propose to explore how language, in addition to visual observations, may contribute to object-centric representation learning. There has also been work that uses other types of supervision, such as dynamic prediction (Kipf et al., 2020; Bear et al., 2020) and multi-view consistency (Prabhudesai et al., 2020). In this paper, we focus on unsupervised learning of object-centric representations from static images and language.

Visual concept learning. Learning visual concepts from language and other forms of supervision provides useful representations for various downstream tasks, such as image captioning (Yin and Ordonez, 2017; Wang et al., 2018), visual-question answering (Yi et al., 2018; Huang et al., 2019), shape differentiation (Achlioptas et al., 2019), image classification (Mu et al., 2020), and scene manipulation (Prabhudesai et al., 2020). Previous work has been focusing on various types of representations (Ren et al., 2016; Wu et al., 2017), training algorithms (Faghri et al., 2018; Morgado et al., 2020) and supervision (Johnson et al., 2016; Yang et al., 2018). In this paper, we focus on learning visual concepts that can be grounded in object-centric representations. Recent work on object-centric grounding of visual concepts (Wu et al., 2017; Mao et al., 2019; Hudson and Manning, 2019; Prabhudesai et al., 2020) has shown great success in achieving high performance in downstream tasks and strong generalization from a small amount of data. However, these methods assume pre-trained object detectors to generate object proposals in the scene. In contrast, our LORL learns to individuate objects and associates concepts with the learned object-centric representations without any annotations on object segmentation masks or properties.

3 Preliminaries

Before delving into our language-mediated object-centric representation learning paradigm, we first discuss a general formulation that unifies multiple concurrent unsupervised object representation learning methods and a neuro-symbolic framework for learning visual concepts from language.

3.1 Unsupervised Object-Centric Representation Learning

Given an image I, a typical unsupervised object representation learning model will decompose the scene into a series of *slot* profiles $\{(z_1, x_1, m_1), \ldots, (z_K, x_K, m_K)\}$, where each slot profile is expected to represent an object (or nothing, as the number of slots may be greater than the actual number of objects in the scene). Here z_i is the object feature, x_i is the object image, and m_i is the object mask specifying its location in the scene.

In our paper, we focus on two recent models, MONet (Burgess et al., 2019) and Slot Attention (Locatello et al., 2020). MONet uses a recurrent spatial attention network (Ronneberger et al., 2015) to segment out objects in the scene, and adopts a variational autoencoder (Kingma and Welling, 2014) to encode objects as well as reconstruct object images for self-supervision. At a very high level, its objective function is calculated as

$$\mathcal{L} = \left\| \left(\sum_{k=1}^{K} m_k x_k \right) - I \right\|_2^2 + \beta \cdot \sum_{k=1}^{K} \mathrm{KL}(z_k), \quad (1)$$

where the first term is a pixel-wise $\mathcal{L}_2$ reconstruction loss and the second term computes the KL divergence between the distribution of z_k's and a prior Gaussian distribution.

Slot Attention uses a transformer-like attention network (Vaswani et al., 2017) to extract object features, and decode them with convolutional neural networks to component images and object masks. The model is trained by the same reconstruction loss in the form of the $\mathcal{L}_2$-norm:

$$\mathcal{L} = \left\| \left(\sum_{k=1}^{K} m_k x_k \right) - I \right\|_2^2 . \quad (2)$$

3.2 Neuro-Symbolic Concept Learning

The neuro-symbolic concept learner (NS-CL; Mao et al., 2019) learns visual concepts by looking at images and reading paired questions and answers. NS-CL takes a set of segmented objects in a given image as its input, extracts their visual features with a ResNet (He et al., 2015), translates the input question into an executable program by a semantic parser, and executes the program based on the object-centric representation to answer the question. The key idea of NS-CL is to explicitly represent individual concepts in natural language (colors, shapes, spatial relationships, etc.) as vector space embeddings, and associate them with the object embeddings.

NS-CL answers the input question by executing the program based on the object-centric representation. For example, in order to query the name of the white object in Fig. 2, NS-CL first filters out the object by computing the cosine similarity between the concept *white* and individual object representations, which produces a "mask" vector where each entry denotes the probability that an object has been selected. The output "mask" on

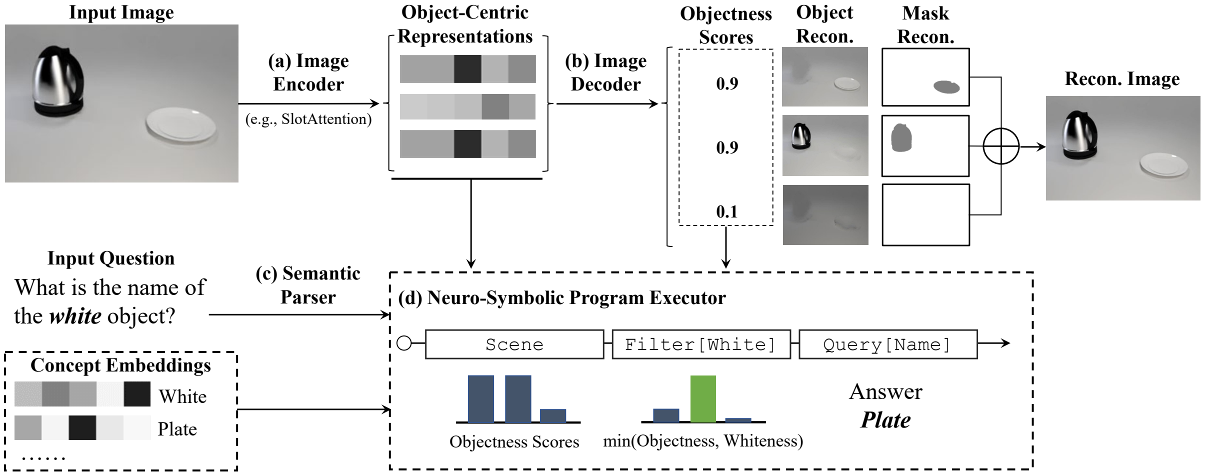

Figure 2: Our LORL contains four modules. (a) An image encoder encodes the input image into a factorized, object-centric representation. (b) An image decoder learns to reconstruct the image from the learned representations. It also decodes an objectness score based on the representation. (c) A pre-trained semantic parser translates the input sentence into an executable program and associates concepts with learnable vector embeddings. (d) A neuro-symbolic program executor takes the object-centric representation, the objectness scores, the parsed program, and concept embeddings as input to predict the answer (if the input is a question) or `TRUE/FALSE` (if the input is a descriptive sentence).

the objects is fed into the next module and the execution will continue. The last query operation produces the answer to the question. The vector embeddings of individual objects and the concepts are jointly trained based on language supervision.

4 Language-mediated, Object-centric Representation Learning

Marrying the ideas of unsupervised object-centric representation learning and neuro-symbolic concept learning, we are able to learn an object-centric representation using both visual and language supervision. Fig. 2 shows an overview of Language-mediated, Object-centric Representation Learning (LORL). In LORL, four modules are optimized jointly: an image encoder, an image decoder, a semantic parser, and a neuro-symbolic program executor.

Image encoder. Given an input image, we first use the image encoder (Fig. 2a) to individuate objects in the scene and extract an object-centric scene representation. It takes the input image as its input, individuates objects in the scene, and produces a collection of latent slot embeddings $\{z_i\}$.

Image decoder. The decoder (Fig. 2b) takes the object-centric representation produced by the image encoder and produces a 3-tuple for each individual slot (x_k, m_k, s_k), where x_k reconstructs the RGB image of the slot, m_k reconstructs the mask, and $s_k \in [0, 1]$ is a scalar indicating the *objectness* of the slot. That is, whether k-th slot corresponds to a *single* object in the scene. Here, we have extended the general pipeline we described in Section 3.1 with an objectness indicator. It serves dual purposes. First, it weights each reconstructed component image while generating the reconstructed image. Mathematically, the reconstructed image I' is computed as: $I' = \sum_{k=1}^{K} s_k \cdot (m_k x_k)$. Second, it mediates the output of all `filter` operations in the program executor.

In this paper, we will experiment with two image encoder-decoder options: MONet (Burgess et al., 2019) and Slot Attention (Locatello et al., 2020). They are both compatible with the learning paradigm described above. For both models, we use a single linear layer to predict the objectness score for each slot on top of the second-last layer of their image decoders.

Semantic parser. A pre-trained semantic parser (Fig. 2c) will translate the input question into an executable program composed of primitive operations, such as `filter`, which filters out objects with certain concepts and `query`, which queries the attribute of the input object. We use roughly the same domain-specific language (DSL) for representing programs as CLEVR (Johnson et al., 2017a, see also the appendix for details). All concepts that appear in the program, such as *white*, are associated with distinct, learnable concept embedding vectors.

Q: There is a plastic thing; are there any heavy metal things behind it?

P: `scene, filter[plastic], relate[behind], filter[heavy, metal], exist`

A: True

Q: What number of ceramic things are there?

P: `scene, filter[ceramic], count`

A: 1

Q: The small plate is what color?

P: `scene, filter[small], filter[plate], query[color]`

A: purple

(a) Examples on Shop-VRB-Simple

D: The color of the back is brown.

P: `scene, filter[back], query[color], equal[brown]`

D: The number of legs there is 4.

P: `scene, filter[leg], count, equal[4]`

D: There is a part left of the cyan seat, its color is red.

P: `scene, filter[cyan, seat], relate[left], equal[red]`

(b) Examples on PartNet-Chairs

Figure 3: In Shop-VRB-Simple, questions involve seven different attributes of objects in the scene: *name, size, weight, material, color, shape, mobility*. In PartNet-Chairs, images are paired with sentences describing the *names* and *colors* of the parts in the scene, and their relationships.

Neuro-symbolic program executor. The program executor (Fig. 2d) takes the object-centric representation from the image encoder $\{z_k\}$, the objectness score $\{s_k\}$ from the image decoder, the concept embeddings and the program generated by the semantic parser as its input. It executes the program based on the visual and concept representations to answer the question.

The original program executor in NS-CL (Section 3.2) assumes a pre-trained object detector for generating object proposals. In LORL, we associate each object representation with an objectness score s_k. Recall that a `filter` operation in NS-CL produces a mask vector indicating whether an object has been selected. Here, we mediate the output of an `filter(c)` operation as $\min(s_k, \texttt{filter(c)})$. Intuitively, a slot will be selected only if, first, it has concept c and, second, it corresponds to a single object in the scene.

Training paradigm. During training, we jointly optimize the image encoder, the image decoder, and the concept embeddings. They are trained by minimizing the loss $\mathcal{L}$:

$$\mathcal{L} = \alpha \cdot \mathcal{L}_{\text{perception}} + \beta \cdot \mathcal{L}_{\text{reasoning}}.$$

For MONet-based image encoder-decoder, we use Equation 1 as the perception loss $\mathcal{L}_{\text{perception}}$, while for Slot Attention-based encoder-decoder, we use Equation 2. The neuro-symbolic program executor produces a distribution over candidate answers to the input question. We use the cross-entropy loss between the predicted answer and the ground truth answer as $\mathcal{L}_{\text{reasoning}}$.

We use a three-stage training paradigm in LORL. First, we train the model with only visual inputs with $\mathcal{L}_{\text{perception}}$ for N_1 epochs. Next, we fix the image encoder and the image decoder, and optimize the concept embeddings with the loss term $\mathcal{L}_{\text{reasoning}}$ for N_2 epochs. During this second stage, the image encoder and the decoder can already produce decent object segmentation results. Finally, we jointly optimize all three modules for N_3 epochs. We provide detailed information about the hyperparameters for different models in the appendix.

5 Experiments

We first evaluate whether the representations learned by LORL lead to better image segmentation with the help of language. We then evaluate how these representations may be used for instance retrieval, visual reasoning, and referring expression comprehension.

5.1 Image Segmentation

Data. We use two datasets for image segmentation evaluation. The first, Shop-VRB-Simple, is based on Shop-VRB (Nazarczuk and Mikolajczyk, 2020), a dataset of complex household objects and question-answer pairs. The second is based on chairs in PartNet (Mo et al., 2019), a dataset where the objects are different parts of a chair. Fig. 3 shows some examples from the two datasets.

Shop-VRB is a visual reasoning dataset, similar to CLEVR (Johnson et al., 2017a), but with complex household objects of different sizes, weights, materials, colors, shapes, and mobility. Because the original Shop-VRB dataset includes very small and highly transparent objects and complex backgrounds, which current unsupervised representation learning models cannot handle, we generate 10K images with a clean background ourselves us-

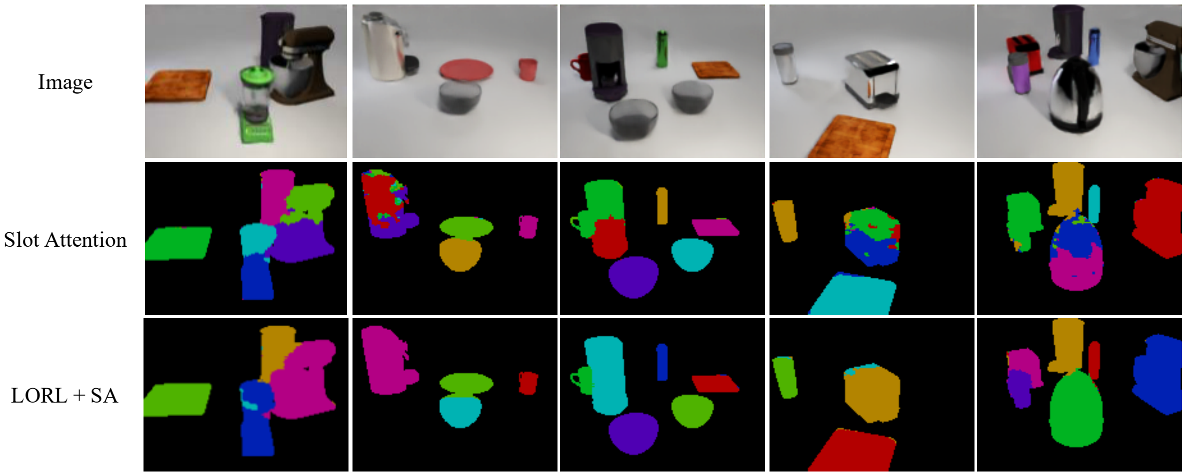

Figure 4: Visualization on Shop-VRB-Simple. Pixels with the same color represent a mask produced by the models. The Slot Attention model often fails to segment blenders, coffee makers, and toasters. LORL helps to greatly improve its results.

(a)	ARI↑	GT Split↓	Pred Split↓
Slot Attention	83.51$_{\pm 2.3}$	15.68$_{\pm 1.9}$	13.19$_{\pm 1.5}$
LORL + SA	**89.23**$_{\pm 1.6}$	**9.95**$_{\pm 1.6}$	**10.18**$_{\pm 1.3}$

(b)	Slot Attention	LORL + SA
Coffee maker	39.4$_{\pm 7.0}$	**21.9**$_{\pm 8.3}$
Blender	38.9$_{\pm 11.5}$	**17.7**$_{\pm 3.4}$
Toaster	33.4$_{\pm 3.9}$	**16.4**$_{\pm 7.2}$

Table 1: (a) Results on Shop-VRB-Simple. LORL helps to improve Slot Attention (SA; Locatello et al., 2020) in all metrics. (b) The Ground Truth split ratio for the three object categories where SA most commonly fail. LORL helps SA to reduce the ratio by 50%.

ing large objects from the dataset. We also pair every image with 9 questions, resulting in 90K questions in total. The test split has 960 images and 8.6K questions. We name this variant Shop-VRB-Simple.

While the previous literature on unsupervised object segmentation mainly focuses on settings where objects are spatially disentangled, we also explore how language may help when objects of interest are different parts of a global shape. To this end, we collect a new dataset, PartNet-Chairs, using chair shapes from PartNet. Every image here shows a chair, where each part of the chair (legs, seat, back, arms) is randomly assigned a color. We select six different chair shapes with one or four legs and zero or two arms. We generate 5K images for training. Each image is paired with 8 descriptive sentences generated from human-written templates, resulting in 40K examples in total. The test split has 960 images. Each sentence describes the *name* and *color* of parts. We provide all templates in the supplementary material. We are interested in whether object-centric representation learning models may separate these parts and whether and how language may help in this scenario.

Baselines. We use MONet (Burgess et al., 2019) and Slot Attention (Locatello et al., 2020) as the image modules (Modules 1 and 2), and evaluate how the incorporation of language may improve their performance. Because MONet is color-sensitive, and on Shop-VRB-Simple, many objects have diverse colors and specular reflection, it does not produce meaningful results there. Thus we only show results with MONet on PartNet-Chairs. We show results with Slot Attention on both datasets.

Metrics. We use three metrics for evaluation. Following (Greff et al., 2019), we first use the Adjusted Rand Index (ARI; Rand, 1971; Hubert and Arabie, 1985). It treats segmentation as a clustering problem: each mask is the cluster index that the pixels within belong to. ARI is computed as the similarity between the predicted and ground truth clusters, and ranges from 0 (random) to 1 (perfect match).

In practice, we found this pixel-wise metric is sensitive to the size of objects: a model that infrequently makes mistakes on large objects will have lower ARI than one that frequently mis-segments small objects. Thus, we in addition design two object-centric metrics:

- **Ground Truth Split Ratio** (GT Split) measures the ratio of objects (GT masks) that are covered by more than one prediction mask.
- **Prediction Split Ratio** (Pred Split) measures the ratio of prediction masks that cover more

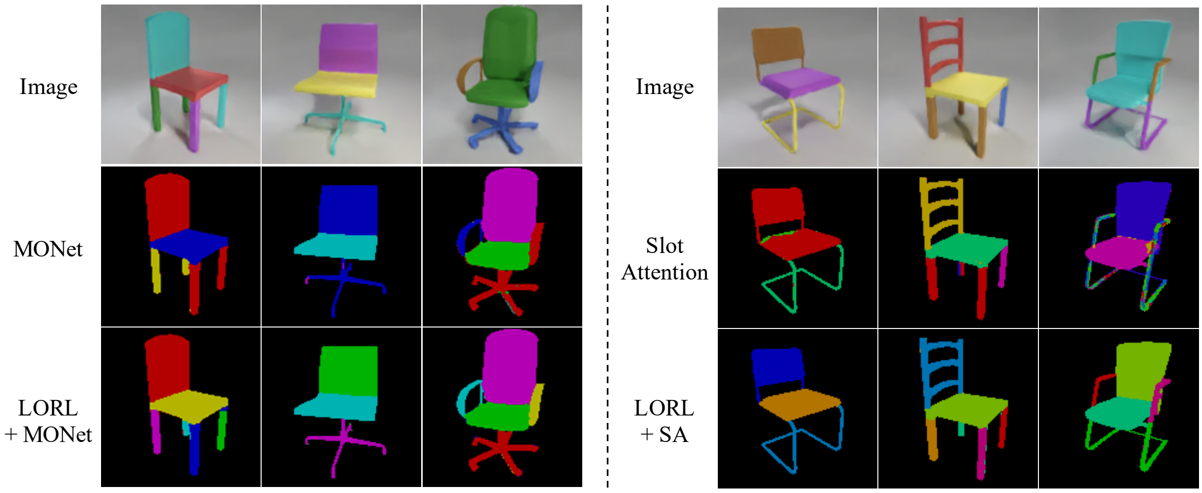

Figure 5: Visualization on PartNet-Chairs. Pixels with the same color represent a mask produced by the models. LORL successfully recognizes different parts in various situations.

	ARI↑	GT Split↓	Pred Split↓
MONet	$91.41_{\pm 3.7}$	$10.3_{\pm 5.1}$	$14.09_{\pm 5.2}$
LORL + MONet	$94.91_{\pm 2.1}$	$4.95_{\pm 0.7}$	$4.02_{\pm 2.5}$
Slot Attention	$87.32_{\pm 3.6}$	$12.54_{\pm 6.6}$	$22.99_{\pm 5.0}$
LORL + SA	$\mathbf{95.81}_{\pm 1.0}$	$\mathbf{3.39}_{\pm 1.1}$	$\mathbf{2.92}_{\pm 1.0}$

Table 2: Quantitative results on PartNet-Chairs. All numbers are in percentage. LORL consistently improves MONet's and Slot Attention's performance on segmentation.

than one object (GT mask).

Concretely, we first assign each pixel to the prediction mask with the maximum value at the pixel. We say a prediction mask covers an object if it covers at least 20% of the object's pixels. The GT and Pred Split ratios are thus defined as:

$$\text{GTSplit} = \frac{\#\text{ of objects that are covered by} > 1 \text{ masks}}{\#\text{ of objects that are covered by} > 0 \text{ masks}},$$

$$\text{PredSplit} = \frac{\#\text{ of masks that cover} > 1 \text{ objects}}{\#\text{ of masks that cover} > 0 \text{ objects}}.$$

Ideally, there is a one-to-one correspondence between objects and predicted masks, with both GT Split and Pred Split being 0. Please refer to the appendix for detailed comparison of the proposed metrics with other metrics.

Results. The quantitative results on SHOP-VRB-Simple are summarized in Table 1. We show the mean and standard error on each metric over 3 runs. Since our semantic parsing module is trained on paired question-program pairs, it achieves nearly perfect accuracy (>99.9%) on test questions. Thus, in later sections, we will focus on evaluating object segmentation, concept grounding, and downstream task performances. LORL helps Slot Attention achieve better segmentation results in all three metrics. From visualizations in Fig. 4, we find that the original Slot Attention model struggles with metallic objects; but with LORL, it performs much better in those cases.

To further explore how LORL helps Slot Attention on failure cases, we calculate the Ground Truth Split Ratio for each object category, and find that Slot Attention most often fail to segment coffee makers, blenders, and toasters as a whole. These objects have complex sub-parts and their appearance changes quickly when the viewpoint changes. With the help of language, Slot Attention improves consistently over its ablative variants across all the three metrics, reducing the GT Split by 50% on average (Table 1b). Furthermore, we include ablation studies on how different types of questions and different modules (the objectness score module and the concept learning module) contribute to the performance improvement in the appendix.

On PartNet-Chairs, LORL also helps both MONet and Slot Attention improve with a large margin, as shown in Table 2. The results are averaged over 4 runs. MONet in general performs well on this dataset, though it still sometimes merges different parts with the same color into a single mask. An example can be found in Fig. 5, column 3, where the blue arm and the blue bottom in the input image are put into the same mask by MONet. Such an issue is alleviated in LORL + MONet. Fig. 5 also includes examples to show how LORL helps Slot Attention.

As shown in Table 2, the improvement on Slot Attention is larger and more consistent, compared

	$k=1$	$k=3$	$k=5$
Slot Attention	$54.07_{\pm 2.6}$	$43.70_{\pm 1.7}$	$37.02_{\pm 1.7}$
LORL + SA	$\mathbf{94.03}_{\pm 0.6}$	$\mathbf{91.03}_{\pm 1.3}$	$\mathbf{87.71}_{\pm 1.7}$

Table 3: The percentage (%) of retrieved objects that belong to the same category as the query object. With LORL, objects within the same category are more likely to be close to each other in the feature space. The results are averaged over 3 runs and standard errors are given.

	QA Accuracy
LORL + SA (No FT)	$62.79_{\pm 1.6}$
LORL + SA	$\mathbf{92.72}_{\pm 1.0}$

Table 4: Our three-stage training paradigm improves visual concept learning. Without fine-tuning (i.e., the third training stage), the question answering accuracy drops by 30%. The results are averaged over 3 runs and standard errors are given.

with the improvement on MONet. We hypothesize that this is because the two models adopt different approaches for aligning object features and masks. While MONet uses separate modules for segmentation and object representation learning, Slot Attention obtains masks by directly decoding object representations. Having a shared representation might have allowed Slot Attention to gain more from language supervision.

5.2 Instance Retrieval

We now analyze the learned object representations on Shop-VRB-Simple. We first use them for instance retrieval: for each model, we randomly select a segmented object and use its learned representation to search for its k nearest neighbors in the feature space. Then, for each selected object, we compute how many of the k nearest neighbors belong to the same category. During searching, we only consider object representations whose corresponding mask, after decoding, has at least an Intersection over Union (IoU) of at least 0.75 with a ground truth object mask. We sample 1,000 object features from each model for evaluation.

Table 3 includes results with $k = 1, 3, 5$, suggesting that the object representations learned by LORL + Slot Attention are better for retrieval, compared with features learned by Slot Attention alone without language. This is because Slot Attention often confuses categories that are visually similar but conceptually different, such as *baking tray* and *chopping board.*

5.3 Visual Reasoning

As another analysis, we also evaluate how the learned representation of LORL + Slot Attention performs on visual question answering on the Shop-VRB-Simple dataset. Here we compare with an ablated version of LORL, where we only train the model for the first two stages, as stated at the end of Section 4. We do not train the model for the third stage—jointly optimizing or fine-tuning all three trainable modules. We name this ablation LORL + SA (No FT). Through this analysis, we hope to understand the importance of joint training of the vision modules (Modules 1 and 2) and the reasoning module (Module 4).

Table 4 shows that joint training is crucial for visual reasoning. This resonates with the previous result, where visually similar objects are clustered together in the latent space, impeding the usefulness of the information encoded.

5.4 Referring Expression Comprehension

Finally we evaluate the representations learned by LORL on referring expression comprehension, where given an expression referring to a set of objects in the scene, like “The white plates”, the model is expected to return the corresponding object masks. After learning all needed concepts from question-answer pairs, LORL can naturally handle referring expression without any further training, if we assume a pre-trained semantic parser.

We choose the IEP-Ref model (Liu et al., 2019) as our baseline. It uses a module approach and receives direct segmentation supervision. On Shop-VRB, we adapt the code provided by (Liu et al., 2019) to generate 17K training examples, only for IEP-Ref, and 1.7K testing referring expressions for evaluating both LORL and IEP-Ref. Measured in Recall@0.5 (the ratio of the recalled objects based on an IoU threshold of 0.5), IEP-Ref performs better than LORL, but the margin is small (90.1% *vs.* 84.4%). Note that while IEP-Ref has been trained on 17K training examples with ground truth object segmentations, LORL does not require any training data on referring expression comprehension. The relatively comparable results are strong evidence that the representations learned by LORL also transfer to a new task.

6 Conclusion

We have proposed Language-mediated, Object-centric Representation Learning (LORL), a paradigm for learning object-centric representations from vision and language. Experiments on Shop-VRB-Simple and PartNet-Chairs show that language significantly contributes to learning better representations. This behavior is consistent across two unsupervised image segmentation models.

Through systematic studies, we have also shown how LORL helps models to learn object representations that encode conceptual information, and are useful for downstream tasks such as retrieval, visual reasoning, and referring expression comprehension.

A Domain-Specific Language (DSL)

LORL extends the domain-specific language of the CLEVR dataset (Johnson et al., 2017a) to accommodate descriptive sentences. Specifically, we add an extra primitive operation: `Equal(X, y)`. It takes two inputs. In our case, the first argument `X` is the output of a `Query`, `Exist`, or `Count` operation. All three operations output a distribution over possible answers. The second argument `y` is either a word or number, such as `TRUE`, *white*, or 4. The `Equal` operation computes the probability of `X=y`. In LORL, models are trained to maximize the output probability.

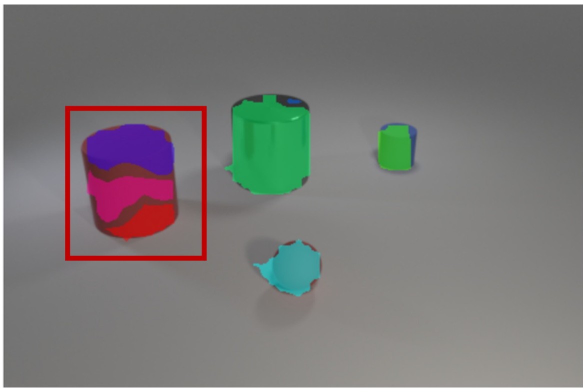
B Hyperparameters

For optimization hyperparameters, we largely adopt original settings in Burgess et al. (2019) and Locatello et al. (2020). Table 5 summarizes the hyperparameters for the loss weights (α and β), the number of training epochs of different stages (N_1, N_2, N_3), and the batch size. We early-stop the training when QA performance converges. We skip the second training phase on PartNet-Chairs, because the first phase (vision-only) yields poor segmentation performance on this dataset. Establishing a meaningful grounding of concepts could be hard in this case. If we keep the second training phase for LORL + Slot Attention on PartNet-Chairs, the model converges slower in the third training phase (15 more epochs in our experiments), but the final performance remains the same.

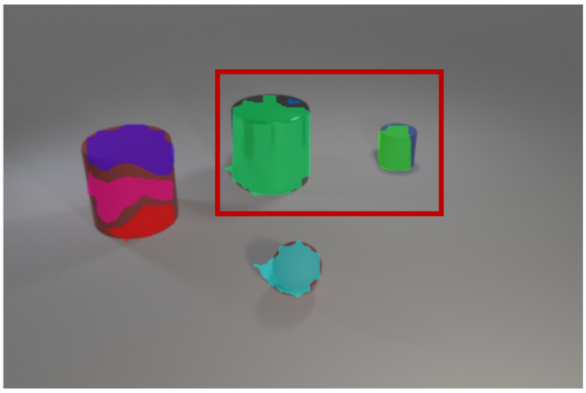
	Shop-VRB	PartNet-Chairs	
	Slot Attention	MONet	Slot Attention
α	1	0.01	1
β	0.1	1	0.1
Batch Size	64	64	64
N_1	90	100	50
N_2	20	0	0
N_3	80	200	200

Table 5: Hyperparameters of LORL

Learning rate scheduling. For Slot Attention models, during the first training stage (perception-only), we use the learning rate schedule described in the original paper on both datasets. Initially, the learning rate is linearly increased from zero to 4×10^{-4} in the first 10K iterations. After that, we decay the learning rate by 0.5 for every 100K iterations. On PartNet-Chairs, after the first stage, Slot Attention models continue to use the same learning rate scheduling. For Shop-VRB-Simple, we switch to a fixed learning rate of 0.001 during N_2 phase, which takes 20 epochs. After 20 epochs, we decrease the learning rate to 2×10^{-4}. We further decrease the learning rate to 2×10^{-5} after another 65 epochs. We use the Adam optimizer (Kingma and Ba, 2015) for Slot Attention models.



(a) There are 4 objects in the scene; one of them is split into 3 masks. Thus, GT Split $= 1/4 = 0.25$.



(b) There are 5 masks in the scene; one of them covers two objects. Thus, Pred Split $= 1/5 = 0.2$.

Figure 6: Two examples on how GT/Pred Split Ratios are computed.

For MONet models, we use RMSProp with a learning rate of 0.01 during the first stage, and use 0.001 for the second and the third stage.

Meanwhile, we also follow NS-CL (Mao et al., 2019) to use curriculum learning. Specifically, in the second training stage, we limit the number of objects in the scene to be 3. In the third training stage, we gradually increase the number of objects in the scene and the complexity of the questions.

C Implementation Details

In this section, we provide additional implementation details of our experimental setups and metrics.

GT and Pred split ratios. In this paper, we have introduced two new metrics for evaluating the performance of unsupervised object segmentation: namely, the GT split and and the Pred split ratio.

A simple example of how we can compute

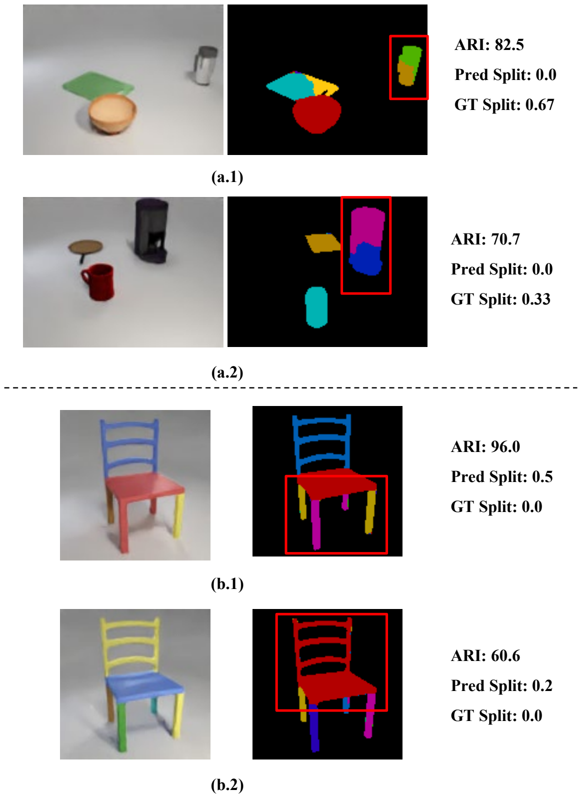


Figure 7: Comparison of ARI and GT/Pred Split Ratios on example images. Pixels with the same color represent a mask produced by the models. We find that ARI is very sensitive to the size of objects, while split ratios capture object-level failures where an object is split or multiple objects are merged.

GT/Pred split ratios is shown in Fig. 6. At a high level, the GT split ratio computes the percentage of objects that are split into multiple parts in model segmentation. Meanwhile, Pred split ratio computes the percentage of objects that are merged into a single object in model segmentation. We introduce these two new metrics because the ARI score is evaluated at the pixel level and does not account for the variance of object sizes. By contrast, GT split and Pred split metrics are computed at the object level. This difference is illustrated in Fig. 7.

For concrete examples, in the Fig. 6 (a.1), two objects, the chopping board and the thermos, are wrongly segmented. In Fig. 6 (a.2), only one object mis-segmented. However, the ARI score of the first image is much higher because the coffee maker has a large size. GT split ratio is evaluated on the object level and thus favor the second one. Similarly, in the Fig. 6 (b.1), the four legs are merged into two masks, while in Fig. 6 (b.2), the seat and the back of the chair are merged into a single object. However, the first segmentation result has a significantly higher ARI score because the chair legs only contribute to a small area in the image. In this paper, we propose to jointly use ARI scores and the proposed GT/Pred split ratio to evaluate segmentation masks.

Throughout the paper, we have been using IoU = 0.2 as the threshold while computing the GT/Pred split ratios. Table 6 summarizes the results with different IoU thresholds. LORL consistently improves the baseline.

Referring expression comprehension. In this experiment, the data is generated using the code adapted from Liu et al. (2019). It contains two types of expressions, the first one directly refers to an object by its properties: for example, "the white plate". The second type of sentences refers to the object by relating it with another object: for example, "the object that is in front of the mug." The output of the model is the masks of all referred objects. The dataset is composed of the same set of concepts and same DSL as in the Shop-VRB-Simple.

We use the IEP-Ref model proposed in Liu et al. (2019) as a baseline. It is adapted from its prior work IEP (Johnson et al., 2017b). IEP-Ref first translates the referring expression into a sequence of primitive operations, which are implemented as different modular networks. The model takes the image feature extracted by a CNN as input and executes the program by chaining these component networks. It outputs a segmentation mask on objects being referred to. During training, groundtruth segmentation masks are needed.

For all methods, including ours and the baseline, we assume a pretrained semantic parser. Since the neuro-symbolic program executor outputs a distribution over all objects indicating whether they are selected, we directly multiply its output with the object segmentation masks to get the final output.

D Additional Results

The following section presents a collection of ablation studies on different modules of LORL, as well as a few extensions.

Objectness score. To validate the effectiveness of the proposed objectness score module, we hereby compare two models: the original Slot Attention model and the Slot Attention model augmented with the proposed objectness score module. Both models are trained using images only (there is no language in the loop), on the Shop-VRB-Simple

	Thres = 0.1		Thres = 0.3	
	GT Split↓	Pred Split↓	GT Split↓	Pred Split↓
Slot Attention	$23.71_{\pm 1.5}$	$23.45_{\pm 4.1}$	$8.91_{\pm 0.7}$	$7.47_{\pm 0.9}$
LORL + SA	$\mathbf{17.74}_{\pm \mathbf{1.4}}$	$\mathbf{18.15}_{\pm \mathbf{1.2}}$	$\mathbf{5.86}_{\pm \mathbf{1.3}}$	$\mathbf{5.67}_{\pm \mathbf{0.7}}$

	ARI↑	GT Split↓	Pred Split↓
Slot Attention	$\mathbf{83.51}_{\pm \mathbf{2.3}}$	$\mathbf{15.68}_{\pm \mathbf{1.9}}$	$13.19_{\pm 1.5}$
SA + Obj score	$83.4_{\pm 1.8}$	$16.57_{\pm 1.5}$	$\mathbf{12.71}_{\pm \mathbf{0.8}}$

Table 7: Ablation study of the objectness score module on Shop-VRB-Simple. The results are averaged over 3 runs and standard errors are given.

	ARI↑	GT Split↓	Pred Split↓
SA (image-only)	$83.51_{\pm 2.3}$	$15.68_{\pm 1.9}$	$13.19_{\pm 1.5}$
Count only	$85.52_{\pm 1.7}$	$13.86_{\pm 2.0}$	$12.56_{\pm 1.4}$
Exist only	$86.29_{\pm 2.2}$	$15.34_{\pm 2.9}$	$10.33_{\pm 1.1}$
Query only	$88.79_{\pm 1.1}$	$10.64_{\pm 1.7}$	$9.03_{\pm 0.5}$
All types	$\mathbf{89.23}_{\pm \mathbf{1.6}}$	$9.95_{\pm 1.6}$	$\mathbf{10.18}_{\pm \mathbf{1.3}}$

Table 8: Ablation study of using different types of questions to train LORL + SA on Shop-VRB-Simple. The standard errors are computed based on 3 runs.

dataset. The Table 7 summarizes the result. The objectness module alone does not contribute to the segmentation performance.

Question type. In this section, we investigate how different types of questions affect LORL. We use the Shop-VRB-Simple dataset for evaluation. There are three types of questions in the dataset, counting (e.g., how many plates are there?), existence (e.g., is there a toaster?), and query (e.g., what is the color of the mug?). We train LORL +SA with only one single type of questions (the number of total questions is the same).

Results are summarized in Table 8. In general, training on all three types of questions improves the segmentation accuracy. The largest gain comes from the query question. Interestingly, the best result is achieved when trained on the original dataset, where the ratio of counting, existence, and query questions is 1:1:7. Note that all these models are trained with the same number of questions and thus they are directly comparable with each other.

Data efficiency. In addition, we provide another analysis by comparing models trained with different number of question-answer pairs. The results are shown in Table 9. Adding more language data consistently improves the result. All results are based on the LORL +SA model trained on the Shop-VRB-Simple dataset.

	ARI↑	GT Split↓	Pred Split↓
25% (22.5K)	81.01	14.31	15.34
50% (45K)	84.39	14.79	9.37
75% (67.5K)	86.53	11.67	11.52
100% (90K)	89.23	9.95	10.18

Table 9: Ablation study of using different number of questions to train LORL + SA on Shop-VRB-Simple.

Visual reasoning baselines. To establish a baseline for visual reasoning tasks, we present the results of two visual reasoning approaches IEP (Johnson et al., 2017b) and NS-CL (Mao et al., 2019) for reference on the Shop-VRB-Simple dataset, as shown in Table 12. All models are trained with the same set of question-answer pairs. Note that NSCL has the access to a pretrained object detection module, while LORL +SA and IEP do not. LORL +SA outperforms IEP, which is trained with exactly the same amount of supervision as ours. It also achieves a comparable result as NS-CL.

Integration with SPACE. SPACE (Lin et al., 2020) is another popular method for unsupervised object-centric representation learning. SPACE uses parallel spatial attention to decompose the input scene into a collection of objects, and it is also compatible with the proposed learning paradigm LORL. We include additional results of LORL +SPACE on the CLEVR dataset. Shown in the Table 11, LORL +SPACE shows a significant advantage over the vanilla SPACE model. Additionally, we find that SPACE shows poor segmentation results on Shop-VRB-Simple and ParNet-Chairs, no matter whether it is integrated with LORL. For example, it frequently segments complex objects into too many fragments on Shop-VRB-Simple. We conjecture that this is because SPACE was designed for segmenting objects of similar sizes.

Baseline using language supervision. We also conducted an additional baseline model that uses language supervision in a different way. Specifically, based on the Slot Attention model, we use a GRU to directly encode question and answer, and concatenate it with the image feature to obtain the object representation. On Shop-VRB-Simple, this

	Precision			Recall		
	@0.5	@0.75	@1	@0.5	@0.75	@1
LORL + SA (NO)	$59.52_{\pm 0.7}$	$54.13_{\pm 2.2}$	$36.36_{\pm 3.6}$	$\mathbf{94.96_{\pm 1.2}}$	$\mathbf{86.4_{\pm 3.6}}$	$\mathbf{58.07_{\pm 5.7}}$
LORL + SA	$\mathbf{89.47_{\pm 0.7}}$	$\mathbf{79.37_{\pm 1.2}}$	$\mathbf{52.48_{\pm 1.6}}$	$94.72_{\pm 0.1}$	$84.02_{\pm 0.6}$	$55.55_{\pm 1.2}$

Table 10: Concept quantification evaluation. The number after @ indicates the IoU threshold. The results suggest that objectness score improves the precision of concept quantification.The results are averaged over 3 runs.

	ARI↑	GT Split↓	Pred Split↓
SPACE (Lin et al., 2020)	72.34	29.2	12.38
LORL + SPACE	**97.82**	**2.04**	**2.17**

Table 11: Segmentation performance of SPACE and LORL +SPACE on CLEVR. The integration of LORL improves the result.

	QA Accuracy
LORL + SA (No FT)	$62.79_{\pm 1.6}$
IEP (Johnson et al., 2017b)	$78.3_{\pm 0.1}$
NSCL (Mao et al., 2019)	$\mathbf{97.9_{\pm 0.0}}$
LORL + SA	$92.72_{\pm 1.0}$

Table 12: Question answering accuracy on the Shop-VRB-Simple dataset. The results are averaged over 3 runs and standard errors are given.

model does not show improvement over the Slot Attention baseline: ARI $= 76.4\%$, GT Split $= 29.2\%$, Pred Split $= 13.6\%$. This suggests the effectiveness of LORL.

Concept quantification. Although LORL without the objectness score can achieve a comparable result in terms of QA accuracy, objectness score is crucial if we want to evaluate how models discover objects in images. Here, we show that, on the Shop-VRB-Simple dataset, LORL +SA shows significant improvement in recovering a holistic scene representation.

Specifically, we extract a scene graph for each scene, where each node corresponds to a detected object. We represent each node i as a set of concepts C_i associated with the object (e.g., $\{$*large, brown, wooden, chopping board*$\}$). We associate a concept with a detected object if its cosine similarity with the object representation is greater than 0. We heuristically remove nodes that are not associated with any concepts (by treating them as “background” objects) or have objectness scores that are smaller than 0.5. This results in a scene graph, where each node corresponds to a detected object. In the following, we compare it against the groundtruth scene graph.

For each pair of groundtruth node i and detected node j, we compute the concept IoU score based on their associated concepts C_i and C_j as:

$$IoU_{ij} = \frac{|C_i \cap C_j|}{|C_i \cup C_j|}.$$

Next, we perform a maximum weight matching between the detected scene graph and the groundtruth scene graph with the Hungarian algorithm. We use the IoU score as the weight for every edge and remove edges whose IoU score is smaller than a given threshold. Finally, based on the macthing, we can compute the precision and recall of the detected scene graph. We show the average precision and recall over the entire test set images in Table 10. The results suggest that objectness score significantly improves the precision of the extracted concepts.

Entheos: A Multimodal Dataset for Studying Enthusiasm

Carla Viegas

Malihe Alikhani
University of Pittsburgh
Pittsburgh, USA
`malihe@pitt.edu`

Abstract

Enthusiasm plays an important role in engaging communication. It enables speakers to be distinguished and remembered, creating an emotional bond that inspires and motivates their addressees to act, listen, and coordinate (Bettencourt et al., 1983). Although people can easily identify enthusiasm, this is a rather difficult task for machines due to the lack of resources and models that can help them understand or generate enthusiastic behavior. We introduce Entheos, the first multimodal dataset for studying enthusiasm composed of video, audio, and text. We present several baseline models and an ablation study using different features, showing the importance of pitch, loudness, and discourse relation parsing in distinguishing enthusiastic communication.

1 Overview

Although different emotional constructs such as *anger* and *happiness* have been studied extensively in the field of natural language processing (NLP), more fine-grained emotional expressions such as enthusiasm or charisma are relatively unexplored. Such models and datasets can benefit different areas of NLP and AI. Multimodal human-machine interaction can be more effective if systems can find a deeper understanding of more complex emotional responses or generate appropriate emotionally-aware communicative presentations. Given the importance of enthusiasm in teaching (Bettencourt et al., 1983; Zhang, 2014), for instance, researchers are studying the effect of virtual agents and robots that can behave in an enthusiastic manner (Liew et al., 2017, 2020; Saad et al., 2019). The current research is far from generating natural enthusiastic behavior.

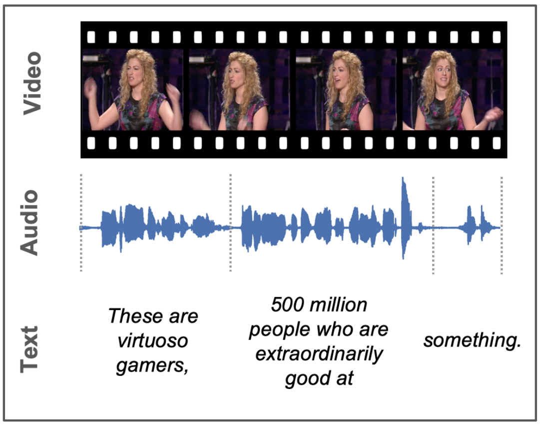

Figure 1: An enthusiastic sample from the Entheos dataset, showing aligned video frames, audio, and text.

Although previous research results in psychology, education, and business have studied the importance of enthusiasm in communication (Bettencourt et al., 1983; Sandberg, 2007; Keating, 2011; Antonakis et al., 2019), it is relatively unexplored in the NLP and dialogue literature. We take a step to bridge this gap by introducing the first multimodal dataset labeled with levels of enthusiasm following the definition that Keller et al. (2016) provided.

Our contributions are as follows: First, we present Entheos (ἔνθεος: being possessed by a god, root for enthusiasm), the first multimodal dataset of TED talk speeches with annotated enthusiasm level[1] (Section 3). It contains sentence segments, labeled as either monotonous, normal, or enthusiastic. Figure 1 shows an example of an enthusiastic sample. Second, in search of finding multimodal signals for understating enthusiasm, we present an analysis of our data to identify attributes present in enthusiastic speech in different modalities (Section 3.5 and 5). Finally, we also provide several baseline models using different kinds of features extracted from text, speech, and video. In

addition, we show the importance of identifying discourse relations in predicting enthusiasm (Section 5).

2 Related Work

In this paper, we focus on investigating resources and models that can help us gain insights into ways by which computers can understand and predict enthusiasm. This topic is relatively unexplored in the computer science field although it has been extensively studied in psychology (Bettencourt et al., 1983; Sandberg, 2007; Keating, 2011; Antonakis et al., 2019).

Enthusiasm Limited work exists on the automatic detection of enthusiasm and has been mainly done in the text domain. Inaba et al. (2011) worked on the detection of enthusiasm in human text-based dialogues, using lexical features and word co-occurrences with conditional random fields in order to distinguish enthusiastic utterances from non-enthusiastic ones. They defined enthusiasm as "the strength of each participant's desire to continue the dialogue each time he/she makes an utterance". In our work, we instead combine different modalities and features to detect enthusiasm and we define an enthusiastic speaker as "stimulating, energetic, and motivating" (Keller et al., 2016). Tokuhisa and Terashima (2006) also worked with human-to-human conversational dialogues and annotated dialogue acts (DAs) and rhetorical relations (RRs) on a sentence-level. An enthusiasm score in the range of 10-90 was given without providing examples to the annotators. The relationship between DAs, RRs, and enthusiasm was analyzed based on the frequencies. They found that affective and cooperative utterances are significant in an enthusiastic dialogue. We detected RRs automatically and trained a feed forward network to classify enthusiasm in three levels: monotonous, normal, and enthusiastic. During data annotation, examples for each category were available as references. Twitter data have also been used to detect enthusiasm. Mishra and Diesner (2019) created a dataset with enthusiastic and passive labels. Enthusiastic tweets had to include personal expression of emotion or call to action, whereas passive tweets lacked clear emotive content or call to action. They trained logistic regression models using salient terms. We evaluate emotional expressions in several modalities. We use acoustic features that relate to emotion such as pitch and voice quality, and also Facial Action Units extracted from videos which measure the intensity of different facial expressions.

Charisma Enthusiasm is also a trait that can be displayed by charismatic speakers (Spencer, 1973), which in addition are perceived as competent, passionate, and self-confident (Niebuhr, 2020). Charisma is a desired trait for leaders in economy and politics (Antonakis et al., 2019; De Jong and Den Hartog, 2007) because it can influence followers to undertake personally costly yet socially beneficial actions. Niebuhr et al. (2016) have investigated the prosodic attributes of charismatic speakers. They analyzed pitch level, pitch variation, loudness, duration of silence intervals, etc and concluded that charisma can be trained as far as melodic features are concerned. In addition to analyzing the relationship of different attributes with enthusiasm, we also trained a model that can distinguish between different levels of enthusiasm.

Although sentiment analysis and emotion detection have been studied extensively in unimodal and multimodal frameworks as shown in several surveys (Marechal et al., 2019; Garcia-Garcia et al., 2017; Seyeditabari et al., 2018; Sudhakar and Anil, 2015) there is a gap in the analysis, detection and generation of enthusiastic behavior. Our dataset will allow to extend the work in understanding human behavior and also generate more natural virtual agents (Zhang, 2014; Keller et al., 2014; Liew et al., 2020; Viegas et al., 2020).

3 Entheos Dataset

In this section we present the Entheos dataset. We describe our domain choice and label selection, the annotation process, extracted features, as well as statistics of the dataset.

3.1 Data Acquisition

Enthusiastic speakers are passionate about their message, wanting to gain their audience for their purpose and persuading them to change their perspective or take action. Given that TED is well-known for spreading powerful messages that can change attitudes and behavior, we use TED talk speeches as our domain for creating a multimodal enthusiasm dataset. We randomly selected 52 male and female speakers from the TEDLIUM corpus release 3 (Hernandez et al., 2018), which contains audio of 2351 talks. Transcripts were obtained

Rating	Description
4: Advanced	Excellent use of vocal variation, intensity and pacing; vocal expression natural and enthusiastic; avoids fillers
3: Proficient	Good vocal variation and pace; vocal expression suited to assignment; few if any fillers
2: Basic	Demonstrates some vocal variation; enunciates clearly and speaks audibly; generally avoids fillers (e.g. um, uh, like)
1: Minimal	Sometimes uses a voice too soft or articulation too indistinct for listeners to comfortably hear; often uses fillers
0: Deficient	Speaks inaudibly; enunciates poorly; speaks in monotone; poor pacing; distracts listeners with fillers

Table 1: Description of the Public Speaking Competence Rubric (PSCR) (Schreiber et al., 2012) evaluated as potential label to describe the use of vocal expressions and paralanguage during a talk.

Vocal Attributes	Description	Rating
Variation	Vocal variety is the spice of speech. Tone, pace, and volume should all be varied over the course of a presentation.	4: excellent, 3: good, 2: some, 1: almost no vocal variation, 0: speaks in monotone
Intensity	Speaks loudly and clearly enough for listeners to hear and understand what is being said.	4: excellent use, 3: good, 2: enunciates clearly and speaks audibly , 1: sometimes voice too soft or articulation too indistinct for listeners to comfortably hear, 0: inaudibly, enunciates poorly
Pacing	Speaks in an understandable rate and places pauses for emphasis.	4: excellent use including well placed pauses, 3: good, 2: pace is appropriate but could have more/less pauses, 1: poor pacing, 0: poor pacing with no/too many pauses
Expression	Emotion delivered by the voice.	4: natural and enthusiastic, 3: suited to assignment, 2: some expressions, 1: few expressions, 0: no expressions)

Table 2: Fine-grained description of vocal attributes derived from PSCR, evaluated as potential label categories on sentence-level.

through the Google cloud transcription service[2]. The talks were segmented into sentences, based on punctuation. We extend the samples from the TEDLIUM corpus with aligned video segments downloaded from the official TED website.

3.2 Label Selection and Temporal Granularity

In order to define the temporal granularity for annotation and what labels to use, we performed preliminary annotation experiments with three annotators.

Three audio recordings of talks were chosen from speakers with different proficiency level. One recording was a TED talk by Al Gore[3], and the remaining were recordings of participants in a pilot study with our institution in which they introduce themselves and describe their skills.

We evaluated two different temporal granularities: sentence-level and entire talk. In addition, we explored the use of three different sets of labels, which will be described in the following.

PSCR (Public Speaking Competence Rubric) PSCR (Schreiber et al., 2012) was developed to effectively assess students' skills in public speaking. It is composed of eleven skills that are assessed during speaking with a 0-4 scale. We focused on the seventh, which evaluates the effective use of vocal expression and paralanguage to engage the audience. During annotation, annotators had Table 1 available for a detailed description on how the speaker articulates for the corresponding rating.

Vocal Attributes Based on the PSCR descriptions we crystallized four main components of the effective use of the voice: vocal variation, intensity, pacing, and expression. Each one was evaluated with a score of 0-4 and described as depicted in Table 2.

Enthusiasm and Emphasis As a final set of labels, we decided to use intuitive categories, namely enthusiasm and emphasis. For enthusiasm, we chose the definition provided by Keller et al. (2016) as they study enthusiasm in context of spoken

---

[2] `https://cloud.google.com/speech-to-text`

[3] `https://www.ted.com/talks/al_gore_averting_the_climate_crisis`

Category	Description	Rating
Enthusiasm	Speaker is passionate, energetic, stimulating, and motivating.	0: monotonous, 1: normal, 2: enthusiastic
Emphasis	One or more words are emphasized by speaking louder or pronouncing them slowly.	0: no emphasis, 1: emphasis existent

Table 3: Intuitive labels used to evaluate as potential categories to annotate sentence-level samples.

Label	Fleiss' κ	Agreement
PSCR	0.31	fair
Variation	0.56	moderate
Intensity	0.81	almost perfect
Pacing	0.55	moderate
Expression	0.63	substantial
Enthusiasm	**0.82**	**almost perfect**
Emphasis	**0.87**	**almost perfect**

Table 4: Inter-rater agreement using different labels computed with Fleiss' kappa with interpretations based on Landis and Koch (1977). Enthusiasm, emphasis, and vocal intensity achieved almost perfect agreement.

monologues (similar to our data) while Inaba et al. (2011) studied written dialogues. We also asked annotators to label enthusiasm in three levels: monotonous, normal, and enthusiastic. As Table 3 shows, annotators were asked to label emphasis as existent or not, depending on whether words were emphasized by speaking louder or pronouncing words slowly.

Experiment Description The experiment was composed of two parts. First the entire audio recordings were played and the annotators were asked to use only the PSCR annotation scheme, rating each talk with a single score. Afterwards, seven sentences of each talk were played with pauses in between to allow annotation using vocal attributes, enthusiasm and emphasis labels. Each sentence was annotated with six scores. For both parts, the annotators had access to the description of the labels during annotation as shown in Tables 1,2,3. Once all annotators finished labeling a sample, the next one was played.

Results and Conclusion In Table 4 the inter-rater agreement for the different annotation schemes is shown in terms of Fleiss' kappa Landis and Koch (1977). We can see that PSCR, which rated the entire talk, has the lowest agreement. Vocal variation and pacing have moderate agreement, while vocal intensity, enthusiasm, and emphasis show almost perfect agreement.

Given these results, we annotated audio recordings on a sentence-level using enthusiasm and emphasis labels.

3.3 Data Annotation Protocol

Our study was approved by our institution's human subject board and annotators were paid $20/h. Seventeen subjects participated in data annotation and signed the consent form before the study. For data annotation, an internal tool was created that enabled annotators to listen to audio samples and annotate them through their web browser at their time of convenience. As labeling availability fluctuated, instead of randomly choosing samples from the entire dataset, we decided to release small batches of data to obtain as many annotations per sample as possible. In a bi-weekly rhythm, small batches of 200 samples were available to annotate in a randomly chosen order for each annotator. As our definition for enthusiasm (Table 3) allows subjective interpretations, we included three reference audio files for each enthusiasm level in the web interface of our annotation tool as depicted in Figure 2. Annotators were indicated to listen to the reference files after every 10 labeled samples and when insecure on how to label a sample. In addition, annotators were given the definition of enthusiasm and emphasis shown at Table 3. Besides enthusiasm and emphasis, also the corresponding perceived gender was annotated. We limited the options for perceived gender to female and male, based on prior work which used these two genders to improve the performance in emotion detection (Li et al., 2019). Samples with laughter or clapping were asked to be labeled as noisy files.

Annotator Quality Assessment: Annotation was performed by 17 different annotators. As noisy annotations are common when crowdsourcing and not using expert annotators due to spammers and malicious workers (Burmania et al., 2015), we com-

Figure 2: Layout of the annotation interface. On the top left is the sample to be annotated and below are the different labels: perceived gender, enthusiasm, and emphasis. On the top center is the option to mark the sample as noisy if laughter or clapping is present. On the right side are reference samples for the three different levels of enthusiasm.

pared the percentage agreement of each individual's annotations with a preliminary majority vote. The analysis showed that 12 annotators had lower agreement than 30%. The same annotators had also labeled less than 17% of the data. To ensure high quality of annotation we used the remaining five annotators who labeled more than 50% of the data. The remaining annotators identify themselves as latino, asian, and white. We removed all samples that had only one or two different annotations and computed the final majority vote for the remaining 1,126 samples. To confirm high inter-rater agreement, we computed Cohen's kappa (McHugh, 2012) in a pairwise manner for the five annotators and obtained an average agreement of 0.66.

3.4 Final Data Selection

Out of 1,819 labeled samples, we kept 1,126 which had more than one annotation. The selected samples are from 113 different TED talk speeches, being 60 from male and 53 from female speakers. We created a test split with 108 samples from five speakers of each perceived gender. The training set, composed by 55 male and 48 female speakers, has a total of 1,018 samples. There is no overlap of speakers between training and test set. In Figure 3 (top) we can see the label distribution in our train-test split.

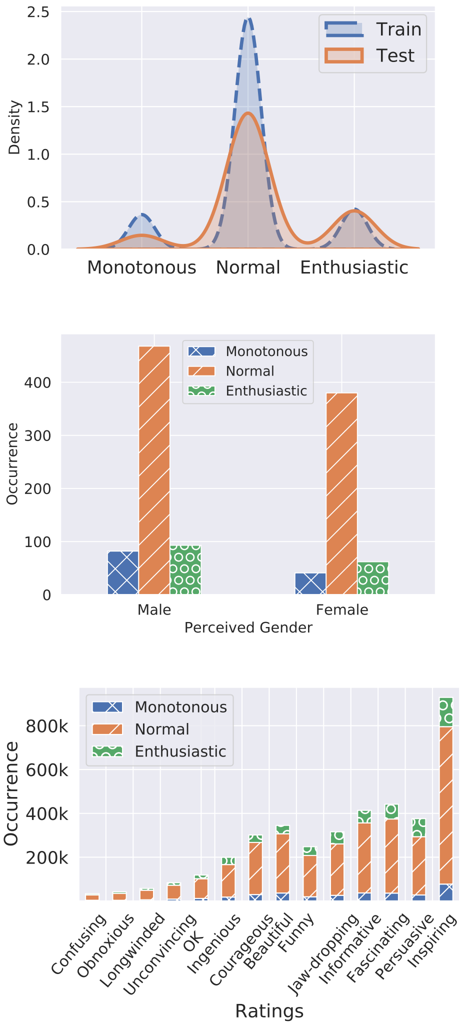

Figure 3: From top to bottom: Label distribution in our train-test split, among perceived gender, and ratings given by TED viewers. Top: Training set and testing set reflect the same imbalance of class labels. Center: Female speakers have proportionally fewer monotonous samples and more normal samples than male, but the same proportion of enthusiastic samples. Bottom: Samples labeled as enthusiastic have been mainly rated as fascinating, persuasive, and inspiring. They have rarely been rated negatively.

3.5 Data Statistics

In the following we will describe the relationship between the different enthusiasm levels and other attributes of the talks such as viewer ratings, number of views and comments, and perceived gender of the speakers. This metadata was obtained from a Kaggle competition[4] that collected data about TED talks until September 21st, 2017.

In Figure 3 (center), we can see that the enthusi-

---

I'm talking about losing it in the same way that we lost the dinosaurs, actually losing it never to be seen.

Figure 4: An overview of our proposed multimodal dataset and model for predicting levels of enthusiasm using different features extracted from video, audio, and text.

asm levels are similarly distributed for both gender labels. We computed the Pearson's chi-squared test for independence to evaluate if there is a significant difference in enthusiasm level between gender. With a significance level of 5%, we obtained $p = 0.04$, meaning that gender of the speaker and enthusiasm level are dependent of each other. In Figure 3 (bottom), the label distribution among the different ratings that were given by viewers is shown. There are nine positive ratings (funny, beautiful, ingenious, courageous, informative, fascinating, inspiring, persuasive, jaw-dropping) and five negative ratings (longwinded, confusing, unconvincing, ok, obnoxious) which viewers could select. The ratings have been sorted by increasing number of enthusiastic samples. We can see that the negative ratings have the least number of enthusiastic samples. The ratings with the three highest numbers of enthusiastic samples are fascinating, persuasive and inspiring. We also performed two one-way ANOVAs to evaluate if the number of views and comments depend on the enthusiasm level. The resulting p-values were correspondingly $p = 0.3844$ and $p = 0.6892$ which means that views and comments are not influenced by the enthusiasm level of the speaker.

4 Computational Experiments

In the experiments of this paper, we aim to establish a performance baseline for the Entheos dataset using only the enthusiasm annotations. We train our model with different feature combinations to understand the role of different modalities in enthusiasm detection (see Figure 4). In the following we describe different features that were extracted and the model architecture that we used.

4.1 Features

Given the small number of labeled samples, instead of training an end-to-end model, we extract different features that will serve as input for our model. In the following we will describe the features used per modality.

Video: As enthusiasm is related to emotions, we extracted Facial Action Units (FAUs) which describe the intensity of muscular movements in the face based on the Facial Action Coding System (FACS) (Friesen and Ekman, 1978). We used OpenFace (Baltrusaitis et al., 2018) to obtain the intensity of 18 FAUs in a scale of 0-5. As FAUs vary over time, we computed the average and standard deviation for each AU and concatenated them in a feature of 36 dimensions per sample.

Acoustic: We extracted different audio features using OpenSMILE (Eyben et al., 2010), a toolbox that can extract over 27k features. We extracted four different feature combinations, which have been thoroughly studied in the speech community in affective computing tasks: a) eGEMAPS (88 attributes) (Eyben et al., 2015), b) Interspeech 2009 Emotion Challenge (384 attributes) (Schuller et al., 2009), c) Interspeech 2010 Paralinguistic Challenge (1582 attributes) (Schuller et al., 2010), and d) Interspeech 2013 Compare (6373 attributes) (Schuller et al., 2013). Each feature collection differs in the selection of features, functionals, and statistical measures. Examples of features covered are voice quality (jitter and shimmer), pitch (F0), energy, spectral, cepstral (MFCC) and voicing related low-level features (LLDs) as well as a few LLDs including logarithmic harmonic-to-noise ratio (HNR), spectral harmonicity, and psychoacoustic spectral sharpness.

Text: As a low-level feature, we used the bert-large-uncased model[5] to obtain word-embeddings on a sentence-level. For each sample we obtained a feature of 768 dimensions. As high-level features, we extracted two types of discourse relations: Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) and Penn Discourse Treebank (PDTB) (Miltsakaki et al., 2004; Prasad et al., 2008) relations. We used the RST parser from Wang et al. (2017) and the PDTB parser from Lin et al. (2014) for automated discourse relation annotation. Elementary discourse units (EDU) were obtained by using the method presented by Wang et al. (2018). For both parsers, samples can have more than one relation or none at all. The annotations were converted into a bag-of-words representation, obtaining features of 18 dimensions for RST and 4 for PDTB.

4.2 Model Architecture

Our model is composed by four fully connected layers with ReLU activation functions in between. We use concatenation to combine different features in the multimodal setting. Given our imbalanced dataset, we compute class weights, which represent the relation of samples per label and the total sample number. The class weights are then passed to our loss function (cross entropy loss) to give more weight to samples of the underrepresented classes. We use the Adam optimizer (Kingma and Ba, 2015) and during training, we perform early stopping to avoid overfitting. We train the model for a three class problem using all enthusiasm levels and also in a binary manner, combining "monotonous" and "normal" labels to the category called "non-enthusiastic".

5 Results and Evaluation

In this section, we present the performance results of our model using different combinations of features. We also evaluate the performance of the discourse parsers used and show statistical analysis of visual and acoustic features. All results of our statistical analysis are shown in the Appendix A.

5.1 Predicting Enthusiasm level

For each feature combination, we performed hyperparameter search with 10-fold cross-validation. The best hyperparameter combination was used to train the model with the entire training set. We evaluated the performance of the models on our test set. In Table 5, the weighted average results for precision, recall, and F1-score are shown. We see that in the unimodal case, BERT embeddings perform the best in the binary classification as well as in the three-class problem. Although PDTB has a higher F1-score in the binary case, RST performs better in the multi-class problem. Out of the different audio features, eGEMAPS performs slightly better than the other acoustic features. In the multi-class case, IS09 features are the best performing acoustic features.

When all features except AUs are combined, we reach the highest F1-score for the binary problem, improving the best unimodal performance by 0.08. We also see that combining both discourse relation features with eGEMAPS and BERT improves F1-score by 0.08 compared to using only one of them. In the multi-class problem, the best performing feature combination shows only a slight improvement of 0.04 compared to the unimodal case. Although manually annotating the entire resource was beyond the scope of this paper, we believe that it is necessary to understand the weaknesses and strengths of automatic parsers when used in spoken monologues. With current efforts being made in the field of creating discourse parsers for speech, the role of discourse parsers for enthusiasm detection will be better understood.

5.2 Evaluating the Effect of Discourse Features

We see in Table 5 that discourse relations help the model achieve the highest F1-score. However, we obtained the discourse relations by using discourse parsers that are trained on Wall Street Journal data[6], which is different from monologues.

To evaluate the performance of the parsers, 40 samples of our data were manually annotated with RST and PDTB relations by two annotators. The annotation protocol was approved by our institution's human subject research center. The inter-rater agreement was $\kappa = 0.88$. The accuracy of the RST parser on our data sample was 46.7 and for the PDTB parser 60.0. Although the accuracy of the parsers is low using our data, we have seen that concatenating both discourse relation features

EGEMAPS + RST + PDTB + BERT + AU	0.81/0.65	0.65/0.58	0.68/0.60

Table 5: Weighted average precision, recall, and F1-score for binary (**B**) and multiclass (**M**) classification. The same model architecture was used to train different feature combinations. BERT embeddings performed best in the unimodal setting. Combining acoustic with text features performed best in the multimodal setting.

to BERT and eGEMAPS improved our model's performance from an F1-score of 0.64 to 0.83 in the binary classification.

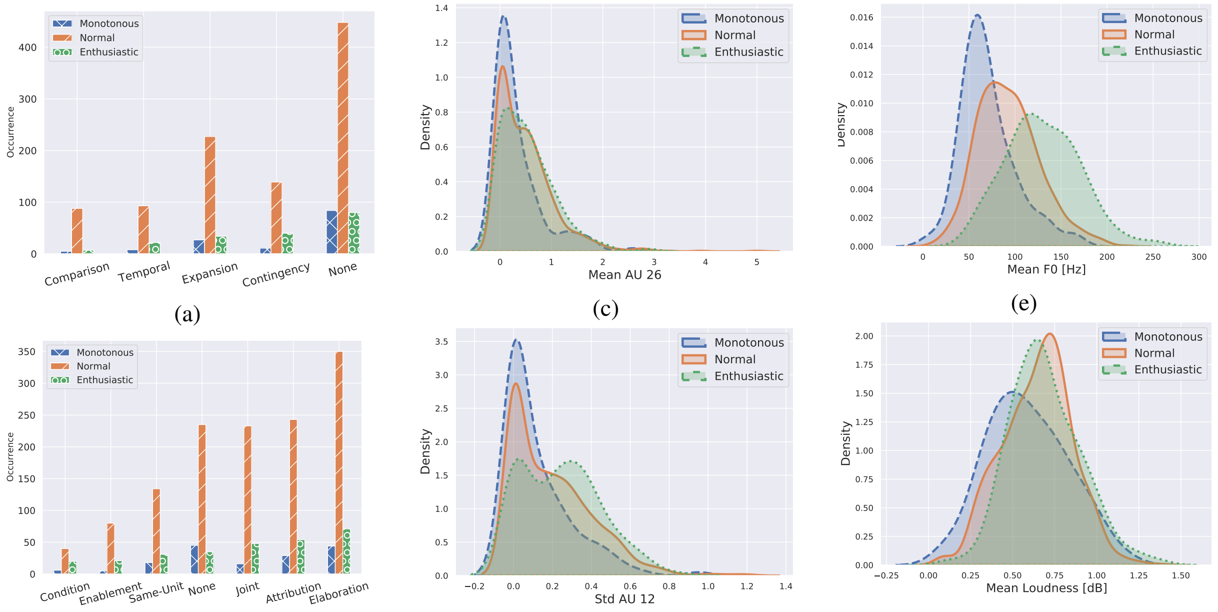
In Figure 5(a,b) we evaluated the relative occurrence of each enthusiasm level for RST and PDTB relations in ascending order of enthusiastic samples. In Figure 5a we can see that most samples do not have any discourse relation. However, there is a clear difference in the number of monotonous and enthusiastic samples that show *contingency*, as well as *temporal* relations. In Figure 5b we see that enthusiastic samples compared to monotonous samples use more elaboration, attribution, and joint relations. We performed the Pearson Chi Square test to verify our null hypotheses that discourse relations and enthusiasm level are independent from each other. We obtained a p-value of 0.0001 for PDTB and a p-value of 0.008 for RST, which permits us to reject our null hypothesis, meaning that the discourse relations influence the level of enthusiasm.

5.3 Investigating Visual Features

Given that AUs have not helped our model improve, we evaluated their dependence with our labels. We performed two separate one-way ANOVAs to evaluate the dependence of the mean of the 18 AUs with our labels, as well as the standard deviation of the AUs with our labels. The AUs with p-value < 0.05 are AU 12 (lip corner puller), AU 15 (lip corner depressor), AU 17 (chin raiser), and AU 26 (jaw drop). In Figure 5(c,d) the label distribution for the mean of AU 26 and standard deviation of AU 12 is shown. In both cases, we can observe that monotonous samples have more frequently a mean and standard deviation of zero compare to enthusiastic samples. We can also see in Figure 5d that enthusiastic samples have more frequently a standard deviation of AU 12 > 0.02.

5.4 Investigating Acoustic Features

We have seen that acoustic features are important in improving our model's performance. In this section we want to evaluate if pitch (F0) and loudness are independent from enthusiasm level. We perform a one-way ANOVA for the mean F0 per sample and its enthusiasm level, as well as for the mean loudness. Both p-values are < 0.05, meaning that the enthusiasm labels depend on the acoustic features. In Figure 5e, we can see that monotonous samples have a lower mean F0 than that of enthusiastic samples. We can also see in Figure 5f that monotonous samples have lower mean loudness than that of enthusiasm. These observations agree with the intuition that enthusiastic speakers speak louder and increase their pitch.



(a) (c) (e)

(b) (d) (f)

Figure 5: Label distribution of different enthusiasm levels in relation to discourse relations (a,b), acoustic features (c,d), and facial action units (e,f). In (a), most samples had no PDTB relation, however there is a visible difference between monotonous and enthusiastic samples in the occurrence of temporal and contingency relations. In (b), RST relations show that enthusiastic samples compared to monotonous samples use more elaboration, attribution, and joint relations. In (c), we can see that monotonous samples have more often low intensities for AU26 (jaw drop) than enthusiastic samples. (d) shows that monotonous samples have mostly very low standard deviation for AU12 (lip corner puller), but enthusiastic samples have higher standard deviation. In (e), we can see that enthusiastic samples have a higher mean F0 (pitch) compared to monotonous samples. (f) shows that monotonous speech tends to have lower mean loudness compared to enthusiastic speech.

6 Discussion and Conclusion

We present the first multimodal dataset for enthusiasm detection called Entheos[7] and discuss several baseline models. In addition, we present qualitative and quantitative analyses for studying and predicting enthusiasm using the three modalities of text, acoustic, and visual.

Our work has several limitations. TED talks are a very specific form of monologues as they are well-rehearsed and prepared. However, it is more likely that we can find enthusiastic speakers or well-structured sentences in TED talks. To understand enthusiastic behaviors in daily conversations, more data from other domains need to be annotated and studied. We hope that our annotation protocol will help other researchers in the future.

Further theoretical and empirical research is needed for better studying enthusiastic behaviors in general. The signals and definitions that we have worked with are not fine-grained or well-connected when exploring different modalities. Facial expressions and gestures can potentially provide meaningful contributions. Our experiments with facial action units were not successful. Our baseline approach used statistical information of each AU instead of the raw signal, which may dilute useful information. More experiments are needed to evaluate if and how AUs can help predict enthusiasm.

We hope our resources provide opportunities for multidisciplinary research in this area. Given the difficulties of annotating multimodal datasets in this domain, future work needs to investigate weakly supervised approaches for labeling multimodal data.

A Statistical Tests

In this section we present the results of the statistical tests performed to the facial action units and prosody features extracted from the entire dataset.

A.1 AU Statistical Tests

In order to understand which AU influence the enthusiasm level, we performed two different statistical tests: ANOVA for the three levels of enthusiasm (monotonous, normal, enthusiastic), and T-test for two levels of enthusiasm (enthusiastic, non-enthusiastic). In Table 6 on the left we can see the results of the ANOVA, analyzing the mean value of the different AUs per sample with the three levels of enthusiasm. All mean AUs that show p-value < 0.05 are highlighted. As AU 26 has the lowest p-value, the label distribution is shown in Figure 5c.

In Table 6 on the right we can see the results of the ANOVA, analyzing the standard deviation of the different AUs per sample with the three levels of enthusiasm. As AU 12 has the lowest p-value, the label distribution is shown in Figure 5d.

We also performed T-tests for the binary case using the labels enthusiastic and non-enthusiastic. Table 7 on the left shows that AU 17 (chin raiser)

Mean Action Unit	F-Statistic	P-value
AU 01	0.1393	0.87
AU 02	0.4541	0.6351
AU 04	1.415	0.2434
AU 05	0.385	0.6805
AU 06	1.1288	0.3238
AU 07	0.3578	0.6993

Table 6: ANOVA significance test for three levels of enthusiasm and AU mean values on the left and standard deviation of AU on the right. AUs with lowest p-value are highlighted.

is the only AU with a p-value < 0.05. The distribution of the average values of AU 17 are shown in Figure 6(a). For comparison, the distribution of the average AU 02 (outer brow raiser) with highest p-value is shown in Figure 6(b). For both analysis, ANOVA and T-test, the differences of standard deviations among the enthusiasm levels are statistically significant for almost all AUs. This is not the case when analyzing the average values of AUs.

A.2 Prosody Statistical Tests

We performed statistical significance tests using the mean and standard deviation for F0 (pitch) and loudness. In Table 8(left), the ANOVA analysis results are shown and in Table 8(right), the results of the T-test. In both significance tests all variables have a p-value< 0.05, which means that all of them influence the enthusiasm level. Figure 6(c-f) show the label distribution for different values of the variables used in the significance test.

Are Rotten Apples Edible? Challenging Commonsense Inference Ability with Exceptions

Abstract

Previous studies have argued that pre-trained language models encode commonsense relational knowledge (e.g. that *apples* are *edible*). However, simultaneous work has revealed that such models are often insensitive to context, even ignoring overt contextual cues such as negations. In this paper, we investigate whether masked language models (the BERT family) can move beyond naive associative biases (e.g., *apple* → *edible*) when the context warrants (e.g. ranking *inedible* higher when presented with the information that the *apple* is *rotten*). We introduce the WINOVENTI procedure, which adversarially exploits generic associations in masked language models to create model-specific Winograd-style entailment schemas. Using our constructed WINOVENTI challenges set of over $2,000$ schemas, we show that language models in the BERT family experience a steep drop in performance on prompts that require them to pick answers which require reasoning about context (e.g., from 89.8% to 18.4% for $\text{BERT}_{\text{LARGE}}$). We present evidence that language models exhibit different associative biases, suggesting a need for future work in developing and analyzing frameworks similar to WINOVENTI that are tuned to model-specific weaknesses.

1 Introduction

Humans exhibit commonsense knowledge through their ability to identify generics (e.g., that a dog has four legs) while still recognizing that exceptions to such rules are possible (e.g., that there are cases of three-legged dogs) (Greenberg, 2007), and that the probability of such exceptions can vary based on the context (e.g. "*the dog is running*" vs. "*the dog is hobbling*"). A prerequisite to comparing a machine's performance to human intelligence is, hence, the verification that machines can exhibit a sensitivity to context that would allow them to perform as well on cases that require reasoning about exceptions as on cases that require recalling generic associations.

Recent work (Petroni et al., 2019) has shown that large pretrained language models, in particular Masked Language Models (MLMs) such as BERT (Devlin et al., 2018) are competent at associating entities with their common characteristics. For example, $\text{BERT}_{\text{LARGE}}$ readily recalls *apple* → *edible* and *charcoal* → *hot*. However, as demonstrated by Ettinger (2020) and Kassner and Schütze (2019), BERT is insensitive to various overt contextual cues, notably negation. For example, given the context "*The shower is* ___," $\text{BERT}_{\text{LARGE}}$ predicts the words "*cold*", "*long*", and "*empty*", the same top 3 predictions it makes given the context "*The shower is not* ___". Such results suggest that while language models like BERT capture many commonsense patterns, such success might be limited to inferences involving common generalizations (appearing in an affirmative context, or using common lexical associations) and not those involving exceptions (appearing in a negative context, or requiring the models to choose less frequently associated lexical items).

In this paper, we investigate whether it is indeed the case that the "commonsense reasoning" exhibited by MLMs is limited to frequent generalizations as opposed to exception cases. We make three main contributions. First, we present the WINOVENTI procedure (§2) for identifying model-specific associative biases and adversarially building Winograd-style challenges (Levesque et al., 2012) to test models' commonsense inference ability. Second, we apply the WINOVENTI procedure to evaluate the commonsense inference performance of a suite of pre-trained MLMs (§3). We find that all the evaluated models experience dramatic performance drops on prompts that require the models to reason about exceptions to commonsense generaliza-

WINOVENTI Procedure Summary

Step 1: Identifying Generic Associations
Sample In: { honey, tarantula }
Sample Out **($\text{BERT}_{\text{LARGE}}$)**: honey → good,
tarantula → poisonous,
tarantula → female
See Table 3

Step 2: Collecting Exceptions of Associations
Sample Out: (honey, good) → terrible
(tarantula, poisonous) → safe
(tarantula, female) → male

Step 3: Adversarial Filtering
Sample Out **($\text{BERT}_{\text{LARGE}}$)**: True, True, False
Rationale*: In the last example,* $\text{BERT}_{\text{LARGE}}$ *associates the exception characteristic (male) with the entity (tarantula) more strongly than the generic association (female).*

Step 4: Collecting Premises
Sample Prompt:
(1) The honey is [good/terrible].
(2) The tarantula is [poisonous/safe].
Sample Out: (1) After adding honey to my tea, it was (delicious/oversweet).
(2) Kim was (terrified/thrilled) when he asked her to hold the tarantula.

Step 5: Challenge Set Validation
Sample Out: `False`, `False`
Rationale*: In the first example, word association can be used to select the correct answer. In the second, the property-to-association mapping is not one-to-one, causing ambiguity.*

Table 1: Summary of the WINOVENTI pipeline for constructing common sense inference challenge set.

tions. Humans, in contrast, perform consistently well (∼90%) across inferences in our data. Third, we release our human-curated evaluation dataset of 2,176 sentence pairs probing inferences about commonsense generalizations and exceptions. All of our code and data are available at `http://http://commonsense-exception.github.io`.

2 WINOVENTI Procedure

2.1 Overview

The WINOVENTI procedure aims to produce Winograd-style sentence pairs to test models' ability to reason about common sense generics and exceptions. For example, a sentence pair might look like the following:

s_g: Zeke says that the apple is delicious. The apple is [MASK]. → edible > inedible

s_e: Zeke says that the apple is rotten. The apple is [MASK]. → inedible > edible

That is, we seek to generate pairs of sentences–which we call s_g and s_e, for generic and exception–which differ by a single word (w_g/w_e), such that that difference should lead to a change in the relative probability of other words (o_g/o_e) in the context. For example, the presence of w_e = *"rotten"* causes o_e = *"inedible"* to be more probable given s_e than given s_g. We seek to generate such pairs adversarially, meaning that, in the example above, we want to ensure that the model generally associates *"edible"* with *"apple"* and thus performing correctly on s_e requires using context to override this prior association.

Our five-step procedure is summarized in Table 1. First (§2.2), given a model and a target noun, we identify the model's *generic associations* (or just *generics*), i.e., the characteristics that the model tends to associate with the noun in a generic context. For example, given a target noun *"apple"*, we might identify *"edible"* as one such association. Second (§2.3), crowd workers are asked to provide contrasting characteristics (or *exceptions*) that could plausibly describe the noun. For example, workers might provide *"inedible"* or *"plastic"* as characteristics that contrast with *"edible"* in the context of *"apple"*. Third (§2.4), we perform an adversarial post-processing step in which we filter out worker-provided exceptions that the model associates with the target more strongly than the original generic. That is, if a worker provides the characteristic *"poison"* and it turns out that the model associates *"poison"* with *"apple"* more strongly than it associates *"edible"* with *"apple"*, we would filter *"poison"* out of our list of exceptions. Fourth (§2.5), we crowdsource premise pairs that would ideally effect the relative probability of the generic characteristic vs. the exception characteristic, such as those shown in s_g and s_e above. Finally (§2.6), the schemas are validated by human annotators, after which we filter out annotations that are trivial or ambiguous. Using this five-step procedure, we construct the $\text{WINOVENTI}_{\text{BERT LARGE}}$ challenge set of 2,176 sentence pairs.[1]

---

[1] Available at: `http://commonsense-exception.github.io`.

Prompt pairs	**Generic/Exception Outcomes**
s_g = Regina screamed when she picked up the pan. The pan is _.	**hot** / cold
s_e = Regina shivered when she picked up the pan. The pan is _.	hot / **cold**
s_g = Tonight Mike's pets would be happy. The pet food is _.	**available** / unavailable
s_e = Tonight Mike's pets would be hungry. The pet food is _.	available / **unavailable**

Table 2: Examples of our schemas. Each *prompt* contains a *premise* with an underlined *special word* (first sentence) and an *outcome sentence*. s_g = generic prompt. s_e = exception prompt. All prompts and exception outcomes are crowdsourced, whereas *generic outcomes* are generic associations identified in some MLM ($\text{BERT}_{\text{LARGE}}$, in our paper). Correct answers are in bold.

We draw our target nouns from the THINGS dataset (Hebart et al., 2019) which consists of 1,854 concepts from 27 semantic categories. All of our crowdsourcing tasks are run on Surge (`surgehq.ai`), a high-quality crowdsourcing platform similar to Amazon Mechanical Turk. For the exception and premise generation stages (§2.3 and §2.5), we recruited 100 workers through a qualification task that required the workers to walk through the entire WINOVENTI pipeline. The validation annotation (§2.6) could be performed by anyone on the Surge platform. The pay per response for the crowdsourcing stages is as follows, chosen based on difficulty and time taken to complete the task: (1) exception generation (§2.3): \$0.1, (2) premise generation (§2.5): \$0.3, (3) challenge set validation (§2.6): \$0.2, and (4) human performance: \$0.03.

2.2 Step 1: Identifying Generic Associations

Given a set of target nouns, our first step is to find a set of generic associations which models associate with the noun regardless of context. To do this, we focus on the widely-used $\text{BERT}_{\text{LARGE}}$ model (Devlin et al., 2018), specifically the HuggingFace cased, whole word masking implementation (24-layer, 1024 hidden dimension, 16 attention heads, 336M parameters). We base our procedure off of the insight from Ettinger (2020), which demonstrated BERT's insensitivity to negation. For example, given the contexts "*A robin is (not) a [MASK],*" BERT's top two predictions would share {*bird, robin*} in common, or given the contexts "*A daisy is (not) a [MASK],*" BERT's top three predictions would share {*daisy, rose, flower*} in common. Our experiments show that this behavior holds consistent for other MLMs such as RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2019), Longformer (Beltagy et al., 2020), SqueezeBERT (Iandola et al., 2020), and MobileBERT (Sun et al., 2020). Thus, to identify context-invariant associations, we feed in both affirmative and negated templates[2] of the form "*The* `[ENTITY]` *is (not) [MASK]*". We then define the models *generic associations* to be the set of words that are in common between the top-k predictions in the affirmative context and the top-k predictions in the negative context. We experiment with $k \in \{1, 3, 5, 8\}$. Table 3 shows generic associations generated for $\text{BERT}_{\text{LARGE}}$ in this way for different values of k.

k	**Generic Associations for $\text{BERT}_{\text{LARGE}}$**
1	desk → empty, tarantula → poisonous, couch → comfortable, syrup → sweet, honey → sweet, compass → accurate
3	desk → there, tarantula → edible, couch → empty, syrup → bitter, honey → good, compass → true
5	desk → full, tarantula → {female, male}, couch → warm, syrup → edible honey → edible, compass → right
8	desk → {mine, clean}, tarantula → small couch → {clean, big}, syrup → orange, honey → {delicious, there, honey} compass → wrong

Table 3: Examples of $\text{BERT}_{\text{LARGE}}$ generic associations for different values of k. Generic associations are cumulative across different k values (e.g., in the end, we have *compass* → { accurate, true, right, wrong }).

How similar are associations across models? Since our dataset is constructed in particular to be adversarial against $\text{BERT}_{\text{LARGE}}$, it is relevant to ask whether such a dataset will be equally adversarial against all models in the BERT family. To quantify whether models in the BERT family (described in §3.2) differ in the generic associations

---

[2] We use a simple set S of two templates that differ in the ending punctuation (S = {"*The* `[ENTITY]` *is [MASK].''*, *``The* `[ENTITY]` *is [MASK],''*}).

Model name	k = 1	k = 3	k = 5
$\text{BERT}_{\text{BASE}}$	0.59	0.26	0.17
$\text{BERT}_{\text{LARGE}}$	1	1	1
$\text{RoBERTa}_{\text{SMALL}}$	0.61	0.2	0.11
$\text{RoBERTa}_{\text{LARGE}}$	0.57	0.19	0.12
DistilRoBERTa	0.53	0.15	0.08
DistilBERT	0.57	0.18	0.12
SqueezeBERT	0.6	0.23	0.13
MobileBERT	0.65	0.28	0.16
$\text{ALBERT}_{\text{BASE}}$	0.42	0.07	0.04
$\text{ALBERT}_{\text{LARGE}}$	0.51	0.1	0.07
$\text{ALBERT}_{\text{XLARGE}}$	0.59	0.18	0.08
$\text{ALBERT}_{\text{XXLARGE}}$	0.48	0.13	0.07

Table 4: Jaccard similarity of Generic Associations made by models with respect to $\text{BERT}_{\text{LARGE}}$. The closer to 1, the more similar.

identified using this procedure, we compute the Jaccard similarity–i.e., $\frac{|A \cap B|}{|A \cup B|}$, with A and B being the set of associations made by two models. Table 4 shows the results for $k = 1, 3$, and 5. $\text{BERT}_{\text{BASE}}$ and $\text{BERT}_{\text{LARGE}}$ have the highest similarity (with a mean Jaccard score of 0.72). Most other models only share roughly half of the generic associations with another model. As k increases, generic associations start to differ across models (signified by a decrease in the Jaccard similarity score). This signifies that models differ significantly in the generic associations that they make.

Qualitatively, associations made by BERT-family, RoBERTa-family and other models differ from one another. While the evaluated RoBERTa-family models display a slight tendency to associate the words *"empty"*, *"broken"*, *"dead"* with many nouns, the BERT-family models tend to make other associations such as *"used"*, and *"edible"*. ALBERT models, on the other hand, make quite different associations from all other models, such as *"adjustable"*, *"gone"*, *"a"*, and *"covered"* (with a full 41% of the associations made by $\text{ALBERT}_{\text{XXLARGE}}$ being *"adjustable"*).

As we base this study on the associations made by $\text{BERT}_{\text{LARGE}}$, future work is to be done to extract the different associations made by other MLMs to pose a harder and richer set of challenges for those models.

2.3 Step 2: Crowdsourcing Exceptions to Generic Associations

Given the identified associative biases, we then use crowdsourcing to find alternative characteristics that can be true of the noun, but are perhaps less stereotypically associated (e.g., *"apples"* can be *"inedible"* if, for example, they are made of plastic, or are poisoned). Workers are given statements of the form "*The* `[NOUN]` *is* `[PROPERTY]`" where `[PROPERTY]` is one of the generic associations collected as described above (e.g., "*The apple is* *edible*"), and then is asked to provide up to three adjectives that would describe `[NOUN]` in the case where it is *not* `[PROPERTY]` (e.g., in the case that the "*apple*" is not "*edible*"). To increase the quality of tasks presented to workers in later stages, we also ask workers in this stage whether or not a presented statement makes sense, and filter out any sentences which workers flag as nonsensical. Of the noun-property associations generated in our first step, 10.45% are filtered out in this step.

The model-generated associative pairs can be noisy. Particularly, we note that as we increase k, the model becomes more likely to generate nonsense pairs (e.g., *glass* → *glass*, *dart* → *legal*, *triangle* → *circular*), and that the stereotypical strength of association decreases (as shown in Table 3). Thus, to increase the quality of the final challenge set and minimize workers' confusion, our pipeline uses two main criteria to select which association pairs to present to workers. First, associations are selected in an increasing order of k, meaning we would include all associations at $k = 1$ first, and then those at $k = 3$, and so on. Second, the templated statements presented to workers are ranked according to perplexity scores assigned to them by a unidirectional language model. For each k of interest, we identify the inflection point in the perplexity score, and only retain samples for which the perplexity is below this point. At the end when we have gathered more samples than we plan to post, we perform a final round of inflection point identification and retention. This leaves us with 1990 entity-association pairs.

To construct $\text{WINOVENTI}_{\text{BERT LARGE}}$, we selected 1990 entity-bias pairs to present to workers (331 pairs were of 1-associative biases, 780 of 3-associative biases, 825 of 5-associative biases, and 54 of 8-associative biases). 28 workers participated in this stage, and for each task workers were paid \$0.1. At the end, we received $2,994$ valid exception annotations from crowd workers.

2.4 Step 3: Adversarial Filtering

The goal of adversarial filtering is to make sure that a model clearly favors the generic association with a target noun (identified by an MLM) over an exception association (crowdsourced) without any additionally introduced context. A triplet of (*Target Noun*, *Generic Association*, *Exception Association*) passes our adversarial filtering stage if the probability that the model associates the *Generic Association* with the *Target Noun* (through statements of template "*The* `[NOUN]` *is* ___") is higher than that which the model associates with the *Exception Association*.

This filtering is adversarial in that, by making sure that a model innately favors one association (e.g., *edible*) with a target noun (e.g., *apple*) over another (e.g., *inedible*), the model has to demonstrate a strong enough sensitivity to context to select the other association over the one that it innately prefers (e.g., when presented with the information that the *apple* is *rotten*).

In the construction of WinoVenti$_{\text{BERT LARGE}}$, after adversarially filtering using BERT$_{\text{LARGE}}$, we retained $2,745$ (*Target Noun*, *Generic Association*, *Exception Association*) triplets. Some examples of triplets that were filtered out (in the same format) are: (*stair*, *long*, *short*), or (*mug*, *full*, *empty*).

2.5 Step 4: Crowdsourcing Premises

As a result of Step 3, we have a set of (noun, generic associations, exception associations) triplets that have met our adversarial filtering criteria. We then ask workers to create a minimal pair of *premise* sentences (s_g/s_e) differing by exactly one word (w_g/w_e) which differ in whether the *generic outcome* (o_g) or the *exception outcome* (o_e) is the most probable continuation. For example, given the triplet (*"apple"*, *"edible"*, *"inedible"*), our sentence pair might be $s_g =$ *"the apple is <u>sweet</u>* and $s_e =$ *"the apple is <u>rotten</u>*. To minimize the cognitive load on crowdworkers while still communicating these requirements, we provided examples of two good and two bad premise pairs with a brief explanation each of why each was good/bad, covering all the requirements above.[3] We also encouraged workers to be creative and provide premises that have diverse sentence structures. In total, $2,745$ premise pairs were collected. Table 5 shows several examples of contexts generated in this way.

Crowdsourced Premises
Given: The mail is [anonymous/identifiable]. **Annotation:** I received a letter in the mail from a (stranger/friend).
Given: The pill is [safe/unsafe]. **Annotation:** You will feel (better/worse) if you take the pill.
Given: The paper bag is [empty/full]. **Annotation:** I took a (folded/heavy) bag to the store.
Given: The timer is [accurate/inaccurate]. **Annotation:** Jim was (early/late) to work of his timer.
Given: The bed is [comfortable/uncomfortable]. **Annotation:** Lola slept [soundly/miserably].

Table 5: Premise annotations collected given a target noun and the identified generic/exception associations, combined into a natural language sentence of format "*The* ___ *is* ___" presented to workers.

2.6 Step 5: Challenge Set Validation

We evaluate each sentence pair using two criteria. First, is it the case that the contexts differentiate the probabilities of o_g and o_e such that o_g only makes sense given s_g and o_e only makes sense given s_e. E.g., given "*Matthew says that the apple is rotten. The apple is [MASK]*", can *edible* be a sensible answer)? Second, we ensure that the special words are not synonymous with the outcomes, i.e., that w_g and o_g are not synonyms, nor are w_e and o_e. If the majority of workers (out of three) judge the sentence pairs to pass the above criteria, the pair is deemed valid. Criterion 1 is to ensure that the outcomes are unambiguous to humans, while criterion 2 is to ensure that synonymy can not be used to trivially find the correct answer. For example, criterion 1 filtered out prompts such as "*Mary made popsicles out of vitamins. The popsicle is [MASK].*" where both the choices (*edible / nutritious*) could apply. Criterion 2 filtered out prompts like "*The doctor used a <u>loaded</u> test tube. The test tube is [MASK].*" where the correct answer (*filled/hollow*) could easily be selected using word association. Of the $2,678$ prompt pairs posted for evaluation, 502 were filtered out for failing at least one of the two aforementioned criteria, leaving us with the

---

[3] Our exact instructions and examples given to workers are provided in Appendix A.2

final challenge set of $2,176$ prompt pairs ($4,352$ prompts in total).

2.7 WinoVenti Challenge Set

To summarize, the final WINOVENTI$_{\text{BERT LARGE}}$ challenge set consists of $2,176$ prompt pairs ($4,352$ challenge prompts in total) about 978 distinct entities. Each entity has at most 5 generic associations, for a total of 186 distinct generic associations identified by BERT$_{\text{LARGE}}$ across all entities. The length of premises are on average 8 words. Using SpaCy's Part of Speech tagger, we identified that the special words (w_g and w_e) across different premises are predominantly adjectives (apprx. 34%), nouns (apprx. 30.3%), and verbs (apprx. 22.4%), with the presence of other parts of speech such as adverbs, adpositions, numbers, determiners, proper nouns, or pronouns. Approximately 54.5% of the premises have the special words in the last third, 28.4% in the middle third, and the rest 16.9% in the first third of the premise. The challenge set is available at `http://commonsense-exception.github.io/`.

3 Experiments

3.1 Task Definition

The task is defined as: given a pair of sentences (s_g, s_e) with the format in Table 2, and the pair of single-word candidate outcomes (o_g, o_e), does the model correctly rank o_g as more probable than o_e given s_g (general test), and, symmetrically, rank o_e as more probable than o_g given s_e (exception test). An MLM's performance is reported as the percentage of sentences for which the language model successfully gives the correct answer a higher probability of filling in the blank than the incorrect answer. Each model is evaluated on three different subsets of the full WINOVENTI$_{\text{BERT LARGE}}$ dataset, as follows: **All** refers simply to the entire WINOVENTI$_{\text{BERT LARGE}}$ challenge set (which is only adversarially filtered using BERT$_{\text{LARGE}}$); **Individual** refers to a model-specific subset of WINOVENTI$_{\text{BERT LARGE}}$, specifically those pairs which result after additionally model-specific adversarial filtering; **Intersection** refers to the set of 188 prompts (94 each for the general test and the exception test) that result when we take the intersection of each of the model-specific subsets generated described in Individual. Note that both Individual and Intersection reflect the performance of models in an adversarial setting, and we do not expect these subsets to show meaningfully different results. We include Intersection simply so that we can compare all models on a fixed test set in an apples-to-apples setting, since the Individual subsets will vary from one model to the next.

3.2 Models

We study the performance of the following pretrained models (HuggingFace implementation) on our WINOVENTI$_{\text{BERT LARGE}}$ challenge set:

BERT-family We used BERT$_{\text{BASE}}$ (cased) and BERT$_{\text{LARGE}}$ (cased, trained with a whole word masked language modeling objective) models (Devlin et al., 2018). We also evaluated DistilBERT (Sanh et al., 2019) (cased), which has 40% less parameters than BERT while still performing almost as good as the original model. MobileBERT (Sun et al., 2020), similarly seeking to compress and accelerate the BERT model, is also included in our experiments (uncased). Additionally, our experiments also evaluated SqueezeBERT (Iandola et al., 2020) (uncased), which has a similar bidirectional transformer architecture like BERT, but uses grouped convolutions instead of certain fully-connected layers.

RoBERTa-family Our experiments also evaluate RoBERTa$_{\text{BASE}}$ and RoBERTa$_{\text{LARGE}}$ (Liu et al., 2019) versions that were trained on a masked modeling objective. RoBERTa build on BERT, differing in hyperparameter choices and pre-training objective. We also used DistilRoBERTa (Sanh et al., 2019), which follows the same training and distillation process as DistilBERT, but based on RoBERTa instead.

ALBERT-family We additionally evaluated ALBERT$_{\{\text{BASE, LARGE, XLARGE, XXLARGE}\}}$ models (Lan et al., 2019). Built off of BERT, ALBERT is designed to reduce the number of parameters and perform better on downstream tasks with multi-sentence inputs.

3.3 Finetuning

To evaluate how the models perform after being fine-tuned on datasets that contain exceptions in similar sentence structures to our challenge set, we fine-tuned a subset of the models in question (BERT$_{\text{BASE}}$, RoBERTa$_{\text{BASE}}$, DistilRoBERTa, SqueezeBERT, MobileBERT, and ALBERT$_{\text{BASE}}$) on two subsets of our dataset, the *half* and the *full* exception train sets. The *half*

	All		**Individual**			**Intersection**	
Model name	**Generic**	**Exceptn**	**Generic**	**Exceptn**	**N**	**Generic**	**Exceptn**
BERT$_{\text{BASE}}$	83.0	23.1	89.3	16.7	1871	96.0	8.3
BERT$_{\text{LARGE}}$	89.8	18.4	89.8	18.4	2176	97.4	11.4
RoBERTa$_{\text{BASE}}$	79.5	27.2	87.3	18.8	1801	95.6	12.7
RoBERTa$_{\text{LARGE}}$	81.3	29.2	91.1	18.9	994	95.6	17.5
DistilRoBERTa	78.3	26.5	91.1	13.1	948	93.9	14.0
DistilBERT	85.8	19.4	89.8	15.2	1628	94.8	12.7
SqueezeBERT	85.5	21.1	92.1	13.6	1823	97.4	7.9
MobileBERT	82.7	23.0	89.8	15.6	1856	96.9	7.0
ALBERT$_{\text{BASE}}$	77.4	28.0	87.2	18.4	1525	94.3	11.0
ALBERT$_{\text{LARGE}}$	79.6	26.8	87.6	18.9	1324	93.9	12.2
ALBERT$_{\text{XLARGE}}$	80.7	31.9	89.0	23.5	777	96.1	13.1
ALBERT$_{\text{XXLARGE}}$	77.7	32.4	80.0	32.4	959	83.8	31.9
Human performance	91.1	90.2	-	-	-	-	-

Table 6: Models' performance on our *generic* and *exception* prompts. Generic tests evaluate whether, given a generic prompt, the model would rank the generic outcome o_g higher than the exception o_e). Exceptn tests similarly check if the exception outcome o_e is ranked higher than the generic o_g given an exception context.

exception set is created by selecting half of the WinoVenti$_{\text{BERT LARGE}}$ challenge set (2176 out of 4352 schemas). 50% of the training schemas (1088 out of 2176) are selected to be generic schemas, and the rest are exception schemas. With this configuration, models are fine-tuned on both generic and exception schemas, and are sequentially evaluated on unseen challenges (with a similar distribution of 50% generic schemas and 50% exception).

With the *full exception* train set, models are fine-tuned exclusively on exception schemas. From the set of exception challenges (2176 schemas), we performed a 80-20 train-test split to select the *full exception* train set. To evaluate models trained on the *full exception train set*, in addition to evaluating the model accuracy on the held out exceptions (20% - 435 of the 2176 exception schemas), we also evaluate the fine-tuned models' on (1) all the generic challenges (2176 schemas), and (2) on a test set similar to the above where half of the schemas are generic challenges and another half are unseen exception challenges (870 schemas). The different test scenarios help us understand how finetuning on exception challenges influences models' performance on not only unseen exception challenges, but also on generic challenges.

3.4 Results and Analysis

Table 6 shows each model's performance across each data subset (All, Individual, and Intersection) broken down by task (i.e., generic vs. exception test). Across the board, models perform significantly better on the generic tests than on the exception tests (where accuracies are well below the random baseline of 50%). This provides strong evidence that models do not truly encode "common sense", but rather simply recall generic associations in a context-agnostic manner.

Looking closely at the results on the All subset, we see that models' performance on the generic test is overall lower and the performance drop on the *exception test* is less dramatic, compared to the results on the Individual and Intersection subsets. This trend is expected, since, after adversarial filtering, each model is only evaluated on prompts where the model is inherently (before being introduced to any additional context) skewed towards choosing the generic association as a description of the target noun. Even so, the numbers on this All set are informative: they emphasize that models' apparent success at recalling "commonsense" associations is likely largely driven by artifact. That is, when assessed on a set of common sense inferences that don't necessarily involve words from the top of a model's distribution in a given context, performance is quite poor. On inspection, we see that, for models outside the BERT family, the poor performance is often attributable to low probabilities for both the generic and exception outcomes (o_g and o_e) in both contexts, meaning the difference between the probabilities is often small. In other words, these models don't encode the same generic associations that $\text{BERT}_{\text{LARGE}}$ encodes and, moreover, don't encode much difference at all between o_g and o_e.

Error Analysis Looking closely at specific prompts on which models succeed and fail reveals some interesting trends. For each model, we look at the top 20 sentences from the *exception test* on which the model exhibited the largest errors, where the size of the error is measured by the difference in the probability that the model assigns to the incorrect outcome (in this case o_g) compared to the correct outcome (o_e). For $\text{BERT}_{\text{LARGE}}$, we find that 55% of these top 20 failures involve strong generic associations (i.e., those generated with $k = 1$). A full 65% are cases when o_g is "*empty*", suggesting that $\text{BERT}_{\text{LARGE}}$ prefers to assign high probability to this word across all contexts (see §2.2). In contrast, looking at the top 20 sentences on which $\text{BERT}_{\text{LARGE}}$ performed best, we learn that only one involves $o_g =$"*empty*", and only four involve strong generic associations ($k = 1$).

Performing similar analysis for the other BERT-family models ($\text{BERT}_{\text{SMALL}}$, DistilBERT, MobileBERT, SqueezeBERT), we see that the majority of the successes involve non-associative noun-characteristic pairs (i.e., pairs where the characteristic is not identified as a generic association with the noun by our procedure described in Section 2.2). For $\text{BERT}_{\text{SMALL}}$ and DistilBERT, 40% of their 20 most successful cases involved nouns for which the models did not encode any generic associations. For SqueezeBERT and MobileBERT, it is 55% and 60%, respectively. This may signify stronger a relationship between a model **not** identifying a generic association with a target noun and that model being sensitive to a change in context about that target noun.

Fine-tuning Analysis The results of our fine-tuning experiments are shown in Figure 1 (with additional results in §A.1). We see that, in general, fine-tuning models on a dataset that contains exceptions (where the challenge format remains the same between the train and test sets) can increase the performance on unseen exceptions, but does so at the expense of performance on generic prompts. Specifically, when we train on a mix of generic and exception schemas (our *half exception set*), the model improves only slightly in performance on exceptions, and converges to the same trend as the un-finetuned model: i.e., performance on generics far exceeds that on exceptions. In contrast, when we train on only exception schemas (our *full exception set*), the performance on unseen exception challenges increases faster and more significantly, but this increase is at the expense of the rapid decrease of performance on generic challenges.

This poor performance on exceptions (at the expense of their performance on generics), suggests that the conceptual associations encoded by MLM models is fairly shallow: even with finetuning, the models are not able to differentiate these types of context-specific associations in a way that allows them to perform well on both types of inferences simultaneously. Future work is needed to develop models with different architectures or loss functions that might be capable of encoding more nuanced conditional associations.

4 Related Work

Ettinger et al. (2017) bring up the fundamental problem of NLP models ignoring rare language phenomena, as they typically rely on independently and identically distributed probably-approximately-correct model of learning, and as they often use overly simplistic loss functions. Complementary to our project, Ettinger et al. (2017) encourage robust error analysis of NLP systems through developing challenges that are based on linguistic phenomena, and that have a low barrier to entry.

Common sense and probing. NLP has been interested in encoding commonsense relations for a long time (Liu and Singh, 2004). Recent work has shown how pre-trained LMs exhibit common sense knowledge even before fine-tuning (Petroni et al., 2019), and that they can be built and used to mine more commonsense information (Bosselut et al., 2016; Davison et al., 2019). While this signifies how LMs encode some common sense and prototypical properties of nouns (Weir et al., 2020), many researchers are pointing out these models' insensitivity to context (Ettinger, 2020; Ravichander et al., 2020), which is antithetical to common sense.

Challenge Sets Many existing challenge sets have provided concrete frameworks to evaluate models inference ability, through coreference resolution (notably Winograd Schema Challenge - WSC (Levesque et al., 2012)) or pronoun resolution (notably in PDP (Morgenstern et al., 2016)). In this work, similar to the Winograd Schemas (Levesque

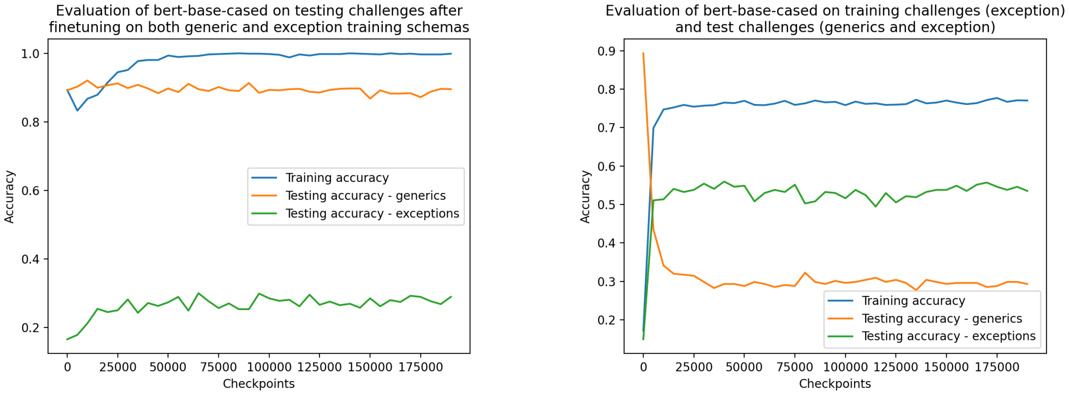

Figure 1: **Left**: Fine-tuning $\text{BERT}_{\text{BASE}}$ on a dataset that contains both generics and exceptions results in a minimal increase in performance on exceptions. **Right**: Fine-tuning $\text{BERT}_{\text{BASE}}$ on a dataset containing only exceptions results in an increase in performance on exceptions, at the expense of the accuracy on generics.

et al., 2012), we also generate pairs with a similalr structure (pairs of premises that differ in one word that would determine the answer). However, while Winograd schemas are model-agnostic, our approach factors in models' behavior in the design of schemas in order to guarantee models' bias towards one specific answer (for each prompt).

Sakaguchi et al. (2020) build the WINOGRANDE adversarial challenge set through using language models to detect and filter out schemas with language-based biases that would trivialize the task of picking the correct answer. WINOGRANDE aims to minimize the chance of models getting the right answers for the wrong reasons (through leveraging simple lexical associations that are annotation artifacts by human annotators). Our key motivation, meanwhile, is to adversarially leverage the biases that models associate with entities to "trick" them into choosing incorrect answers. Our work uses adversarially constructed test sets to expose heuristics that models use. This technique has been used widely in probing/analysis work, e.g., (Glockner et al., 2018; Naik et al., 2018; Jia and Liang, 2017; Nie et al., 2019; McCoy et al., 2019). The idea of improving models performance on "exceptions" to "generalizations" also shares much in common with work on bias and fairness in NLP (Rudinger et al., 2018; Zhao et al., 2018, 2019).

Gardner et al. (2020) propose the development of *contrast sets*, which can be developed by manually perturbing existing datasets in small but meaningful ways that would change the gold label. Our work, in contrast, factor in models' insensitive associations into the construction of challenges in addition to a slight change in context that is leveraged by contrast sets. Kaushik et al. (2019) similarly propose using *counterfactually-augmented data* to make models more robust against spurious associations. Our work adds to this work by demonstrating that fine-tuning on exception challenges can increase the performance of models on tail cases at the expense of the performance on generic prompts.

5 Conclusion

We present the WINOVENTI procedure, which adversarially exploits generic associations in masked language models to create model-specific Winograd-style schemas. Using our constructed $\text{WINOVENTI}_{\text{BERT LARGE}}$ challenge set, we test whether MLMs can move beyond their naive associations to select the more likely outcomes depending on the input context. We find a steep drop in models' performance on our challenges that require a sensitivity to context. We present evidence that generic associations differ from one model to another, highlighting the need for other model-specific challenge sets that are tuned to associative biases of models other than $\text{BERT}_{\text{LARGE}}$, and to (2) develop and analyze frameworks like WINOVENTI.

A Appendices

A.1 Fine-tuning Experiment

A.2 Crowdsourcing Instructions

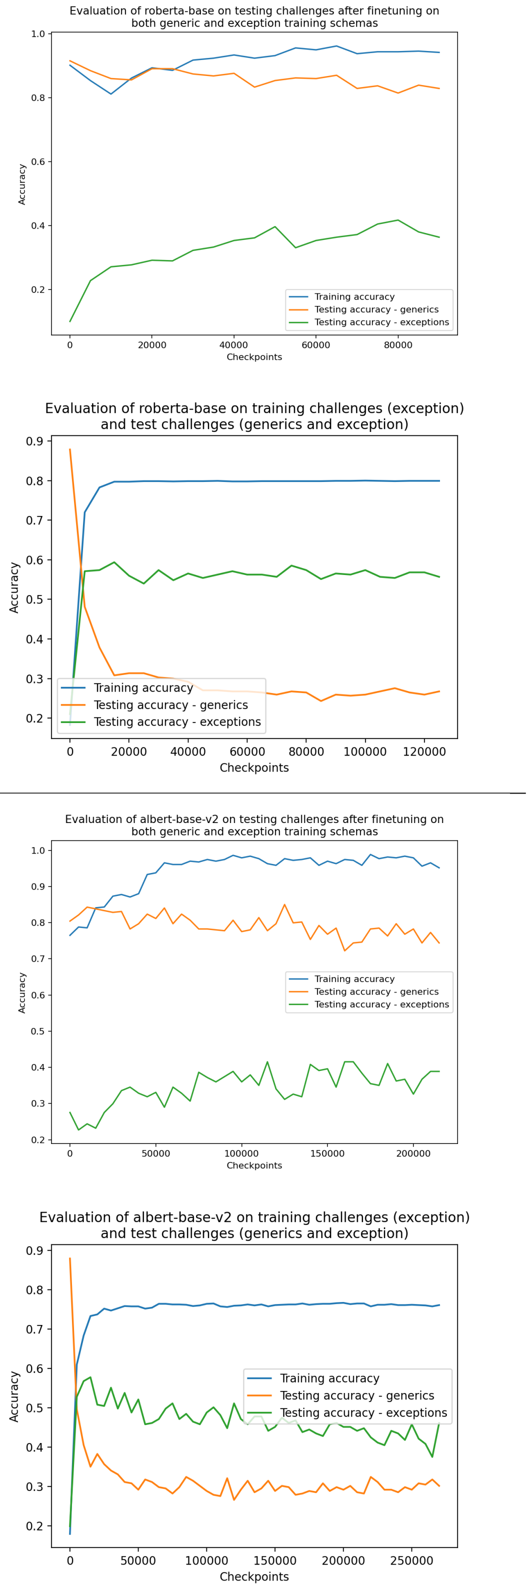

Figure 2: Fine-tuned ALBERT$_{\text{BASE}}$ and RoBERTa$_{\text{BASE}}$ show the same negative relationship between generic and exception performances. Fine-tuned RoBERTa$_{\text{BASE}}$ shows a higher increase in performance on unseen exceptions in comparison to BERT$_{\text{BASE}}$.

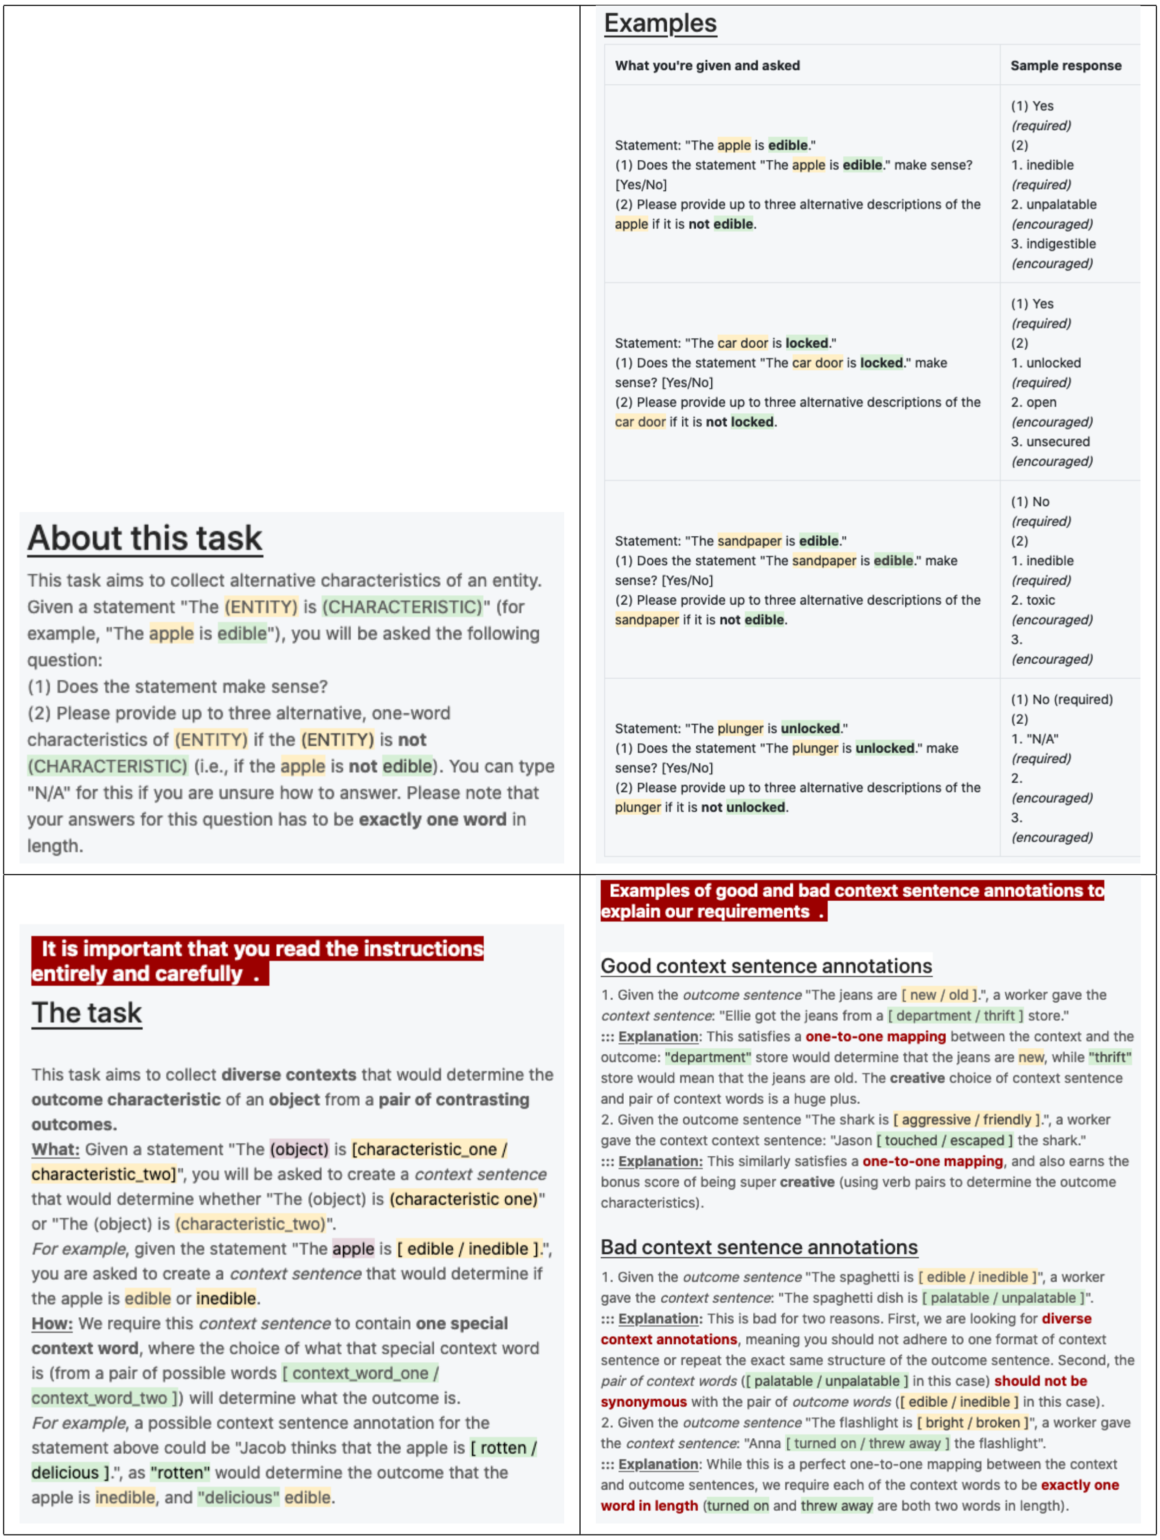


About this task

This task aims to collect alternative characteristics of an entity. Given a statement "The (ENTITY) is (CHARACTERISTIC)" (for example, "The apple is edible"), you will be asked the following question:

(1) Does the statement make sense?

(2) Please provide up to three alternative, one-word characteristics of (ENTITY) if the (ENTITY) is **not** (CHARACTERISTIC) (i.e., if the apple is **not** edible). You can type "N/A" for this if you are unsure how to answer. Please note that your answers for this question has to be **exactly one word** in length.

Examples

What you're given and asked	Sample response
Statement: "The apple is **edible**." (1) Does the statement "The apple is **edible**." make sense? [Yes/No] (2) Please provide up to three alternative descriptions of the apple if it is **not edible**.	(1) Yes *(required)* (2) 1. inedible *(required)* 2. unpalatable *(encouraged)* 3. indigestible *(encouraged)*
Statement: "The car door is **locked**." (1) Does the statement "The car door is **locked**." make sense? [Yes/No] (2) Please provide up to three alternative descriptions of the car door if it is **not locked**.	(1) Yes *(required)* (2) 1. unlocked *(required)* 2. open *(encouraged)* 3. unsecured *(encouraged)*
Statement: "The sandpaper is **edible**." (1) Does the statement "The sandpaper is **edible**." make sense? [Yes/No] (2) Please provide up to three alternative descriptions of the sandpaper if it is **not edible**.	(1) No *(required)* (2) 1. inedible *(required)* 2. toxic *(encouraged)* 3. *(encouraged)*
Statement: "The plunger is **unlocked**." (1) Does the statement "The plunger is **unlocked**." make sense? [Yes/No] (2) Please provide up to three alternative descriptions of the plunger if it is **not unlocked**.	(1) No (required) (2) 1. "N/A" *(required)* 2. *(encouraged)* 3. *(encouraged)*

It is important that you read the instructions entirely and carefully .

The task

This task aims to collect **diverse contexts** that would determine the **outcome characteristic** of an **object** from a **pair of contrasting outcomes.**

What: Given a statement "The (object) is [characteristic_one / characteristic_two]", you will be asked to create a *context sentence* that would determine whether "The (object) is (characteristic one)" or "The (object) is (characteristic_two)".

For example, given the statement "The apple is [edible / inedible].", you are asked to create a *context sentence* that would determine if the apple is edible or inedible.

How: We require this *context sentence* to contain **one special context word**, where the choice of what that special context word is (from a pair of possible words [context_word_one / context_word_two]) will determine what the outcome is.

For example, a possible context sentence annotation for the statement above could be "Jacob thinks that the apple is [rotten / delicious].", as "rotten" would determine the outcome that the apple is inedible, and "delicious" edible.

Examples of good and bad context sentence annotations to explain our requirements .

Good context sentence annotations

1. Given the *outcome sentence* "The jeans are [new / old].", a worker gave the *context sentence*: "Ellie got the jeans from a [department / thrift] store."

::: **Explanation**: This satisfies a **one-to-one mapping** between the context and the outcome: "department" store would determine that the jeans are new, while "thrift" store would mean that the jeans are old. The **creative** choice of context sentence and pair of context words is a huge plus.

2. Given the outcome sentence "The shark is [aggressive / friendly].", a worker gave the context context sentence: "Jason [touched / escaped] the shark."

::: **Explanation:** This similarly satisfies a **one-to-one mapping**, and also earns the bonus score of being super **creative** (using verb pairs to determine the outcome characteristics).

Bad context sentence annotations

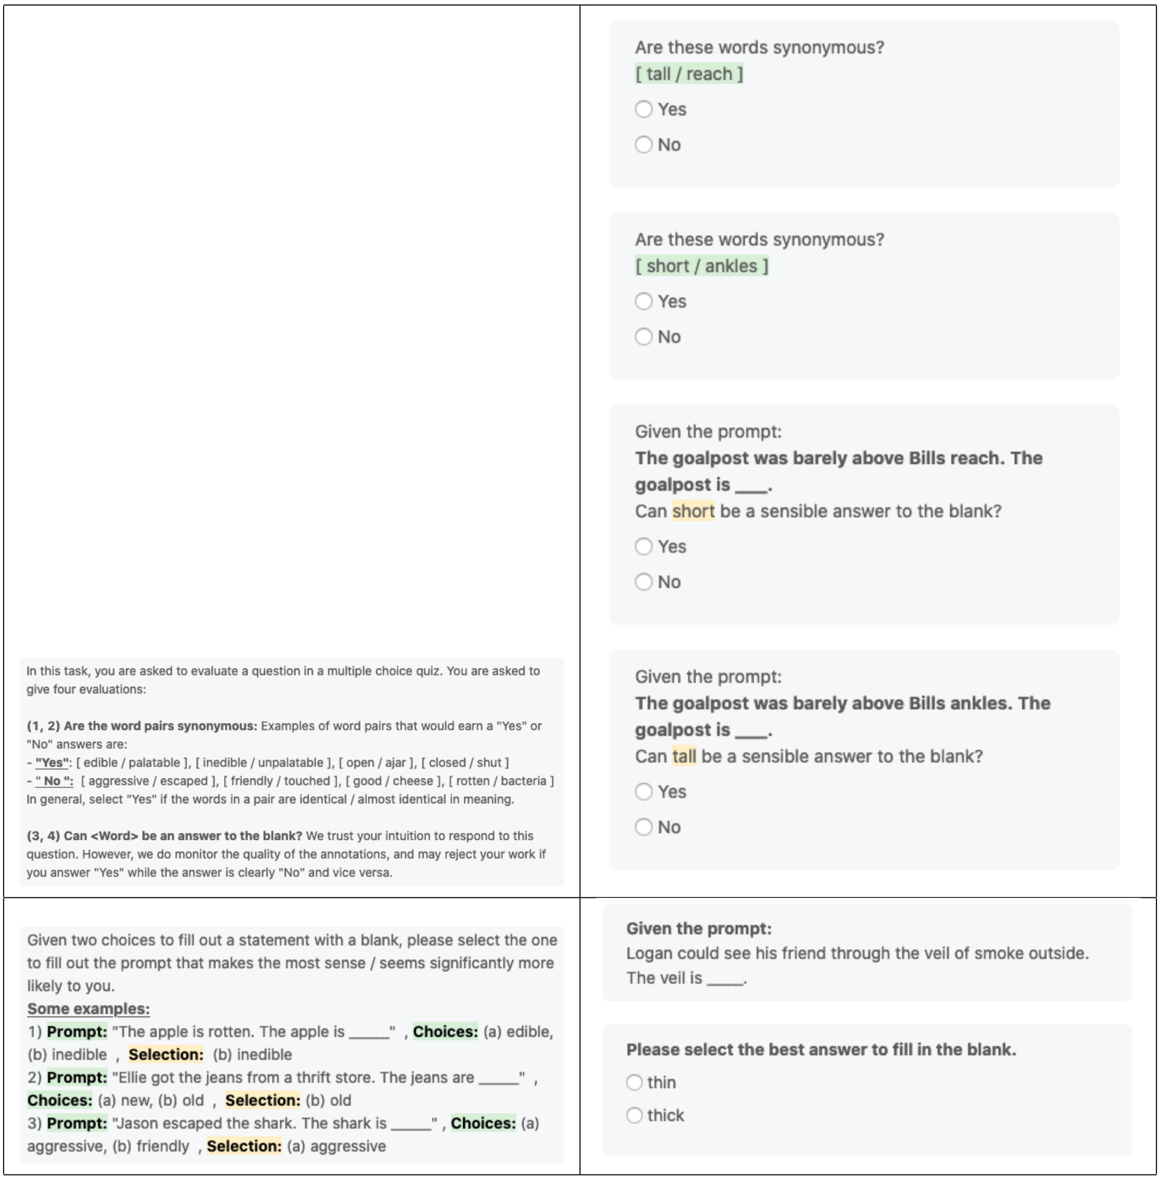
1. Given the *outcome sentence* "The spaghetti is [edible / inedible]", a worker gave the *context sentence*: "The spaghetti dish is [palatable / unpalatable]".

::: **Explanation**: This is bad for two reasons. First, we are looking for **diverse context annotations**, meaning you should not adhere to one format of context sentence or repeat the exact same structure of the outcome sentence. Second, the *pair of context words* ([palatable / unpalatable] in this case) **should not be synonymous** with the pair of *outcome words* ([edible / inedible] in this case).

2. Given the *outcome sentence* "The flashlight is [bright / broken]", a worker gave the *context sentence*: "Anna [turned on / threw away] the flashlight".

::: **Explanation**: While this is a perfect one-to-one mapping between the context and outcome sentences, we require each of the context words to be **exactly one word in length** (turned on and threw away are both two words in length).

Figure 3: **Top Left**: Exception Association Collection - Instructions. **Top Right**: Exception Association Collection - Examples. **Bottom Left**: Premise Collection - Instructions. **Bottom Right**: Premise Collection - Examples.



In this task, you are asked to evaluate a question in a multiple choice quiz. You are asked to give four evaluations:

(1, 2) Are the word pairs synonymous: Examples of word pairs that would earn a "Yes" or "No" answers are:
- **"Yes"**: [edible / palatable], [inedible / unpalatable], [open / ajar], [closed / shut]
- **" No ":** [aggressive / escaped], [friendly / touched], [good / cheese], [rotten / bacteria]

In general, select "Yes" if the words in a pair are identical / almost identical in meaning.

(3, 4) Can <Word> be an answer to the blank? We trust your intuition to respond to this question. However, we do monitor the quality of the annotations, and may reject your work if you answer "Yes" while the answer is clearly "No" and vice versa.

Are these words synonymous?
[tall / reach]
○ Yes
○ No

Are these words synonymous?
[short / ankles]
○ Yes
○ No

Given the prompt:
The goalpost was barely above Bills reach. The goalpost is ____.
Can short be a sensible answer to the blank?
○ Yes
○ No

Given the prompt:
The goalpost was barely above Bills ankles. The goalpost is ____.
Can tall be a sensible answer to the blank?
○ Yes
○ No

Given two choices to fill out a statement with a blank, please select the one to fill out the prompt that makes the most sense / seems significantly more likely to you.

Some examples:
1) **Prompt:** "The apple is rotten. The apple is _____" , **Choices:** (a) edible, (b) inedible , **Selection:** (b) inedible
2) **Prompt:** "Ellie got the jeans from a thrift store. The jeans are _____" , **Choices:** (a) new, (b) old , **Selection:** (b) old
3) **Prompt:** "Jason escaped the shark. The shark is _____" , **Choices:** (a) aggressive, (b) friendly , **Selection:** (a) aggressive

Given the prompt:
Logan could see his friend through the veil of smoke outside. The veil is _____.

Please select the best answer to fill in the blank.
○ thin
○ thick

GRICE: A Grammar-based Dataset for Recovering Implicature and Conversational rEasoning

UCLA Center for Vision, Cognition, Learning, and Autonomy
`{z.zheng,s.qiu,lfan,yixin.zhu}@ucla.edu, sczhu@stat.ucla.edu`
`https://zilongzheng.github.io/Grice/`

Abstract

Understanding what we genuinely *mean* instead of what we literally *say* in conversations is challenging for both humans and machines; yet, this direction is mostly left untouched in modern open-ended dialogue systems. To fill in this gap, we present a grammar-based dialogue dataset, GRICE, designed to bring implicature into pragmatic reasoning in the context of conversations. Our design of GRICE also incorporates other essential aspects of modern dialogue modeling (*e.g.*, coreference). The entire dataset is systematically generated using a hierarchical grammar model, such that each dialogue context has intricate implicatures and is temporally consistent. We further present two tasks, the implicature recovery task followed by the pragmatic reasoning task in conversation, to evaluate the model's reasoning capability. In experiments, we adopt baselines that claimed to have pragmatics reasoning capability; the results show a significant performance gap between baseline methods and human performance. After integrating a simple module that explicitly reasons about implicature, the model shows an overall performance boost in conversational reasoning. These observations demonstrate the significance of implicature recovery for open-ended dialogue reasoning and call for future research in conversational implicature and conversational reasoning.

Alice: Did you see the apples?
Bob: There is a basket in the dining room.
`(The apples are in the dining room.)`
Alice: How many?
Bob: There are at least two.
`(I am not sure how many apples are there.)`
Alice: Did you put them there?
Bob: I was in the kitchen.
`(I didn't put the apples in the dining room.)`
Alice: Are all the oranges there?
Bob: Some are there.
`(Not all the oranges are in the kitchen.)`
Alice: What about the pears?
Bob: They are in the living room.
`(The pears are not in the kitchen.)`

Figure 1: **An example of the conversation in the proposed GRICE dataset.** Each round of dialogue includes a question, an answer that may contain implicature, and a recovered statement that converts the implicature to explicature. Different colors highlight coreference flows.

1 Introduction

> "When a diplomat *says* yes, he *means* 'perhaps'; when he *says* perhaps, he *means* 'no'; when he says no, he is not a diplomat."
> —Voltaire, quoted in Spanish in Escandell (1996) (Korta and Perry, 2020)

Voltaire's above quote is an epitome of a crucial aspect of conversation; the meaning of the very same word or token varies according to its context and goes *beyond* what we *literally* say, which is the central character of the field of pragmatics. Such a high-level comprehension of *utterance* is more than traditional semantics and logic; it is often believed to involve the construction of the speaker's intents, beliefs, and social institutes (Grice, 1975; Korta and Perry, 2020). For instance (see Fig. 1), when asked "did you see the apples?", one would not merely say "yes" or "no"; instead, one should provide an answer that is cooperative, truthful, informative, relevant, and perspicuous (Davis, 2016) based on the inferred speaker's intent and belief. Consequently, in the above example, a person would instead answer the actual location without mentioning any positive or negative words. Such a teleological account echoes Grice's core insight that "language use is a form of rational action; hence, technical tools for reasoning about rational action should elucidate linguistic phenomena" (Goodman and Frank, 2016).

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2074–2085
August 1–6, 2021.

In stark contrast, such a goal-directed perspective of conversational reasoning has been largely ignored in the modern literature of Natural Language Processing (NLP) (but see Dale and Reiter (1995); Nematzadeh et al. (2018) as exceptions). The recent development of open-ended dialogue systems has a clear trend that adopts state-of-the-art deep learning or deep reinforcement learning methods, fueled by hardware accelerations and massive sets of labeled data. However, the inspiring progress was recently challenged by researchers (Shum et al., 2018; Young et al., 2018); there remain valid concerns that systems are simply imitating human responses by regressing a large amount of training data without truly understanding it. Although we see an emerging field of conversational reasoning (*e.g.*, Moon et al. (2019); Cui et al. (2020)), existing work fails to account for the pragmatics perspective within conversations: Human speakers usually do not speak their thoughts or intentions *directly*; it has to be inferred from the conversational context.

To fill the gap between the current open-dialogue systems and the future humanlike dialogue systems, we design a new open-dialogue dataset generation protocol, which we refer as Grammar-based dataset for Recovering Implicature and Conversational rEasoning (GRICE), in homage to H. P. Grice for his influential theory in explaining and predicting conversational implicatures (Grice, 1975). Specifically, our design follows four principles.

First, we design the GRICE dataset with a focus of *conversational implicature* (Grice, 1975), "one of the single most important ideas of pragmatics" (Levinson, 1985). Naturally, the ability to successfully perform **implicature recovery** in conversation (Borg, 2009) would be a suitable indicator of a system's performance; we adopt it as part of our evaluation protocols. To recover conversational implicature into explicit ones with only information and context in the dialogue, an ideal model should reason about the dialogue context and the relations among dialogue entities.

Second, we emphasize the comprehension of the *conversational context* and adopt the **conversational reasoning** as part of the evaluation protocols. Again, we take the conversation in Fig. 1 as the example: When the speaker says "I was in the kitchen," what she really means is that she was not in the dining room and therefore could not put the apples there. The same response would have the opposite meaning when the question becomes "Were you in the kitchen?". Such a swift switch according to its dialogue context is a quintessential demonstration that human communication is a context-dependent endeavor (Fetzer, 2017) and a dynamic construct, which relates communicators and the language that they use in a dialectical manner (Bateson, 2000).

Third, we build the GRICE dataset by incorporating five different types of implicature; see details in Section 4. To resolve these types of implicature, the algorithm ought to make a proper prediction or inference of intents and beliefs by representing and reasoning about *triadic* relations (Saxe, 2006): the speaker's belief, the addressee's belief, and what they have or communicate in common.

Fourth, in comparison to prior work, Facebook bAbi (Weston et al., 2016) and its follow-up work ToM (Nematzadeh et al., 2018) that evaluate different aspects of reasoning with a set of toy tasks, the proposed GRICE dataset does not sacrifice crucial characteristics of modern open-dialogue systems. On the contrary, by integrating pragmatics and implicature in conversation, we hope to shed light on some challenging issues in open-ended dialogue:

- *Coreference* resolution (Chen et al., 2017; Kottur et al., 2018) refers to finding all expressions that refer to the same entity in the conversation. The significance of resolving coreference becomes even more profound in conversations with implicature; Fig. 1 gives an example and highlights the coreference flows in different colors.
- *Commonsense* reasoning (Sap et al., 2019; Talmor et al., 2019; Speer et al., 2017) received an increasing attention in NLP. Notably, researchers have proposed the Winograd (Levesque et al., 2012) and WinoGrande (Sakaguchi et al., 2020) to examine commonsense reasoning. For conversations with implicature, commonsense reasoning reflects a crucial concept of *relevance*. For instance, to resolve the implicature in the conversation "A: I am out of petrol. B: There is a garage around the corner.", one needs to have the commonsense that "a garage could store petrol."
- *Logic*-based methods were once thought to be the "ideal language" approach to the semantics of human language (Russell, 1903), but were later challenged by Wittgenstein (1953, 1969) and Grice (1975). However, this disagreement should not prohibit the central role of logical forms in reasoning tasks. In fact, it would be interesting to investigate if the modern end-to-end trainable methods could benefit from logical forms in conversational reasoning.

The remainder of this paper is organized as follows. We review related work on dialogue dataset, implicature, and conversational reasoning in Section 2. In Section 3, two tasks are defined for evaluations. We present detailed design, generation, and analysis of the GRICE dataset in Section 4. By introducing two evaluation protocols, we provide the performance of baseline models with discussions of results and future directions in Section 5.

2 Related Work

Dialogue Datasets Dialogue datasets have been focusing on predicting the next most-likely response by imitating the teacher's responses (human corpus) (Lowe et al., 2015; Zhang et al., 2018; Wu et al., 2018). However, as pointed out by Cui et al. (2020), prior datasets and associated methods lack proper explicit reasoning modules; it later becomes evident that such reasoning modules serve as the scaffold in building a humanlike conversational agent. Of note, a model's reasoning capability is minimal if it simply converts reasoning challenges into a categorization problem when predicting the utterances; it still tends to choose the most frequent answer given the training set without genuinely understanding the context and underlying meaning.

To the best of our knowledge, the proposed GRICE dataset is the first open-dialogue dataset that explicitly integrates implicature; see a detailed comparison in Table 1. We hope our careful design would encourage and even necessitate future models to make explicit reasoning on conversational contexts, commonsense, and agent's intents and beliefs. The most similar dataset in terms of the format is DREAM by Sun et al. (2019), a conversational dataset with a question-answering (QA) task. However, the design of the DREAM dataset does not require much reasoning; answers can be directly extracted. The most similar dataset in terms of the task is CoQA by Reddy et al. (2019), which considers pragmatics and QAs over literature paragraphs; our GRICE dataset differs by reasoning over the *dialogue context* between two agents.

Implicature Implicature has been extensively studied in the field of linguistics and philosophy since the inception of pragmatics; Grice (1975)'s four maxims—quality, quantity, relevance, and manner—founded the principles of the interpretation of conversation implicature. Two neo-Gricean typologies of conversational implicature include Horn and Ward (2004)'s Q- and R-implicature and Levinson (1985)'s Q-, I-, and M-implicature. The relevance theory developed by Sperber and Wilson (1986) offers an alternative account to Gricean and neo-Gricean theory. In general, although these doctrines provide crucial insights into the field, they focus more on philosophical debates over toy examples without deriving computational solutions or quantitatively validating the ideas on modern large-scale natural language datasets.

Although a few computational models have been proposed recently (*e.g.*, Frank and Goodman (2012); Goodman and Stuhlmüller (2013)), these models assume the space of utterance and possible semantic meanings are finite or given, so that models only need to pick up one over others based on the shared context. Other models focus on more specific tasks; for instance, recovering the direct meaning from the indirect answer using scalar adjectives (de Marneffe et al., 2010; De Melo and Bansal, 2013), conducting analysis on the ironic implicature behind simile (Veale and Hao, 2010).

By generating paired sentences in a semi-automatic fashion with human annotations, Jeretic et al. (2020) recently devise a dataset with a focus on scalar implicature (Hirschberg, 1985). In comparison, the proposed GRICE dataset has a much more natural setup and broader scope by combining the multi-round open-dialogue with conversational implicature. Additionally, leveraging a grammar representation for fine-grained control, the GRICE dataset is generated in a fully automated fashion without human annotations. We hope such a design could boost research in implicature, pragmatics, and conversational reasoning at a large scale.

Conversational Reasoning In the past four years, we have witnessed an increasing interest in conversational reasoning in various contexts. OpenDialKG (Moon et al., 2019) incorporates external knowledge graphs to the dialogue context to provide extra entities as responses. Visual Dialog (Wu et al., 2018; Zheng et al., 2019; Das et al., 2017) takes images as external multi-modalities to reason with dialogue context to generate visually grounded responses jointly. MuTual (Cui et al., 2020) modifies English reading comprehension to select the next best response by machine reasoning.

However, prior efforts have ignored the fact that humans commonly do not directly speak out answers. The proposed GRICE dataset is a complement of prior conversational reasoning tasks; it focuses on implicature with conversational reasoning, which does not reject multi-modalities as they could be a source of commonsense knowledge.

Table 1: Comparing GRICE with existing conversational datasets.

Dataset	**Task**	**Context**	**Source Domain**
Ubuntu (Lowe et al., 2015)	Next Utterances Prediction	Dialogue	Ubuntu Chat logs
PERSONA-CHAT (Zhang et al., 2018)	Next Utterances Prediction	Dialogue	Persona
Douban (Wu et al., 2017)	Next Utterances Prediction	Dialogue	Open Domain
MuTual (Cui et al., 2020)	Next Utterances Prediction	Dialogue	Listening Comprehension
DREAM (Sun et al., 2019)	Question Answering	Dialogue	English Language Exams
CoQA (Reddy et al., 2019)	Conversational QA	Paragraph	Literature
GRICE (ours)	Implicature recovery & Question Answering	Dialogue	Open Domain with implicature

3 Task Definition

To evaluate how well a model "understands" the dialogue presented in the proposed GRICE dataset, we devise two tasks: the implicature recovery task and the conversational reasoning task, wherein the latter task depends on the successful completion of the former task. Below, we introduce the setup and evaluation protocol of each task.

Alice: Where are the oranges?
Bob: They may be in the kitchen or the patio.
Alice: What about the apples?
Bob: Jack put them in the kitchen and went to the bedroom.

(a) A sample dialogue with two rounds.

(A) Jack went to the bedroom and then put the apples in the kitchen.
(B) Jack put the apples in the kitchen and then went to the bedroom.
(C) Jack went to the bedroom and then put the oranges in the kitchen.
(D) The apples are in the bedroom.

(b) Implicature recovery evaluated with multiple choices.

Q_1: Where are the apples?
A_1: Kitchen
Q_2: Who moved the apples?
A_2: Jack
Q_3: Does Bob know where the oranges are?
A_3: No

(c) Conversational reasoning evaluated by QAs.

Figure 2: **Examples of two tasks defined in GRICE dataset.** (a) Given a multi-round open-dialogue, an algorithm is asked to perform (b) implicature recovery and (c) conversational reasoning in the form of QAs.

Task 1: Implicature Recovery Formally, an n-round dialogue occurring between two agents is represented by a sequence of QA-pairs $\{(Q_1, A_1), (Q_2, A_2), ..., (Q_n, A_n)\}$, where Q_i is the question raised by the first agent, A_i is the response provided by the second agent, which may contain an implicature. To complete this task, a model is asked to identify if A_i is a statement containing implicature, and if this is true, to resolve the implicature to its explicit form, *i.e.*, to perform implicature recovery.

The implicature recovery is evaluated in the form of multiple choices: For each utterance, the ground-truth condition (with implicature) and its explicit form are given when generating the dialogue; the explicit form, which not only recovers the implicature but also resolves coreferences in the utterance, serves as the correct answer in the multiple choices. We then sample three possible answers from the candidate pools, given a set of manually defined *speech templates* (see details in Section 4). Figs. 2a and 2b show an example: The last utterance by Bob implicates (by the word "then") the temporal order between "put them in the kitchen" and "went to the living room." Thus, the correct implicature recovery should resolve "them" as "the apples" and recover the correct temporal order.

Two strategies developed by existing work could be adopted to address this task. One strategy is to train a model that directly chooses an answer from the candidate answers. Another more challenging strategy is to train a generator that chooses the answer by computing the log-likelihood scores and ranking the candidate answers as done by Das et al. (2017). To quantitatively evaluate the performance, we use the standard response selection metrics (Lowe et al., 2015; Wu et al., 2017; Cui et al., 2020): Top 1 Recall (R@1) and Mean Reciprocal Rank (MRR) (Voorhees et al., 1999).

Task 2: Conversational Reasoning To evaluate the open-ended conversational reasoning, we follow the same protocols as in Weston et al. (2016) and Nematzadeh et al. (2018) with comprehensive QAs. For each dialogue, we generate questions by randomly sampling the *conversational contexts* (see Section 4), and each question could be answered by a single word; see Fig. 2c for examples.

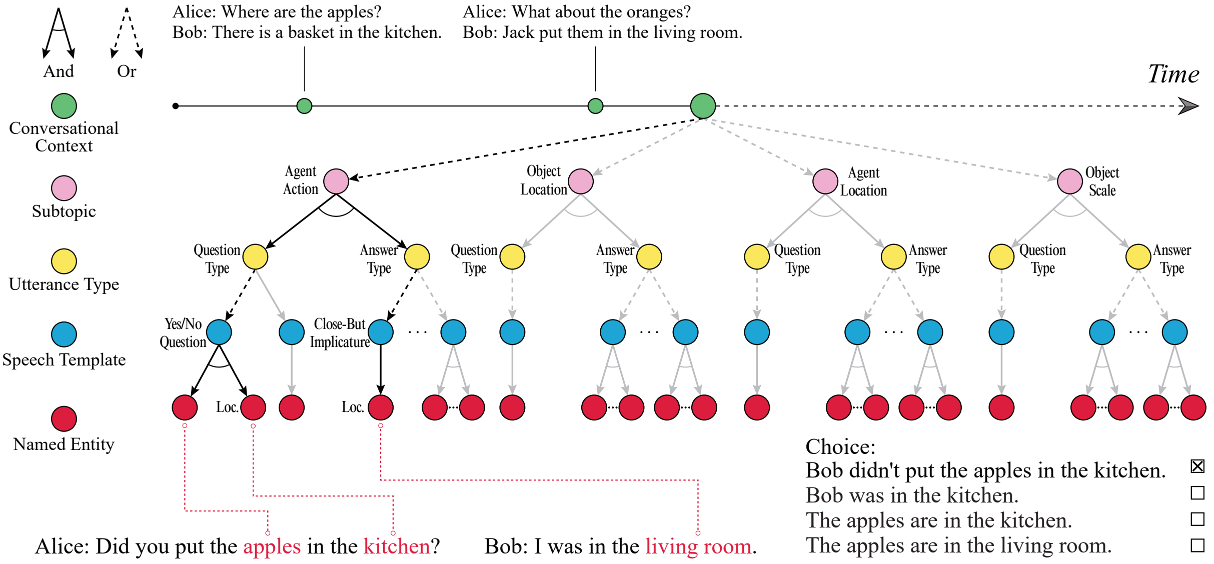

Figure 3: The graphical illustration of the grammar production rules for the GRICE dataset.

4 Creating the GRICE Dataset

Representation We adopt a structural grammar model, Temporal And-Or Graph (T-AOG) (Qi et al., 2020; Edmonds et al., 2019a; Tu et al., 2013), to represent the dialogue context due to its expressiveness of hierarchical dialogue structure and temporal-dependent dialogue flow. We represent one *turn* of the dialogue as an AOG (Bonczek et al., 1979, 1981; Pearl, 1984; Zhu and Mumford, 2007) that has a hierarchy of five levels: conversational context, subtopic, utterance type, speech template, and named entity. AOGs are connected w.r.t. temporal constraints in order to assemble the T-AOG.

Formally, an AOG (*i.e.*, each turn of the dialogue) has two sets of non-terminal vertex: (i) a set of And-nodes, wherein each node represents the decomposition of a larger concept (*e.g.*, subtopics) into smaller components (*e.g.*, utterance types), and (ii) a set of Or-nodes, wherein each node branches to an alternative decomposition (*e.g.*, a conversational context could have different types of subtopics), enabling the model to reconfigure the overall dialogue. An instance of AOG can be constructed by selecting a child node for each Or-node, resulting in a parse graph.

Fig. 3 illustrates an example of AOG. Specifically, the root node of one dialogue turn is an Or-node, representing the current conversational context. Represented by an And-node, each child node of the root note denotes a subtopic of the current dialogue turn. The subtopic is composed of a set of utterance types, further decomposed into speech templates filled by named entities. Instantiating an AOG by selecting Or-nodes would produce a complete utterance of a dialogue turn and pose constraints on the next dialogue turn.

Conversational Context We follow Weston et al. (2016) to represent dialogue context by a simulated world with various dialogue entities: *objects*, *locations*, and *agents*. We randomly initialize a world for each dialogue snippet by (i) positioning objects in locations with a random scalar (one, two, ...), (ii) randomly setting a location for each agent as the "previous agent location," and (iii) for each $\langle object \rangle$ in $\langle location \rangle$, randomly selecting an $\langle agent \rangle$ in $\langle location \rangle$ to denote that "$\langle agent \rangle$ put the $\langle object \rangle$ in the $\langle location \rangle$."

Subtopic In this dataset, we focus on four different subtopics: *agent_location*, *agent_action*, *object_location* and *object_scale*; see examples in Table 3. Specifically, *agent_location* queries the location of some $\langle agent \rangle$. The example in Table 3 implicates that "Jack was in the kitchen." Similarly, *object_location* queries the location of some $\langle object \rangle$. *Agent_action* queries the previous action taken by some $\langle agent \rangle$ on some $\langle object \rangle$. Typically, the action can be identified as an $\langle agent \rangle$ put $\langle object \rangle$ in the $\langle location \rangle$. *Object_scale* queries the quantity of some $\langle object \rangle$. In particular, an algorithm should also be able to reason about the strength among the quantifying phrases, such as *at least*, *some*, and *all*. A typical example shown in Table 3 implicates that "Bob does not know if all the apples are in the kitchen."

Utterance Type Utterance type concerns how to generate a QA-pair correctly. For questions, the

Table 2: **Definitions and examples of five types of implicature in the proposed GRICE dataset.** Following the conventional notation, S denotes the positive answer of the question, and S^+ denotes its stronger proposition.

Category	Definition	Example
Relevance	Implicating the answer to an expressed or implied question by stating something related to the answer by implication or explanation.	Alice: Where did you see the apples? Bob: There is a basket in the kitchen. (The apples are in the kitchen.)
Strengthening	Implicating a stronger proposition S^+ when not understatement.	Alice: Are some of the apples in the kitchen? Bob: All of them are there. (Not just some, but all of the apples are in the kitchen.)
Limiting	Implicating the **denial** of S^+.	Alice: Are all the apples in the kitchen? Bob: Some are. (**Not all** apples are in the kitchen.)
Ignorance	Implicating that one **does not know** whether S^+ is true (or that S^+ may or may not be true).	Alice: Where did you see Jack? Bob: He was in the kitchen or the bedroom. (I am not sure where Jack was.)
Close-But	Implicating a **negative** answer to a question by affirming something close to a positive answer in contextually salient respects.	Alice: Did you put the apples in the kitchen? Bob: I was in the living room. (I did not put the apples in the kitchen since I was in somewhere else.)

Table 3: Categories and examples of different subtopics in GRICE dataset.

Subtopic	Example
agent_location	Alice: Where was Jack? Bob: I saw him in the kitchen.
agent_action	Alice: Did you put the apples in the kitchen? Bob: I was in the bedroom.
object_location	Alice: Where can I find the apples? Bob: They are in the kitchen, if not the living room.
object_scale	Alice: Are all the apples in the kitchen? Bob: At least four are there.

query types of each subtopic are manually defined. For example, the question regarding *Agent_location* can be a yes/no question ("were you in the kitchen?") or a where question ("where were you?"). For answers, we focus on five different types of implicature (Huang, 2017; Horn and Ward, 2004; Davis, 2016): *relevance*, *strengthening*, *limiting*, *ignorance*, and *close-but*; see Table 2 for detailed definitions and examples.

Diversity We follow Weston et al. (2016) to use a simple automated grammar to makes the conversation more natural and diverse: We assign a set of synonyms for each verb; *e.g.*, we randomly replace (i) *put* with *left*, *dropped*, or *placed*, and (ii) *went* with *travelled*, *journeyed*, or *walked*.

Since coreference is a crucial feature in the conversational context in GRICE dataset, we track agents, objects, and locations mentioned in previous conversations and replace them with deixis in the following conversational context.

Additionally, we build a set of follow-up questions for each type of dialogue action to challenge the model's ability to reason about the omission in utterances. Take Fig. 2 as an example; the question "What about the apples?" should be interpreted or recovered as "Where are the apples?" during the reasoning procedure.

Candidate Answer Generation To generate candidate answers for each round of dialogue for the implicature recovery task, we define four different strategies tailored to produce challenging candidates. Among all four candidate answers, besides the ground-truth condition in its explicit form, the other three candidate answers are randomly sampled from the candidate pool, composed by applying the following strategies; see Fig. 4 for examples of each strategy:

1. Statements that are similar to the ground-truth condition but with wrong coreferenced entities.
2. Randomly sampled true condition but with irrelevant facts.
3. Randomly sampled wrong facts from the current conversational context.
4. Manually created statements that are close to the true condition but are in fact wrong.

Conversation:
Alice: Where are the oranges?
Bob: Jack said he saw some in the kitchen.
Alice: Did he put them there?
Bob: He put them there and went to the bedroom.
`(Jack put the oranges in the kitchen and then went to the bedroom.)`

Examples of generated candidate answers:
1. Bob put the oranges in the kitchen and then went to the bedroom.
2. Jack was in the bedroom.
3. The oranges are in the bedroom.
4. Jack went to the bedroom and then put the oranges in the kitchen.

Figure 4: **The candidate answers for the implicature recovery task are generated following four different strategies.** 1. Statements that are similar to the ground-truth condition but with wrong coreferenced entities. 2. Random sampled true condition but with irrelevant facts. 3. Random sampled wrong facts from the conversational context. 4. Manually created statements that are close to the true condition but are in fact wrong.

Questions We follow Weston et al. (2016) to generate questions about the dialogue context. After sampling the dialogue turns and finalizing the dialogue context, we query current dialogue states in terms of agent locations/actions and object locations/scales. Inspired by Nematzadeh et al. (2018), we further add belief queries (*e.g.*, "does Bob know where the oranges are?") to test the model's capability of belief reasoning; see Fig. 2 for examples.

5 Experiments

We randomly sample 6,000 dialogues as the train set and additional 4,000 dialogues as the dev set to evaluate baseline models; each dialogue contains 10 dialogue turns and 3 questions. Detailed distributions of implicature types are listed in Table 4. For the test set, we sample 1,000 dialogues in each implicature category, resulting in a total of 5,000 dialogues. Each test dialogue contains 3–5 dialogue turns and one question on implicature. All data is clean and noiseless.

Setup We model both tasks as a query over the conversational context. Specifically, for the implicature recovery task, we define $h_t = (Q_t, A_t)$ as the queried sequence and the $H_t = \{(Q_1, A_1), ..., (Q_{t-1}, A_{t-1})\}$ as the past dialogue context. Then the task is to predict the explicit form $E_t = f(h_t, H_t)$. For the conversational reasoning task, we treat the entire history as the input context and the question as the query sequence. The task is then modeled as a Sequence-to-Vector framework that maps the query with its context to the vocabulary space. We implemented all models in PyTorch and trained using ADAM (Kingma and Ba, 2014) with a learning rate of 0.001 for 40 epochs.

Table 4: Distribution of implicature types (%).

	Train	Dev
Explicit Answer	27.3	29.6
Implicature	72.7	70.4
Relevance	9.9	9.3
Strengthening	22.5	22.9
Limiting	6.3	6.4
Ignorance	23.5	21.2
Close-But	10.5	10.8

5.1 Baseline Models

We evaluate 5 representative baseline models for both tasks on the GRICE dataset. The baseline models are chosen on the basis of performing well on synthetic language datasets (*e.g.*, Facebook bAbi) or similar tasks and easy adoption to perform conversational reasoning tasks. We additionally test the performance of transformer-based language models, claimed to have strong reasoning capabilities.

LSTM We start with a simple dual LSTM model: one LSTM to encode the history context as a long context sequence, and another LSTM to encode the queried sequence. A simple MLP fuses two encoded vectors to predict answers.

Recurrent Entity Network (EntNet) EntNet (Henaff et al., 2017) is an RNN-based memory-augmented architecture, capable of capturing the sequential nature and learning relevant entities with their properties by gated recurrent units and weight matrices. Our implementation is based on its official open-sourced code[1].

Relation Network (RelNet) Santoro et al. (2017) propose a neural model for relational reasoning. The algorithm considers each pair of sentences together with the question as inputs. Our implementation is based on its official open-sourced code[2].

Memory Network (MemNN) We follow Weston et al. (2015) to build a memory network[3] that takes each round of history context as a supporting fact and stores it in the memory bank; the algorithm

---

[1] `https://github.com/jimfleming/recurrent-entity-networks`

[2] `https://github.com/siddk/relation-network`

[3] `https://github.com/facebook/MemNN`

is expected to learn to refer to the memory when predicting answers. Specifically, we use an LSTM to encode each round of history and compute the association matrix between the queried sequence and the memory bank. We apply a softmax to the association matrix to get the attended weight of the dialogue history. Finally, we compute the attended dialogue history embedding and combine it with the queried embedding using a simple MLP to predict answers.

Transformer-based Language Model Fine-tuning transformer-based language models (*e.g.*, GPT (Radford et al., 2018) and BERT (Devlin et al., 2019)) has shown superior performance on conversational reasoning tasks (Sun et al., 2019). We use BERT-base-uncased [4] as our pre-trained model and apply it to the conversational reasoning task by adding a single linear layer to generate answers from the target vocabulary set.

Human Performance We randomly selected 100 dialogues and assigned them to 40 human subjects in a between-subject design; 20 subjects for the implicature recovery tasks, and another 20 subjects for the conversational reasoning task.

5.2 Evaluation and Results

Implicature Recovery We start by evaluating the performance of the baseline models on the implicature recovery task. As discussed in Section 3, we evaluate under two different settings to predict the implicature recovery results: the discriminative setting and the generative setting (marked by "-Gen"). For the discriminative setting, we take the encoder output and compute the similarity score with each candidate answer to predict the final choice. For the generative setting, we train the encoder-decoder framework using the teacher-forcing algorithm by minimizing the negative log-likelihood between the generated answers and the ground-truths. Overall, the generative setting is more challenging than the discriminative one; see Table 5 for results on dev and test sets.

Conversational Reasoning We follow Weston et al. (2016) and Nematzadeh et al. (2018) on performance evaluation of the conversational reasoning task, measured by the accuracy score in the vocabulary space; see Table 6 for the results of all the baseline models on the dev and test sets.

Table 5: Performance on implicature recovery task.

	Dev		Test	
Model	R@1	MRR	R@1	MRR
LSTM	81.92	0.9046	83.54	0.9145
EntNet	89.07	0.9445	91.15	0.9523
RelNet	93.02	0.9623	95.33	0.9602
MemNN	96.76	0.9833	97.29	0.9862
LSTM-Gen	62.28	0.7763	65.02	0.7784
MemNN-Gen	86.29	0.9305	88.79	0.9418
Human	99.00	-	98.50	-

Table 6: Performance on conversational reasoning task.

	Accuracy (%)	
Model	Dev	Test
LSTM	59.77	55.82
EntNet	57.91	53.17
RelNet	63.02	65.50
MemNN	64.66	67.32
BERT	67.21	71.06
MemNN w/ inf	69.24	73.12
Human	98.50	97.50

Analysis Comparing the model performance with the human performance in Tables 5 and 6, we see a consistent and competent performance in human subjects, whereas the model performance of the conversational reasoning task drops significantly even after a relatively good performance on the implicature recovery task. This contrast indicates that the models that perform well on the implicature recovery task may not really "understand" the conversational context to be used in the following conversational reasoning task.

To further test this hypothesis, for the implicature recovery task, we additionally pre-train an inference encoder that predicts the explicit/recovered answer under the generative settings (MemNN w/ inf), given the previous dialogue history. This additional inference model is further appended into the basic model and fused to predict the final answer. Such a setting would be a reasonable test to see how well a model could perform if they explicitly incorporate the recovered implicature from the implicature recovery task to solve the later conversational reasoning task. As shown in both Table 6 and Fig. 5, we observe that the conversational reasoning performance improves an average 5% with this additional inference module; for certain implicature types, it boosts the performance for more than 25%. Of note, it even outperforms the previous state-of-the-art model that fine-tunes the pre-trained Bert model, indicating the significance of incorporating an explicit module of implicature recovery for pragmatic reasoning in conversation.

6 Discussions and Future Work

Synthetic Corpus *vs.* Natural Corpus Creating synthetic datasets is commonly challenged in the current deep learning community due to the potential unnaturalness of the generated corpus. Nevertheless, it is worth noting that the axes along which the dataset is unnatural are unrelated to our primary focus—pragmatic implicature. By carefully and systematically incorporating the pragmatic phenomena existing in daily conversations, the proposed GRICE dataset, though synthetic, could be considered as one additional dimension in evaluating language models. In fact, although moving towards natural conversations may increase the diversity of responses, it will also introduce two potential problems: (i) Most daily conversational snippets only consist of one or fewer implicature, which cannot highlight the core challenges presented in the proposed GRICE dataset. (ii) The implicatures in natural dialogues are unstructured, requiring experts to label their explicit form, which may introduce errors and uncertainties.

Direct Evaluation *vs.* Indirect Evaluation Although the proposed GRICE dataset incorporates the triadic relations among agents and additional challenges (*e.g.*, coreference, commonsense) presented in modern dialogue systems, it is difficult to directly evaluate these aspects in an open-ended dialogue system, especially with implicature. One may use an indirect metric, *i.e.*, whether the system performance would improve after integrating such modules. Moving forward, we call for future research to design more direct evaluation metrics in addition to the present implicature recovery and conversational reasoning tasks.

Human Performance *vs.* Machine Performance The experimental results show that the existing models do exhibit a certain level of reasoning capability, though weak. Additionally, the performance gap between the implicature recovery and conversational reasoning tasks leaves us with many mysteries. Humans seem to be reasonably consistent in solving both tasks, whereas current models are not. One possible explanation is that the computational model is able to fit the relatively confined space of the implicature recovery task based on the training data, but fails to incorporate such knowledge for the more open-ended conversational reasoning task. This possible explanation is further backed up by the above experiment with an additional inference module.

Another potential reason is that existing models may lack *generalizability* that can leverage knowledge learned from known implicature to solve unseen conversations. In other words, they can only *memorize* token patterns from existing corpus rather than understand the *rationale* behind the language context, thus would fail to perform deductive or abductive reasoning tasks. Similar observation has been investigated by other reasoning tasks, including IQ test (Zhang et al., 2019a,b, 2021b), number sense (Zhang et al., 2020), causal reasoning (Edmonds et al., 2018, 2019b, 2020; Zhang et al., 2021a), and more generic generalization tasks (Lake et al., 2015; Xie et al., 2021; Li et al., 2021; Zhu et al., 2020).

Fundamentally, how could we properly leverage the knowledge extracted during the implicature recovery task for the following conversational reasoning task? Levinson (1995) argues that human conversation depends on intention-ascription, where inferences must be made way beyond the data, therefore forming an *abductive* process. A possible and promising future direction would be using a neural-symbolic solver, capable of handling noisy inputs using neural-network modules and reasoning about the answers in a logic-like style.

Abstract

Retrofitting is a technique used to move word vectors closer together or further apart in their space to reflect their relationships in a Knowledge Base (KB). However, retrofitting only works on concepts that are present in that KB. RetroGAN uses a pair of Generative Adversarial Networks (GANs) to learn a one-to-one mapping between concepts and their retrofitted counterparts. It applies that mapping (post-specializes) to handle concepts that do not appear in the original KB in a manner similar to how some natural language systems handle out-of-vocabulary entries. We test our system on three word-similarity benchmarks and a downstream sentence simplification task, and achieve the state of the art (CARD-660). Altogether, our results demonstrate our system's effectiveness for out-of-knowledge and rare word generalization.

1 Introduction

Retrofitting word embeddings with a KB (Faruqui et al., 2015; Speer and Chin, 2016; Mrkšić et al., 2017) means taking a vector space of word embeddings and finding a mapping that moves some of these word vectors closer together and others further apart, such that these vectors' new positions in the vector space are in better agreement with the relationships between the same words (a.k.a., concepts) in a KB (Speer and Chin, 2016; Mrkšić et al., 2017). However, the retrofitting process can only work on concepts that are actually present in the KB (a.k.a., constraints), which means that retrofitting can get us improved performance in semantic tasks only on the overlapping vocabulary between the KB and the word embeddings. Post-specialization(Vulić et al., 2018; Kamath et al., 2019) is a solution to this problem; it is a series of techniques that try to (1) learn the mapping that retrofitting establishes and (2) generalize the mapping to the rest of the embedding vocabulary.

We develop and present a post-specialization system called RetroGAN that builds upon the approach presented as AuxGAN (Ponti et al., 2018) by extending it to have a pair of Generative Adversarial Networks (GANs) (Goodfellow et al., 2014). A regular GAN minimizes the loss when learning the function for post-specialization. Our pair works in a cyclic manner to minimize the losses of both the post-specialization and the inverse to ensure that there is a one-to-one mapping between the two domains. This constrains the outputs for unseen data in both domains and leads to achieving higher performance for unseen concepts.

2 Related Work

Within the field of retrofitting, work has been done in exploring the various ways of infusing constraints or KBs into word embeddings. The original work by (Faruqui et al., 2015) only used synonymy relationships but not antonymy relationships, which meant that word embeddings with similar (synonymous) semantics in the KB would be pulled together, but word embeddings with dissimilar (antonymous) semantics would not be separated. The Attract-Repel work by (Mrkšić et al., 2017) addressed this shortcoming by incorporating antonymy relationships in a retrofitting procedure: synonymous embeddings are *attracted* to each other, while antonymous embeddings are *repelled* against each other. This line of work was continued with the work done by Lexical Entailment Attract-Repel (Vulić and Mrkšić, 2018)(LEAR),

Word	Distributional Neighbor	Retrofitted Neighbor
Dog	dog, dogs, puppy, pup , canine, pet, doggie, beagle, dachshund, cat	dog, beagle, pooch, dachshund, puppy, mutt, poodle, Rottweiler, canine, labrador
Doggo	pooch, doggies, bae, chihuahua, rad, pug, kitty, dane, furbabies, `\uf602`	doggies, pooch, dachshund, four-legged, Yorkie, corgi, whippet, amigos, Weimaraner, Dog

Table 1: Results of the 10 most similar embeddings for "dog" and "doggo" for FastText embeddings. The distributional neighbors are the closest embeddings in the original distributional space and the retrofitted neighbors are the closest in the RetroGAN post-specialized space. We can see that "doggo" was near slangs such as "bae" and "furbabies", but after post-specialization, it gets closer to words that we regard as semantically similar to "dog." The one-to-one mapping that RetroGAN provides is key to being able to incorporate useful semantic information into rare-words possibly like "doggo".

which looks to add the asymmetric lexical entailment relationship to Attract-Repel. [1]

Building on these works, a series of techniques called *post-specialization* were developed. These techniques consist on utilizing neural models to learn retrofitting mappings such as (Glavaš and Vulić, 2018) and (Ponti et al., 2018; Kamath et al., 2019) which use a Deep Feed-forward Neural Network and a Generative Adversarial Network (GAN) respectively. Post-specialization permits, provided a static word embedding, to generate its retrofitted counterpart on the fly with a trained system. A concrete example is in table 1.

As it stands, attention has been shifted to using contextual embeddings such as those produced from BERT (Devlin et al., 2019) on downstream tasks. Only recently have there been efforts in incorporating external, KB assertions into pre-trained transformer-based systems (e.g., KnowBERT (Peters et al., 2019), Align-mask-select (Ye et al., 2019), and LIBERT (Lauscher et al., 2019)). LIBERT bridges contextual and retrofitted embeddings by leveraging the knowledge in retrofitted embeddings to find lexical tuples that are fed into BERT to focus on their lexical information.

GANs have been utilized extensively in the image domain to create lifelike images. CycleGAN (Zhu et al., 2017) and other cyclic systems (Kim et al., 2017) have been utilized to perform style transfer (i.e. apply certain distinctive characteristics from one image domain into another). CycleGAN serves to learn a, possibly unpaired, one-to-one mapping from one domain to another. To effectively utilize paired data, the work by (Tripathy et al., 2018) modifies the CycleGAN architecture to include a conditional cyclic loss in which new discriminators are conditioned to determine if a generated sample is real or not based on a given, possibly paired, input. This in turn permits leveraging paired data to improve the one-to-one mapping.

3 RetroGAN

RetroGAN is a system that builds on (Ponti et al., 2018) by utilizing a CycleGAN-like architecture (i.e., we use a pair of GANs cyclicly but our layers are different from the original CycleGAN). We chose the CycleGAN-like architecture because, in our domain, the cycle-consistency constraints can enforce a one-to-one mapping from original embeddings to retrofitted embeddings. This mapping guarantees that unseen concepts will have their own, unique retrofitted counterparts. We use RetroGAN to learn the mapping of Attract-Repel (Mrkšić et al., 2017) retrofitting (with the *synonymy* and *antonymy* constraints from the Attract-Repel paper(Mrkšić et al., 2017)) on a subset of static word embeddings (i.e.., FastText (Bojanowski et al., 2017), and Numberbatch (Speer et al., 2017)), and perform post-specialization on the entire set.

3.1 Model & Architecture

RetroGAN consists of two GANs that interplay to balance a combination of losses to transform a particular word embedding $x_i \in X$ from its original domain X to its counterpart $y_i \in Y$ in the retrofitted domain Y, and vice-versa. In both GANs that we employ, the generator consists of an input layer followed by 2 hidden dense layers with 2048 neurons and each followed by a dropout layer (with a percentage of 0.2 for the dropouts), and a final linear output layer with the same dimensionality as the input. The output of this layer, for the trained $G : X \to Y$ produces the post-specialized embeddings (i.e. a batch of 32 FastText embeddings produces 32 post-specialized embeddings). The hidden layers employ the ReLU (Nair and Hinton, 2010) activation function. Our discriminators have a similar structure (an input layer, 2 hidden

---

[1] We do not use LEAR because in the original work, it did not alter the similarity tasks results, but they can be exchanged.

layers with dropout but a percentage of 0.3), however, the second hidden layer is followed by a batch normalization layer and the output is a single neuron with a sigmoid activation. The reason for the batch normalization layer was to stabilize the training. We also utilized a third and fourth conditional discriminator following (Tripathy et al., 2018), to leverage the cyclic architecture on paired data.

A novelty in RetroGAN is the combination of cyclic and non-cyclic optimization objectives: the regular adversarial loss for both GANs (L_{GAN}); the cyclic loss for both generators (L_{CYC}); the identity loss for both generators (L_{ID}); the max margin loss similar to (Weston et al., 2011; Ponti et al., 2018) for both the generators and additionally for the cycle of generators (L_{MM}); and the conditional cycle consistency loss (L_{cCYC}) introduced in (Tripathy et al., 2018). The combined objective has the following form:

$$\begin{aligned} L(G,F,D_X,D_Y) = L_{GAN}(G,D_Y,X,Y)+ \\ L_{GAN}(F,D_X,X,Y) + \lambda L_{CYC}(G,F)+ \\ \gamma L_{ID}(G,F,X,Y) + L_{MM}(G,F,X,Y)+ \\ \varsigma L_{cCYC}(G,F,D_{cX},D_{cY},X,Y) \end{aligned} \tag{1}$$

where $G : X \rightarrow Y$ is the generator that maps the source domain X of plain word embeddings to the target domain Y of retrofitted word embeddings; $F : Y \rightarrow X$ is the generator that does the opposite; D_X and D_Y are the discriminators for the corresponding domains; and D_{cX}, D_{cY} are our cycle conditional discriminators. For brevity, we only go into details on L_{MM} and L_{cCYC}. The other losses are the standard ones found in their respective works: L_{GAN} is the adversarial loss from (Goodfellow et al., 2014). L_{CYC} is the cycle consistency loss from (Zhu et al., 2017) with a scaling factor of λ (which we set to 1); and L_{ID} is the identity loss from (Zhu et al., 2017), which we scale with γ (which we set to 0.01). L_{ID} serves as a check of whether the embedding is already in the correct domain. L_{MM} is the max margin loss with random confounders as used by (Ponti et al., 2018), and as a novel aspect, we add a cyclic margin loss:

$$\begin{aligned} L_{MM}(G,F,X,Y) = \Sigma_{i=1}^{||x||}\Sigma_{j=1|j\neq i}^{k}\tau[\\ (\delta_{MM} - cos(G(x_i),y_i) + cos(G(x_i),y_j))+ \\ (\delta_{MM} - cos(F(y_i),x_i) + cos(F(y_i),x_j))+ \\ \boldsymbol{(\delta_{MM} - cos(G(F(y_i)),y_i) + cos(G(F(y_i)),y_j))+} \\ \boldsymbol{(\delta_{MM} - cos(F(G(x_i)),x_i) + cos(F(G(x_i)),x_j))}] \end{aligned} \tag{2}$$

Equation 2, intuitively, tries to make generated embeddings similar to their gold-standard and different from confounders. RetroGAN further enforces this constraint across the cycle. Lastly, we have L_{cCYC} which is the conditional cycle loss (Tripathy et al., 2018)[2], which we scale with ς (set to 1):

$$\begin{aligned} L_{cCYC}(G,F,D_{cX},D_{cY},X,Y) = \\ E_{x\sim p_{data}}[log(D_{cX}(G(x),x))]+ \\ E_{x\sim p_{data}}[log(1-D_{cX}(G(x),F(G(x))))]+ \\ E_{y\sim p_{data}}[log(D_{cY}(F(y),y))]+ \\ E_{x\sim p_{data}}[log(1-D_{cY}(F(y),G(F(y))))] \end{aligned} \tag{3}$$

3.2 Experimental Setup

To train our system we utilize the ADAM (Kingma and Ba, 2015) optimizer with a learning rate of 5e-5 for the generators and 1e-4 for the non-conditional discriminators. We do not train the discriminators used in the regular GAN loss, and instead train the ones in the conditional cycle consistency loss. We also note that we did not perform explicit fine tuning of the scaling parameters, but we will do so in future work through a grid search. We train for 312,500 mini-batches which is the equivalent to the AuxGAN training, using a batch size of 32.

In our tests we use the English Common Crawl FastText with sub-word information (FT-CC) and Numberbatch 19.08 (NB) to see how performance would be affected by using embeddings that were already retrofitted with a large KB. We ran the Attract-Repel (Mrkšić et al., 2017)[3] procedure on all these embeddings then proceeded to perform our post-specialization tests on learning the mapping from FT-CC to the resulting retrofitted embeddings.

We ran the word similarity benchmarks: SimLex (SL)(Hill et al., 2015) SimVerb (SV)(Gerz et al., 2016), and the Cambridge Rare Word (C660) dataset (Pilehvar et al., 2018). We utilize the Disjoint (evaluating words which were **not seen** in the constraints) and Full (evaluating words which were **seen** in constraints) settings from (Ponti et al., 2018) for SL and SV, and evaluate C660 on the Full setting to test performance on rare words. The maximum values for the similarity benchmarks while training are listed in table 2.

We trained the publicly available AuxGAN model on 10 epochs of 1M iterations (which in AuxGAN is a single embedding pair rather than a batch of pairs) with both plain stochastic gradient descent (SGD) and ADAM (learning rate of 0.1) and selected the best performing one (ADAM) to

---

[2] In future work we will additionally incorporate the paired conditional adversarial loss.

[3] We use the default settings found in `https://github.com/nmrksic/attract-repel`

Table 3: Out of knowledge tests: We evaluate the performance of retrofitting and post specialization at varying percentages of test words seen in constraints. The full table can be seen in Appendix B

compensate for convergence speed discrepancies. Additionally, similar to (Ponti et al., 2018) we also evaluated on Light-LS (Glavaš and Štajner, 2015) with the default dataset (Horn et al., 2014) to test downstream performance. We evaluate the accuracy of simplification substitutions(i.e., the amount of words that are substituted correctly when compared to a gold standard). We utilize the first 500k words in FT-CC and the complete Numberbatch (generating the vocabulary's FastText embeddings as the distributional model). To test the retrofitted embeddings we substitute them in the original set.

3.3 Results & Discussion

RetroGAN outperforms AuxGAN in the majority of similarity benchmarks. We note that RetroGAN sets the state of the art on the rare-words benchmark (C660)(previously, to the best of our knowledge, it was 0.543 and 0.55 in (Yang et al., 2019; Fukuda, 2020)). In the similarity results for Full , we note the same observations that were noted in AuxGAN: there are some inconsistent gains and losses, which may be due to the combination of loss functions which may make the systems imprecise; although they spread the knowledge throughout the embeddings, they lose some precision when compared with the original retrofitted embeddings. The results for the lexical simplification (Light-LS) can be seen in table 4 where RetroGAN dominates.

We wanted to compare the out-of-knowledge (OOK) performance more in depth and to do this, we joined the words in SimLex (SL) and SimVerb (SV) and selected increasingly larger amounts of them ({5,10,25,50,75,100}%). We then selected the constraints that included these words, trained RetroGAN and AuxGAN with these constraints, and evaluated performance on SL, SV, and C660. Part of this can be seen in table 3. We see that RetroGAN's performance increases every time that new constraints are added, whereas AuxGAN's performance begins to peak after 25% of the constraints which may indicate more efficient knowledge distribution thanks to the cyclic system. Later on, the performance of RetroGAN kept increasing, but was less than the base retrofitted embeddings, possibly because of the lack of precision from the combination of losses. Lastly, we performed a small ablation study (Appendix A) on RetroGAN's losses. We note that the max-margin loss from (Ponti et al., 2018) is necessary for high performance in all the tests. We also notice that the cyclic (cyclic max-margin and cycle conditional discriminator) losses are essential for improved performance on the OOK and rare-word similarity benchmarks. We also see that the removal of the cyclic max-margin loss speeds up early learning and its addition stabilizes later learning respectively which may indicate a need to balance this. Future work will explore how to balance this losses, but it may be possible to put a scheduler to enable the loss after a peak. More details on the ablation study can be found in Appendix A.

Models	FT-CC	NB
Distributional	0.6553	0.6974
Attract-Repel	0.6993	0.6874
AuxGAN	0.7214	0.7335
RetroGAN	**0.7595**	**0.7735**

Table 4: Light-LS accuracy on (Horn et al., 2014)

4 Conclusion

This work presents an improvement on post-specialization work through the use of a CycleGAN-like system called RetroGAN. We show that RetroGAN gives improved performance in both the Full (words which were seen in knowledge/constraints) and the Disjoint (words which were **not** seen in the constraints) evaluation settings for three benchmarks. It additionally has better performance on a downstream lexical simplification task, further confirming its improved generalization ability. We conclude that RetroGAN is an improved system for post-specializing embeddings for rare and OOK concepts.[4]

A Ablation Tests

We performed a small ablation study to examine how the multiple losses in RetroGAN affect performance. A one-by-one removal of these can be seen in figures 2(a),2(b),2(c),2(j),2(k),2(l). A toggle of each of the losses can be seen in: 2(a),2(b),2(c),2(j),2(k),2(l). The difference between the toggle and one-by-one removal is that in the toggle, we simple turn off the specified loss and leave the others untouched, whereas in the one-by-one removal we turn off one-by-one the losses, in this way we can see the individual effects, and the group effects. We evaluated the FT-CC and the Attract-Repel retrofitted FT-CC in the same scenarios as the evaluations before (Disjoint and Full). We note that the Disjoint setting for Card includes some of the words in the constraints.

The max margin loss utilized by (Ponti et al., 2018) (*one_way_maxmargin_loss*) is essential for high performance on the datasets. Without this loss, in all of the figures, we see that the scores in all our tests fall by at least by 0.1. This is seen in both the toggle and the one-by-one case. We can also see that the Cyclic version of this loss (*cycle_maxmargin_loss*) slows down learning initially, but stabilizes it in later iterations. We can see that by removing it we get higher performance in earlier iterations but the performance decays as more iterations are given. This may be because it tries to enforce that the semantic components of the embeddings be similar after going through the cycle, but it may be a hard objective to achieve. This loss is especially useful for the rare-word Card-660 evaluation. By looking at the toggle ablation test for this loss, we can see that it indeed can lead to better earlier performance, however it decays with time.

The identity loss (*id_loss*) helps to stabilize the training in later iterations. Removal of this loss significantly affects the disjoint settings, and the reason for it may be that it gives some indication of the important semantic components of the vectors that are being post-specialized. This in the disjoint setting leads to significant performance reductions on the later iterations. Interestingly enough, by toggling off only this loss, we can see that it leads to better performance, which means that with all the other losses, it may contain redundant information that may hinder performance, however if the model relies on the loss without other losses, its information is useful.

The Cycle Conditional discriminator loss (*cycle_discriminator_loss*) also contributes to the stability and generalization of the later learning. Removing this loss does not improve early learning, save on the Card-660 dataset, and in most of the other tests, there is not a large noticeable difference. However, on the disjoint setting we do see that it performance decays in later iterations. We suspect the conditioning helps slightly in the stabilization, and generalization of the system, but its effect is not too much.

The Cycle Loss (*cycle_mae_loss*), also stabilizes and helps in the generalization of our system. We can see in the disjoint settings in particular, that its removal hinders the model in later iterations. We suspect that since the consistency is not being enforced, the model does not learn effectively to preserve important, possibly non-semantic, parts from the distributional and the retrofitted domain.

As a practical recommendation, we suggest removing the cyclic max-margin loss either completely (pausing the training early at it's peak around 50k-100k iterations), or toggling it after this initial training to get the speedup and the generation. Another practical recommendation may be to disable the identity loss all by itself. The other losses can be maintained as they are described in this work.

B Out-of-knowledge Scalability Tests

In table 5 we test the performance of post specialization as more constraints are added into the retrofitting process. We note that AuxGAN's performance saturates after 50% whereas RetroGAN keeps learning, albeit less accurately than the retrofitting system. These tests were run for 100k batches on RetroGAN and for 10M iterations (312500 RetroGAN batches) on AuxGAN.

C Additional embedding pre-processing

Input and output vectors are divided by the Euclidean (2) norm. This helps slightly in the performance of the semantic comparison benchmarks. No other pre-processing is done on the vectors.

D Architecture Details

In figure 1, we can see the architecture that RetroGAN uses. On a training step, the losses are calculated as follows. For the cyclic losses, the system samples embeddings from the distributional embeddings and their retrofitted counterparts and these samples are passed to the generators (1, 5 in the figure). Then, the generators' output is passed to the counterpart generator (Distributional Generator passes to Retrofitted Generator and vice versa, seen as 3 in the figure). The output of this is then used to calculate the max margin loss, and passed on to the subsequent discriminator to calculate the cycle discriminator loss (2, 4 in the figure). In addition to this, after going through the cycle of generators (1 or 5, 3 in the figure) we train the conditional discriminators by conditioning on real inputs from the retrofitted or distributional embeddings, or by conditioning on fake inputs (6,7 in the figure).

The amount of parameters in each model and the layers can be found in table 6.

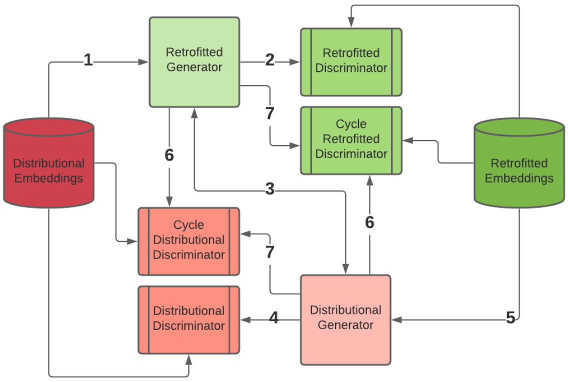

Figure 1: Architecture diagram for RetroGAN

E Parameter Tuning

We performed a parameter tuning using the Ray tuning library, to try and generate a configuration that would be optimal for RetroGAN. We utilized the ASHA Scheduler(Li et al., 2020) along with the following search space configuration:

```
config = {
"g_lr" : tune.qloguniform(0.00005,
.1,0.00005),
"d_lr" : tune.qloguniform(0.00005,
.1,0.00005),
"one_way_mm":True,
"cycle_mm":True,
"cycle_dis":True,
"id_loss":True,
"cycle_loss":True,
"batch_size":tune.choice([16,32,64]),
"generator_size":tune.choice([512,
1024,2048]),
"discriminator_size":
tune.choice([512,1024,2048]),
"generator_hidden_layers":
tune.choice([1,2,3]),
"discriminator_hidden_layers":
tune.choice([1,2,3]),
"dis_train_amount":
tune.choice([1,2,3])
}
```

We used the SimVerb score to guide the parameter optimization, because it was the score that involved the largest sample of words. We also utilized a machine with two Intel processors with 48 cores in total, 128GB of RAM, an NVIDIA P6000 and a NVIDIA 1080TI. We used 25 samples in the optimization due to time constraints, although this value can be expanded more. We also ran this for 35 epochs, because the performance after that would become relatively stable and not increase greatly.

The best results from the optimization are the following:

```
{
’g_lr’: 0.00495,
’d_lr’: 0.00885,
’one_way_mm’: True,
’cycle_mm’: True,
’cycle_dis’: True,
’id_loss’: True,
’cycle_loss’: True,
’batch_size’: 32,
’generator_size’: 2048,
’discriminator_size’: 2048,
’generator_hidden_layers’: 1,
’discriminator_hidden_layers’: 3,
’dis_train_amount’: 1
}
```

Abstract

ICD coding aims to automatically assign International Classification of Diseases (ICD) codes from unstructured clinical notes or discharge summaries, which saves human labor and reduces errors. Although several studies are proposed to solve this challenging task, none distinguishes the importance of different phrases with a word window. Intuitively, informative phrases should be more useful for the prediction. This paper proposes a feature compressed ICD coding model named Fusion to address this issue. In particular, we propose an attentive soft-pooling approach to compress the sparse and redundant word representations into informative and dense ones as local features. Besides, we use the key-query attention mechanism for modeling the inner relations among local features to generate the global features, which are further used to predict ICD codes. Experiments on two widely used datasets demonstrate that Fusion outperforms baselines. However, on the MIMIC-III Full dataset, we find that none of the state-of-the-art approaches significantly perform better than others. Thus, automated ICD coding is still a challenging task.

1 Introduction

The International Classification of Diseases (ICD) coding system helps standardize the recording of diagnoses and treatments assigned to patients by medical professionals in the world. These ICD codes are generated from massive unstructured clinical notes. However, manual code assignments is labor-intensive and prone to errors. Thus, automatic ICD code assignment becomes an urgent need in the healthcare domain.

Traditional machine learning methods (Larkey and Croft, 1996) tried to tackle this task based on feature extraction. However, it does not work well since clinical notes are noisy and complex. Recently, deep learning-based approaches (Cao et al., 2020; Xie et al., 2019; Li and Yu, 2020; Mullenbach et al., 2018) are proposed to improve its performance. Among others, convolutional methods (Cao et al., 2020; Xie et al., 2019; Li and Yu, 2020; Mullenbach et al., 2018) outperform other approaches. Besides, some studies try to incorporate external information to further improve the performance (Cao et al., 2020; Xie et al., 2019). However, they still suffer the following issues.

- **Redundant Information Deduction**. The clinical notes are noisy and complex, where only some key phrases are highly related to the coding. However, convolutional methods treat all the word windows equally, ignoring that different words have different importance and should be weighted differently within word windows. Besides, the sliding windows used in the convolutional methods produce a lot of redundant information. Thus, it is important to reduce the non-informative and redundant information and distinguish the contributions of different convolutional features.

- **Interactions among Local Features**. Most existing approaches such as MultiResCNN (Li and Yu, 2020) only use the local features for coding obtained using different filters. However, they ignore the importance of interactions among different local features. For example, *sleep apnoea (OSA)* and *insomnia* are related to *hypertension* and *ischaemic heart disease* (Harrison and Wood, 1949). Thus, combining different local features may discover new useful patterns to improve coding.

To tackle these issues, we propose a feature compressed ICD coding model named Fusion, which can automatically compress the local fea-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2096–2101
August 1–6, 2021.

tures and further learn global features to enhance the coding performance. In particular, Fusion takes an attention-based soft-pooling approach to compress local features learned by word convolutions, passing residual convolution blocks. By aggregating all the local features from different convolutional filters, Fusion then applies key-query attention mechanism to model interactions among local features and obtain global ones. A code-wise attention mechanism is then used to learn a feature vector associated with each ICD code. This vector is finally used to make a prediction. Experiments on two public datasets show that Fusion outperforms state-of-the-art baselines over five evaluation metrics. Moreover, we find that none of the existing approaches outperforms others on the MIMIC-III Full dataset. Thus, automated ICD coding is still an open challenge.

2 Related Work

Traditional machine learning models have been applied to automatically extract ICD codes using the hand-crafted feature vectors as the inputs (Larkey and Croft, 1996; Gundersen et al., 1996; Franz et al., 2000; Pestian et al., 2007; Farkas and Szarvas, 2008). However, they did not achieve satisfactory performance due to the difficulty of extracting useful features from complex and noisy clinical notes. Deep learning models have shown their superiority for this task, including recurrent-based deep models (Shi et al., 2017; Li et al., 2018; Xu et al., 2019) and convolution-based models (Kim, 2014; Mullenbach et al., 2018; Cao et al., 2020; Li and Yu, 2020). In general, convolutional models perform better than recurrent-based ones. Several studies try to incorporate advanced pretrained language model BERT (Devlin et al., 2019), ICD code descriptions (Wang et al., 2018; Mullenbach et al., 2018; Xie and Xing, 2018; Li and Yu, 2020), ICD code structure (Wang et al., 2020; Cao et al., 2020), and knowledge graph (Cao et al., 2020; Xie et al., 2019) to improve the performance.

3 Model

The goal of automated ICD coding is to predict a set of unique ICD codes $\mathcal{Y}$ from the code set $\mathcal{C} = \{c_1, c_2, \cdots, c_s\}$ when given clinical note $D = \{w_1, w_2, \cdots, w_n\}$, where $\mathcal{Y} \subseteq \mathcal{C}$, s is the number of unique ICD codes, and n is the number of words in D. This task is challenging since s is very large, which is over 15,000 for ICD-9 codes and 60,000 for ICD-10 codes, respectively. Besides, extensive noisy information exists in the clinical note D.

To solve these challenges, we propose a feature denoised model (Fusion) for automated ICD coding as shown in Figure 1. This model consists of five modules: the input layer, the compressed convolutional layer, the feature aggregation layer, the code-wise attention layer, and the prediction layer. Next, we introduce the details of each module in the following subsections.

3.1 Input Layer

We take the clinical note $D = \{w_1, w_2, \cdots, w_n\}$ as the model input. For each unique word w_i, word2vec (Mikolov et al., 2013) is used to pretrain its embedding, which is denoted as $\mathbf{e}_i$, a d_e-dimensional embedding. Thus, the input of Fusion is a matrix $\mathbf{D} = \{\mathbf{e}_1, \mathbf{e}_2, \cdots, \mathbf{e}_n\}$.

3.2 Compressed Convolutional Layer

Given the input data $\mathbf{D}$, the compressed convolutional layer aims to learn dense and informative word representations, which are further used to learn the clinical note representation. In particular, we first use convolutional neural networks (CNN) to learn word representations and then propose an attention-based soft-pooling approach to compress those representations. Finally, residual convolution blocks (He et al., 2016) are introduced as MultiResCNN (Li and Yu, 2020) on top of the compressed features.

3.2.1 Word Convolution

CNNs are powerful for text classification tasks (Kim, 2014) that they have multiple filters with different kernel sizes (i.e., word windows) to capture diverse patterns. Let m be the number of filters. The kernel of each filter f_i is denoted as k_i. Thus, we can apply m different 1-dimensional convolutions on the input data $\mathbf{D}$. For the i-th filter, we have

$$\mathbf{x}_j^i = conv(\{\mathbf{e}_j, \mathbf{e}_{j+1}, \cdots, \mathbf{e}_{j+k_i-1}\}; \mathbf{W}_x^i), \quad (1)$$

where $conv(\cdot;\cdot)$ represents the 1-dimensional convolutional operation, and $\mathbf{W}_x^i$ denotes the learned parameter.

3.2.2 Attention-based Soft-pooling

The word convolutional operation uses sliding windows, which produces redundant information existing in adjacent word representations. Thus, to

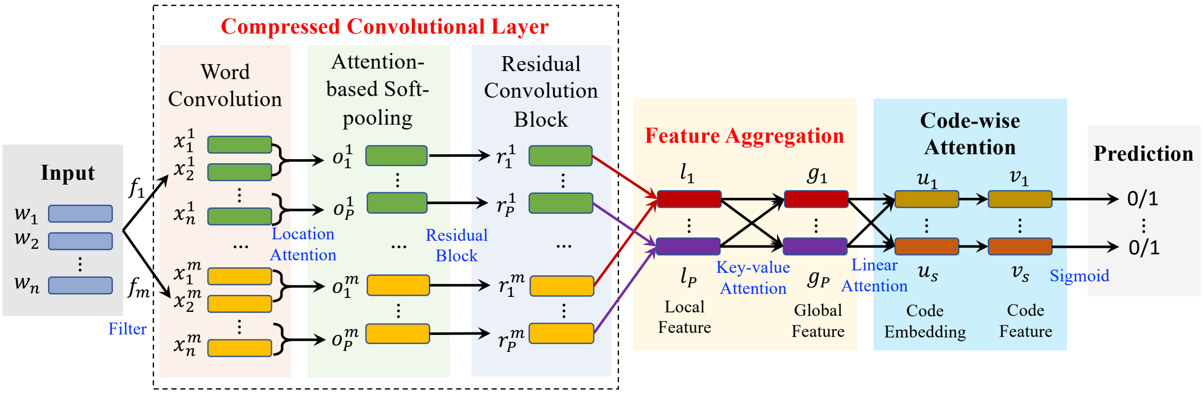

Figure 1: Overview of the proposed Fusion.

remove such information, we propose to compress word representations learned by Eq. (1) via an attention-based soft-pooling operation.

Given a word w_j, its neighboring words $\{w_{j+1}, \cdots, w_{j+g-1}\}$, and the corresponding filter f_i, we first learn the local-based attention scores $\alpha_j^i = \mathbf{W}_\alpha^i \mathbf{x}_j^i + b$ with softmax function, i.e., $[\beta_j^i, \cdots, \beta_{j+g-1}^i] = softmax([\alpha_j^i, \cdots, \alpha_{j+g-1}^i])$, where $\mathbf{W}_\alpha^i$ and b are learnable parameters. Then we conduct attention-based soft-pooling on the g words and obtain the compressed representation as in Eq. (2).

$$\mathbf{o}_p^i = \sum_{q=j}^{j+g-1} \beta_q^i \mathbf{x}_q^i \tag{2}$$

In such a way, the whole n word representations learned by Eq. (1) will be replaced by $P = \lceil \frac{n}{g} \rceil$ new representations, i.e., $\{\mathbf{o}_1^i, \mathbf{o}_2^i, \cdots, \mathbf{o}_P^i\}$. In such a way, we can reduce the number of word representations and obtain more dense ones.

3.2.3 Residual Convolution Block

For each filter f_i, we now have a denoised matrix $\{\mathbf{o}_1^i, \mathbf{o}_2^i, \cdots, \mathbf{o}_P^i\}$ that represents the input $\mathbf{D}$. To avoid vanishing gradients and train the model easier, we also introduce residual blocks on top of the compressed features. In particular, we replace the batch norm layer with the group norm layer. Let a denotes the number of residual blocks, and we have $\mathbf{r}_p^i = ResidualBlcok(\{\mathbf{o}_p^i, \cdots, \mathbf{o}_{p+a-1}^i\})$.

3.3 Feature Aggregation Layer

Since m filters are used to obtain m compressed features, we concatenate them together as the local features, i.e., $\mathbf{l}_p = [\mathbf{r}_p^1, \cdots, \mathbf{r}_p^m]$. Then the whole document can be represented by a matrix $\mathbf{D}_l = \{\mathbf{l}_1, \mathbf{l}_2, \cdots, \mathbf{l}_P\}$. However, such an aggregation only takes local information into account but ignores the interactions with the remaining words.

Thus, we propose to use the key-query attention mechanism (Vaswani et al., 2017) to learn a global feature representation for each compressed word window. Thus, we have the global features $\mathbf{D}_g = [\mathbf{g}_1, \cdots, \mathbf{g}_P] = attention([\mathbf{l}_1, \cdots, \mathbf{l}_P])$.

3.4 Code-wise Attention Layer

Due to a large number of labels, directly using the global features $\mathbf{D}_g$ to make predictions may not perform well. Thus, we use a code-wise attention layer to generate a matching vector for each ICD code used to make a prediction. Let $\mathbf{u}_k$ represent the embedding of the k-th ICD code, i.e., c_k. Then we calculate the attention weights on all the global features using $\mathbf{u}_k$, i.e., $[\gamma_1^k, \cdots, \gamma_P^k] = softmax([\mathbf{u}_k \mathbf{g}_1, \cdots, \mathbf{u}_k \mathbf{g}_P])$. Then the code-wise vector can be obtained by $\mathbf{v}_k = \sum_{p=1}^{P} \gamma_p^k \mathbf{g}_p$.

3.5 Prediction Layer

Using the code-wise vector $\mathbf{v}_k$, we can make a prediction using the sigmoid function, i.e.,

$$\tilde{y}_k = (1 + \exp(\mathbf{w}_k^\top \mathbf{v}_k))^{-1}, \tag{3}$$

where $\mathbf{w}_k$ is the learnable parameter vector. Finally, cross-entropy loss function on a specific clinical note $\mathbf{D}$ is used to optimize the proposed model.

$$\mathcal{L} = -\sum_{k=1}^{s} (y_k \log(\tilde{y}_k) + (1 - y_k) \log(1 - \tilde{y}_k)). \tag{4}$$

4 Experiment

4.1 Datasets

We conduct experiments on two public datasets MIMIC-III 50 and MIMIC-III Full (Johnson et al.,

Table 1: Experiment results on MIMIC-III 50 and MIMIC-III Full datasets.

2016) to extract ICD-9 codes from discharge summaries. We use the same setting as previous works (Mullenbach et al., 2018; Shi et al., 2017; Li and Yu, 2020; Cao et al., 2020). The MIMIC-III 50 dataset contains the top 50 most frequent codes, 8,067, 1,574, and 1,730 discharge summaries for training, development, and testing, respectively. The MIMIC-III Full dataset consists of 8,921 codes, 47,719, 1,631, and 3,372 discharge summaries for training, development, and testing, respectively. The number of labels on the MIMIC-III Full dataset is significantly greater than that on the MIMIC-III 50 dataset, making the task more difficult.

4.2 Metrics and Parameter Settings

We follow previous work (Mullenbach et al., 2018) and use Micro Macro AUC (area under the ROC), Micro Macro F1, and Precision@K scores as metrics. For MIMIC-III 50, we report Precision@5 (P@5) and P@8 for MIMIC-III Full. We use the same parameter setting as MultiResCNN (Li and Yu, 2020)[1], and set g as 2 in our experiments, i.e., compress two features together.

4.3 Baselines

Existing studies either only take clinical notes as the inputs or incorporate external information, working with notes to enhance the performance. Our work belongs to the first category. For the "note only" category, we employ C-MemNN (Prakash et al., 2017), C-LSTM-ATT (Shi et al., 2017), CAML (Mullenbach et al., 2018), DR-CAML (Mullenbach et al., 2018), and MultiResCNN (Li and Yu, 2020) as baselines. We also use HyperCore (Cao et al., 2020), and MSATT-KG (Xie et al., 2019) as baselines, which incorporate the ICD code ontology to enhance the performance. Since all the approaches use the same settings, we directly use the results reported in the original papers.

4.4 Performance Analysis

Table 1 shows the experimental results of all approaches in terms of different metrics. We can observe that Fusion outperforms all the baselines on the MIMIC-III 50 dataset in terms of all metrics. Compared to the best baselines, the scores of Macro Micro F1 and P@5 obtained by Fusion improve over 7%, 6%, and 5%, respectively. These results clearly demonstrate the effectiveness of the proposed feature compression and aggregation approaches for the automated ICD coding task.

Compared with the baselines only taking notes as the input, the proposed Fusion achieves the highest scores on the MIMIC-III Full dataset. Although HyperCore and MSATT-KG incorporate external information to improve the performance, the performance of Fusion is still comparable. We also can observe that on the MIMIC-III Full dataset, none of the methods can be significantly better than others. The reason may be that all the models cannot be trained sufficiently with the huge number of ICD code labels on noisy, sparse, and unstructured medical clinical notes, which makes this task more challenging.

4.5 Ablation Study

In this section, we remove parts of the full Fusion model to validate the contribution of each individual module. Table 2 shows the ablation study results. "MaxPool" means replacing our soft-pooling layer with the traditional max-pooling layer. As shown in Table 2, the results drop on all metrics, which indicates the importance and benefits of using the proposed soft-pooling layer. Max-pooling will lose part of critical information during the compression and is not differentiable. With soft-pooling, the key information can be better preserved during the compression process, since

Table 2: Ablation Experiment results on MIMIC-III 50 and MIMIC-III Full datasets.

the selection process is guided by the gradient.

"DocLevel" refers to replacing the code-wise attention layer with the single document-level attention. The attention is based on the document feature, and all codes use the same attention weight during the prediction instead of calculating code-specific attention weights. Thus, all codes will use the same feature for the prediction. In such a way, much unrelated information will also be kept. For example, we do not want to preserve the heart-failure-related information while predicting the COPD code. As a result, most scores drop significantly compared to the original design. The introduction of the code-specific attention makes it possible that the predictor can dynamically adjust the attentions based on the cases. Thus, the redundant information can be better removed with our design.

5 Conclusion

In this paper, we propose Fusion for the automated ICD coding task. In particular, Fusion focuses on compressing redundant feature information, distinguishing the importance of adjacent phrases, and considering interactions among local features. We conduct experiments on two widely-used datasets to show the effectiveness of Fusion in terms of five evaluation metrics. From experimental results on the MIMIC-III Full dataset, we find that automated ICD coding is still challenging due to the noisy data and a large number of ICD code labels.

Abstract

The advent of large pre-trained language models has made it possible to make high-quality predictions on how to add or change a sentence in a document. However, the high branching factor inherent to text generation impedes the ability of even the strongest language models to offer useful editing suggestions at a more global or *document* level. We introduce a new task, DOCUMENT SKETCHING, which involves generating entire draft documents for the writer to review and revise. These drafts are built from sets of documents that overlap in form – sharing large segments of potentially reusable text – while diverging in content. To support this task, we introduce a Wikipedia-based dataset of analogous documents and investigate the application of weakly supervised methods, including use of a transformer-based mixture of experts, together with reinforcement learning. We report experiments using automated and human evaluation methods and discuss relative merits of these models.

1992 Democratic National Convention

2016 Democratic National Convention

From Wikipedia, the free encyclopedia

The **2016 Democratic National Convention** was a presidential nominating convention, held at the Wells Fargo Center in Philadelphia, Pennsylvania, from July 25 to 28, 2016. The convention gathered delegates of the Democratic Party, the majority of them elected through a preceding series of primaries and caucuses, to nominate a candidate for president and vice president in the 2016 United States presidential election. Former U.S. Secretary of State Hillary Clinton was chosen as the party's nominee for president by a 54% majority of delegates present at the convention roll call, defeating primary rival Senator Bernie Sanders, who received 46% of votes from delegates, and becoming the first female candidate to be formally nominated for president by a major political party in the United States. Her running mate, Senator Tim Kaine from Virginia, was confirmed by delegates as the party's nominee for vice president by acclamation.

1 Introduction

Large pre-trained language models such as T5 and GPT-3 (Raffel et al., 2019; Brown et al., 2020) have enabled impressive progress on a variety of natural language generation tasks by producing fluent, coherent long texts (Rashkin et al., 2020; Zellers et al., 2019). While automated document-level generation seems tantalizingly within reach, a high branching factor presents significant challenges in tailoring generated documents to the specific requirements of users. Topic drift and "hallucination" of information are endemic to these models (Wiseman et al., 2017). These risks have ensured that end-user applications involving text generation (e.g., Smart Compose, Smart Reply, Grammarly) still require a human to remain in control of content and are restricted to individual sentences or even smaller segments of text (Chen et al., 2019; Kannan et al., 2016; Alikaniotis and Raheja, 2019; Prabhumoye et al., 2019; Faltings et al., 2021).

Can large generative language models be used to assist user writing at the document level while the user still controls the factual content? A possible answer lies in the observation that a substantial portion of day-to-day writing involves some form of reuse. Similar documents (e.g., monthly reports, sales letters, job descriptions) are effectively recycled by changing those segments that need to be modified (Fig. 1).[1] Moreover, documents containing analogous texts are often found collocated in repositories, a common practice for organizations that manage professional documents.[2] The high branching factor that impedes the application of long-form generation might thus be mitigated if models were to exploit conventionally-structured analogous "reusable" texts to produce a "sketch" that captures prototypical document-level text structure. In this view, initial sketches would assist authors by reducing the manual editing effort

(planning, inserting and deleting content, etc.). A good sketch would reflect structural patterns and reusable text, and provide indication, beyond static boilerplate, of locations where user input might be warranted. This could be especially beneficial for novice writers who would otherwise have to read many analogous documents before developing a full picture of what is entailed in writing such documents.[3] A fully-implemented dynamic system might update other portions of the document to reflect modifications introduced by the user.

In this work, we propose a new task, called DOCUMENT SKETCHING, in which initial template-like prototype documents are generated from collections of analogous documents. To support this task, we collected a dataset consisting of approximately 20K Wikipedia documents with similar textual characteristics.[4] For this new task, inspired by previous work in measuring machine translation post-editing productivity (Tatsumi, 2009; Specia and Farzindar, 2010), we define an automatic evaluation metric based on Word Error Rate (Snover et al., 2006; Tomás et al., 2003). We compare against strong baseline models including a mixture of experts model and a reinforcement learning approach designed to handle multi-source inputs and a weak supervision setting. Finally, we provide experimental analysis of these models, using automated and human evaluation studies.

2 Related Work

2.1 Document Generation

Recent work leverages the success of large pretrained language models to generate long texts such as stories (Rashkin et al., 2020), reviews (Cho et al., 2019a,b) and fake news (Zellers et al., 2019). Most end-user applications for assisting user writing, however, are confined to sentence-level generation (Chen et al., 2019; Kannan et al., 2016; Alikaniotis and Raheja, 2019; Prabhumoye et al., 2019; Faltings et al., 2021). Our work focuses on *document-level* writing assistance in which a document sketch is constructed from a set of similar documents.

2.2 Template-Based Generation

Some existing work induces templates as an intermediate step for performing tasks like text summarization or response generation. Most use a retrieval-based method to extract similar references from the training corpus as prototypes (Cao et al., 2018; Yang et al., 2019; Wang et al., 2019; Gao et al., 2019; Peng et al., 2019), and learn to separate salient information and latent template structure. Cai et al. (2019) induce an intermediate template for response generation explicitly, but from a single retrieved relevant response. Similar prototype editing work (Guu et al., 2018; Hashimoto et al., 2018; Fabbri et al., 2020) focuses on short text (e.g., a question or a single sentence) or structured output (e.g., code snippet) editing. Oya et al. (2014); Magooda and Litman (2019); Yang et al. (2020); Li et al. (2018) convert each single input text into a template with blanks using rule-based methods. Other work such as (Wiseman et al., 2018) and (Gangadharaiah and Narayanaswamy, 2020) relies on a knowledge base or a domain/task specific ontology to segment text sequences into templates.

2.3 Multi-Sequence Processing

Multiple Sequence Alignment (MSA), widely used in the biological domain (Sauder et al., 2000) to align multiple biological sequences like proteins, has long been leveraged for text pattern matching (Barzilay and Lee, 2003; Alonso et al., 2004). We adopt this method to align input documents and create heuristic templates as weak supervision.

Other tasks taking multiple text sequences as input include multi-document summarization, which seeks to generate an abstractive text summary of multiple input documents (Liu and Lapata, 2019; Chu and Liu, 2019), and multi-source machine translation (Nishimura et al., 2018; Garmash and Monz, 2016) that encodes input texts in multiple source languages and translates them into a target language. Cho et al. (2021) generate a question from input documents by applying a multi-encoder model with a transformer-based coordinator.

3 Problem Definition

We introduce the task of document sketching, which aims to facilitate the authoring process by generating a template-like document draft, based on a collection of sampled similar documents. Formally, the task can be defined as follow: given a set of n documents $X = \{x_1, x_2, ..., x_n\}$, generate

---

[3] Our experiments in Section 6 also show that drafts derived from multiple analogous documents are more effective than those derived from one or two documents.

[4] We release our data and source code for dataset construction and experiments at `https://github.com/ellenmellon/document_sketching`.

a text sequence s that can be used as the sketch to reduce the human effort involved in composing a target document y.

Evaluation Metrics As in most text generation tasks, we rely on human evaluation (see details in Section 6.3) to draw final conclusions on system comparison. However, due to the high cost of human evaluation, we use automatic evaluation metrics for system development.

It is difficult (and expensive) to collect human-written sketches as references. However, since a generated sketch s is used to help the user complete writing a target document y (i.e., post-editing), we can instead use the target document as a reference and calculate the extra edits required to transform a sketch into that target document. Inspired by the previous uses of word error rate (WER) in evaluating machine translation (Snover et al., 2006; Tomás et al., 2003) and evidence of reasonable correlation between WER and human post-editing productivity (Tatsumi, 2009; Specia and Farzindar, 2010), we propose to assess the effectiveness of s in the completion of y based on WER and the Levenshtein distance (abbreviated as 'lev') between s and y:

$$\begin{aligned}\mathrm{score}(s, y) &= 1 - \mathrm{WER}(s, y) \\ &= 1 - \frac{\mathrm{lev}(s, y)}{|y|}\end{aligned} \tag{1}$$

The higher $\mathrm{score}(s, y)$ is, the fewer minimum number of word-level insertion and deletion edits a user would need to complete writing y if starting from s. To account for the lexical and phrasal variety of writing a target document, we calculate the average score of multiple reference documents Y:

$$\mathrm{score}(s, Y) = \frac{1}{m}\sum_{i=1}^{m}\left(1 - \frac{\mathrm{lev}(s, y_i)}{|y_i|}\right) \tag{2}$$

where $Y = \{y_1, y_2, ..., y_m\}$ and m denotes the number of reference documents.

4 Data

We collect our dataset from the English Wikipedia dump (June 20, 2020). We first group documents into collections with analogous texts, with the observation that articles with shared reusable structural texts also tend to have similar titles. These collections are then split into training, validation and test sets. This dataset is designed for a weakly supervised setting, as gold sketches are unavailable.

% Percent (Category)	Example Collection Titles
90.0 (reasonable)	__ Academy Awards; Super Bowl __
10.0 (arguable):	
5.8 (partial name)	Bob __ (ice hockey)
2.9 (X of a location)	__ of the United States
1.4 (other)	Origin of the __

Table 1: Quality analysis of over 200 randomly selected document collections.

4.1 Wikipedia Document Collections

We observe that Wikipedia article titles provide a strong indication of whether documents are likely to share structural text (i.e., can be put in the same collection) or not. For example, it is reasonable to consider articles with titles like "Super Bowl I", "Super Bowl II" and so on to comprise a document collection of the annual championship game. Therefore, we group documents whose titles are identical but for one token at a specific position. In the "Super Bowl" example, the document titles are the same up to the third token in each title, and the collection can be named "Super Bowl __". It is worth noting that collecting these articles based on their titles is simply reflective of how similar documents in Wikipedia tend to cluster. Our task setup only requires a set of references as the input (e.g., documents organized in the same directory), without the need to have reference documents to share titles.

Title matching can yield noise in the extracted document collections, so we apply simple yet effective restrictions in the extraction pipeline. We empirically set the minimum number of documents per collection to 15 and the minimum document title length to 3 tokens. We randomly select and inspect over 200 extracted collections, and find 90% of them contain analogous documents for a certain topic (examples in Tab. 1). The remaining 10% are less clear, but can be usefully grouped into 3 classes as in Tab. 1. To further reduce noise in each collection, we apply Eq. (2) to calculate the average similarity score of each document with the other documents in a collection, removing those with an average score lower than an empirically chosen threshold -1.5. Finally, we keep document collections with more than 5 documents and truncate them to a maximum of 50 documents, which are divided into train, validation, and test sets in the ratio of 0.8/0.1/0.1. The collection statistics are summarized in Tab. 2.

	Train	Valid	Test	Overall
# Collections	15.7k	2.0k	2.0k	19.7k
# Docs / Collection	21.1	21.3	21.0	21.1
# Tokens / Doc	80.6	79.3	80.3	80.5

Table 2: Document Collection Statistics.

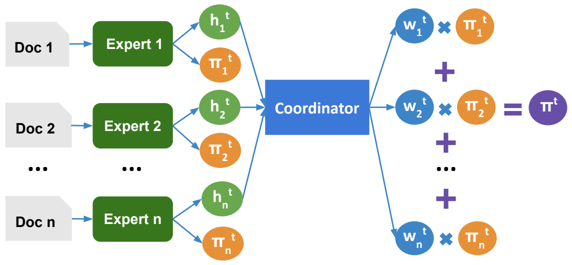

Figure 2: Mixture of Experts (MoE) Framework.

4.2 Task Data Points

We divide each document collection into multiple smaller collections of analogous documents. For standard supervised training, each data point consists of 1 document d to construct a heuristic sketch as weak supervision (see details in Section 5) and up to 9 input documents X. For evaluation, additional 4 documents are used as references Y for calculating the score in Eq. (2). Since document collections whose title tokens differ by a number usually contain documents about events or entities of different times, we order the documents in ascending numerical order to imitate practical scenarios where humans sketch a document by looking at collections of previously written documents. We divide each collection into data points with up to 14 (=1+9+4) documents for all dataset splits, yielding 24k, 3.1k and 3.0k data points (smaller collections) for train, validation, and test sets, respectively.

5 Approach

Since gold document sketches are not available for supervised training, we first perform weakly supervised training by constructing heuristic sketches as targets. Then we apply reinforcement learning strategies for text generation.

5.1 Weakly-Supervised Learning

Heuristic Labels As described in Section 4, each data point has one document d for creating the weak-supervised sketch. We conduct pair-wise sequence alignment (using the Ratcliff-Obershelp algorithm (Ratcliff and Metzener, 1988)) for d and each input document $x_i \in X$, and count the relative alignment ratio (the number of tokens being aligned divided by $|X| = n$) of each token in d. We retain tokens with this ratio above a threshold and replace other tokens with an ellipsis token to form the heuristic target sketch s given X. Consecutive ellipses are merged. The threshold is empirically set at 0.6, which yields the highest average $\text{score}(s, Y)$ on the validation set.

Mixture of Experts (MoE) To generate an initial document sketch, the model needs to take multiple input documents. The most obvious way to do this is to concatenate all input documents into a single long sequence and feed that into an encoder-decoder model like T5 (Raffel et al., 2019). However, processing long sequences in such models is memory-consuming and lack of structure makes it difficult for the model to perform document-level coordination. We therefore use a mixture of experts (MoE) framework, in which a coordinator decodes a token at one timestamp by taking the hidden state and the output vocabulary distribution from each expert that processes a single document. Fig. 2 shows the overall framework of MoE.

The experts have the same encoder-decoder structure and aim to generate s by each encoding a separate single input document only. All experts share the same model parameters. At each decoding timestamp t, the i^{th} expert encodes x_i as well as previously decoded tokens from a coordinator $\tilde{s}_1 ... \tilde{s}_{t-1}$ (or $s_1 ... s_{t-1}$ during training), and outputs a probability distribution π_i^t over all vocabulary words. The coordinator is a transformer-based encoder that takes the hidden state at the current timestamp h_i^t of each i^{th} expert, and outputs a weight w_i^t with a final linear layer. The output weights are used to calculate a weighted sum of the probability distributions from their corresponding experts $\pi_t = \sum_{i=1}^{n} w_i^t \pi_i^t$, where π_t is the final distribution for generation at timestamp t.

5.2 Reinforcement Learning

We leverage reinforcement learning (RL) to further improve generation quality. For each training example with input X, we generate a sequence $\hat{s}$, which is sampled from the probability distribution at each time step, $p(\hat{s}_t | \hat{s}_1 ... \hat{s}_{t-1}, X)$. We observe that directly optimizing the evaluation function proposed in Eq. (2) at the sequence level, using a vanilla policy gradient (PG) or a self-critical sequence training (TD-SCST) algorithm (Rennie et al., 2017;

Paulus et al., 2018; Pasunuru and Bansal, 2018), can lead to instability during training as the reward cannot be calculated until the end of generation (Celikyilmaz et al., 2018). Therefore, we instead use a token-level incremental reward that is based on the change to the original reward function $r(\hat{s}, Y) = \text{score}(\hat{s}, Y)$ from each sampled token $\hat{s}_t$, given references Y:

$$r_t(\hat{s}_t, Y) = r(\hat{s}_{1...t}, Y) - r(\hat{s}_{1...t-1}, Y). \quad (3)$$

The training objective can be written as:

$$L_{\text{RL}} = \sum_{t=1}^{T} -r_t(\hat{s}_t, Y) p(\hat{s}_t | \hat{s}_1 ... \hat{s}_{t-1}, X) \quad (4)$$

where $T = |\hat{s}|$. Since optimizing RL loss alone runs the risk of compromising the language model (Paulus et al., 2018; Pasunuru and Bansal, 2017), we use a mixed loss as follows:

$$L_{\text{MIX}} = \lambda L_{\text{RL}} + (1 - \lambda) L_{\text{MLE}} \quad (5)$$

where λ is a hyperparameter to be tuned.

6 Experiments

6.1 Setup

To leverage the recent success in such transformer-based generation models, neural generation models in our experiments are initialized with the base version of T5 (Raffel et al., 2019; Wolf et al., 2020), an encoder-decoder architecture pre-trained on a variety of text-to-text tasks.[5] All hyperparameters are tuned on the validation set. For MoE, we first fine-tune T5-base to obtain a "single expert" model to initialize each individual component model of the MoE. The "single expert" is trained by leveraging a sequence-to-sequence objective as in T5, with each of the n training (input, output) pairs: (x_1, s), (x_2, s), ..., (x_n, s) from a data instance. This is followed by training a complete MoE model as described in Section 5. We use greedy beam search as the decoding strategy for all generative models with a beam size of 4 (the default value in T5-base). We observe that consecutive ellipses and uninformative tokens hurt readability. To improve the readability of output sketches, we apply minor post-processing to all models in our experiments: we merge consecutive ellipses if all tokens between them are punctuation or among the 30 most frequent tokens.[6] Sentence-terminating periods are excepted.

Training and Parameters T5 has about 220 million parameters and MoE has about 310 million parameters in total. The average training time is about 20 hours for T5 and about 30 hours for MoE on a single Tesla V100 node (32GB) with 3 epochs. It takes an additional 10 hours to train a single expert in MoE. For MoE+RL, we use 4 V100 nodes and it takes about 2 days for training. During training, we tune batch size, learning rate and warm-up steps for T5. For MoE and MoE+RL, there is a separate pair of learning rate and warm-up steps for the coordinator. Each batch size is tuned within a range of [1, 32] (with no more than 3 values for each model); each warm-up step is tuned at $\{4000, 8000, 16000\}$; each learning rate is tuned in $\{1e^{-5}, 3e^{-5}, 1e^{-4}\}$. For RL training, we observe performance gain only when λ is relatively large, so we tune $\lambda \in \{0.95, 0.97, 0.99\}$ (similar to Celikyilmaz et al. (2018)). In order to avoid the situation where the models learn to not generate ellipses that lead to unreadability, we set the cost for deleting an ellipsis to be much smaller (0.1) in the reward function. In addition, we randomly select three seed values for each model. Each model is trained with the above parameter value combinations. We apply grid parameter search for T5 and MoE, and random search for MoE+RL. Hyperparameters are tuned based on automatic evaluation score (1-WER) on the validation set.

The best hyperparameter configurations for best-performing models were: **T5**: batch size = 2, warm-up step = 4000, learning rate = $3e^{-5}$; **MoE**: batch size = 15, warm-up step = 8000, learning rate = $3e^{-5}$, warm-up step (coordinator) = 4000, learning rate (coordinator) = $1e^{-4}$; **MoE+RL**: batch size = 4, warm-up step = 4000, learning rate = $3e^{-5}$, warm-up step (coordinator) = 4000, learning rate (coordinator) = $3e^{-5}$, $\lambda = 0.99$.

6.2 Systems

Non-neural systems include the following approaches: **Last-pair**: The output is the aligned boilerplate text between the last pair of ordered input documents (as described in Section 4, in cases where the differing title token is time-related, the last pair refers to the most recent two docu-

---

[5] Note that T5 can be easily replaced by Other pre-trained generative models like BART (Lewis et al., 2020) in our model framework.

[6] `https://github.com/first20hours/google-10000-english`

ments); **Last-retrieval**: The last document is retrieved as the initial draft; **MSA**: We apply the multi-sequence alignment approach (Barzilay and Lee, 2003), to align tokens in input documents and replace tokens that have too few alignments (threshold tuned on valid set) with ellipses; **Consensus-MSA**: This resembles how we generate heuristic drafts as weak supervision in Section 5.1. However, instead of using the held-out document d to create the skeleton, we use the input document x_i that gives the highest value of $\sum_{j=1}^{n} \mathrm{score}(x_i, x_j)$.

We evaluate the following neural approaches: **T5 (zero-shot)**: We directly apply T5 without finetuning. We use T5 to encode each input document individually and at each decoding timestamp, we combine probability distributions from all T5 decoders with average pooling. As T5 rarely generates ellipses, we insert an ellipsis token if the probability of the top candidate token w from the combined distribution is below a threshold α that is tuned on the validation set (i.e., $p(w) < \alpha$).[7] We used the "summarize :" prefix in the zero-shot setting, this being is the most similar T5 pre-trained tasks to ours; **T5 (doc-finetune)**: We finetune T5 with all input documents concatenated into a single string input (with a special separator token) and each target document (instead of the heuristic sketch) as the generation target; **T5**: Similar to the *T5 (doc-finetune)* setting, but with the heuristic sketch defined in Section 5 as the generation target; **MoE**: This is the mixture of experts model described in Section 5, also trained with the heuristic sketches as the weak supervision; **MoE + RL**: This is the RL model described in Section 5, with the trained MoE as the warm-start.

6.3 Results

Automatic Evaluation We use the automatic evaluation of Section 3 for system development while relying on human evaluation to draw final conclusions on system comparison. However, we observe reasonable consistency between our automatic and human evaluation results. We report automatic evaluation results in Tab. 3. The first numerical column includes overall results of the test set, and the remaining columns categorize the results into three roughly equi-sized levels of similarity among documents within the input document set, estimated on the basis of average pair-wise edit distance normalized by length.

System	All	Input document similarity High	Med.	Low
last-retrieval	−0.242	0.338	−0.284	−0.733
last-pair	0.147	0.410	0.063	−0.021
MSA	0.149	0.374	0.072	0.012
consensus-MSA	0.202	**0.438**	0.132	0.047
T5 (zero-shot)	0.000	0.000	0.000	0.000
T5 (doc-finetune)	0.050	0.382	−0.014	−0.197
T5	0.182	0.389	0.124	0.044
MoE	0.205	0.411	0.147	0.069
MoE+RL	**0.213**	0.414	**0.158**	**0.077**

Table 3: Automatic evaluation scores (1−WER) of overall test examples and scores categorized by input document similarity levels.

System A	System B	Prefer A	Prefer B
MoE	consensus-MSA	**50.70%**	39.28%
MoE	T5	**46.15%**	42.88%
MoE	MoE+RL	**49.93%**	39.65%

Table 4: Human evaluation scores. A number in bold indicates that the system is significantly better at $p < 0.03$, computed using 10k bootstrap replications.

Among non-neural models, we observe that multi-sequence alignment approaches outperform last-retrieval and last-pair where only one or two input documents are leveraged to produce the initial draft. We also notice that consensus-MSA with a "central" document as the skeleton is more effective than the standard MSA that treats all inputs equally. When directly applying zero-shot T5, we notice that when the threshold α described in Section 6.2 equals 1.0 (i.e., the output is always an empty string), the model can achieve the best score 0. This is partly because that none of the T5 pre-trained tasks is the same as ours. In addition, simply exploiting the generation probability at each decoding timestamp can be problematic. For example, when decoding a frequently-appearing entity with multiple tokens, the first token might have low probability given the preceding context while subsequent tokens can be more probable simply because they frequently appear with the first token. T5 with supervision from the target document (doc-finetune) yields a much lower score than T5 finetuned with the heuristic draft. This is mostly because the complete target document contains much more information than can be inferred from the input; the model learns to hallucinate facts, necessitating heavy deletion by users.

MoE outperforms T5, which indicates that hav-

---

[7] Since the original T5 was not trained with ellipsis as a special token, each T5 decoder uses its own greedily decoded token if an ellipsis is inserted ($p(w) < \alpha$).

Collection Title Target Document	__ Waterford Senior Hurling Championship The '1960 WSHC' was the 60th staging of the WSHC since its establishment by the Waterford County Board in 1897. ing a coordinator to communicate between each individual encoder and decoder effectively improves model performance. We also experiment with coordinators using a simple linear layer and find that transformer-based ones are much more effective. Applying RL on top of a trained MoE model helps further improve the model performance in automatic evaluation. We denote the RL approach as MoE+RL in Tab. 3. Warm-starting RL with a MoE model close to fully-converged gives slightly better results than with an fully-converged MoE model.

The rightmost three columns in Tab. 3 divide test examples into 3 roughly equal-sized levels of similarity among documents within the input document set ('high', 'medium', 'low'). Both last-retrieval and T5 (doc-finetune) models drop dramatically as the input similarity decreases, mostly because they contain a lot of hallucinated content, an issue that is even more severe when there is little overlapping structure or factual content among the input documents. MoE based models are much more robust to low input similarity compared to the baselines. For the group with the most similar input documents, consensus-MSA gives the best score, while MoE based models yield much better performance in the other two groups.

Human Evaluation In order to avoid bias in human judgments, we control possible confounding factors including sequence length and the number of ellipses in a sequence during decoding (Nakov et al., 2012; Guzmán et al., 2015). We apply a tuneable penalty for each confounding factor (at inference time only) for each neural model (Murray and Chiang, 2018) to generate examples for human evaluation, such that the average output length and number of ellipses in each sequence from all neural systems compared in Tab. 4 are almost the same.[8] We notice that such normalization does not affect the automatic evaluation score of each system much and the system ranks do not change.

Human evaluation was conducted using crowd-sourced workers. Judges were presented with paired randomized outputs and target documents, and were instructed to choose their preference for a starting point for writing the target document in order to save editing time.[9] Judgments were based on a five-point Likert scale, and ties were permitted. Four judges evaluated each pair, and metrics were imposed to block poorly performing judges. Sample sizes are 1000 for all system pair comparisons.

Results in Tab. 4 confirm that MoE outperforms consensus-MSA and T5. Although RL helps improve automatic evaluation scores on top of MoE, human judges mostly prefer MoE over MoE+RL. The fact that applying RL can hurt readability (Paulus et al., 2018; Pasunuru and Bansal, 2018) may explain why MoE+RL achieves higher automatic scores yet worse human scores than MoE. We observe that MoE+RL has occasional difficulty predicting where ellipsis tokens should be, which hurts sketch readability. Moreover, since our task is a subjective one (e.g., different preferences for more/less verbose sketches), a customized RL reward (e.g., different cost for deletion and insertion for WER calculation) should be applied in real applications to reflect different user preferences.

6.4 Analysis

We investigated the differences in model performance when the input documents have different similarity scores. When the similarity is lower, models tend to produce drafts that are harder to interpret because they generate a higher percentage of generic or ellipsis tokens, although MoE and MoE+RL are less vulnerable to this. Tab. 7 shows the average percentage of generated ellipsis or punctuation tokens for each system when the input document similarity is high or low. We can see that when the similarity score is higher, the two statistical numbers do not differ greatly between systems, except that MSA has a much higher percentage of ellipses. When similarity is low, MoE and MoE+RL have much lower percentages of ellipses or punctuation, compared with other models.

Tab. 5 shows two examples of system outputs. These examples are from the clusters of high and low input similarity respectively. When the input similarity is high, content tokens from consensus-MSA are included in the target document while the neural models tend to generate more hallucinated tokens. This explains the better score consensus-MSA achieves in the higher input similarity cluster. We also notice that when the similarity is high, consensus-MSA generally has better coverage of overlapped content between input documents, and its generated drafts are on average more than 10% longer than other systems. When the similarity is low, the second example shows that all systems generate shorter outputs due to less shared structure between input documents. In this case, consensus-MSA starts to include more content that does not necessarily appear in the target and MoE-based models generate more reasonable sketches and contain fewer ellipses and uninformative tokens, which can hurt the sketch readability.

7 Discussion

Since gold document sketches are difficult to annotate, there remain challenges of how to leverage or create better weak supervision. We may also want models to adjust to users' personalized preferences over document sketches (e.g., some may prefer more deletions than insertions or vice versa) in practical application deployment, where RL can play a major role by having models directly optimized by customized rewards.

We show that MoE-based models tend to generate more readable sketches by outputting fewer ellipses and functional tokens, though in some cases it can be difficult to guess what should fill a given ellipsis. An interesting future study could examine how the placement and number of ellipses in a sketch affects readability. We would also like to explore whether replacing ellipsis tokens with some more contentful label (e.g., entity type) or a retrieved sample content for a gap (Xu et al., 2021) could help make sketches more interpretable.

An initial document sketch provides the reusable text structure that allows a user to fill in detailed content. Interactive document generation can be seen as the next step of our document sketching task that dynamically fills in more local contexts based on users' inputs. We suggest that RL could again

---

[8] Since MoE has a more balanced average sequence length and the number of ellipses, we keep MoE unchanged and adjust T5 and MoE+RL to have the same values as MoE.

[9] Ideally, it would be preferable to directly measure editing productivity through usability testing, but this is impractical in a crowd worker setting, and dependent on confounding factors such as design of the user interface.

Collection Title Target Doc Title	1960 United States Presidential Election in __ 1960 United States Presidential Election in Colorado

play a major role towards building such writing assistants, with rewards from a real user or a user simulator. We notice, for example, in Tab. 6 that given user input in the first sentence, the subsequent generated sentences become much more specific and relevant to the new input.

8 Conclusions

We have presented a new task, DOCUMENT SKETCHING, designed to generate draft documents that users can edit. To support this task, we introduced a new dataset and a weakly supervised learning setting. Experimental results show that deep learning models outperform established multi-sequence alignment approaches.

Ethical Considerations

We believe this paper to be part of body of work that can mitigate some of the ethical pitfalls (Bender et al., 2021) of large pre-trained models such as GPT-3 (Raffel et al., 2019). While the present work does not entirely prevent misuse, e.g., by a malicious user trying to promote misinformation, Automatic Document Sketching can be more broadly framed as a form of *controllable* generation, which places greater control into the hands of the users. As such it is complementary to ongoing research on fake news detection (Zellers et al., 2019), toxicity detection (Han and Tsvetkov, 2020; Pavlopoulos et al., 2020), and consistency detection in, e.g., summarization (Maynez et al., 2020; Wang et al., 2020). Human subjects (crowdworkers) were paid at a rate higher the legal minimum wage in our locale (Washington State, U.S.A.).

Trade the Event: Corporate Events Detection for News-Based Event-Driven Trading

Zhihan Zhou **Liqian Ma** **Han Liu**
Department of Computer Science, Northwestern University
`{zhihanzhou, liqianma}@u.northwestern.edu`
`hanliu@northwestern.edu`

Abstract

In this paper, we introduce an event-driven trading strategy that predicts stock movements by detecting corporate events from news articles. Unlike existing models that utilize textual features (e.g., bag-of-words) and sentiments to directly make stock predictions, we consider corporate events as the driving force behind stock movements and aim to profit from the temporary stock mispricing that may occur when corporate events take place. The core of the proposed strategy is a bi-level event detection model. The low-level event detector identifies events' existences from each token, while the high-level event detector incorporates the entire article's representation and the low-level detected results to discover events at the article-level. We also develop an elaborately-annotated dataset ***EDT*** for corporate event detection and news-based stock prediction benchmark. EDT includes 9721 news articles with token-level event labels as well as 303893 news articles with minute-level timestamps and comprehensive stock price labels. Experiments on EDT indicate that the proposed strategy outperforms all the baselines in winning rate, excess returns over the market, and the average return on each transaction. [1]

1 Introduction

By shaping investors' perceptions and assessments of companies, financial news has significant impacts on the stock market (Engle and Ng, 1993; Tetlock, 2007). News-based stock prediction models are thus developed to automatically discover signals of stock market movements from the countless news articles that generated every moment. (Kalyani et al., 2016; Shah et al., 2018; Mohan et al., 2019).

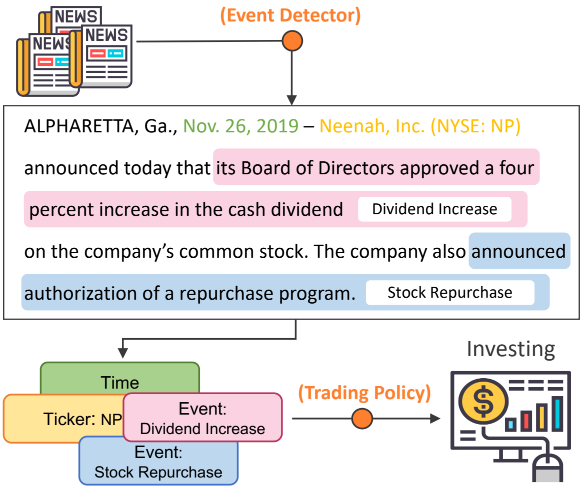

Figure 1: Overview of the event-driven trading strategy

Previous studies mainly rely on textual features and sentiment analysis to forecast the stock movements (Fung et al., 2003; Liu, 2018; Huynh et al., 2017). Both of them, however, often face the problem of poor explainability and low signal-to-noise ratio. Textual feature-based methods often formulate the stock prediction as a text classification problem by directly predicting the rise and fall of stocks based on the extracted features. These models fail to make reasonable trading decisions since they omit the reasons behind stock price changes. Sentiment-based methods avoid this problem by regarding the news articles' sentiments as the indicator of stock movement. However, news sentiment is subjective, which can be greatly affected by the author's standpoint and writing style.

Unlike textual features and sentiments, corporate events are objective facts that impact how investors perceive and assess the related companies. Thus, we resort to corporate events to make more convincing and explainable stock predictions. Jacobs et al. (2018) achieves corporate events detection by splitting a news article into sentences and detecting

---

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2114–2124
August 1–6, 2021. ©2021 Association for Computational Linguistics

events on each of them with multi-label sentence classification. This method, however, discards the global contextual information of the entire article and fails to indicate the evidence of events' existences. We believe that detecting events at a smaller granularity (e.g., at the token-level) is beneficial on both model training and application sides. During training, explicitly assigning a label to each token gives the model specific guidelines of what to identify. On the application side, each detected event is supported by one or more subsequences of the original article, allowing users to easily distinguish the predicted results.

However, singly detecting events from the token-level may result in a lack of macro understandings of the entire article. To tackle this, we introduce a bi-level event detection model, in which a low-level detector identifies the subsequences that describe specific events by classifying each token. And a high-level detector takes the predicted results from low-level and integrates them with the input article's global contextual information to predict the probabilities of each event's existence.

Another problem with existing models is that they ignore the timeliness of news articles. Most of them utilize news articles to predict the related securities' rise/fall on the following trading day(s). However, stock prices are very likely to change immediately in response to noteworthy news. Thus, the stock movement in the following trading day(s) may not accurately reflect a news article's influence. To tackle this, we make stock predictions as soon as a news article is published and perform tradings at that moment with the proposed trading policies.

Based on the event detection model and trading policies, we construct an event-driven trading strategy that simultaneously detects corporate events from news articles, indicates the subsequences that describe the detected events, and performs trading on the related stocks. By running the strategies against massive historical data in EDT, we demonstrate the superiority of the proposed strategy in terms of excess returns over the market and the average return on each transaction. The experiment results also reveal the timeliness of news and the effectiveness of corporate events in indicating stock movement.

The main contributions of our paper are as summarized follows: (i) We introduce a novel event-driven trading strategy that detects trading signals from arbitrary unlabeled news articles; (ii) We present ***EDT***, an elaborately-annotated dataset with 300000+ news articles for corporate event detection and news-based trading benchmark. (iii) We propose a bi-level event detection model that integrates macro and fine-grained understandings to effectively identify corporate events;

2 Problem Definition

We aim to construct an event-driven trading strategy that automatically detects corporate events from news articles and performs trading accordingly. The proposed strategy consists of two components: *bi-level event detector* and *trading policy*.

The low-level event detector identifies events from each token. We formulate the low-level event detection as a sequence labeling problem. The label set $\mathcal{L} = \{e_1, e_2, ..., e_k, O\}$ consists of k pre-defined events and a special label O that stands for ***Noevent*** [2]. We define an article $\boldsymbol{x} = (x_1, x_2, ..., x_n)$ as a sequence of tokens and define its label sequence as $\boldsymbol{y} = (y_1, y_2, ..., y_n)$. The same event may be mentioned multiple times in an article, and a single article may contains multiple events. If a subsequence $\boldsymbol{x'} = (x_t, x_{t+1}, ..., x_{t+s})$ of $\boldsymbol{x}$ describes the ***event i***, $\{y_j\}_{j=t}^{t+s}$ are labeled as e_i. All the other words are labeled as O. The low-level event detection is defined as follows: given an article $\boldsymbol{x}^* = (x_1, x_2, ..., x_n)$, find its best label sequence $\boldsymbol{y}^* = (y_1, y_2, ..., y_n)$. We say ***event i*** is detected by the low-level detector if $e_i \in \boldsymbol{y}^*$. Based on the low-level detected results, the high-level event detector calculates the probability of each event's existence. We say ***event i*** is detected by the high-level detector if its existence probability is larger than a given threshold. We combine the predictions on both levels as the final prediction. When events are detected, the *trading policy* decides when to buy and sell the related securities.

3 Strategy

This section discusses the proposed strategy by respectively introducing the event detector and the trading policies.

3.1 Event Detector

Before training the model to detect events, we first equip it with prerequisite knowledge of the financial domain by performing a *domain adaptation*.

---

[2] events that are not included in $\{e_i\}_{i=1}^{k}$ are also considered as *Noevent*

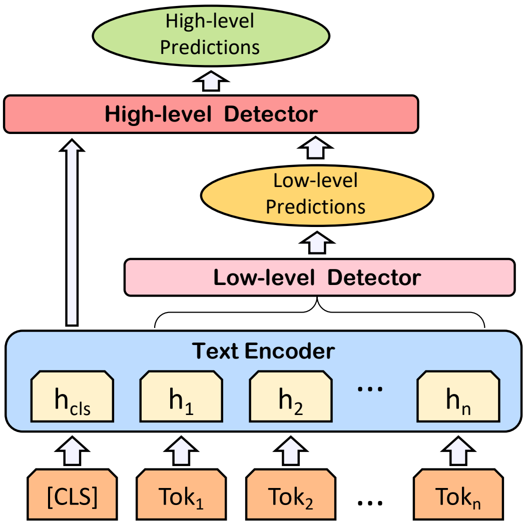

Figure 2: Model overview. The low-level detector identifies corporate events from each token, while the high-level detector summarizes the low-level predictions and the input representation to detect events at the article-level

3.1.1 Domain Adaptation

Since the same event can be expressed with significantly different terms and descriptions, and the same terms can refer to different meanings, understanding the event itself and its related terms is of great importance. We perform domain adaptation by training the model with Masked-Language-Model (MLM) loss on a financial encyclopedia as well as financial news articles. Section 4.3 discusses this corpus in details. During training, 15% tokens of an input sequence are masked, and the model is asked to predict the masked tokens. The prediction is essentially a multi-class classification over the entire vocabulary. We optimize the model with the *Categorical CrossEntropy* loss calculated on all the masked tokens.

3.1.2 Bi-Level Event Detection

As shown in fig. 2, the event detection model takes an article as input and respectively detects events from two levels. Each article is concatenated with a special token [CLS]. The Transformer-based text encoder calculates a series of hidden states for each token. We consider [CLS]'s last hidden state h_{cls} as the representation of the entire article, and h_i as the representations of *token i*.

The low-level detector identifies the subsequences that describe corporate events. For a given label set $\mathcal{L}$ (section 2) with $K+1$ labels (e.g., K pre-defined events and a "*Noevent*"), the detector assigns $K+1$ scores to each token by performing a multi-classes classification based on the token's representation. Each score stands for the confidence of finding a specific event at this position. These scores are concatenated and passed to the high-level detector. During training, we calculate the *Categorical CrossEntropy* loss for each token of an article and average them as the article's low-level loss.

The high-level detector concatenates the low-level prediction as well as the entire article's representation to calculate the probability of each event's existence. We formulate it as a multi-label classification problem. Specifically, we assign K binary labels to each article and represent them with a K-length label vector. For articles without any events, their label vectors are all-zero. If *event i* occurs in an article, the i-th component of its label vector is set to 1. We utilize the *Binary CrossEntropy with Sigmoid* as the loss function. This function considers the K-label classification as K independent binary classification problems. Specifically, it uses the $Sigmoid$ function to map each vector component of the high-level detector's output to $(0, 1)$. We consider the mapped score of each event as its probability of existing in the input article. We then calculate the *Binary CrossEntropy* loss between the mapped score and the binary label of each event. The losses of all the events are summed as the high-level detector's loss. We sum the losses of the low-level and high-level detectors to simultaneously optimize the detectors and the text encoder.

3.1.3 Ticker Recognizer

To make the proposed strategy applicable to arbitrary news articles, besides detecting events, we also recognize the related securities (e.g., company) to trade on.

Each security listed on an exchange has a unique ticker, which is a unique arrangement of characters (e.g., Amazon's ticker at the NASDAQ exchange is AMZN). To recognize the tickers, we download company-ticker pairs (e.g., Amazon v.s. AMZN) for all the securities listed on NYSE and NASDAQ from Yahoo[3]. For a given article, we perform string matching between the article and all the company-ticker pairs. If multiple company-ticker pairs are matched, we choose the one that occurs the most times. Some tricks are employed to improve the accuracy and efficiency. For example, the company-

---

[3] `finance.yahoo.com`

ticker pairs that match the title's first few words are assigned higher confidence. Although a single article may include multiple securities, we only recognize the one that occurs most to simplify the setting.

3.2 Trading Policy

To minimize other factors' influences, in this paper, we trade only on stocks instead of any derivatives (e.g., options). We relate each detected event to a *long* or *short* trading signal singly based on its event type. Events that may result in a stock price rise are considered as *long* signals, while events that may lead to a fall of stock prices are considered as *short* signals.

We implement two trading policies named **Trade-At-End** and **Trade-At-Best**. Both of them long (e.g., buy) the related stocks for *long* signals and perform short-selling for *short* signals. We define a transaction as a buy(sell) and a sell(buy) of the same stock. The policies always start a transaction (e.g., perform a buy or a short-selling) at the first available time when an event is detected.

Trade-At-End (k): This policy holds a started transaction for k trading days and closes the transaction on the last day when the market closes.

Trade-At-Best (k): This policy closes a transaction at the best price (e.g., highest for sell and lowest for buy) within k trading days from the start date. It estimates the profit that a trader can gain at most within k trading days with a detected event.

4 Data

In this section, we discuss the *EDT* dataset. EDT contains data for three purposes: 1. corporate event detection (section 4.1); 2. news-based trading strategy benchmark (section 4.2); 3. financial domain adaptation (section 4.3).

4.1 Data for Event Detection

We choose 11 types of corporate events that have relatively predictable and straightforward impacts on the stock price based on financial knowledge.

4.1.1 Event Type

In this work, we only focus on non-periodic corporate events. Trading on periodic corporate events such as *Earning Call* is much trickier since investors can access their information from multiple sources in advance. We leave them for future works.

Guidance Increase (GI) Guidance is a company's public estimates of its upcoming-quarter/fiscal year earnings. This event includes the announcements of guidance increase or upgrade.

Acquisition (A) An acquisition event happens when a company announces to purchase all or a portion of another company's shares or assets.

New Contract (NC) The new contract event refers to a company announcement of being awarded a new contract.

Stock Split (SS) A stock split event refers to a company that divides the existing shares of its stock into multiple new shares.

Reverse Stock Split (RSS) This is the reverse process of the stock split, which consolidates the number of existing stock shares into fewer shares.

Positive Clinical Trial & FDA Approval (CT) This event includes (i) positive trial results from clinical studies; (ii) receiving FDA approval, clearance, or being granted by FDA to market legally in the United States.

Stock Repurchase (SR) A company's stock repurchase events include declaring, reinstatement, or increasing a stock buyback plan.

Dividend (RD) The dividend is a distribution of some of a company's profits paid to its shareholders.

Dividend Cut (DC) A dividend cut means to reduce, stop, or suspend a pre-announced dividend.

Dividend Increase (DI) A dividend increase refers to an increase in the regular dividend.

Special Dividend (SD) A special dividend is an event that a company declares a non-recurring dividend paid to its shareholders.

4.1.2 Detailed information

Event	Num.	Event	Num.

SS	76		

Table 1: Number of articles in *EDT* for each event.

We collect 9721 English news articles, of which 2266 articles contain at least one of the above events. Table 1 shows the number of articles that corresponds to each event. The rest 7455 articles are news articles that do not contain any of the above events. We expect them to help the model better distinguish the event-related articles from the non-event ones. Among them, we deliberately include hundreds of non-event articles that are highly similar to event-related ones. An example here is "Apple announces a stock repurchase program" v.s. "Apple announces the completion of the recently announced stock repurchase program", in which we do not expect the latter one to have a significant influence on the stock price.

These news articles are downloaded from PRNewswire[4], Businesswire[5] and GlobeNewswire[6] using keywords-search. The keywords for each event are manually determined based on samples of that event. Each article's title, subtitle, and main text are concatenated after data cleaning (e.g., remove special symbols). We annotate each article with token-level labels. Two human annotators are asked to independently mark the subsequences that best describe the pre-defined corporate events. The annotations of an article are produced if the annotators give the same result. Otherwise, they discuss the best annotations.

We randomly sample 80% articles of each event and combine them with 80% of non-event articles to form the training data. The rest are considered as the validation data.

4.2 Data for Strategy Evaluation

We develop this data to benchmark news-based stock prediction models and trading strategies. To accurately account for the stock movement, the news articles should be original-sourced. To mimic the real-world situation, the news articles should be diverse enough (e.g., in different categories). Thus, we choose PRNewswire and Businesswire as the article collection sources and download all the English news from PRNewswire (Mar 1st, 2020 - Apr 30th, 2021) and Businesswire (Aug 16th, 2020 - May 6th, 2021). We remove the articles that exist in the training data (section 4.1.2). Since some pre-defined events are infrequent (e.g., stock split), to ensure that there are at least a few samples of every event, we add all the articles of the validation data (section 4.1.2) to this data. After data cleaning, there are 303893 news articles.

Each article comes with a minute-level timestamp, which allows researchers to locate the exact event happening time. Generally, news-based trading strategy evaluation involves four steps. (i) Identify trading signals (e.g., corporate events or sentiments) from news articles; (ii) For each article where trading signals are detected, recognize the related company(ticker); (iii) Get the recognized company's stock price data around the publish time of the news; (iv) Perform transactions based on trading policies.

To enable researchers without ticker recognizers and historical stock price data to benchmark their models/strategies, we assign each article with an automatically recognized ticker as well as detailed price labels of that ticker. With the detailed price labels of each news article, strategy evaluation can be as easy as "counting the price changes on the articles that are recognized as trading signals".

Specifically, an article's price labels includes: *open* / *close* prices at the first minute we can trade on, *highest* / *lowest* prices in the following 1/2/3 trading days, *close* prices in the following 1/2/3 trading days, and the minute-level timestamp corresponding to each price. If available, we take the prices in the pre-market and after-hours into consideration since many corporate events are announced in these periods, and stock prices may change greatly during these times. The price labels are empty for articles where no ticker is recognized or the historical price data is unavailable. Among all the evaluation data, 106619 articles come with non-empty price labels.[7]

4.3 Data for Domain Adaptation

The corpus for domain adaptation contains financial news articles and a financial terms encyclopedia, which is considered as unstructured domain knowledge. For encyclopedia, we download 6260 explanatory documents from Investopedia[8]. Each document explains a specific financial term and describes the role it may play in the financial market. For news articles, we directly utilize all the news articles of the training data (section 4.1.2).

5 Experiment

In this section, we first exhaustively compare Bi-level Detection with baselines under different settings. Then, we discuss how each event contributes to the overall trading results. Lastly, we analyze the profitability and practicality of the proposed strategy in real-world stock trading.

---

[4] `https://www.prnewswire.com/`

[5] `https://www.businesswire.com/`

[6] `https://www.globenewswire.com/`

[7] We acquire historical stock price data from `https://polygon.io/`

[8] `https://www.investopedia.com/`

Among the 11 corporate events in the EDT dataset, we do not trade on the **Dividend** since we do not consider it to have a significant influence on stock prices. Among the rest, we consider **Reverse Stock Split** and **Dividend Cut** to have negative influences on the stock price, while the others to have positive influences. We evaluate the performance of the proposed strategy with backtesting. Backtesting is widely used to evaluate a trading strategy's effectiveness by running the strategy against historical data. We perform trade on all the detected trading signals for each model.

Metrics For a "buy" transaction, we define its return as $\frac{P_{sell}-P_{buy}}{P_{buy}}\%$, while for a "short-selling", we define its return as $\frac{P_{sell}-P_{buy}}{P_{sell}}\%$. Here, P stands for the price. If a transaction's return is greater than or equal to 0, we call it a "win". If a transaction's return is greater than or equal to 1%, we call it a "big win". For each model, we calculate its **winning rate**, **big win rate** (rate of big wins among all the transactions) and **average return on each transaction**. We also evaluate the models' excess returns over the market, where we consider the *S&P 500* index as the benchmark of the market performance. The **market return** is estimated as the return of buying *S&P 500 index ETF* for \$10000 on Mar 1st, 2020 and sell all of them on May 6th, 2021[9]. For each model, we start with \$10000 cash and invest \$2000 to each trading signal. When available cash is less than \$2000, we invest 20% of available cash to the detected signal. We report the **excess returns** of each model, which equals to a model's **total returns** minus the **market return**. [10] We assume there is a 0.3% commission fee on each transaction.

Model Hyperparameters We employ the pretrained BERT (Devlin et al., 2018) model as the text encoder. Specifically, we use the *bert-base-cased* checkpoint. Both the low-level and high-level detectors consist of a hidden layer and an output layer. There are 2048 hidden units in the hidden layer. We utilize AdamW optimizer with batch size 32 and learning rate 5e-5 to train the encoder and detectors together for 5 epochs. We set the maximum input length as 256 since we find almost all the events mentioned in a news article exist in its first 256 tokens. Training of the model costs 15 minutes on 4 Nvidia RTX 2080Ti GPUs. We conduct each experiment with 3 different random seeds and report the average results.

Trading Details For Trade-At-End, we execute a stop loss of 20% (e.g., sell a stock immediately when it falls 20%). In all the experiments, we only trade on the news articles where the historical price data of the detected ticker is available at the minute when the article is published. In other words, we ignore all the news articles that are not published during the market hours and articles where the historical price data is incomplete.

5.1 Baseline

Vader (Gilbert, 2014) is a rule-based sentiment analysis model that assigns *positive*, *negative*, and *neutral* scores to an article. We consider news articles with a positive score greater than 0.2 as *long* trading signals.

BERT-SST is a BERT-based (Devlin et al., 2018) sentiment analysis model trained on the Stanford sentiment treebank (SST) dataset. We respectively consider news articles with a positive score greater than 0.995 and 0.9 as *long* trading signals to reduce the threshold's influences on the final results.

Sentence (Jacobs et al., 2018) splits an article into sentences and performs sentence-level event detection based on multi-label text classification. It was original implemented with SVM and LSTM. We re-implement it with BERT to compare it fairly with our models. We split each article into sentences with the NLTK toolkit (Loper and Bird, 2002) to train and evaluate the model.

BERT-CRF (Lafferty et al., 2001) was originally proposed as a Conditional Random Fields-based sequence labeling model, which combines emission scores given by BERT and learned transition scores to find the global optimal label sequence for each input. We re-implement it to perform event detection singly on the token-level. Following the literature, we use different learning rates for the CRF(1e-3) and the BERT(3e-5) components.

5.2 Main Results

Table 2 and 3 respectively shows the models' 1-day and 2-day trading results. The result of 3-day trading is consistent. Due to space limitations, we present it in appendix A. As shown in the tables,

---

[9] In accordance to the time span of data for evaluation

[10] Since Trade-At-Best always finishes the transaction at the best price, its winning rate is always 100% and its total returns is almost linearly related to the number of transactions. Thus, we only report the average return of this policy.

Model	TAE (1)			TAB (1)	
	Win Rate	**Ave. Return**	**Exc. Returns**	**Ave. Return**	**Num. Trans.**
Vader (Gilbert, 2014)	52.8‖24.3%	0.06%	-$8116	1.72%	4327

Bi-level Detection (ours)	52.3‖**40.8**%	**1.56**%	$**59375**	**11.53**%	3118

Table 3: This table shows the 2-day trading result, in which we start each transaction at the news article's publish time and end the transaction after 2 trading day.

our model outperforms all the baselines on average return and exceed return under all the settings.

Results of Ticker Recognizer To evaluate the performance of ticker recognizer, we manually label tickers for 1674 news articles. The proposed ticker recognizer succeeds in 1643 of them (accuracy: 98.15%). Although it obtains a satisfactory performance, its imperfect recognition may slightly impair the evaluation of trading strategies, since it may point out the incorrect securities for the strategies to trade on.

Results of Trade-At-End Even with the simple trading policy, our model achieves an average return of 1.74% and an exceed return of $84443 (844%) in 1-day trading.

Experiments on Vader and BERT-SST show that the sentiment of a news article can indicate the stock movement to some extend. For example, BERT-SST achieves great winning rates, and it successfully outperforms the market index by a considerable margin. However, these signals tend to results in small stock movements. Thus, sentiment-based models achieve poor average returns. On the other hand, event-based models obtain much higher average returns, demonstrating the superiority of corporate events over news sentiments in indicating stock movements.

Although the Sentence model highly outperforms the sentiment-based methods, compared to our models, it is less robust to ambiguous articles, and it is more likely to miss the events that are described in several continuous sentences. By utilizing global context information and detecting events from the token level, our model identifies more trading signals and avoids more potential traps.

Bi-level Detection also achieves better performance than BERT-CRF under all the settings. The improvements mainly come from the high-level detector. By combining the global contextual information with token-level detected results, Bi-level Detection is more robust and more effective. When the low-level detector generates false alarms on some ambiguous tokens or fails to detect events that are not explicitly described, the high-level detector may point it out after analyzing the meaning of the entire article.

Results of Trade-At-Best This trading policy is designed to measure the ceiling of trading signals given by each model. Under this setting, Bi-level Detection obtains a 9.11% average return that dramatically exceeds all the sentiment-based models, indicating how significant the stock price changes when corporate events take place. Com-

Metric	Policy	Event Type									
		A	CT	DC	DI	GI	NC	RSS	SD	SR	SS

Table 4: The table shows **Bi-level Detection**'s 1-day and 3-day trading results on each event, where **WR.** stands for the winning rate and **AR.** stands for the average return on each transaction. Each column respectively shows the results of Acquisition(A), Clinical Trial(CT), Dividend Cut(DC), Dividend Increase(DI), Guidance Increase(GI), New Contract(NC), Reverse Stock Split(RSS), Special Dividend(SD), Stock Repurchase(SR) and Stock Split(SS).

Model	TAE (1)			TAB (1)
	Win Rate	Ave. Return	Exc. Returns	Ave. Return
Bi-level Detection - Open	**54.5**||**34.2**%	**1.74**%	$**84443**	**9.11**%
Bi-level Detection - Close	51.4||29.5%	-0.07%	-$12026	4.50%

Table 5: This table shows **Bi-level Detection**'s 1-day trading results when start transactions respectively with the ***Open*** price and ***Close*** price at the minute that the event is detected.

pared to other event-based models, Bi-level Detection achieves much better performance in identifying corporate events.

5.3 Event Analysis

Table 4 shows Bi-level Detection's 1-day and 3-day trading results on each event. As shown in the table, the Dividend Increase has the smallest influence on the stock price, while the Reverse Stock Split and Clinical Trial significantly impact the stock prices.

Reverse Stock Split and Special Dividend are the most profitable corporate event, yet they are relatively rare. Acquisition, Clinical Trial and New Contract are ubiquitous, and they also lead to significant stock movements. However, comparisons between TAE and TAB's profits indicate that these events are relatively trickier to trade. Although the ideal policy TAB achieves dramatic profits, TAE makes much fewer profits, indicating that the stocks may oscillate significantly after these events. On the other hand, Special Dividend and Reverse Stock Split are comparatively easier to trade on.

Different events also affect the stock prices in different periods. We measure the influence by comparing TAB (1) and TAB (3)'s average return on the same event. They achieve close average returns on Acquisition, Clinical Trial, and Stock Repurchase, indicating that the stock prices do not continue to change sharply after the first day. In contrast, Stock Split impacts the stock price for a more extended period.

Thus, an ideal trading strategy should take the above factors into account. For example, it may assign different weights to each event based on their profitability and use a different policy to trade each event based on their potential price change patterns.

5.4 Profitability in Real-world

In this section, we discuss the possible profitability of the proposed strategy in real-world trading. Backtesting against historical data shows that the proposed strategy dramatically outperforms the market index. However, this result is based on two main assumptions.

First, we assume the cost of time in acquiring the news articles and making trading decisions is almost 0. Table 5 indicates the significance of timeliness, in which **Bi-level Detection - Open** starts transactions with the ***Open*** price at the minute that the news article is published (e.g., price at 11:23:00), while **Bi-level Detection - Close** starts with the ***Close*** price at that minute (e.g., price at 11:23:59). As shown in the table, when the model trades tens of seconds after the publish time of the news article, it greatly underperforms the market index and achieves a negative average return on each transaction. These results demonstrate that the profitability of an event-based model highly depends on how "quick" one can perform tradings after a piece of news is published.

Second, we assume we can always buy/sell the desired amount of stock shares and ignore the liquidity of the stocks. When the investment scale is relatively small, this assumption doesn't have a big impact. However, as the investment scales up, the liquidity may greatly constrain the model's profitability.

6 Related Works

Text-base Stock Prediction Existing methods usually count on textual features and sentiment analysis to forecast the stock movements (Hagenau et al., 2013; Mohan et al., 2019; Xie and Jiang, 2019; Huynh et al., 2017; Liu, 2018; Mittal and Goel). Hagenau et al. (2013) utilizes N-Gram, Noun-phrases, and 2-words combinations of corporate announcements to predict the stock movement. The influence of financial news on the stock market is also widely explored (Engle and Ng, 1993; Tetlock, 2007). In recent years, researchers resort to support vector machine and deep neural network to analyze financial news articles (Liu, 2018; Xie and Jiang, 2019; Ding et al., 2015; Huynh et al., 2017). Mohan et al. (2019) combines news text (e.g., sentiment, tf-idf, and word2vec representation) with historical stock data to predict future stock prices. Event-based stock predictions are also introduced. Ding et al. (2015) extract events from news articles, calculate event embedding, and use it to predict direction of stock moves. Ben Ami and Feldman (2017) build sentiment-type trading signals with word polarities and event-type trading signals with existing information extraction platform and demonstrates the superiority of event over sentiment in making trading decisions.

Event Detection General domain event detection that aims to recognize structured schemata/frames from the text has been widely explored by data-driven supervised learning methods (Ahn, 2006; Mitamura et al.). In the economic domain, however, existing approaches (Arendarenko and Kakkonen, 2012; Hogenboom et al., 2013; Xie et al., 2013) usually exploit knowledge-based and rule-based methods, which require extensive hand-designed rules and ontology. Recent works conceptualize corporate events as sequences of text that reported company-related occurrences and introduce data-driven methods to solve financial event detection with text classification (Ein-Dor et al., 2019; Jacobs et al., 2018). Ein-Dor et al. (2019) explored a Wikipedia-based supervised method to detect the sentences that may include corporate events. Jacobs et al. (2018) propose a multi-label sequence classification model to detect specific corporate events from news articles.

7 Conclusion

This paper introduces an event-driven trading strategy based on corporate event detection from news articles. We introduce a bi-level event detection model that utilizes global and local information to identifies corporate events. Experiments on the presented dataset EDT demonstrate the proposed model's superiority over all the baselines. The results also signify the corporate event's timeliness and effectiveness in indicating stock movement.

In future work, we plan to explore more on both the event detection model and trading policy. We expect to involve external knowledge and few-shot learning methods to relieve the event detection model from the data imbalance and data-scarce scenarios. On the trading policy side, we aim to explore more types of events and customize different policies for each event based on the potential price change patterns it may lead to.

Abstract

Prior knowledge plays a critical role in decision-making, and humans preserve such knowledge in the form of natural language (NL). To emulate real-world decision-making, artificial agents should incorporate such generic knowledge into their decision-making framework through NL. However, since policy learning with NL-based action representation is intractable due to NL's combinatorial complexity, previous studies have limited agents' expressive power to only a specific environment, which sacrificed the generalization ability to other environments. This paper proposes a new environment-agnostic action framework, the language-based general action template (L-GAT). We design action templates on the basis of general semantic schemes (FrameNet, VerbNet, and WordNet), facilitating the agent in finding a plausible action in a given state by using prior knowledge while covering broader types of actions in a general manner. Our experiment using 18 text-based games showed that our proposed L-GAT agent which uses the same actions across games, achieved a performance competitive with agents that rely on game-specific actions. We have published the code at https://github.com/kohilin/lgat.

1 Introduction

The incorporation of natural language processing (NLP) and reinforcement learning (RL) is an important research field for using knowledge, represented in the form of language, in the decision-making of artificial agents (Luketina et al., 2019). One critical topic is the capability to describe an agent's actions with natural language (NL) (Narasimhan et al., 2015; Yuan et al., 2019). An agent with such a capability can estimate the plausibility of actions on the basis of prior knowledge accessible through language (Narasimhan et al., 2018). Suppose that an agent receives a request, "*give me some water*"; a common sense idea like "*water exists in the kitchen*" will definitely help the agent determine the right direction to go in. If actions are represented in language, for example, GO TO KITCHEN, we can straightforwardly connect knowledge to actions by referring to language resources (Fulda et al., 2017). NL is useful for accessing knowledge to achieve plausible decision-making, and this language capability would be fundamental in developing intelligent agents.

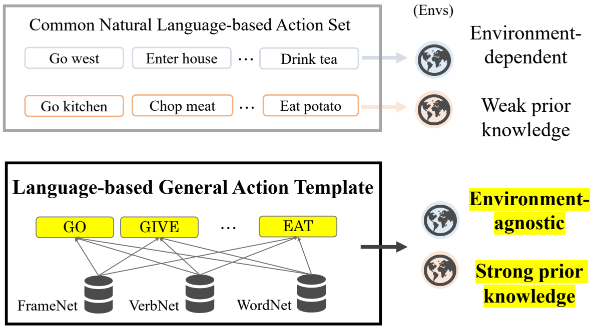

Figure 1: Common action templates and L-GAT.

However, NL is complicated for current RL agents to acquire due to its high expressive power (Hausknecht et al., 2020). The rich vocabulary and complex grammar of NL result in a huge action space that is intractable for existing RL algorithms. Although we can train an agent by restricting the expressive power to a specific environment (Narasimhan et al., 2015; He et al., 2016), such constraints sacrifice the inherent advantage of using NL as the action representation for domain-independent learning. Our objective is to make better trade-offs between expressive power and the learnability of NL-based RL.

Interactive fiction (IF) games serve as a practical testbed for NL-based RL, where an agent and environment communicate with each other through

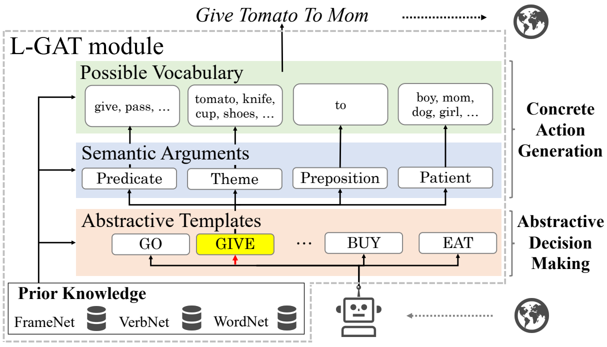

Figure 2: Action generation flow with L-GAT.

textual information (Côté et al., 2019). The agent needs to understand a textual state and generate an appropriate NL action command. In the experiments of previous studies, various constraints on the action space have been used for the convergence of learning, such as simple grammar and vocabulary (Narasimhan et al., 2015), effective ground-truth actions for a state (He et al., 2016), and game-specific templates (Hausknecht et al., 2020). These constraints are problematic, especially when applying the same algorithm to other environments. There are several studies that address this by implementing heuristic rules (Hausknecht et al., 2019) or training an action generator with observation-action pairs of human-play (Yao et al., 2020), but they still have a non-trivial bias toward IF games.

In terms of prior knowledge, word embeddings and language models have shown success at reducing the action space (Fulda et al., 2017; Yao et al., 2020). Although such continuous representations have achieved notable performances for broader NLP tasks, they are basically trained with word co-occurrences. We cannot flexibly manipulate the knowledge contained in these continuous representations because it is difficult to selectively encode the desired knowledge into them (Zhou et al., 2020). To make the most of prior knowledge expressed in NL, we should take advantage of other linguistic resources as well that provide fine-grained information more explicitly, such as the hierarchical structure of words (Miller, 1998), the semantics of a sentence (Fillmore et al., 2003), and common sense (Speer et al., 2017).

Thus, we propose a new environment-agnostic action framework on the basis of general semantic schemes, the language-based general action template (L-GAT). Figure 1 shows the overall architecture compared with the environment-dependent action templates commonly used, and Figure 2 illustrates the flow of generating an action with L-GAT. The agent with L-GAT first determines "*what to do*" at an abstractive level with generally defined action templates and then specifies "*how to do it*" by generating a concrete action on the basis of connected prior knowledge.

Our contributions with L-GAT are three-fold. First, we propose an environment-agnostic action framework based on general semantic schemes such as FrameNet (Fillmore et al., 2003), VerbNet (Schuler, 2006), and WordNet (Miller, 1998). Second, we develop a hierarchical action-generation algorithm in which the agent performs abstractive decision-making and then generates a concrete action command. Third, we introduce a method for dynamically reducing the action space with static knowledge from multiple external resources and contextual information from a state. We have published the code with which future studies can easily use L-GAT as an action generation module.

2 Related Work

The action space problem of NL-based actions has been addressed in previous work. LSTM-DQN (Narasimhan et al., 2015) enables an agent to learn a policy in a simple verb-object format in synthetic environments. DRRN (He et al., 2016) is a ranking-based method in which the agent selects an action from among admissible actions given by a game engine. Game-specific templates were proposed for Jericho (Hausknecht et al., 2020). The agent selects one of the templates and fills in the gaps in the chosen template. TDQN (Hausknecht et al., 2020) and KGA2C (Ammanabrolu and Hausknecht, 2020) agents have used these templates and succeeded at learning a policy in various games. NAIL (Hausknecht et al., 2019) solves IF games with action generation heuristics.

Language resources have also been used for reducing the action space. Fulda et al. (2017) extracted the affordances of words with word embeddings and restricted objects that can be taken for a specific verb. A language model is leveraged to filter non-plausible word combinations (Kostka et al., 2017). Recently, Yao et al. (2020) proposed the contextual action language model (CALM), which trains a language model with human-play transcriptions and uses it as an action candidate generator. By combining it with a ranking-based method, CALM showed significant performance even without a ground-truth for admissible actions.

3 Problem Setting

In this section, we formally define our problem setting, RL agents with NL-based actions. An NL-based action a, such as GO TO KITCHEN and GIVE SOME WATER TO JOHN, consists of N words: $a = \{w_1, w_2, \ldots, w_N\}, w_i \in \mathcal{V}$, where each w_i is a word and $\mathcal{V}$ is vocabulary. Given a state s, we represent an optimal NL-based action in the state with $a^*_{(s)}$ and the words composing it with $w^*_{(i,s)}$, respectively. Following the previous studies, each $w \in \mathcal{V}$ is estimated with an independent Q-function as $Q_{(i)}(s, w)$, where i is the position of a word, and $\mathcal{Q}(s, a)$ is defined as $\Sigma_i Q_{(i)}(s, w)$. A policy π is evaluated with a cumulative reward as:

$$V^\pi(s) = \mathbb{E}\left[\sum_{t=0}^{\infty} \gamma^t R(s_t, a_t) \,\middle|\, s_0 = s, a_0 = a\right],$$

where R is a reward function for a state-action pair, and γ is a discount factor. Then, the Q-functions $\mathcal{Q}^*$, Q^* corresponding to the optimal policy are learned by minimizing the following loss:

$$\mathcal{L} = (R(s, a) + \gamma \bar{\mathcal{Q}}^*(s', a') - \mathcal{Q}^*(s, a))^2,$$

where $\bar{\mathcal{Q}}^*(s', a') = \Sigma_i \max_{w'} \bar{Q}^*_{(i)}(s', w')$ with the next state s', the next word w', and the target Q-function $\bar{Q}$. Then, we obtain each word of the optimal action as: $w^*_{(i,s)} = \arg\max_w Q^*_{(i)}(s, w)$. However, this optimization could be intractable depending on N and the size of $\mathcal{V}$ due to the exponential complexity $\mathcal{O}(|\mathcal{V}|^N)$.

Hence, we consider restricting the vocabulary space for each position i for the action and state s to make this optimization problem tractable. Specifically, we want to find a subset $\mathcal{V}_{(i,s)}$ of $\mathcal{V}$ for each (i, s) such that $|\mathcal{V}_{(i,s)}|$ is much smaller than $|\mathcal{V}|$. Also, $\mathcal{V}_{(i,s)}$ must include the optimal word $w^*_{(i,s)}$ for the original optimization problem because replacing $\mathcal{V}$ with $\mathcal{V}_{(i,s)}$ should not change the optimal solution. Assuming that we have $\mathcal{V}_{(i,s)} \subset \mathcal{V}$, the computational complexity decreases from $\mathcal{O}(|\mathcal{V}|^N)$ to $\mathcal{O}(\prod_{i=1}^{N} |\mathcal{V}_i|)$, where $\mathcal{V}_i$ is one of the largest $\mathcal{V}_{(i,s)}$ for all s.

To define $\mathcal{V}_{(i,s)}$, we use knowledge $\mathcal{K}$:

$$\mathcal{V}_{(i,s)} = \varphi(i, s, \mathcal{K}, \mathcal{V}),$$

where φ is a set-valued function. Then, we need to determine the function φ that minimizes $|\mathcal{V}_{(i,s)}|$ but keeps the i-th word of an optimal NL-based action in $\mathcal{V}_{(i,s)}$:

$$\min |\mathcal{V}_{(i,s)}|, \text{ s.t. } w^*_{(i,s)} \in \mathcal{V}_{(i,s)}.$$

Note that, although the above formulation assumes that $\mathcal{V}_{(i,s)}$ always contains the optimal words $w^*_{(i,s)}$, it is practically impossible because the optimal words are unknown a priori and estimated through the learning process. Therefore, we need to approximate φ so that the estimated $\mathcal{V}_{(i,s)}$ is likely to contain $w^*_{(i,s)}$ as much as possible. We introduce our implementation of the approximation in Section 4.4.

4 Method

We now introduce our proposed method; the language-based general action template (L-GAT). L-GAT is a framework of NL-based actions for environment-agnostic RL agents. In L-GAT, we define actions on the basis of general semantic schemes, such as FrameNet (Fillmore et al., 2003), VerbNet (Schuler, 2006), and WordNet (Miller, 1998), which enables an agent to use connected knowledge to reduce the action space.

In this section, we first provide an overview of L-GATand then give details on its action command, definition, and generation algorithm.

4.1 Overview

L-GAT adopts hierarchical modeling for action generation to handle the vast space of NL-based action. Specifically, an agent with L-GAT first determines "*what to do*" at an abstractive level (e.g., decide to **give**) and then next determines "*how to do it*" at a concrete level (e.g., decide to give **tomato** to **mom**) as shown in Figure 2. This two-step strategy is intuitive and natural as a general procedure for decision-making (Lazaridou et al., 2020). From the viewpoint of RL, we can reduce the action space because the number of abstractive actions is much smaller than that of all possible words in the whole vocabulary. Also, the chosen abstractive action further restricts the words available for generating a complete action (e.g., we cannot eat a table)

To use such hierarchical modeling, L-GAT defines the **Abstractive Action Template** with a hierarchical structure consisting of three components: **Frame**, **Role**, and **Lexicon**. Figure 3 illustrates the hierarchical structure of

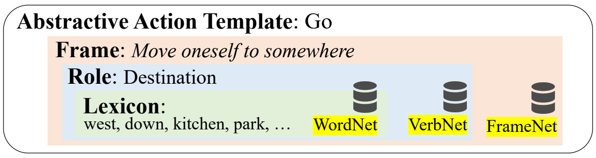

Figure 3: Abstractive action template Go and its hierarchical components; Frame, Role, and Lexicon.

an abstractive action template, Go. The frame defines the semantics of Go (e.g., *move oneself to somewhere*), the role represents a conceptual argument required to perform the action (e.g., `Destination`), and the lexicon represents concrete words that can be used for one of the roles in the frame (e.g., *west*, *down*, and *kitchen*). Using the generation algorithm, the agent selects an appropriate word from the lexicon for each frame's role in the chosen abstractive action template.

FrameNet and VerbNet inspired the hierarchical structure of L-GAT. Both resources provide semantic schemes that describe our daily behaviors conceptually. For example, similar to the Go template, FrameNet has a relevant scheme, "self-motion", with required arguments such as Goal and Source. Also, we connect the lexicon of L-GAT to WordNet to represent the hierarchical relationships of words. The word hierarchy enables agents to generalize candidate words (e.g., hyponyms of "*direction*," such as "*west*," can be used for the Go template) and interact with diverse environments. Thus, by designing actions on the basis of these general semantic schemes, we can naturally make L-GAT environment-agnostic and familiar with general prior knowledge.

Note that the templates of L-GAT are easily configurable depending on the environment. Such customizability is practically essential to applying the scheme to diverse domains, which is costly or difficult for an environment-dependent action set or language model-based generator.

4.2 Action Command

L-GAT generates an action command in a fixed format as: $a = v + n_1 + p + n_2$, with at most four slots for a verb (v), two nouns (n_1, n_2), and a preposition (p). An action command is generated by the action templates explained in the next section, and n_1, n_2, and p are not necessarily used depending on the template. To prevent the exponential growth of the action space, we decided to add these hard constraints to a generable format. However, we consider the aforementioned format to be able to cover most of the primary actions demanded by agents, such as *go kitchen* and *put cup on table*.

4.3 Action Definition

This section introduces the abstractive action template and its components. In this paper, we manually defined 41 abstractive action templates for L-GAT (see Appendix A). For the construction of each template, we chose relevant semantic schemes from FrameNet and VerbNet, and then aggregated them in a compatible form with the actions of RL agents. Table 1 shows three templates as references, and we will refer to them throughout this section.

Abstractive Action Template. A template T is defined as a tuple $T = \langle f, r_{(v)}, r_{(n_1)}, r_{(p)}, r_{(n_2)} \rangle$ where f is the frame, and $r_{(v|n_1|p|n_2)}$ are the roles for each slot. The frame defines the template's semantics. The roles represent required arguments for performing an action. Each word in an action command is an instance of its corresponding role and selected from the lexicon explained later.

Frame. Each frame has connections to semantically relevant entities in FrameNet (called *Semantic Frames*), and ones in VerbNet optionally (called *Verb Classes*). For example, the Give template is related to the semantic frame *Giving* and the verb class *give-13.1*. We use FrameNet as the basis because the granularity of the descriptions is more suitable for our purpose than VerbNet.

Role. For the definition of our roles, we borrow VerbNet's *Thematic Roles*, which refer to the semantic relationship between a predicate and its argument. VerbNet defines 30 thematic roles in total, and L-GAT uses 15 of them by taking into account their frequency and meaning. FrameNet also has a similar concept called *Frame Elements*; however, it is too fine-grained for RL agents' actions. Therefore, we use the thematic roles of VerbNet as the basis and annotate the related frame elements as additional information. We also define three special roles: `Predicate`, `Preposition`, and `Null`. `Predicate` is used only for the verb slot and references to verb nodes in WordNet. We selected these nodes on the basis of the representative verbs given by the connected frame entities of FrameNet and VerbNet (e.g., we chose "go.v.02" and "enter.v.01" for the

	f	$r_{(v)}$	$r_{(n_1)}$	$r_{(p)}$	$r_{(n_2)}$
L-GAT	Go	`Predicate`	`Destination`	`Null`	`Null`
FrameNet	Self-motion	-	Goal, Place, Area, Path	-	-
VerbNet	-	-	Destination	-	-
WordNet	-	go.v.02, enter.v.01	location.n.01, ...	-	-
L-GAT	Give	`Predicate`	`Theme`	`Preposition`	`Recipient`
FrameNet	Giving	-	Theme	-	Recipient
VerbNet	give-13.1	-	Theme	-	Recipient
WordNet	-	give.v.01	object.n.01	(to)	people.n.01, person.n.01
L-GAT	Eat	`Predicate`	`Patient`	`Null`	`Null`
FrameNet	Ingestion	-	Food	-	-
VerbNet	eat-39.1-1	-	Patient	-	-
WordNet	-	eat.v.01	food.n.01	-	-

Table 1: Examples of abstractive action templates in L-GAT with connections to FrameNet, VerbNet, and WordNet.

`Predicate` of the Go template on the basis of representative verbs given by the semantic frame "self-motion"). `Preposition` has prepositions available that often accompany verbs in a frame, and we manually defined these prepositions. `Null` means not using the slot for action generation. For example, the Go template uses only v and n_1.

Lexicon. The simplest way of defining the lexicon is to list all possible words manually or statistically; however, such a procedure would be non-scalable or hard to configure. Therefore, we decided to annotate nodes in WordNet as the representation. We selected general nodes such as "location.n.01" for the `Destination` of the Go template and "food.n.01" for the `Patient` of the Eat template. The hierarchical word relations in WordNet enables L-GAT to structurally determine candidate words such as by choosing the hyponyms of annotated nodes.

4.4 Action Generation

We propose three techniques for action generation with L-GAT: **Hierarchical Prediction**, **Word Masking**, and **Template Masking**. An agent with L-GAT generates an action as follows. The agent determines the abstractive action template and then selects a word for each slot from among candidates (Hierarchical Prediction). The candidates for each slot are filtered by using information from the state and the chosen template (Word Masking). By precomputing Word Masking for all templates in advance of the template selection, L-GAT can provide possible templates for a state by excluding templates that cannot generate any action command (Template Masking). The algorithm is described in Algorithm 1 and Figure 4. L-GAT has five Q-functions; one for estimating the template $Q(s, T)$, and the others for estimating words $Q_{(\cdot)}(s, w)$ where $(\cdot)$ denotes one of the slots v, n_1, p, or n_2.

Algorithm 1 Action Generation with L-GAT.

```
Input: $s$, Output $a$
$\mathcal{V}_{(\cdot,*,s)} \leftarrow$ compute the restricted vocabulary for all templates
$\mathcal{T} \leftarrow$ exclude templates with empty $\mathcal{V}_{(\cdot,T,s)}$
$T \leftarrow$ select a template from $\mathcal{T}$
$v, n_1, p, n_2 \leftarrow$ select words from $\mathcal{V}_{(\cdot,T,s)}$
$a \leftarrow$ decode with $v, n_1, p, n_2$
```

4.4.1 Hierarchical Prediction

L-GAT first selects a template T with $Q(s, T)$ and then generates words for each slot as: $w_{(\cdot)} = \arg\max_{\hat{w}} Q_{(\cdot)}(s, \hat{w}), \hat{w} \in \mathcal{V}_{(\cdot,T,s)}$, where $\mathcal{V}_{(\cdot,T,s)}$ is vocabulary that is restricted for the target slot of the template T in the state s. L-GAT computes $\mathcal{V}_{(\cdot,T,s)}$ as: $\mathcal{V}_{(\cdot,T,s)} = \{w \mid m(\cdot, s, T, w) = 1, w \in \mathcal{V}\}$, where m is a *masker function* that returns 1 for a generable word in the target slot by considering s and T. The masker function is our approximation of φ explained in Section 3, and we introduce the details in the next section.

4.4.2 Word Masking

We included five sub-masker functions; Role masker, Language Model (LM) masker, Part-of-Speech (PoS) masker, Stopword masker, and Observation masker. Each of them returns 1 for generable words. Then, we define $m(\cdot, s, T, w) = 1$ only when all the sub-maskers return 1. Next we give the definitions of the five sub-maskers.

Role masker. The Role masker filters words that are not semantically compatible with a given role

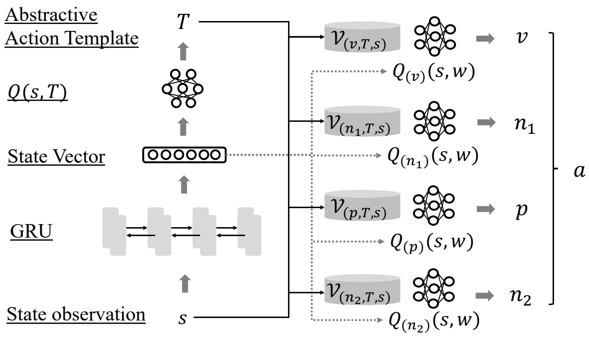

Figure 4: L-GAT model without Template Masking.

by referring to the annotated WordNet nodes as mentioned in §4.3. For the noun slots, it enables hyponym words of the reference nodes to be produced. For example, for the n_1 slot of the EAT template, it returns 1 for hyponym words of the *food.n.01* node such as *water* and *tomato* (see Table 1). For the v slot (i.e., `Predicate`), it returns 1 for lemmas of the annotated nodes themselves such as *go.v.01* = *go* and *enter.v.01* = *enter*. All words have 1 in the p slot, and no words have 1 in any `Null` slot.

LM masker. The LM masker filters contextually irrelevant candidates with an LM. The LM takes an observation suffixed with a verb of the template as the input (an example is given in Appendix B), and it predicts the following word. On the basis of the estimated probability of next words, the LM masker returns 1 for the top-k words. At the v and p slots, all words have 1. We used a pre-trained GPT-2 (Radford et al., 2019) and set $k = 50$.

PoS, Stopword, and Observation maskers. The PoS masker filters words in which a PoS is not matched with the expected one. Specifically, it returns 1 for verbs in the v slot, for nouns in the n_1 and n_2 slots, and for prepositions in the p slot. The word-PoS mapping follows WordNet in terms of verbs and nouns, and we prepared a fixed list of prepositions. The Stopword masker prohibits the generation of stopwords such as determiners (e.g., *a*, *the*) and pronouns (e.g., *he*, *them*). We prepared a fixed list, and the masker returns 1 for words that are not on the list. The Observation masker filters unseen words from observation. It returns 1 for words that appeared in the last observation.

4.4.3 Template Masking

L-GAT also filters unavailable templates in a state with the $\mathcal{V}_{(\cdot,T,s)}$ of each template. $\mathcal{V}_{(\cdot,T,s)}$ is empty when one of the sub-maskers denies the use of a word, and this occurs for all words in $\mathcal{V}$. An empty $\mathcal{V}_{(\cdot,T,s)}$ means that no appropriate objects exist for performing the action (e.g., we cannot eat anything if no eatable objects exist.). Thus, L-GAT selects a template as: $T = \arg\max_{T\in\mathcal{T}} Q(s,T)$, where $\mathcal{T}$ is a set of templates in which $\mathcal{V}_{(\cdot,T,s)}$ is not empty for all slots except for NULL slots.

Limitations	Methods				
	TD	KG	NA	CA	LG
Game-specific vocab	y	y	y	n	y
Game-specific template	y	y	n	n	n
Admissible actions	y	y	n	n	n

Tuned Rules for IFGs	n	n	y	n	n
Exclude no-effect acts	y	y	n	y	n

Table 2: Limitations in action generation. Method names come from their first two characters.

5 Experiment

In our experiment, we measured performance in IF games in Jericho (Hausknecht et al., 2020). We compared our L-GAT agent with agents who rely on environment-dependent actions. We also performed detailed analysis such as on action coverage and action space reduction and masker ablation study on L-GAT. Furthermore, to evaluate the generalization ability of L-GAT, we also conducted an extended experiment in which a single agent solved all games.

5.1 Settings

Game environment. We selected 18 games in Jericho on the basis of the performance in previous studies. We did not select any game that was too hard for most of the existing agents to learn.

Baselines. There were four existing agents tested in Jericho; TDQN (Hausknecht et al., 2020), KGA2C (Ammanabrolu and Hausknecht, 2020), NAIL (Hausknecht et al., 2019), and CALM (Yao et al., 2020). The limitations related to their action generation are summarized in Table 2 (see also §2).

In the experiments with TDQN, KGA2C, and CALM, these methods preselected steps by excluding no-effect actions that do not change the world state for faster and stable learning. This limitation is not appropriate for testing general action sets such as L-GAT because the game engine explicitly restricts the action space.

Games	Max Score	TDQN	KGA2C	CALM	NAIL	TDQN+	L-GAT	Cover Ratio (#)
		(w/ step preselection)			(w/o step preselection)

Norm Avg.	-	9.8%	14.1%	15.5%	8.0%	9.9%	8.9%	82%

Table 3: Average scores of last 100 episodes. Those of TDQN, KGA2C, NAIL, and CALM come from their respective papers. TDQN, KGA2C, and CALM cannot be fairly compared with L-GAT because of step preselection by excluding no-effect actions. TDQN+ and L-GAT are our implementations containing all steps regardless of action effectivity. Cover ratio shows proportion of generable walkthrough actions with L-GAT, and number in parentheses is total number of effective walkthrough actions.

To focus on the comparison of environment-dependent and agnostic action templates, we re-implemented the TDQN algorithm in our code base (denoted as TDQN+), in which all steps were counted regardless of action effectivity. Also, we implemented TDQN+ without the admissible action limitation; the difference in the above limitations between TDQN+ and L-GAT is their template types only (i.e., game-specific or general templates). Thus, we mainly compared NAIL, TDQN+, and L-GAT. Although a comparison with the original scores of TDQN, KGA2C, and CALM would not be fair, we also add them as references for completeness.

Note that the vocabulary limitation is practically needed because any action containing unknown words for a game engine cannot be accepted even though the action command is semantically correct. CALM overcame this vocabulary issue by learning the word distribution of action commands used in IF games from human-play transcriptions.

Model and training details. Following the works of Hausknecht et al. (2020); Yao et al. (2020), we used a bidirectional GRU as our observation encoder, and the observation string was augmented by combining the observations returned by the "look" and "inventory" commands. All Q-functions were implemented with a multi-layered perceptron with the same hyperparameters. In an episode, we limited the number of steps to 100 at most and ran agents with ten environments in parallel. In addition to the rewards given by the games, we gave an exploration bonus of 1 when an agent found an unseen state in the episode (Yuan et al., 2019). We put the hyperparameter details in Appendix C. We trained three agents with different random seeds and used their average score for the evaluation.

5.2 Results

We report the results of the game performance, action coverage by L-GAT, action space reduction by L-GAT, and an ablation study on Word Masking. Finally, we introduce the results of a single agent that solved multiple games.

Game performance. Following the previous studies, we calculated the average score of the last 100 episodes, and the results are shown in Table 3. The average normalized score (raw score divided by the maximum score) was 8.0% for NAIL, 9.9% for TDQN+, and 8.9% for L-GAT. Even though the action templates of L-GAT were designed in a general manner, our agent achieved reasonable performance across games and outperformed NAIL and TDQN+ in six games.

NAIL and L-GAT performed poorly in enchanter and snacktime compared with TDQN+. In these games, a number of critical actions for advancing the story were missing because their generable actions are defined outside of a specific game. For example, artificial words like spells (e.g., *frotz*, *gnusto*) appear in enchanter, and they are intractable with L-GAT, which uses only common language. As an additional investigation, we added a "SPELL" action to L-GAT for producing these spell words and re-trained an agent with the enchanter game; the score of L-GAT then increased to 20.0, which was close to the score of TDQN+ (22.9).

The scores of KGA2C (14.1%) and CALM (15.5%) were significantly higher. This suggests that their techniques, such as the dynamic state graph encoding and the domain adaptation of LM's outputs, are promising, and we will investigate their importance for our framework as future work.

Walkthrough coverage. Jericho provides an action trajectory called a *walkthrough* that solves a game. We assessed how much L-GAT covered walkthrough actions. The detailed procedure of this assessment is explained in Appendix C. The right-most column in Table 3 shows the cover ratio of the walkthrough actions for L-GAT. The average coverage across games was 82%, and around 90% or more of the actions were covered in half of the games. A lower coverage ratio ($< 70\%$) was observed in balances (53%), spellbrkr (57%), ztuu (62%), and library (69%). In their walkthrough actions, we frequently found artificial words (e.g., *rezrov*), named entities such as person's name (e.g., *give card to Alan*), and modifiers for objects (e.g., *wear fur suit*, *take ticket 2306*). Although the first case might be out-of-scope of L-GAT, the second and third are critical because they must appear in an interaction with real-world environments.

Action space reduction. We evaluated how much the action space was reduced in L-GAT by applying Word Masking (4.4.2) and Template Masking (4.4.3). For each slot in each available template (v, n_1, p, and n_2), we counted the number of words that were accepted by these techniques. Compared with the size of the whole vocabulary, the number of words was significantly reduced by 94% for v (24.8 words on average after reduction), 82% for n_1 (117.9 words), 99% for p (7.7 words), and 59% for n_2 (292.2 words).

Masker ablation. Figure 5 shows the learning curves of the L-GAT agents without one of the sub-maskers for Word Masking in zork1. A significant effect was observed with the Role masker. Specifically, the agent without the Role masker took more episodes to find the scored trajectory and degraded the overall performance. The PoS and Stopword maskers were not critical, which might be because their restrictions are already covered by the Role masker. The LM and Observation maskers had non-trivial effects. Since the Role masker enables relatively broader words in noun slots (i.e., hyponyms of a general word), contextual restrictions given by the LM and Observation maskers helped the agent identify available objects.

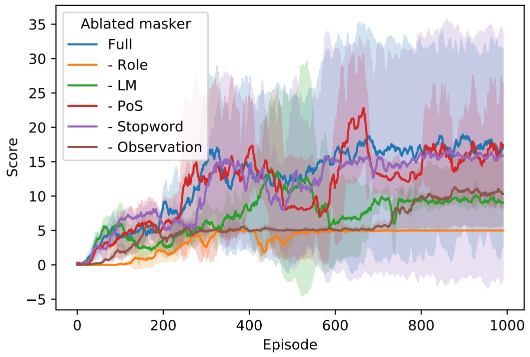

Figure 5: Masker ablation of L-GAT in zork1.

Table 4: Average scores of last 100 episodes in game-independent agent experiments.

Game-independent agent To investigate the generalization ability of L-GAT, we conducted a multi-task experiment where a single agent solved all the games. We prepared two types of agents: 1) a *multi-task agent*, who learns with all 18 games and solves each game, and 2) a *Zero-shot agent*, who learns with 17 games and solves the remaining unseen game. Note that L-GAT can be naturally applicable to this experimental setting. In terms of the implementation of TDQN+, we accumulated all the unique templates used in training games as available templates. Table 4 shows the game scores. Both TDQN+ and L-GAT largely decreased in score compared with Table 3, in which we trained and tested a specific agent for each game. Also, as expected, the zero-shot situation was more difficult. Whereas L-GAT outperformed TDQN+, the scores were far from achieving the goal. It was still challenging to obtain an environment-agnostic agent even though the action set itself is defined in a general manner.

6 Limitations and Future Work

Although L-GAT showed a better performance in our experiment, there is still room for improvement to enhance its language capability. We here discuss L-GAT's limitations and future improvements.

Experiments in environments other than text-based games. One of the advantages of L-GAT is its action generality. Jericho is a reasonable testbed for L-GAT because of the diverse games and strong NL interpreter. However, the performance in other environments such as dialogue systems (Dinan et al., 2019) and 3D video games (Gordon et al., 2018) will also be critical metrics because objectives for IF-game agents are not necessarily compatible with ones for real-world agents. Testing with real-world like environments will lead to insights for improving L-GAT.

Enhancement of expressive power. In our experiment, L-GAT had a high action coverage in the IF games. However, the format of generable actions is fixed, and we observed several critical disabilities with generating frequently used expressions. For example, L-GAT cannot cope with multi-word expressions (e.g., *turn on*, *New York*) and modified nouns (e.g., *red cup*, *dog in the room*). Note that we can make them generable without adding extra slots, such as by inserting multi-word expressions in the vocabulary and integrating a reference resolution module. A technique that increases the expressive power but keeps or decreases the action space would be a desirable enhancement.

Zero-shot learning in L-GAT The general-purpose property of L-GAT can be seen as a zero-shot learning problem. Recently, Jain et al. 2020 proposed a new experiment to assess the adaptability of an RL agent to unseen states such as by using a new tool with the knowledge of known tools. L-GAT potentially can work for such a zero-shot situation. For example, let us assume that an L-GAT agent has a learned policy for attacking a monster with a hammer, and he then encounters a monster, but only a sword is available. Even if the agent did not know how to or even use a sword at all, he may be able to use it because L-GAT has knowledge on attacks with "*weapon*" (i.e., the `Instrument` role of the ATTACK template has a weapon node in WordNet, and "*sword*" is a hyponym of "*weapon*"; see Table 1 in Appendix A). Investigation into the adaptability to unseen states would be a promising analysis for L-GAT.

Connection to wide NLP resources and tools. Although we developed L-GAT on top of general semantic schemes such as FrameNet, VerbNet, and WordNet, the required information for efficient decision-making cannot be covered with only those resources. Intelligent agents must comprehend common sense, causality, and world-knowledge (Luketina et al., 2019). Research on NLP has created various resources such as for retrieving information from Wikipedia (Chen et al., 2017), inferring the next action from a current state (Zellers et al., 2018), and using a common-sense database (Speer et al., 2017). Integration of such resources into L-GAT is critical future work, and the three general semantic schemes would be helpful for bridging different knowledge bases.

7 Conclusion

We proposed L-GAT as an environment-agnostic language-based action framework for RL agents. We designed L-GAT so that an agent can have a higher language capability to generate its own actions while keeping the action space tractable by using prior knowledge. Our experiment with multiple IF games showed that the L-GAT agent competitively performed against agents with game-specific actions. We discussed the current limitations of L-GAT and its future improvements.

Ethical Consideration

Our research is on defining a new action framework for RL agents. Our proposed method, L-GAT, is for generating actions of RL agents, which is unlikely to produce ethically problematic sentences such as those in hate speech. Also, we can control the vocabulary so that an agent with L-GAT does not produce such problematic sentences. Therefore, we consider the ethical risks of L-GAT to be low and controllable.

A Definitions of Action Templates

We manually defined 41 abstractive action templates in total, and Table 6 shows extended examples. We give definitions of all of the templates at `https://github.com/kohilin/lgat`.

B Masker Function Details

Input for LM masker. The input of the LM masker is an observation string suffixed with one of the verbs in the template. For example, in the case of GIVE with the observation "*You have a cup of water. A boy stands in front of you.*", the input for the n_1 slot is "*... front of you. You gave the,*" and that for the n_2 slot is "*... front of you. You gave it to the.*"

Mask for primitive actions. L-GAT allows an agent to produce primitive actions, related to movement and belongings, regardless of the outputs of the masker function. Specifically, we forcibly assign 1 for direction words (*up*, *down*, *north*, *south*, *east*, *west*, *northwest*, *northeast*, *southwest*, *southeast*) to the n_1 slot in the GO template and *all* to the n_1 slots in the GET and DROP templates.

C Experimental Details

Hyperparameters. Table 5 shows our experimental hyperparameters and values searched for in the hyperparameter search. We tuned the α decay and initial ϵ, minimum ϵ, and ϵ decay for each game and each method. The other parameters were determined by testing with detective, temple, and zork1, and we applied the same settings to all of the games.

Machine specifications. We ran our experiment on Red Hat Enterprise Linux with an Intel(R) Xeon(R) CPU E5-2690 v4 at 2.60 GHz with 500GB of RAM and a single GPU, an NVIDIA TESLA K80.

Training time. Training with one game took approximately 10 ˜15 hours for the L-GAT agents, and 4 ˜6 hours for the TDQN+ agents depending on the game.

Model size. The number of trainable parameters for the L-GAT agent was about 10 million, which slightly changed depending on the vocabulary size of the games.

Table 5: Hyperparameter settings and values in hyperparameter search.

Walkthrough experiment. In the experiment, we investigated how many walkthrough actions were covered by L-GAT. The same transition can be possible with different action strings. Therefore, for each state, we tried all generable strings of L-GAT and checked that at least one of them could produce the same transition with the gold walkthrough action. To judge if two transitions were the same or not, we used the game state hash provided by Jericho. Several walkthrough actions did not change the world state hash. We excluded such no-effect walkthrough actions from the evaluation since completely different actions were classified as replaceable for them.

D Learning Curves of Each Game

Figure 6 shows learning curves of the L-GAT and TDQN+ agents in each game.

MiniLMv2: Multi-Head Self-Attention Relation Distillation for Compressing Pretrained Transformers

Wenhui Wang **Hangbo Bao** **Shaohan Huang** **Li Dong** **Furu Wei**[*]

Abstract

We generalize deep self-attention distillation in MiniLM (Wang et al., 2020) by only using self-attention relation distillation for task-agnostic compression of pretrained Transformers. In particular, we define multi-head self-attention relations as scaled dot-product between the pairs of *query*, *key*, and *value* vectors within each self-attention module. Then we employ the above relational knowledge to train the student model. Besides its simplicity and unified principle, more favorably, there is no restriction in terms of the number of student's attention heads, while most previous work has to guarantee the same head number between teacher and student. Moreover, the fine-grained self-attention relations tend to fully exploit the interaction knowledge learned by Transformer. In addition, we thoroughly examine the layer selection strategy for teacher models, rather than just relying on the last layer as in MiniLM. We conduct extensive experiments on compressing both monolingual and multilingual pre-trained models. Experimental results demonstrate that our models[1] distilled from base-size and large-size teachers (BERT, RoBERTa and XLM-R) outperform the state-of-the-art.

1 Introduction

Pretrained Transformers (Radford et al., 2018; Devlin et al., 2018; Dong et al., 2019; Yang et al., 2019; Joshi et al., 2019; Liu et al., 2019; Bao et al., 2020; Radford et al., 2019; Raffel et al., 2019; Lewis et al., 2019a) have been highly successful for a wide range of natural language processing tasks. However, these models usually consist of hundreds of millions of parameters and are getting bigger. It brings challenges for fine-tuning and online serving in real-life applications due to the restrictions of computation resources and latency.

Knowledge distillation (KD; Hinton et al. 2015, Romero et al. 2015) has been widely employed to compress pretrained Transformers, which transfers knowledge of the large model (teacher) to the small model (student) by minimizing the differences between teacher and student features. Soft target probabilities (soft labels) and intermediate representations are usually utilized to perform KD training. In this work, we focus on task-agnostic compression of pretrained Transformers (Sanh et al., 2019; Tsai et al., 2019; Jiao et al., 2019; Sun et al., 2019b; Wang et al., 2020). The student models are distilled from large pretrained Transformers using large-scale text corpora. The distilled task-agnostic model can be directly fine-tuned on downstream tasks, and can be utilized to initialize task-specific distillation.

DistilBERT (Sanh et al., 2019) uses soft target probabilities for masked language modeling predictions and embedding outputs to train the student. The student model is initialized from the teacher by taking one layer out of two. TinyBERT (Jiao et al., 2019) utilizes hidden states and self-attention distributions (i.e., attention maps and weights), and adopts a uniform function to map student and teacher layers for layer-wise distillation. MobileBERT (Sun et al., 2019b) introduces specially designed teacher and student models using inverted-bottleneck and bottleneck structures to keep their layer number and hidden size the same, layer-wisely transferring hidden states and self-attention distributions. MiniLM (Wang et al., 2020) proposes deep self-attention distillation, which uses self-attention distributions and value relations to help the student to deeply mimic teacher's self-attention modules. MiniLM shows that transferring knowledge of teacher's last layer achieves better performance than layer-wise distil-

lation. In summary, most previous work relies on self-attention distributions to perform KD training, which leads to a restriction that the number of attention heads of student model has to be the same as its teacher.

In this work, we generalize and simplify deep self-attention distillation of MiniLM (Wang et al., 2020) by using self-attention relation distillation. We introduce multi-head self-attention relations computed by scaled dot-product of pairs of queries, keys and values, which guides the student training. Taking query vectors as an example, in order to obtain queries of multiple relation heads, we first concatenate query vectors of different attention heads, and then split the concatenated vector according to the desired number of relation heads. Afterwards, for teacher and student models with different attention head numbers, we can align their queries with the same number of relation heads for distillation. Moreover, using a larger number of relation heads brings more fine-grained self-attention knowledge, which helps the student to achieves a deeper mimicry of teacher's self-attention module. In addition, for large-size (24 layers, 1024 hidden size) teachers, extensive experiments indicate that transferring an upper middle layer tends to perform better than using the last layer as in MiniLM.

Experimental results show that our monolingual models distilled from BERT and RoBERTa, and multilingual models distilled from XLM-R outperform state-of-the-art models in different parameter sizes. The 6×768 (6 layers, 768 hidden size) model distilled from $\text{BERT}_{\text{LARGE}}$ is 2.0× faster, meanwhile, performing better than $\text{BERT}_{\text{BASE}}$. The base-size model distilled from $\text{RoBERTa}_{\text{LARGE}}$ outperforms $\text{RoBERTa}_{\text{BASE}}$ using much fewer training examples.

To summarize, our contributions include:

- We generalize and simplify deep self-attention distillation in MiniLM by introducing multi-head self-attention relation distillation, which brings more fine-grained self-attention knowledge and allows more flexibility for the number of student's attention heads.
- We conduct extensive distillation experiments on different large-size teachers and find that using knowledge of a teacher's upper middle layer achieves better performance.
- Experimental results demonstrate the effectiveness of our method for different monolingual and multilingual teachers in base-size and large-size.

2 Related Work

2.1 Backbone Network: Transformer

Multi-layer Transformer (Vaswani et al., 2017) has been widely adopted in pretrained models. Each Transformer layer consists of a self-attention sub-layer and a position-wise fully connected feed-forward sub-layer.

Self-Attention Transformer relies on multi-head self-attention to capture dependencies between words. Given previous Transformer layer's output $\mathbf{H}^{l-1} \in \mathbb{R}^{|x| \times d_h}$, the output of a self-attention head $\mathbf{O}_{l,a},\ a \in [1, A_h]$ is computed via:

$$\mathbf{Q}_{l,a} = \mathbf{H}^{l-1}\mathbf{W}^{Q}_{l,a} \quad (1)$$

$$\mathbf{K}_{l,a} = \mathbf{H}^{l-1}\mathbf{W}^{K}_{l,a} \quad (2)$$

$$\mathbf{V}_{l,a} = \mathbf{H}^{l-1}\mathbf{W}^{V}_{l,a} \quad (3)$$

$$\mathbf{O}_{l,a} = \text{softmax}(\frac{\mathbf{Q}_{l,a}\mathbf{K}^{\intercal}_{l,a}}{\sqrt{d_k}})\mathbf{V}_{l,a} \quad (4)$$

Previous layer's output is linearly projected to queries, keys and values using parameter matrices $\mathbf{W}^{Q}_{l,a}, \mathbf{W}^{K}_{l,a}, \mathbf{W}^{V}_{l,a} \in \mathbb{R}^{d_h \times d_k}$, respectively. The self-attention distributions are computed via scaled dot-product of queries and keys. These weights are assigned to the corresponding value vectors to obtain the attention output. $|x|$ represents the length of input sequence. A_h and d_h indicate the number of attention heads and hidden size. d_k is the attention head size. $d_k \times A_h$ is usually equal to d_h.

2.2 Pretrained Language Models

Pre-training has led to strong improvements across a variety of natural language processing tasks. Pretrained language models are learned on large amounts of text data, and then fine-tuned to adapt to specific tasks. BERT (Devlin et al., 2018) proposes to pretrain a deep bidirectional Transformer using masked language modeling (MLM) objective. UniLM (Dong et al., 2019) is jointly pretrained on three types language modeling objectives to adapt to both understanding and generation tasks. RoBERTa (Liu et al., 2019) achieves strong performance by training longer steps using large batch size and more text data. MASS (Song et al., 2019), T5 (Raffel et al., 2019) and BART (Lewis et al.,

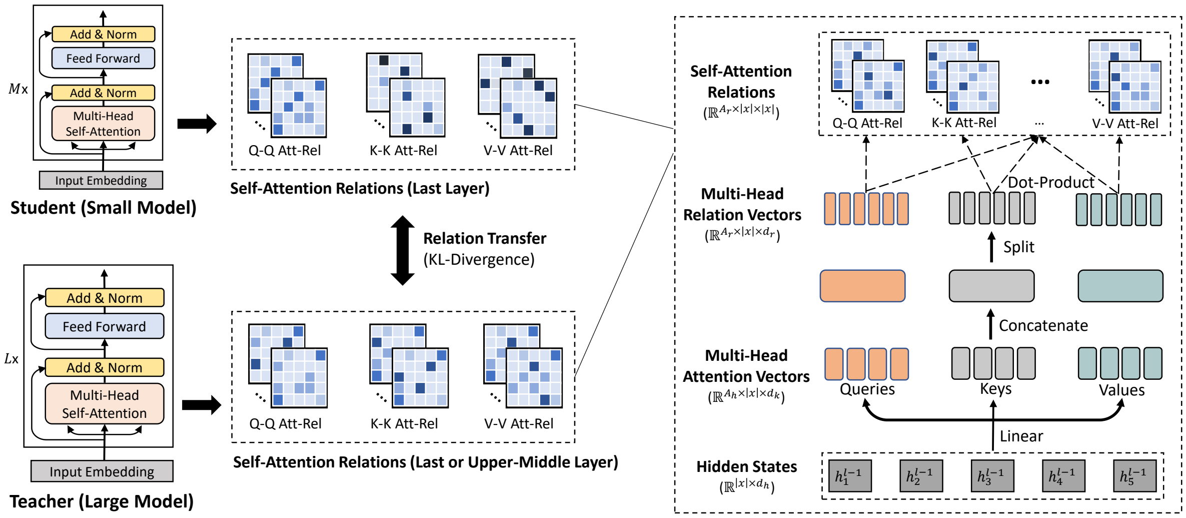

Figure 1: Overview of multi-head self-attention relation distillation. We introduce multi-head self-attention relations computed by scaled dot-product of pairs of queries, keys and values to guide the training of students. In order to obtain vectors (queries, keys and values) of multiple relation heads, we first concatenate self-attention vectors of different attention heads and then split them according to the desired number of relation heads. We choose to transfer Q-Q, K-K and V-V self-attention relations to achieve a balance between performance and training speed. For large-size teacher, we transfer the self-attention knowledge of an upper middle layer of the teacher. For base-size teacher, using the last layer achieves better performance.

2019a) employ a standard encoder-decoder structure and pretrain the decoder auto-regressively. Besides monolingual pretrained models, multilingual pretrained models (Devlin et al., 2018; Lample and Conneau, 2019; Chi et al., 2019; Conneau et al., 2019; Chi et al., 2020) also advance the state-of-the-art on cross-lingual understanding and generation.

2.3 Knowledge Distillation

Knowledge distillation has been proven to be a promising way to compress large models while maintaining accuracy. Knowledge of a single or an ensemble of large models is used to guide the training of small models. Hinton et al. (2015) propose to use soft target probabilities to train student models. More fine-grained knowledge such as hidden states (Romero et al., 2015) and attention distributions (Zagoruyko and Komodakis, 2017; Hu et al., 2018) are introduced to improve the student model.

In this work, we focus on task-agnostic knowledge distillation of pretrained Transformers. The distilled task-agnostic model can be fine-tuned to adapt to downstream tasks. It can also be utilized to initialize task-specific distillation (Sun et al., 2019a; Turc et al., 2019; Aguilar et al., 2019; Mukherjee and Awadallah, 2020; Xu et al., 2020; Hou et al., 2020; Li et al., 2020), which uses a fine-tuned teacher model to guide the training of the student on specific tasks. Knowledge used for distillation and layer mapping function are two key points for task-agnostic distillation of pretrained Transformers. Most previous work uses soft target probabilities, hidden states, self-attention distributions and value-relation to train the student model. For the layer mapping function, TinyBERT (Jiao et al., 2019) uses a uniform strategy to map teacher and student layers. MobileBERT (Sun et al., 2019b) assumes the student has the same number of layers as its teacher to perform layer-wise distillation. MINILM (Wang et al., 2020) transfers self-attention knowledge of teacher's last layer to the student last Transformer layer. Different from previous work, our method uses multi-head self-attention relations to eliminate the restriction on the number of student's attention heads. Moreover, we show that transferring the self-attention knowledge of an upper middle layer of the large-size teacher model is more effective.

3 Multi-Head Self-Attention Relation Distillation

Following MINILM (Wang et al., 2020), the key idea of our approach is to deeply mimic teacher's self-attention module, which draws dependencies between words and is the vital component of Transformer. MINILM uses teacher's self-attention distributions to train the student model. It brings

Table 1: Results of our students distilled from base-size and large-size teachers on the development sets of GLUE and SQuAD 2.0. We report F1 for SQuAD 2.0, Matthews correlation coefficient for CoLA, and accuracy for other datasets. The GLUE results of DistilBERT are taken from Sanh et al. (2019). The rest results of DistilBERT, TinyBERT[2], BERT$_{\text{SMALL}}$, Truncated BERT$_{\text{BASE}}$ and MiniLM are taken from Wang et al. (2020). BERT$_{\text{SMALL}}$ (Turc et al., 2019) is trained using the MLM objective, without using KD. We also report the results of truncated BERT$_{\text{BASE}}$ and truncated RoBERTa$_{\text{BASE}}$, which drops the top 6 layers of the base model. Top-layer dropping has been proven to be a strong baseline (Sajjad et al., 2020). The fine-tuning results are an average of 4 runs.

the restriction on the number of attention heads of students, which is required to be the same as its teacher. To introduce more fine-grained self-attention knowledge and avoid using teacher's self-attention distributions, we generalize deep self-attention distillation in MiniLM and introduce multi-head self-attention relations of pairs of queries, keys and values to train the student. Besides, we conduct extensive experiments and find that layer selection of the teacher model is critical for distilling large-size models. Figure 1 gives an overview of our method.

3.1 Multi-Head Self-Attention Relations

Multi-head self-attention relations are obtained by scaled dot-product of pairs[3] of queries, keys and values of multiple relation heads. Taking query vectors as an example, in order to obtain queries of multiple relation heads, we first concatenate queries of different attention heads and then split the concatenated vector based on the desired number of relation heads. The same operation is also performed on keys and values. For teacher and student models which uses different number of attention heads, we convert their queries, keys and values of different number of attention heads into vectors of the same number of relation heads to perform KD training. Our method eliminates the restriction on the number of attention heads of student models. Moreover, using more relation heads in computing self-attention relations brings more fine-grained self-attention knowledge and improves the performance of the student model.

We use $\mathbf{A}_1, \mathbf{A}_2, \mathbf{A}_3$ to denote the queries, keys and values of multiple relation heads. The KL-divergence between multi-head self-attention relations of the teacher and student is used as the training objective:

$$\mathcal{L} = \sum_{i=1}^{3}\sum_{j=1}^{3} \alpha_{ij}\mathcal{L}_{ij} \tag{5}$$

$$\mathcal{L}_{ij} = \frac{1}{A_r|x|}\sum_{a=1}^{A_r}\sum_{t=1}^{|x|} D_{KL}(\mathbf{R}^T_{ij,l,a,t} \parallel \mathbf{R}^S_{ij,m,a,t}) \tag{6}$$

$$\mathbf{R}^T_{ij,l,a} = \text{softmax}(\frac{\mathbf{A}^T_{i,l,a}\mathbf{A}^{T\intercal}_{j,l,a}}{\sqrt{d_r}}) \tag{7}$$

$$\mathbf{R}^S_{ij,m,a} = \text{softmax}(\frac{\mathbf{A}^S_{i,m,a}\mathbf{A}^{S\intercal}_{j,m,a}}{\sqrt{d'_r}}) \tag{8}$$

where $\mathbf{A}^T_{i,l,a} \in \mathbb{R}^{|x|\times d_r}$ and $\mathbf{A}^S_{i,m,a} \in \mathbb{R}^{|x|\times d'_r}$ $(i \in [1,3])$ are the queries, keys and values of a relation head of l-th teacher layer and m-th student layer. d_r and d'_r are the relation head size of teacher and student models. $\mathbf{R}^T_{ij,l} \in \mathbb{R}^{A_r\times|x|\times|x|}$ is the self-attention relation of $\mathbf{A}^T_{i,l}$ and $\mathbf{A}^T_{j,l}$ of teacher model.

---

[2] In addition to task-agnostic distillation, TinyBERT uses task-specific distillation and data augmentation to further improve the model. We report the fine-tuning results of their public task-agnostic model.

[3] There are nine types of self-attention relations, such as query-query, key-key, key-value and query-value relations.

Model	Teacher	#Param	Speedup	SQuAD2	MNLI-m/mm	QNLI	QQP	RTE	SST	MRPC	CoLA	STS	Avg
BERT$_{\text{BASE}}$	-	109M	1.0×	76.8	84.6/83.4	90.5	71.2	66.4	93.5	88.9	52.1	85.8	79.3
BERT$_{\text{LARGE}}$	-	340M	0.3×	81.9	86.7/85.9	92.7	72.1	70.1	94.9	89.3	60.5	86.5	82.1

Table 2: Results of our 6×768 students distilled form BERT on GLUE test sets and SQuAD 2.0 dev set. The reported results are directly fine-tuned on downstream tasks. We report F1 for SQuAD 2.0, QQP and MRPC, Spearman correlation for STS-B, Matthews correlation coefficient for CoLA and accuracy for the rest.

$\mathbf{R}^{T}_{ij,l,a} \in \mathbb{R}^{|x|\times|x|}$ is the self-attention relation of a teacher's relation head. $\mathbf{R}^{S}_{ij,m} \in \mathbb{R}^{A_r\times|x|\times|x|}$ is the self-attention relation of student model. For example, $\mathbf{R}^{T}_{11,l}$ represents teacher's Q-Q attention relation in Figure 1. A_r is the number of relation heads. If the number of relation heads and attention heads is the same, the Q-K relation is equivalent to the attention weights in self-attention module. $\alpha_{ij} \in \{0, 1\}$ is the weight assigned to each self-attention relation loss. We transfer query-query, key-key and value-value self-attention relations to balance the performance and training cost.

3.2 Layer Selection of Teacher Model

Besides the knowledge used for distillation, mapping function between teacher and student layers is another key factor. As in MiniLM, we only transfer the self-attention knowledge of one of the teacher layers to the student last layer. Only distilling one layer of the teacher model is fast and effective. Different from previous work which usually conducts experiments on base-size teachers, we experiment with different large-size teachers and find that transferring self-attention knowledge of an upper middle layer performs better than using other layers. For BERT$_{\text{LARGE}}$ and BERT$_{\text{LARGE-WWM}}$, transferring the 21-th (start at one) layer achieves the best performance. For RoBERTa$_{\text{LARGE}}$ and XLM-R$_{\text{LARGE}}$, using the self-attention knowledge of 19-th layer achieves better performance. For the base-size teacher, we also find that using teacher's last layer performs better.

4 Experiments

We conduct distillation experiments on different teacher models including BERT$_{\text{BASE}}$, BERT$_{\text{LARGE}}$, BERT$_{\text{LARGE-WWM}}$, RoBERTa$_{\text{BASE}}$, RoBERTa$_{\text{LARGE}}$, XLM-R$_{\text{BASE}}$ and XLM-R$_{\text{LARGE}}$.

4.1 Setup

We use the uncased version for three BERT teacher models. For the pre-training data, we use English Wikipedia and BookCorpus (Zhu et al., 2015). We train student models using 256 as the batch size and 6e-4 as the peak learning rate for $400,000$ steps. We use linear warmup over the first $4,000$ steps and linear decay. We use Adam (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.999$. The maximum sequence length is set to 512. The dropout rate and weight decay are 0.1 and 0.01. The number of attention heads is 12 for all student models. The number of relation heads is 48 and 64 for base-size and large-size teacher model, respectively. The student models are initialized randomly.

For models distilled from RoBERTa, we use similar pre-training datasets as in Liu et al. (2019). For the 12×768 student model, we use Adam with $\beta_1 = 0.9$, $\beta_2 = 0.98$. The rest hyper-parameters are the same as models distilled from BERT.

For multilingual student models distilled from XLM-R, we perform training using the same datasets as in Conneau et al. (2019) for $1,000,000$ steps. We conduct distillation experiments using 8 V100 GPUs with mixed precision training.

4.2 Downstream Tasks

Following previous pre-training (Devlin et al., 2018; Liu et al., 2019; Conneau et al., 2019) and task-agnostic distillation (Sun et al., 2019b; Jiao et al., 2019) work, we evaluate the English student models on GLUE benchmark and extractive question answering. The multilingual models are evaluated on cross-lingual natural language inference and cross-lingual question answering.

GLUE General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2019) consists of two single-sentence classification tasks (SST-2 (Socher et al., 2013) and CoLA (Warstadt et al., 2018)), three similarity and paraphrase tasks (MRPC (Dolan and Brockett, 2005), STS-B (Cer et al., 2017) and QQP), and four inference tasks (MNLI (Williams et al., 2018), QNLI (Rajpurkar et al., 2016), RTE (Dagan et al., 2006; Bar-Haim et al., 2006; Giampiccolo et al., 2007; Bentivogli

Model	Teacher	#Param	SQuAD2	MNLI	QNLI	QQP	RTE	SST	MRPC	CoLA	STS	Avg

et al., 2009) and WNLI (Levesque et al., 2012)).

Extractive Question Answering The task aims to predict a continuous sub-span of the passage to answer the question. We evaluate on SQuAD 2.0 (Rajpurkar et al., 2018), which has been served as a major question answering benchmark.

Cross-lingual Natural Language Inference (XNLI) XNLI (Conneau et al., 2018) is a cross-lingual classification benchmark. It aims to identity the semantic relationship between two sentences and provides instances in 15 languages.

Cross-lingual Question Answering We use MLQA (Lewis et al., 2019b) to evaluate multilingual models. MLQA extends English SQuAD dataset (Rajpurkar et al., 2016) to seven languages.

4.3 Main Results

Table 1 presents the dev results of 6×384 and 6×768 models distilled from BERT$_{\text{BASE}}$, BERT$_{\text{LARGE}}$ and RoBERTa$_{\text{LARGE}}$ on GLUE and SQuAD 2.0. (1) Previous methods (Sanh et al., 2019; Jiao et al., 2019; Sun et al., 2019a; Wang et al., 2020) usually distill BERT$_{\text{BASE}}$ into a 6-layer model with 768 hidden size. We first report results of the same setting. Our 6×768 model outperforms DistilBERT, TinyBERT, MiniLM and two BERT baselines across most tasks. Moreover, our method allows more flexibility for the number of attention heads of student models. (2) Both 6×384 and 6×768 models distilled from BERT$_{\text{LARGE}}$ outperform models distilled from BERT$_{\text{BASE}}$. The 6×768 model distilled from BERT$_{\text{LARGE}}$ is 2.0× faster than BERT$_{\text{BASE}}$, while achieving better performance. (3) Student models distilled from RoBERTa$_{\text{LARGE}}$ achieve further improvements. Better teacher results in better students. Multi-head self-attention relation distillation is effective for different large-size pretrained Transformers.

We report the results of 6×768 students distilled from BERT$_{\text{BASE}}$ and BERT$_{\text{LARGE}}$ on GLUE test sets and SQuAD 2.0 dev set in Table 2. 6×768 model distilled from BERT$_{\text{BASE}}$ retains more than 99% accuracy of its teacher while using 50% Transformer parameters. 6×768 model distilled from BERT$_{\text{LARGE}}$ compares favorably with BERT$_{\text{BASE}}$.

We compress RoBERTa$_{\text{LARGE}}$ and BERT$_{\text{LARGE}}$ into a base-size student model. Dev results of GLUE benchmark and SQuAD 2.0 are shown in Table 3. Our base-size models distilled from large-size teacher outperforms BERT$_{\text{BASE}}$ and RoBERTa$_{\text{BASE}}$. Our method can be adopted to train students in different parameter size. Moreover, our student distilled from RoBERTa$_{\text{LARGE}}$ uses a much smaller (almost 32× smaller) training batch size and fewer training steps than RoBERTa$_{\text{BASE}}$. Our method requires much fewer training examples.

Most of previous work conducts experiments using base-size teachers. To compare with previous methods on large-size teacher, we reimplement MiniLM and compress BERT$_{\text{LARGE-WWM}}$ into a 12×384 student model. Dev results of SQuAD 2.0, MNLI-m and SST-2 are presented in Table 4. Our method also outperforms MiniLM for large-size teachers. Moreover, we report results of distilling an upper middle layer instead of the last layer for MiniLM. Layer selection is also effective for MiniLM when distilling large-size teachers.

Table 5 and Table 6 show the results of our student models distilled from XLM-R on XNLI and MLQA. For XNLI, the best single model is selected on the joint dev set of all the languages as in Conneau et al. (2019). Following Lewis et al. (2019b), we adopt SQuAD 1.1 as training data and evaluate on MLQA English development set for

Table 8: Results of 6×384 model using different number of relation heads.

early stopping. Our 6×384 model outperforms mBERT (Devlin et al., 2018) with 5.3× speedup. Our method also performs better than MiniLM, which further validates the effectiveness of multi-head self-attention relation distillation. Transferring multi-head self-attention relations can bring more fine-grained self-attention knowledge.

4.4 Ablation Studies

Effect of using different self-attention relations We perform ablation studies to analyse the contribution of different self-attention relations. Dev results of three tasks are illustrated in Table 7. Q-Q, K-K and V-V self-attention relations positively contribute to the final results. Besides, we also compare Q-Q + K-K + V-V with Q-K + V-V given queries and keys are employed to compute self-attention distributions in self-attention module. Experimental result shows that using Q-Q + K-K + V-V achieves better performance.

Effect of distilling different teacher layers Figure 2 presents the results of 6×384 model distilled from different layers of BERT$_{\text{BASE}}$, BERT$_{\text{LARGE}}$ and XLM-R$_{\text{LARGE}}$. For BERT$_{\text{BASE}}$, using the last layer achieves better performance than other layers. For BERT$_{\text{LARGE}}$ and XLM-R$_{\text{LARGE}}$, we find that using one of the upper middle layers achieves the best performance. The same trend is also observed for BERT$_{\text{LARGE-WWM}}$ and RoBERTa$_{\text{LARGE}}$.

Effect of different number of relation heads Table 8 shows the results of 6×384 model distilled from BERT$_{\text{BASE}}$ and RoBERTa$_{\text{BASE}}$ using different number of relation heads. Using a larger number of relation heads achieves better performance. More fine-grained self-attention knowledge can be captured by using more relation heads, which helps the student to deeply mimic the self-attention module of its teacher. Besides, we find that the number of relation heads is not required to be a positive multiple of both the number of student and teacher attention heads. The relation head can be a fragment of a single attention head or contains fragments from

5 Discussion

5.1 Comparison with MobileBERT

MobileBERT (Sun et al., 2019b) compresses a specially designed teacher model (in the $\text{BERT}_{\text{LARGE}}$ size) with inverted bottleneck modules into a 24-layer student using the bottleneck modules. Since our goal is to compress different large models (e.g. BERT and RoBERTa) to small models using standard Transformer architecture, we note that our student model can not directly compare with MobileBERT. We provide results of a student model with the same parameter size for a reference. A public large-size model ($\text{BERT}_{\text{LARGE-WWM}}$) is used as the teacher, which achieves similar performance as MobileBERT's teacher. We distill $\text{BERT}_{\text{LARGE-WWM}}$ into a student model (25M parameters) using the same training data (i.e., English Wikipedia and BookCorpus). The test results of GLUE and dev result of SQuAD 2.0 are illustrated in Table 9. Our model outperforms MobileBERT across most tasks with a faster inference speed. Moreover, our method can be applied for different teachers and has much fewer restriction of students.

We also observe that our model performs relatively worse on CoLA compared with MobileBERT. The task of CoLA is to evaluate the grammatical acceptability of a sentence. It requires more fine-grained linguistic knowledge that can be learnt from language modeling objectives. Fine-tuning the model using the MLM objective as in MobileBERT brings improvements for CoLA. However, our preliminary experiments show that this strategy will lead to slight drop for other GLUE tasks.

5.2 Results of More Self-Attention Relations

In Table 9 and 10, we report results of students trained using more self-attention relations (Q-K, K-Q, Q-V, V-Q, K-V and V-K relations). We observe improvements across most tasks, especially for student models distilled from BERT. Fine-grained self-attention knowledge in more attention relations improves our students. However, introducing more self-attention relations also brings a higher computational cost. In order to achieve a balance between performance and computational cost, we choose to transfer Q-Q, K-K and V-V self-attention relations instead of all self-attention relations in this work.

6 Conclusion

We generalize deep self-attention distillation in MiniLM by employing multi-head self-attention relations to train the student. Our method introduces more fine-grained self-attention knowledge and eliminates the restriction of the number of student's attention heads. Moreover, we show that transferring the self-attention knowledge of an upper middle layer achieves better performance for large-size teachers. Our monolingual and multilingual models distilled from BERT, RoBERTa and XLM-R obtain competitive performance and outperform state-of-the-art methods. For future work, we are exploring an automatic layer selection algorithm. We also would like to apply our method to larger pretrained Transformers.

A GLUE Benchmark

The summary of datasets used for the General Language Understanding Evaluation (GLUE) benchmark[4] (Wang et al., 2019) is presented in Table 11.

B SQuAD 2.0

We present the dataset statistics and metrics of SQuAD 2.0[5] (Rajpurkar et al., 2018) in Table 12.

C Hyper-parameters for Fine-tuning

Extractive Question Answering For SQuAD 2.0, the maximum sequence length is 384. The batch size is set to 32. We choose learning rates from {3e-5, 6e-5, 8e-5, 9e-5} and fine-tune the model for 3 epochs. The warmup ration and weight decay is 0.1 and 0.01.

---

[4] `https://gluebenchmark.com/`

[5] `http://stanford-qa.com`

GLUE The maximum sequence length is 128 for the GLUE benchmark. We set batch size to 32, choose learning rates from {1e-5, 1.5e-5, 2e-5, 3e-5, 5e-5} and epochs from {3, 5, 10} for different student models. We fine-tune CoLA task with longer training steps (25 epochs). The warmup ration and weight decay is 0.1 and 0.01.

Cross-lingual Natural Language Inference (XNLI) The maximum sequence length is 128 for XNLI. We fine-tune 5 epochs using 128 as the batch size. The learning rates are chosen from {5e-5, 6e-5}.

Cross-lingual Question Answering For MLQA, the maximum sequence length is 512. We fine-tune 3 epochs using 32 as the batch size. The learning rates are chosen from {5e-5, 6e-5}.

Attending via both Fine-tuning and Compressing

Abstract

Though being a primary trend for enhancing interpretability of neural networks, attention mechanism's reliability and validity are still under debate. In this paper, we try to purify attention scores to obtain a more faithful explanation of downstream models. Specifically, we propose a framework consisting of a learner and a compressor, which performs fine-tuning and compressing iteratively to enhance the performance and interpretability of the attention mechanism. The learner focuses on learning better text representations to achieve good decisions by fine-tuning, while the compressor aims to perform compressions over the representations to retain the most useful clues for explanations with a Variational information bottleneck ATtention (VAT) mechanism. Extensive experiments on eight benchmark datasets show the great advantages of our proposed approach in terms of both performance and interpretability.

1 Introduction

Attention mechanisms (Bahdanau et al., 2014) have achieved great success in various natural language processing (NLP) tasks. They are introduced to mimic the human eye focusing on important parts in the inputs when predicting labels. The existing studies show attention mechanisms can improve not only the performance but also the interpretability of the models (Mullenbach et al., 2018; Xie et al., 2017; Xu et al., 2015). Li et al. (2016) pointed the view: "Attention provides an important way to explain the workings of neural models". Additionally, Wiegreffe and Pinter (2019) showed that attention mechanisms could help understand the inner workings of a model.

The basic assumption of understanding of models with attention scores is that the inputs (e.g., words) with high attentive weights are essential for making decisions. However, as far as we know, it has not been formally verified. Existing research (Jain and Wallace, 2019) also shows that attention is not explicable, and there are a lot of controversy regarding to the result explanations (Wiegreffe and Pinter, 2019; Jain and Wallace, 2019). Moreover, we find that though the attention mechanism can help improve the performance for text classification in our experiments, it may focus on the irrelevant information. For example, in the sentence "A very funny movie.", the long short-term memory model with standard attention (LSTM-ATT) infers a correct sentiment label while pays more attention to the irrelevant word "movie", making the result difficult to explain.

In general, the attention weights are only optimized to encode the task-relevant information while are not restricted to imitate human behavior. In order to enhance the interpretability of the attention mechanism, recent studies turn to integrate the human provided explanation signals into the attention models. Rei and Søgaard (2018) regularized the attention weights with a small amount of word-level annotations. Barrett et al. (2018); Bao et al. (2018) improved the explanation of attention by aligning explanations with human-provided rationales. These methods rely on additional labour consuming labelling for enhancing explanations, which is hard to extend to other datasets or tasks.

In this paper, we aim to train a more efficient and effective interpretable attention model without any pre-defined annotations or pre-collected explanations. Specifically, we propose a framework consisting of a learner and a compressor, which enhances the performance and interpretability of the attention model for text classification[1]. The learner learns text representations by fine-tuning

---

[1] We focus on the task of text classification, but our method can be easily extended to other NLP or CV tasks with attention mechanisms.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2152–2161
August 1–6, 2021.

the encoder. Regarding to the compressor, we are motivated by the effectiveness of the information bottleneck (IB) (Tishby et al., 1999) to enhance performance (Li and Eisner, 2019) or detect important features (Bang et al., 2019; Chen and Ji, 2020; Jiang et al., 2020; Schulz et al., 2020), and present a Variational information bottleneck ATtention (VAT) mechanism using IB to keep the most relevant clues and forget the irrelevant ones for better attention explanations. In particular, IB is integrated into attention to minimize the mutual information (MI) with the input while preserving as much MI as possible with the output, which provides more accurate and reliable explanations by controlling the information flow.

To evaluate the effectiveness of our proposed approach, we adapt two advanced neural models (LSTM and BERT) within the framework and conduct experiments on eight benchmark datasets. The experimental results show that our adapted models outperform the standard attention-based models over all the datasets. Moreover, they exhibit great advantages with respect to interpretability by both qualitative and quantitative analyses. Specifically, we obtain significant improvements by applying our model to the semi-supervised word-level sentiment detection task, which detects the sentiment words based on attention weights via only sentence-level sentiment label. In addition, we provide the case studies and text representation visualization to have an insight into how our model works.

The main contributions of this work are summarized as follows.

- We propose a novel framework to enhance the performance and interpretability of the attention models, where a learner is used to learn good representations by fine-tuning and a compressor is used to obtain good attentive weights by compressing iteratively.

- We present a Variational information bottleneck ATtention (VAT) mechanism for the compressor, which performs compression over the text representation to keep the task related information while reduce the irrelevant noise via information bottleneck.

- Extensive experiments show the great advantages of our models within the proposed framework, and we perform various qualitative and quantitative analyses to shed light on why our models work in both performance and interpretability.

2 Related Work

In this section, we survey related attention mechanisms (Bahdanau et al., 2014) and review the most relevant studies on information bottleneck (IB) (Tishby et al., 1999).

Attention has been proved can help explain the internals of neural models (Li et al., 2016; Wiegreffe and Pinter, 2019) though it is limited (Jain and Wallace, 2019). Many researchers try to improve the interpretability of the attention mechanisms. Rei and Søgaard (2018) leveraged small amounts of word-level annotations to regularize attention. Kim et al. (2017) introduced a structured attention mechanism to learn attention variants from explicit probabilistic semantics. Barrett et al. (2018); Bao et al. (2018) aligned explanations with human-provided rationales to improve the explanation of attention. Unlike these methods that require prior attributions or human explanations, the VAT method enforces the attention to learn the vital information while filter the noise via IB.

A series of studies motivate us to utilize IB to improve the explanations of attention mechanisms. Li and Eisner (2019) compressed the pre-trained embedding (e.g., BERT, ELMO), remaining only the information that helps a discriminative parser through variational IB. Zhmoginov et al. (2019) utilized the IB approach to discover the salient region. Some works (Jiang et al., 2020; Chen et al., 2018; Guan et al., 2019; Schulz et al., 2020; Bang et al., 2019) proposed to identify vital features or attributions via IB. Moreover, Chen and Ji (2020) designed a variational mask strategy to delete the useless words in the text. As far as we are aware, we are the first ones to leverage IB into attention mechanisms to train more interpretable attention with better accuracy.

3 Our Approach

In this section, we introduce our framework consisting of a learner and a compressor with a Variational information bottleneck ATtenttion (VAT) mechanism. Given an attention-based neural network model, we formulate our idea within the framework of variational information bottleneck (VIB) (Tishby et al., 1999). Our framework aims to improve the attention's interpretalility with better performance by restricting the attention to capture the crucial words while filter the useless information.

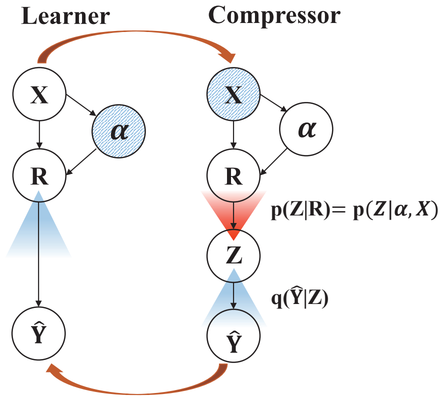

Figure 1: The framework.The learner aims to learn the good text representation X by fine-tuning, and the compressor aims to learn good attention weights by compressing the attentive representations to capture the important words while forget the redundant information via VAT. The blue circles mean the corresponding parameters of the modules are fixed.

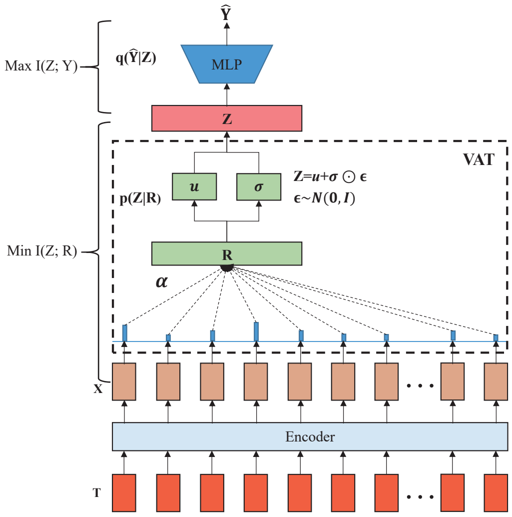

Figure 2: The architecture of our VAT (Compressor). First, we obtain the input text's word representations X via an encoder trained by the learner. Then, we calculate Z by compressing the text representation R that is the weighted sum of X based on the attention α, while remaining the maximum information to judge Y by inputting Z into a MLP classifier for predicting.

3.1 Overview

Our framework is composed of a learner and a compressor, which performs fine-tuning and compressing iteratively (Figure 1). The learner aims to learn a task-specific contextual word representation by fine-tuning. The compressor enforces the model to learn task-relevant information while reduce irrelevant information via IB. We iteratively perform the learner and compressor (fine-tuning and compressing) to improve each other.

Learner. We adopt a basic attention-based neural network model as a learner to learn representations of the words based on the good attention weights learned by the compressor. The model is optimized by cross-entropy loss to learn the label-relevant information. In this phase, we fix the attention's parameters so that the model will focus on updating the encoder to learn word representations.

Compressor. To restrict the attention to capture the vital information while reduce the noise, we integrate IB into attention mechanisms to compress the text attentive representation. We fix the encoder's parameters so that the model will focus on learning the attention weights based on current representations obtained from the learner.

3.2 Basic Attention Model (Learner)

In this section, we describe our learner, which is an attention-based neural network model. First, given a text $T = \{w_1, w_2, ..., w_{|T|}\}$, where $|T|$ is the length of text T, we feed it into an encoder with a word embedding layer. We adopt LSTM and BERT models as our encoder, and other models can also be applied to our framework. We obtain the context-aware word representations $x = [x_1, x_2, ..., x_{|T|}]$, where x_i is the hidden vector of the word w_i.

$$x = encoder(T, \theta_{encoder}), \tag{1}$$

where $\theta_{encoder}$ is the parameters of the encoder.

Based on the contextual word representations, attention mechanism (Bahdanau et al., 2014) [2] is utilized to capture the important parts in the text and obtain the text representation R, which is calculated as,

$$\begin{aligned} R &= \sum_{i=1}^{n} \alpha_i x_i \\ \alpha_i &= \mathrm{softmax}(\mathbf{v}_a^\top \tanh(\mathbf{W}_a x_i)) \end{aligned} \tag{2}$$

where $\theta_{attention} = \{v_a, W_a\}$ is the trainable parameters of the attention, which is not updated in this step to learn the word representation x based the good attention learned by the compressor. $\alpha = [\alpha_1, \alpha_2, ..., \alpha_{|T|}]$ is the attention weights. Finally, we input the text representation R into a

---

[2] In this paper, we only explore the local attention mechanism on our framework, other attention mechanisms (e.g., multi-head attention (Vaswani et al., 2017)) can also be applied. We would like to explore it in future work.

multi-layer perceptron (MLP) to predict the probability. The cross-entropy loss is used to optimize the model.

3.3 Variational Information Bottleneck Attention (Compressor)

The learner optimizes the sentence representations by minimizing the cross-entropy loss, which does not restrict the model to ignore the useless information. Thus, we compress sentence representations R into a latent representation Z that retains most useful information to infer the label Y. We propose to accomplish this by integrating VIB into the attention mechanism (Figure 2).

To ensure Z contains maximum ability to predict Y ($I(Z;Y)$) while has the least redundant information form R ($-I(Z;R)$), we use the standard IB theory (Tishby et al., 1999) and define the objective function as:

$$\max_{\boldsymbol{\alpha}} I(Z;Y) - \beta \cdot I(Z;R) \tag{3}$$

where $I(\cdot;\cdot)$ means the mutual information and β is a coefficient to balance two components. The main challenge is to estimate the lower bound for $I(Z;Y)$ and the upper bound for $I(Z;R)$. [3]

The joint probability $p_\theta(r,y,z)$ can be factored as $p(r) \cdot p(y \mid r) \cdot p_\theta(z \mid r)$ based on the independence assumption [4]. By replacing the conditional distribution $p_\theta(y \mid z)$ with a variational approximation $q_\phi(y \mid z)$, we obtain a lower bound of $I(Z;Y)$. $q_\phi(y \mid z)$ is a simple classifier that runs on a compressed text representation z.

$$\begin{aligned}&\overbrace{\mathbb{E}_{p_\theta(y,z)}[\log \frac{p_\theta(y \mid z)}{p(y)}]}^{I(Z;Y)} - \overbrace{\mathbb{E}_{p_\theta(y,z)}[\log \frac{q_\phi(y \mid z)}{p(y)}]}^{\text{lower bound}} \\ &= \mathbb{E}_{p_\theta(z)}[\mathrm{KL}(p_\theta(y \mid z) \| q_\phi(y \mid z))] \geqslant 0\end{aligned} \tag{4}$$

where $KL[\cdot\|\cdot]$ represents Kullback-Leibler divergence.

Specifically, we regard $p(y)$ as constant and then minimize $\mathbb{E}_{p_\theta(y,z)}[\log q_\phi(y \mid z)]$. Since we must first sample r to sample y, z from $p_\theta(r,y,z)$, the lower bound of $I(Z;Y)$ is computed as,

$$I(Z;Y) \geqslant \mathbb{E}_{p(r,y)}[\mathbb{E}_{p_\theta(z|r)}[\log q_\phi(y \mid z)]] \tag{5}$$

We calculate the upper bound of $I(Z;R)$ by replacing $p_\theta(z)$ with a variational distribution $r_\psi(z)$,

$$\begin{aligned}&\overbrace{\mathbb{E}_{p(r)}[\mathbb{E}_{p_\theta(z|r)}[\log \frac{p_\theta(z \mid r)}{r_\psi(z)}]]}^{\text{upper bound}} - \overbrace{\mathbb{E}_{p(r)}[\mathbb{E}_{p_\theta(z|r)}[\log \frac{p_\theta(z \mid r)}{p(z)}]]}^{\mathrm{I}(Z;R)} \\ =&\mathbb{E}_{p(r)}[\mathrm{KL}(p(z) \| r_\psi(z))] \geqslant 0\end{aligned} \tag{6}$$

The upper bound of $I(Z;R)$ is computed as,

$$\begin{aligned}I(Z;R) &\leqslant \mathbb{E}_{p(r)}[\mathbb{E}_{p_\theta(z|r)}[\log \frac{p_\theta(z \mid r)}{r_\psi(z)}]] \\ &= \mathbb{E}_{p(r)}[\mathrm{KL}[p_\theta(z \mid r) \| r_\psi(z)]]\end{aligned} \tag{7}$$

Then, we obtain the lower bound $\mathcal{L}$ of IB by substituting Equation 5 and 7 into Equation 3:

$$\begin{aligned}\mathcal{L} = \mathbb{E}_{p(r,y)}[&\mathbb{E}_{p_\theta(z|r)}[\log q_\phi(y \mid z)] \\ &- \beta \cdot \mathrm{KL}[p_\theta(z \mid r) \| r_\psi(z)]]\end{aligned} \tag{8}$$

The first component in $\mathcal{L}$ is to keep the most useful information in $p_\theta(z|r)$ for inferring y, while the second one is to regularize $p_\theta(z|r)$ with a predefined prior distribution $r_\psi(z)$ (e.g., Gaussian distribution). To compute $p_\theta(z|r)$, we adopt the reparametrization trick for multivariate Gaussians (Rezende et al., 2014), which obtains the gradient of parameters that derive z from a random noise ϵ.

$$z = u + \sigma \odot \epsilon, \epsilon \sim N(0, I) \tag{9}$$

where $\odot$ means element-wise multiplication. u and σ denote the mean and covariance defined by two functions of R, where $R = \alpha \cdot x$ that is learned based on attention. In particular, two MLP are used to predict u and σ.

Finally, we input the z into a MLP to predict $q_\phi(y \mid z)$ and optimize the attention's parameter via Equation 8.

4 Experiment Setup

We adopt two typical neural network models, attention-based LSTM (Hochreiter and Schmidhuber, 1997) and BERT (Devlin et al., 2019), to explore our VAT algorithm.

4.1 Datasets and Baselines

Datasets To evaluate the effectiveness of our VAT model, we conduct the experiments over eight benchmark datasets: IMDB (Maas et al., 2011), Stanford Sentiment Treebank with (includes SST-1 and its binary version SST-2) (Socher et al., 2013), Yelp (Zhang et al., 2015), AG News (Zhang et al., 2015), TREC (Li and Roth, 2002), subjective/objective classification Subj (Pang and Lee, 2005) and Twitter (Rosenthal et al., 2015, 2014). The statistics information of these datasets are shown in Table 1.

---

[3] We give the main steps as follows and the detailed derivation is provided in supplementary materials.

[4] $Y \to R \to Z$: Y and Z are independent given R.

Table 2: The main results of text classification.

Baselines We compare our model with two kinds of models, basic models (LSTM/BERT-base) and attention-based models (LSTM/BERT-ATT). LSTM-base takes the max-pooling of the LSTM's hidden vectors as text representation. For BERT-base, the "[CLS]" representation is obtained as the sentence representation. LSTM-ATT model is a standard attention-based LSTM model that has the same structure as the learner. We obtain the BERT-ATT by replacing the LSTM encoder with BERT in LSTM-ATT. Our models are marked with VAT (LSTM-VAT, BERT-VAT), which integrate VIB into attention-based neural models.

4.2 Implementation Details

For LSTM-based models, we use GloVe embedding (Pennington et al., 2014) with 300-dimension to initialize the word embedding and fine-tune it during the training. We randomly initialize all out-of-vocabulary words and weights with the uniform distribution $U(-0.1, 0.1)$. For the BERT-based models, we fine-tune pre-trained BERT-base model. The dimension of hidden state vectors of LSTM is 100 and the max sentence length is 256 in our experiments. Adam (Kingma and Ba, 2014) is utilized as the optimizer with learning rate 0.001 (for LSTM-based model) and 0.00001 (for BERT-based model). We also search different values $\beta \in \{0.01, 0.1, 1, 10\}$.

5 Experiments

First, we perform our models and baselines on eight benchmark datasets and visualize the text representation to verify the effectiveness of VAT (Section 5.1). Second, to further investigate our VAT model, we adopt two popular explanation metrics for quantitative evaluation (Section 5.2). Third, we apply our models to semi-supervision sentiment detection task to evaluate the explanation of our model (Section 5.3). Fourth, we explore the influence of our iteration strategy in Section 5.4 and provide case studies in Section 5.5. For the limitation of the space, we may only list the results on parts of the datasets in some cases since the conclusions are similar for other datasets. The complete results are presented in the supplementary materials.

5.1 Main Results

We report the accuracy of our VAT and baselines based on LSTM and BERT (Table 2). From these results, we find the following observations: **1)** our models (LSTM/BERT-VAT) outperform all the corresponding baselines over all the eight datasets, which denotes the effectiveness of our VAT on both LSTM and BERT-based models; **2)** compared with attention-based models (LSTM/BERT-ATT), our models obtain better results. It indicates reducing the irrelevant information in input via VAT can improve the performance of the models.

Furthermore, we visualize the sentence representations obtained from LSTM/BERT-ATT and -VAT models (Figure 3). We randomly select 1000 samples from the test set for each dataset. We can find that our VAT model can reduce the distance of the samples in a class and add the distance of the samples in different classes. For example, it is hard to split the positive samples from the negative ones based on the representations obtained from LSTM-ATT for the IMDB dataset, while the divider line based on our VAT is clear. These ob-

Figure 4: The influence of Top-K for LSTM/BERT-based models in terms of AOPC.

servations show our VAT model can learn a better task-specific representation by enforcing the model to reduce the task-irrelevant information.

5.2 Quantitative Evaluation

In this section, we evaluate our VAT model using two metrics, AOPC and post-hoc accuracy, which are widely used for explanations (Chen and Ji, 2020). Note that well-trained LSTM/BERT-base is used for evaluating the performance of classification.

AOPC. To evaluate the faithfulness of explanations to our models, we adopt the area over the perturbation curve (AOPC) (Nguyen, 2018; Samek et al., 2016) metric. It calculates the average change of accuracy over test data by deleting top K words via attentive weights. The larger the value of AOPC, the better the explanations of the models.

Table 3 displays the results with $K = 5$. We compare our models with random and basic attention-based models. From the results, we observe that: **1)** basic attention-based models (LSTM/BERT-ATT) can find the important words in the sentence to some extent. Comparing with random (Random), LSTM/BERT-ATT obtains significant improvement; **2)** Our models (LSTM/BERT-VAT) outperform the standard attention-based models. It indicates that integrating VIB into the attention mechanism can help improve the interpretability of the models by filtering the useless information; **3)** BERT model is sensitive to the context; deleting the words will destroy the semantic information of the sentence and significantly affect the model's performance.

We also explore the influence of top-K (Figure 4). Intuitively, the more words we delete, the larger accuracy the models reduce. Our models reduce more performance than random and attention-based

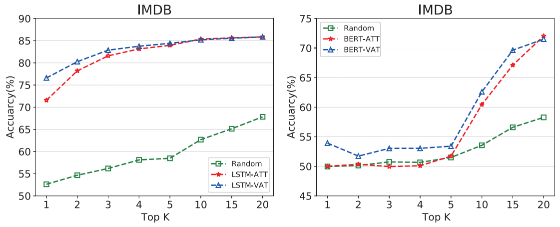
Table 4: The results of post-hoc accuracy.



(a) IMDB (LSTM) (b) IMDB (BERT)

Figure 5: The influence of Top-K for LSTM-based models in terms of post-hoc.

models. For the IMDB dataset, when deleting top 20 words (average length is 268), the accuracy reduces about 19 points for our LSTM-VAT model while it is about 2 points for the random model.

Post-hoc Accuracy. We also adopt the post-hoc accuracy (Chen et al., 2018) to evaluate the influence of task-specific essential words on the performance of LSTM-based and BERT-based models. For each test sample, we select the top K words based on their attentive weights as input to make a prediction and compare it with the ground truth.

Table 4 presents the performance with $K = 5$. **First**, it is interesting to find that the post-hoc accuracy with five most important words on Sbuj dataset (89.10) is even better than the original sentence (89.00). Additionally, we obtain comparable results with only five words for SST-1, SST-2, and Twitter datasets. These show that our model can reduce the noise information since most of the words are useless for predictions in some cases. **Second**, for BERT-based models, the context words are also important for classification even though they may not be task-specific.

Similarly, we investigate the influence of top-K for post-hoc (Figure 5). The LSTM-base model with top-10 words selected by our LSTM-VAT model can achieve comparable results with the original samples in most cases. Additionally, for the IMDB dataset, the accuracy of LSTM-base with one word selected by our VAT model is even better than the one with 20 words selected randomly.

5.3 Semi-Supervised Word-Level Sentiment Detection

We perform semi-supervised word-level sentiment detection in Twitter (Rosenthal et al., 2015, 2014) to evaluate the interpretability of our VAT. This task requires to detect the sentiment words in a tweet via the sentiment polarity of the whole tweet. In the following example from the dataset, positive words ("good" and "fantastic") are marked with a bold font and the overall polarity of the tweet is positive:

Good *morning becky! Thursday is going to be* ***fantastic****!*

We use the SemEval 2013 Twitter dataset, which contains word-level sentiment annotation. We remove the samples with the neutral sentiment. We report word-level precision, recall, and F-measure for evaluating the models (Table 5), the same as (Rei and Søgaard, 2018). Note that we select the top-K (we set it as 1 and 5 here) words according to the attention weights as the sentiment words.

We compare our VAT model with random and attention-based models. The results show attention-based models can capture the important words in the text, to a certain extent. Since our VAT can reduce irrelevant information, it performs better than the standard attention model. Also, LSTM-based models outperform BERT-based models for this task in most cases. It is because that BERT learns much semantic information from the text, and context information plays a vital role in prediction.

5.4 Influence of Iteration

We propose to train the learner and compressor iteratively so that the learner optimizes the word representations based on the good attention, and the compressor optimizes the attention based on the good word representations. To have a deep look at how it works, we first provide our VAT model's accuracy with different iterations (Table 6). From the results, we can find that the model's performance will improve at first, then it will converge.

	Positive						Negative					
	P@1	R@1	F1@1	P@5	R@5	F1@5	P@1	R@1	F1@1	P@5	R@5	F1@5
Random	14.88	4.78	6.56	14.59	23.34	16.06	20.52	5.61	8.19	17.18	23.68	17.97
LSTM-ATT	58.70	26.04	32.73	30.30	54.17	34.70	47.13	15.74	21.39	28.24	42.04	30.33
LSTM-VAT	**65.20**	**29.38**	**36.60**	33.04	**58.40**	37.77	**60.00**	**21.42**	**28.76**	32.70	**49.19**	**35.35**
BERT-ATT	46.44	16.52	21.82	33.13	52.52	35.66	37.74	9.19	13.46	30.82	39.65	30.23
BERT-VAT	55.24	20.62	26.90	**37.26**	58.39	**40.09**	43.83	11.15	16.20	**36.42**	44.55	35.30

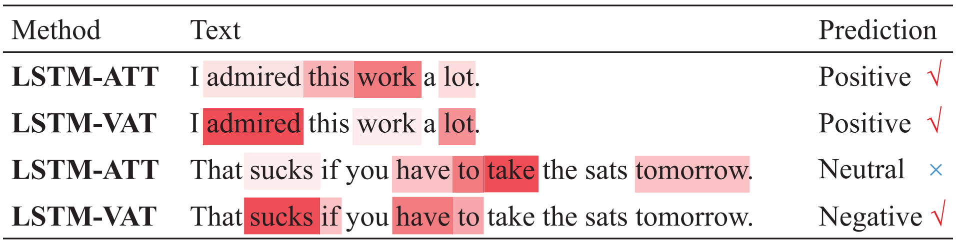
Figure 6: Visualization of text representation obtained from LSTM/BERT-VAT with different iterations. We use t-SNE to transfer 100/768-dimensional feature space into two-dimensional space.



Method	Text	Prediction
LSTM-ATT	I admired this work a lot.	Positive √
LSTM-VAT	I admired this work a lot.	Positive √
LSTM-ATT	That sucks if you have to take the sats tomorrow.	Neutral ×
LSTM-VAT	That sucks if you have to take the sats tomorrow.	Negative √

Figure 7: Two examples of attention visualization. Red denotes the attentive weights of the words. A deeper color indicates a larger value.

	Dataset	0	1	2	3	4	5
LSTM-VAT	Twitter	70.75	71.62	70.96	70.67	71.06	70.98
	IMDB	88.16	88.98	88.22	88.84	88.14	88.60
BERT-VAT	Twitter	74.84	75.26	77.71	77.13	76.68	76.76
	IMDB	91.81	92.06	92.11	92.09	91.92	91.96

Table 6: The accuracy with different iteration number with our LSTM/BERT-VAT model.

Also, we draw change of the sentence representation with different iterations (Figure 6). Similarly, we observe that fine-tuning and compressing iteratively can improve the sentence representations. The samples with the same class are close, and the samples with different classes have a large distance.

5.5 Case Studies

To understand why our proposed VAT model is more effective than the standard attention-based model, we visualize two examples of LSTM-based models using attention heatmaps (Figure 7). **First**, the standard attention-based LSTM model focuses on the wrong words (e.g., "this", "work") even though it predicts the right sentiment while our VAT model finds the correct words (e.g., "admired", "lot"). It indicates integrating IB into attention can help it focus on the key words and reduce the noisy information. **Second**, our proposed model can also improve the attention's performance by capturing the critical words accurately. For example, in the sentence "That sucks if you have to take the sats tomorrow.", our model predicts the right class label by attending the words "sucks" and "have to."

6 Conclusions and Future Work

This paper proposes a VAT-based framework to improve the performance and interpretability of attentions via both fine-tuning and compressing. The experimental results on eight benchmark datasets for text classification verify the effectiveness of our models within this framework. In addition, we apply the framework for sentiment detection, which further demonstrates the superiority in terms of interpretability. It is also interesting to find that training the models by fine-tuning and compressing iteratively is effective to improve the text representations. In the future, we will investigate the effectiveness of our proposed attention framework for other tasks and areas, such as machine translation and visual question answering.

Abstract

Current models for event causality identification (ECI) mainly adopt a supervised framework, which heavily rely on labeled data for training. Unfortunately, the scale of current annotated datasets is relatively limited, which cannot provide sufficient support for models to capture useful indicators from causal statements, especially for handing those new, unseen cases. To alleviate this problem, we propose a novel approach, shortly named CauSeRL, which leverages external causal statements for event causality identification. First of all, we design a self-supervised framework to learn context-specific causal patterns from external causal statements. Then, we adopt a contrastive transfer strategy to incorporate the learned context-specific causal patterns into the target ECI model. Experimental results show that our method significantly outperforms previous methods on EventStoryLine and Causal-TimeBank (+2.0 and +3.4 points on F1 value respectively).

1 Introduction

Event causality identification (ECI) aims to identify causal relations between events in texts, which can provide crucial clues for deep textual understanding (Girju, 2003; Oh et al., 2013, 2017). For example in Figure 1, an ECI system should identify two causal relations in S_1 with mentioned events: **noticed**$_{E1}$ $\xrightarrow{cause}$ **alerted**$_{E3}$ and **alerted**$_{E3}$ $\xrightarrow{cause}$ **ran**$_{E2}$.

To date, most existing methods regard this task as a classification problem and usually train ECI models on annotated data (Hashimoto et al., 2014; Riaz and Girju, 2014b; Mirza and Tonelli, 2016; Hu and Walker, 2017b; Gao et al., 2019). However, the scale of current annotated datasets are relatively limited, where the so far largest dataset EventStoryLine (Caselli and Vossen, 2017) only contains 258 documents, 4316 sentences, and 1770 causal event pairs. As a result, on the limited annotated examples, existing ECI models could not easily capture useful indicators from causal statements, especially for handing those new, unseen cases.

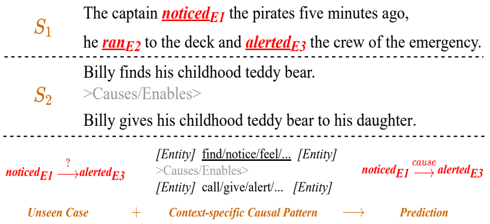

Figure 1: S_1 is a labeled data that contains unseen causal events and their statement when training; S_2 is an external causal statement; The bottom illustrates the context-specific causal pattern in S_2 could help identify the causality of unseen events in S_1.

To address this problem, Liu et al. (2020) employed external event-related knowledge bases (KBs) to enhance the causality inference, where those KBs store inherent causal relations between some given events. For those unseen events and unlabeled causalities in KBs, Liu et al. (2020) proposed a mention-mask based reasoner to enhance the causal statement representation. However, such mention-mask based reasoner is still trained on the human-annotated examples solely. It will still suffer from data limitations and have no capacity to handling unseen contexts. Moreover, Zuo et al. (2020) improved the performance of ECI with the distantly supervised labeled training data. However, their models are still limited to the unsatisfied qualities of the automatically generated data.

To address the insufficient annotated example problem, we employ a large number of external causal statements (Sap et al., 2018; Mostafazadeh et al., 2020) that can support adequate evidence of context-specific causal patterns (Liu et al., 2020)

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2162–2172
August 1–6, 2021. ©2021 Association for Computational Linguistics

for understanding event causalities. For example in Figure 1, the context-specific causal pattern support by an external causal statement S_2 is helpful for identifying the causality of event *noticed*$_{E1}$ and event *alerted*$_{E3}$ in S_1, which is unseen when only training with labeled data. However, different from annotated examples for the ECI task, there are no event annotations in the external causal statements. As a result, it is difficult for the models to learn context-specific causal patterns from them to identify event causalities. To resolve this issue, inspired by Grill et al. (2020), we design a self-supervised representation learning framework to learn enhanced causal representations from external causal statements. Specifically, we iteratively sample two external causal statements, then take each of them as a target to learn the commonalities among them. Intuitively, we believe that the learned commonalities between different causal statements through self-supervision reflect such context-specific causal patterns which are helpful for identifying event causalities in the unseen cases.

Moreover, to incorporate the learned context-specific causal patterns from external causal statements into the target ECI model, we employ a contrastive transfer strategy. In specific, we regard the self-supervised representation learning module as a teacher model that *masters* abundant external causal statements, and the target ECI model as a student model. Methodologically, we make the representation of the causal events encoded by the student model should be close to the causal representation grasped by the teacher model, and keep the representation of the non-causal events away from it. In this way, the mutual information between the teacher and student models could be maximized (Tian et al., 2020). Then the learned context-specific causal patterns could be naturally transferred into the ECI model and the generalization could be improved.

In experiments, we evaluate our model on two benchmarks. The experimental results show that our model achieves SOTA performance. Then, concrete proofs show that the effectiveness of our self-supervised contrast-based framework for context-specific causal patterns learning and transfer.

In summary, the contributions are as follows:

- We propose a novel approach, shortly named **CauSeRL**, which could leverage external causal statements to identify the causalities between events.
- First of all, we design a self-supervised framework to learn context-specific causal patterns from external causal statements. Then, we adopt a contrastive transfer strategy to incorporate the learned context-specific causal patterns into target ECI model for identification.
- Experimental results on two benchmarks show that our model achieves the best performance.

2 Related Work

Event Causality Identification Up to now, identifying the causality implied in the text has attracted more and more attention (Hu and Walker, 2017a; Riaz and Girju, 2014b; Hashimoto et al., 2014; Riaz and Girju, 2014a, 2010; Do et al., 2011; Hidey and McKeown, 2016; Beamer and Girju, 2009; Hu et al., 2017; Hu and Walker, 2017b). Recently, some benchmarks on the event causality have been released. Mirza et al. (2014), Mirza and Tonelli (2016) extracted causal relation of events with a rule-based multi-sieve approach incorporating with event temporal relation. Mirza and Tonelli (2014) annotated the Causal-TimeBank of event causal relations. Caselli and Vossen (2017) annotated the EventStoryLine Corpus for event causality identification in 320 short stories based on the temporal and causal relations annotated dataset (Mostafazadeh et al., 2016). Dunietz et al. (2017) presented BECauSE 2.0, a new version of the BECauSE (Dunietz et al., 2015) of causal relation and other seven relations.

Based on the above benchmarks, Gao et al. (2019) modeled document-level structures to identify the causalities of events. Liu et al. (2020) identified event causalities with the mention masking generalization and external KBs. Zuo et al. (2020) improved the performance of ECI with the distantly automatically labeled training data. However, these methods only rely on a small scale of labeled data. In this paper, we introduce external causal statements to help identify event causalities.

Self-Supervised Representation Learning Self-supervised representation learning cares about producing good features generally helpful for many tasks (Weng, 2019). Wu et al. (2018) proposed MemoryBank, which stores representations of all the data and samples a random set of keys as negative examples. He et al. (2020) provided a framework, MoCo, of unsupervised learning visual representation as a dynamic dictionary

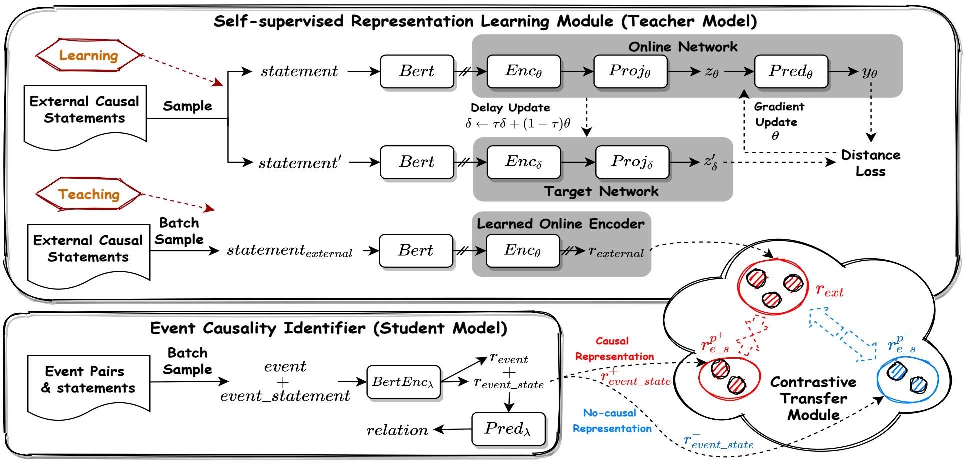

Figure 2: The learning and transfer processes of the proposed CauSeRL for ECI. "//" means stop-gradient.

look-up. Chen et al. (2020) proposed the SimCLR which learns representations for visual inputs by maximizing agreement between differently augmented views of the same sample via a contrastive loss. Grill et al. (2020) claimed a novel representation learning framework relies on two neural networks, BYOL, without using negative samples. CURL (Srinivas et al., 2020) applies the above ideas in reinforcement learning. Inspired by them, we design a self-supervised framework to learn context-specific causal patterns from external causal statements and adopt a contrastive transfer strategy to incorporate them into target ECI model.

3 Methodology

As shown in Figure 2, the whole pipeline process of CauSeRL is divided into two major stages.

- **Self-supervised causal representation learning** (**SelfRL**, Sec. 3.1). In this stage, we design a *self-supervised representation learning module* to learn enhanced causal representations by iteratively sampling two external causal statements, taking each of them as a target to learn their commonalities which reflect context-specific causal patterns.

- **Contrastive representation transfer** (**ConRT**, Sec. 3.2). In this stage, we employ a *contrastive transfer module* to transfer the learned context-specific causal patterns into the ECI target model, the *event causality identifier*, via incorporating the enhanced causal representations from SelfRL.

3.1 Self-Supervised Causal Representation Learning (SelfRL)

SelfRL aims to train a module that masters context-specific causal patterns from external causal statements by learning their enhanced causal representation with a self-supervised framework.

Self-Supervised Representation Learning Module We design a self-supervised module to capture the context-specific causal patterns from external causal statements via learning their enhanced causal representation. However, there are no ECI-specific event annotations in the external causal statements, which makes them unable to be directly used as training data to train the ECI model. To handle this problem, inspired by Grill et al. (2020), we iteratively sample two external causal statements, take each of them as a target to learn their commonalities, that is, the causal representations, which reflect context-specific causal patterns.

In specific, as shown in Figure 2, we configure two networks for SelfRL, an online network, and a target network. The target network provides regression targets to train the online network which makes it learn the commonalities among two input causal statements, that is, the causal representations reflecting different context-specific causal patterns. Structurally, the online network is defined as a set of weights θ which is comprised of three submodules: an *encoder* Enc_θ, a *projector* $Proj_\theta$ and a *predictor* $Pred_\theta$. And the target network has the same architecture as the online network, but no predictor and uses a different set of weights δ.

In specific, we iteratively sample two external causal statements, initially encode them by BERT (Devlin et al., 2019), and input them into two networks respectively. After encoding and projection, the online network and target network respectively output a projection $\boldsymbol{z}_\theta$ and $\boldsymbol{z}'_\delta$. Then the online network outputs a prediction $\boldsymbol{y}_\theta$, and takes the following mean square error between ℓ_2-normalized $\bar{\boldsymbol{y}}_\theta$ and $\bar{\boldsymbol{z}}'_\delta$ as the training objective to learn the commonalities of two causal statements, that are regarded as the context-specific causal patterns.

$$\mathcal{L}_{\theta,\delta} \triangleq \left\|\bar{\boldsymbol{y}}_\theta - \bar{\boldsymbol{z}}'_\delta\right\|_2^2 = 2 - 2 \cdot \frac{\langle \boldsymbol{y}_\theta, \boldsymbol{z}'_\delta \rangle}{\|\boldsymbol{y}_\theta\|_2 \cdot \left\|\boldsymbol{z}'_\delta\right\|_2}, \tag{1}$$

$$\bar{\boldsymbol{y}}_\theta \triangleq \boldsymbol{y}_\theta / \|\boldsymbol{y}_\theta\|_2, \bar{\boldsymbol{z}}'_\delta \triangleq \boldsymbol{z}'_\delta / \left\|\boldsymbol{z}'_\delta\right\|_2. \tag{2}$$

To reduce the bias, we symmetrize the $\mathcal{L}_{\theta,\delta}$ by swapping the input causal statements of the online and target networks to compute $\widetilde{\mathcal{L}}_{\theta,\delta}$.

Learning of SelfRL For the learning of SelfRL, at each step, as shown in Algorithm 1, we minimize the $\mathcal{L}^{tea}_{\theta,\delta}$ to stochastic gradient update the online network respect to the parameters θ only. For the target network, the parameters δ are an exponential moving average of the parameters θ of the online network (Lillicrap et al., 2016):

$$\mathcal{L}^{tea}_{\theta,\delta} = \mathcal{L}_{\theta,\delta} + \widetilde{\mathcal{L}}_{\theta,\delta}, \tag{3}$$

$$\theta \leftarrow \eta_{tea} \nabla_\theta \mathcal{L}^{tea}_{\theta,\delta}, \tag{4}$$

$$\delta \leftarrow \tau\delta + (1-\tau)\theta, \tag{5}$$

where, η_{tea} is the learning rate of the online network, and $\tau \in [0,1]$ is the decay rate that determines the degree of the movement of θ to δ. As shown in Figure 2, when learning, BERT is only used to provide an initial representation for the input statements, and its parameters are not updated.

According to the theoretical analysis by Grill et al. (2020), the addition of a predictor on the online network and the usage of a slow-moving average of the online parameters as the target network encourage SelfRL to encode a more informative causal representation of commonalities within the online projection and avoids collapsed solutions[1].

3.2 Contrastive Representation Transfer (ConRT)

ConRT aims to incorporate the context-specific causal patterns learned in SelfRL from external causal statements into the identifier. As aforementioned, the goal of SelfRL is learning the commonalities among different external causal statements, which does not make the representation learning module have the ability to distinguish the causal and non-causal statements directly. Therefore, we employ a contrastive transfer module to teach the learned context-specific causal patterns to the event causality identifier for training.

Algorithm 1 Two stages training of CauSeRL.

```
Require: External causal statements $\mathcal{C}$ for teacher model
    and event pairs with statements $\mathcal{P}$ for student model.
Training:
Stage: CAUSAL REPRESENTATION LEARNING
    for each batch $\mathcal{C}_{bat} \in \mathcal{C}$ do        ▷ Learning of SelfRL
        for any two causal statements $\in \mathcal{C}_{bat}$ do
            One for online another for target;
            Get $y_\theta$ from $Pred_\theta$ in online network;
            Get $z'_\delta$ from $Proj_\delta$ in target network;
            Swap two statements into two networks;
            Get symmetrical $y_\theta$ and $z'_\delta$;
            Compute $\mathcal{L}_{\theta,\delta}$ and $\widetilde{\mathcal{L}}_{\theta,\delta}$;
        end for
        Compute batch $\mathcal{L}^{tea}_{\theta,\delta}$ in equation (3);
        Stochastic gradient update $\theta$ in equation (4);
        Slow-moving update $\delta$ in equation (5);
    end for
end Stage:

Stage: CONTRASTIVE REPRESENTATION TRANSFER
    for each batch $\mathcal{P}_{bat} \in \mathcal{P}$ do  ▷ Learning of identifier
        for any event pair with statement $\in \mathcal{P}_{bat}$ do
            Get $\boldsymbol{r}_{event}$ and $\boldsymbol{r}_{event\_state}$ from $BertEnc_\lambda$;
            Predict the causality of two events in one pair;
        end for
        Compute batch $\mathcal{L}^{stu}_\lambda$ in equation (6);
        Sample $\mathcal{C}_{bat} \in \mathcal{C}$;

Event Causality Identifier Event causality identification is formulated as a sentence level binary classification problem. Specifically, we design a classifier based on BERT (Devlin et al., 2019) to build our identifier. The input is an event pair and its statement. As shown in Figure 2, we take representation of events $\boldsymbol{r}_{event}$ and their contextual statement $\boldsymbol{r}_{event\_state}$ encoded by $BertEnc_\lambda$ as the input of top MLP predictor. Finally, the output is a binary vector to indicate the causal relation of the input two events expressed by their statement. The parameters of the identifier are defined as λ and the optimization function is the following

---

[1] In this paper, collapse solution means that the model encodes all input statements as the same representation. The slow-moved target network keeps the predictor of the online network always near-optimal, thus avoiding the collapse.

Resource	Original Causal Statement Form	Converted Causal Statement Form
GLU-SPE	Billy finds his childhood teddy bear $> Cause/Enable >$ Billy gives his childhood teddy bear to his daughter	Billy finds his childhood teddy bear, billy gives his childhood teddy bear to his daughter.
GLU-GEN	Someone_A finds Something_A $> Cause/Enable >$ Someone_A gives Something_A to Someone_B	Someone_A finds Something_A, Someone_A gives Something_A to Someone_B.
ATOMIC	PersonX follows PersonY into room $> oWant >$ to know why PersonX is following them	PersonX follows PersonY into room, to know why PersonX is following them.
DISTANT	Fisk was shot to death by his mistress's new lover and Fisk's ex-business partner.	Fisk was shot to death by his mistress's new lover and Fisk's ex-business partner.

Table 1: The original and converted form (the input form of SelfRL) of different causal statements from three resources. GLU-SPE and GLU-GEN denote the specific and general statements from GLUCOSE respectively.

classification cross-entropy function:

$$\mathcal{L}_\lambda^{stu} = \textsc{CrossE}(\text{MLP}([\boldsymbol{r}_{event}; \boldsymbol{r}_{event\_state}])). \quad (6)$$

Contrastive Transfer Module As aforementioned, inspired by Tian et al. (2020), we employ a contrastive transfer strategy to transfer the *"knowledge"* mastered by the teacher (self-supervised representation learning module), that is the context-specific causal patterns, to the student (event causality identifier), which helps the latter to identify the event causalities. The key idea of contrastive transfer is intuitional: maximize the mutual information between the teacher and the student (Tian et al., 2020). Methodologically, we make the representation of the statements of causal events encoded by the student model should be close to the causal representation grasped by the teacher model. By contrast, we keep the representation of the statements of non-causal events away from it.

As shown in Figure 2, at each training step of identifier, we sample a batch of external causal statements into the learned Enc_θ of the online network to obtain their causal representation $\boldsymbol{r}_{ext}$ for teaching. At the same time, we also sample a batch of event pairs with their statements into the $BertEnc_\lambda$ of identifier to obtain the statement representation $\boldsymbol{r}_{event\_state}$ of each event pair. Among one batch, $\boldsymbol{r}_{event\_state}$ consists of the $\boldsymbol{r}^+_{event\_state}$ of causal event pairs and the $\boldsymbol{r}^-_{event\_state}$ of non-causal event pairs. After mapping $\boldsymbol{r}_{external}$, $\boldsymbol{r}^+_{event\_state}$ and $\boldsymbol{r}^-_{event\_state}$ into a same space, we obtain $\boldsymbol{r}_{ext}$, $\boldsymbol{r}^{p^+}_{e\_s}$ and $\boldsymbol{r}^{p^-}_{e\_s}$ respectively. After that, we make $\boldsymbol{r}^{p^+}_{e\_s}$ be close to $\boldsymbol{r}_{ext}$ in the contrastive loss function:

$$\mathcal{L}_\lambda^{con} = \frac{1}{|\mathcal{P}^+|} \sum_{p^+ \in \mathcal{P}^+} \log \frac{e^{(\mathcal{D}(\boldsymbol{r}^{p^+}_{e\_s}, \boldsymbol{r}_{ext})/T)}}{\sum_{p \in P} e^{(\mathcal{D}(\boldsymbol{r}^{p}_{e\_s}, \boldsymbol{r}_{ext})/T)}}, \quad (7)$$

where, P^+ and P are the causal event pairs and all event pairs in one batch respectively, T is a temperature that adjusts the concentration level, and $\mathcal{D}$ is the ℓ_2-distance function to measure the distance of two representation.

Learning of Event Causality Identifier For the training of event causality identifier, we add contrastive loss to the basic classification loss, which could guide the identifier to learn context-specific causal patterns implied in the enhanced causal representation from SelfRL. As shown in Algorithm 1, we minimize the L_λ and stochastic gradient update the λ as following:

$$\mathcal{L}_\lambda = \mathcal{L}_\lambda^{stu} + \mathcal{L}_\lambda^{con}, \quad (8)$$

$$\lambda \leftarrow \eta_{stu} \nabla_\lambda \mathcal{L}_\lambda, \quad (9)$$

where, η_{stu} is the learning rate of the identifier. For evaluation, we predict the causality of input event pair without the contrastive transfer module. Additionally, the T in $\mathcal{L}_\lambda^{con}$ indirectly plays a role in adjusting the influence weight of $\mathcal{L}_\lambda^{stu}$ and $\mathcal{L}_\lambda^{con}$. In specific, for teaching, we take the learned Enc_θ of the online network as the encoder, freeze its parameters, to provide the enhanced causal representation of the external causal statements for contrastive representation transfer.

4 Experiments

4.1 Experimental Setup

Dataset and Evaluation Metrics for ECI Our experiments are conducted on two main benchmarks, including: **EventStoryLine** v0.9 (ESC) (Caselli and Vossen, 2017) described above; and (2) **Causal-TimeBank** (CTB) (Mirza and Tonelli, 2014) which contains 184 documents, 6813 events, and 318 causal event pairs. Same as previous methods, we use the last two topics of ESC as the development set for two datasets. For evaluation, we adopt Precision (P), Recall (R), and F1-score (F1) as evaluation metrics. We conduct 5-fold and 10-fold cross-validation on ESC and CTB respectively, same as previous methods. All the results are the average of three independent experiments.

Data Preparation for Self-Supervised Causal Representation Learning We take four types of external causal statements from three resources. Table 1 illustrates the original form and the converted input form of SelfRL (Sec. 3.1) of the causal statements from three different resources.

- **GLUCOSE** (Mostafazadeh et al., 2020): a large-scale dataset of implicit commonsense knowledge, encoded as causal explanatory mini-theories inspired by cognitive psychology. Each GLUCOSE explanation is stated both as a specific statement (grounded in a given context, **GLU-SPE** in Table 1) and a corresponding general rule (applicable to other contexts, **GLU-GEN** in Table 1).

- **ATOMIC** (Sap et al., 2018): an atlas of machine commonsense, as a step toward addressing the rich spectrum of inferential knowledge that is crucial for commonsense reasoning.

- **DISTANT** (Zuo et al., 2020): the automatically labeled training data for ECI via distant supervision that expresses the causal semantics between events.

Parameters Settings In implementations, all the BERT modules are implemented on BERT-Base architecture[2], which has 12-layers, 768-hiddens, and 12-heads. We employ the one-layer BiLSTM (Hochreiter and Schmidhuber, 1997) as Enc_θ and Enc_δ. For parameters, we set the learning rate of SelfRL (η_{tea}) and identifier (η_{stu}) as 1e-5 and 2e-5 respectively. The size of the space in the contrastive transfer module and the hidden layer of BiLSTM are both set as 50. And we respectively set the decay rate τ of moving average in SelfRL and the temperature of the contrastive loss $\mathcal{L}_\lambda^{con}$ are 0.996 and 0.1 tuned on the development set. Moreover, we also tune the batch size of SelfRL and identifier as 48 and 16 respectively on the development set. And we apply the early stop and AdamW gradient strategy to optimize all models. We also adopt a negative sampling rate of 0.6 for the training of identifier, owing to the sparseness of positive examples in the ECI datasets.

Table 2: Results of event causality identification on two benchmarks. Bold denotes best results; * denotes a significant test at the level of 0.05;

Compared Methods Same as previous methods. For ESC, we prefer 1) **S-Path** (Cheng and Miyao, 2017), a dependency path based sequential method that models the context between events to identify causality; 2) **S-Fea** (Choubey and Huang, 2017), a sequence model explores complex human designed features for ECI; 3) **LR+** and **ILP** (Gao et al., 2019), document-level models adopt document structures for ECI.

For CTB, we prefer 1) **Rule-B**, a rule-based system; 2) **Data-D**, a data driven machine learning based system; 3) **VerR-C**, a verb rule based model with data filtering and causal signals enhancement. These models are designed by Mirza and Tonelli (2014; 2014) for ECI. For both two datasets, 1) we build a baseline **BERT** (our basic proposed event causality identifier); 2) We prefer **MasG** (Liu et al., 2020), a BERT-Large based SOTA model with mention masking generalization; 3) **KnowDis** (Zuo et al., 2020) improved the performance of ECI with the distantly labeled training data.

To make a fair comparison, we employ CauSeRL to retrain MasG and KnowDis to illustrate the effectiveness of our proposed approach for ECI on other methods. In specific, 1) **MasG+CauSeRL**: we retrain MasG with L_λ^{con} based on the CLU-SPE. To be consistent with other BERT-based compared models, we re-construct MasG based on BERT-Base rather than the original BERT-Large of MasG;

2) **KnowDis+CauSeRL**: we regard the automatically distantly labeled causal sentences generated by KnowDis as causal statements to learn in SelfRL, and transfer to KnowDis.

CauSeRL$_{External\text{-}Statement}$: To further illustrate the ability of CauSeRL to learn the context-specific causal patterns for the ECI task, we make CauSeRL learn from four types of external causal statements shown in Table 1 for identifying the causalities between events. $External\text{-}Statement$ denotes what kind of external causal statements.

4.2 Our Method vs. State-of-the-art Methods

Table 2 shows the results of ECI on EventStoryLine and Causal-TimeBank. From the results:

1) Our CauSeRL outperforms all baseline methods and achieves the best performance on F1 value, 52.1% on ESC and 53.2% on CTB respectively. Specifically, CauSeRL outperforms the no-bert (ILP/VerR-C) and bert (MasG/KnowDis) baseline methods by a margin of 7.4%/10.0% and 2.0%/3.4% on two benchmarks respectively. It illustrates the context-specific causal patterns from external causal statements are effective for ECI.

2) Comparing MasG+CauSeRL with MasG, we note that even with BERT-Base, the performance of MasG+CauSeRL is significantly higher than that of MasG based on BERT-Large. This shows that the context-specific causal patterns learned by CauSeRL from external causal statements can effectively alleviate the limitation of mask generalization only relying on limited labeled causal context.

3) Comparing KnowDis+CauSeRL with KnowDis, we find that CauSeRL could more efficiently make use of the automatically labeled causal statements, which learns their context-specific causal patterns to further enhance the ability of models to identify the causalities between events.

4) Comparing different external causal statements. a) GLU-SPE brings the most significant improvement because the specific causal statements from GLU-SPE have complete text structures that are more similar to ECI labeled data and make models easier to learn. There, all the ablation experiments are conducted on GLU-SPE. b) The effects of GLU-GEN and ATOMIC are similar because these two types of statements are abstract causal structures. Although they are similar to the context-specific causal patterns, it is relatively difficult to understand directly. c) The improvement brought by DISTANT is relatively small because of the effects of the noise from distantly labeled data.

5) Comparing CauSeRL with MasG+CauSeRL, we notice that after removing the ConceptNet knowledge enhancement employed by MasG, the external causal statements could be better learned and transferred. This is because MasG directly flattens the event concept knowledge into the statement sequence, which disrupts the statement structure and affects the understanding of the statement.

6) It is worth noting that the improvement on

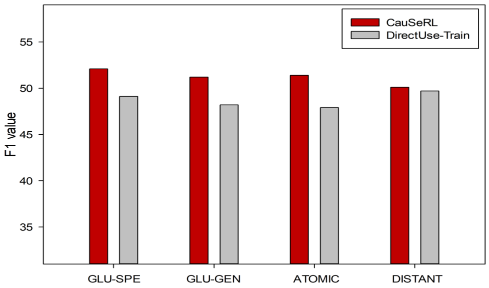

Figure 3: Results of event causality identification on EventStoryLine that directly using external causal statements as the training data of ECI task.

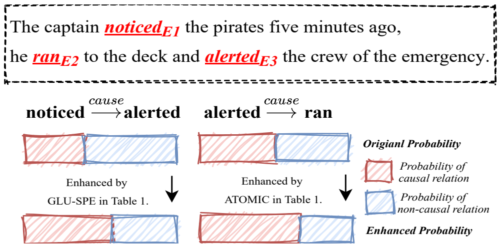

Figure 4: Case study of the probability changes with external causal statements enhancement.

the CTB is higher than that of the ESC, because the amount of labeled data of the former is relatively small, and more need for the help of external causal statements. Moreover, compared with the traditional methods based on features or rules, all BERT-based methods demonstrate high recall value, which is benefited from more training data, knowledge and causal statements.

4.3 Effect of Self-Supervised Causal Representation Learning

We analyze the effect of the self-supervised causal representation learning (SelfRL, Sec. 3.1). As shown in Table 3, from the results, 1) after removing SelfRL, the performance of ECI significantly decreases. This illustrates that the context-specific causal patterns learned by SelfRL are important for the ECI model to understand the causality. 2) Comparing BERT+SelfRL$_{finetune}$ with BERT, the Enc_θ that has learned from external causal statements could improve the performance of ECI to a certain extent. This illustrates that SelfRL could effectively capture the context-specific causal patterns in the statements for identification. 3) Comparing $Enc_{\theta-init}$ + ConRT and $BertEnc_{\lambda-init}$ + ConRT, after representation learning, the fine-tuned Enc_θ could further improve the performance of ECI. This indirectly shows that the context-specific causal patterns learned in the SelfRL is generalized.

4.4 Effect of Contrastive Representation Transfer

We analyze the effect of the contrastive representation transfer (ConRT, Sec. 3.2). As shown in Table 4, from the results, 1) after removing ConRT, the performance of ECI also significantly decreases. This illustrates that the learned causal representations from external statements are not suitable for direct application to ECI, and needs to be effectively transferred that the ConRT focuses on. 2) Comparing BERT + ConRT$_{Enc_\theta}$ with BERT, even if causal representation learning is not carried out in advance, adopting contrast strategy to directly transfer the context-specific causal patterns could also help the inference of event causality to a certain extent. 3) Comparing $Enc_{\theta-freeze}$ + SelfRL with $Enc_{\theta-finetune}$ + SelfRL, we find that the causal representations encoded by pre-trained BERT and BiLSTM have similar effects. Aforementioned, to avoid collapse solutions (Sec. 3.1), we choose the BiLSTM as an encoder in SelfRL that could be initialized completely independently.

4.5 Effect of the Utilization of External Causal Statement

As shown in Figure 3, we regard external causal statements as positive training data for ECI and directly use them to train the BERT baseline model. In specific, we treat two words that play a predicate role in the syntactic structure of each statement as events. From the results, CauSeRL could more effectively make use of causal statements to help understand the causalities of events. In contrast, directly serving as training data is not effective.

4.6 Case Study

As shown in Figure 4, with limited labeled data, the model could not understand the causal relation between event *noticed* and event *alerted*. Fortunately, with the support of the context-specific causal pattern from GLU-SPE in Table 1, the prediction is modified correctly. Moreover, the original model that only trained with limited labeled data is ambiguous about the causal relation between event *alerted* and event *ran*. Influenced by the similar causal statements with the example in Table 1 from ATOMIC, the prediction confidence is improved.

5 Conclusion

We propose a novel approach, CauSeRL, which could leverage external causal statements to identify the causalities of events. First of all, we design a self-supervised framework to learn context-specific causal patterns from external causal statements. Then, we adopt a contrastive transfer strategy to incorporate the learned context-specific causal patterns into the target ECI model for identification. Experimental results on two benchmarks show that our model achieves the best performance.

Abstract

Recently, dense passage retrieval has become a mainstream approach to finding relevant information in various natural language processing tasks. A number of studies have been devoted to improving the widely adopted dual-encoder architecture. However, most of the previous studies only consider query-centric similarity relation when learning the dual-encoder retriever. In order to capture more comprehensive similarity relations, we propose a novel approach that leverages both query-centric and **PA**ssage-centric s**I**milarity **R**elations (called **PAIR**) for dense passage retrieval. To implement our approach, we make three major technical contributions by introducing formal formulations of the two kinds of similarity relations, generating high-quality pseudo labeled data via knowledge distillation, and designing an effective two-stage training procedure that incorporates passage-centric similarity relation constraint. Extensive experiments show that our approach significantly outperforms previous state-of-the-art models on both MSMARCO and Natural Questions datasets[1].

1 Introduction

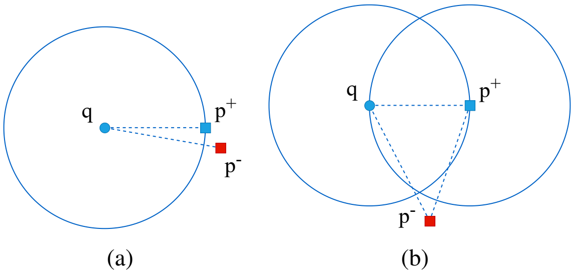

Figure 1: An illustrative case of a query q, its positive passage p^+ and negative passage p^-: (a) Query-centric similarity relation enforces $s(q, p^+) > s(q, p^-)$; (b) Passage-centric similarity relation further enforces $s(p^+, q) > s(p^+, p^-)$, where $s(p^+, q) = s(q, p^+)$. We use the distance (*i.e.,* dissimilarity) for visualization: the longer the distance is, the less similar it is.

With the recent advances of pre-trained language models, dense passage retrieval techniques (representing queries and passages in low-dimensional semantic space) have significantly outperformed traditional term-based techniques (Guu et al., 2020; Karpukhin et al., 2020). As the key step of finding the relevant information, it has been shown that dense passage retrieval can effectively improve the performance in a variety of tasks, including question answering (Lee et al., 2019; Xiong et al., 2020b), information retrieval (Luan et al., 2021; Khattab and Zaharia, 2020), dialogue (Ji et al., 2014; Henderson et al., 2017) and entity linking (Gillick et al., 2019; Wu et al., 2020).

Typically, the dual-encoder architecture is used to learn the dense representations of queries and passages, and the dot-product similarity between the representations of queries and passages becomes ranking measurement for retrieval. A number of studies have been devoted to improving this architecture (Guu et al., 2020; Karpukhin et al., 2020; Xiong et al., 2020a) for dense passage retrieval. Previous studies mainly consider learning query-centric similarity relation, where it tries to increase the similarity $s(q, p^+)$ between a query and a positive (*i.e.,* relevant) passage meanwhile decrease the similarity $s(q, p^-)$ between the query and a negative (*i.e.,* irrelevant) passage. We argue that query-centric similarity relation ignores the relation between passages, and it brings difficulty to discriminate between positive and negative passages. To illustrate this, we present an example in

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2173–2183
August 1–6, 2021.

Figure 1, where a query q and two passages p^+ and p^- are given. As we can see in Figure 1(a), although query-centric similarity relation can enforce $s(q,p^+) > s(q,p^-)$ and identify the positive passages in this case, the distance (*i.e.,* dissimilarity) between positive and negative passages is small. When a new query is issued, it is difficult to discriminate between positive passage p^+ and negative passage p^-.

Considering this problem, we propose to further learn passage-centric similarity relation for enhancing the dual-encoder architecture. The basic idea is shown in Figure 1(b), where we set an additional similarity relation constraint $s(p^+,q) > s(p^+,p^-)$: the similarity between query q and positive passage p^+ should be larger than that between positive passage p^+ and negative passage p^-. In this way, it is able to better learn the similarity relations among query, positive passages and negative passages. Although the idea is appealing, it is not easy to implement due to three major issues. First, it is unclear how to formalize and learn both query-centric and passage-centric similarity relations. Second, it requires large-scale and high-quality training data to incorporate passage-centric similarity relation. However, it is expensive to manually label data. Additionally, there might be a large number of unlabeled positives even in the existing manually labeled datasets (Qu et al., 2020), and it is likely to bring false negatives when sampling hard negatives. Finally, learning passage-centric similarity relation (an auxiliary task) is not directly related to the query-centric similarity relation (a target task). In terms of multi-task viewpoint, multi-task models often perform worse than their single-task counterparts (Alonso and Plank, 2017; McCann et al., 2018; Clark et al., 2019). Hence, it needs a more elaborate design for the training procedure.

To this end, in this paper, we propose a novel approach that leverages both query-centric and **PA**ssage-centric s**I**milarity **R**elations (called **PAIR**) for dense passage retrieval. In order to address the aforementioned issues, we have made three important technical contributions. First, we design formal loss functions to characterize both query-centric and passage-centric similarity relations. Second, we propose to generate pseudo-labeled data via knowledge distillation. Third, we devise a two-stage training procedure that utilizes passage-centric similarity relation during pre-training and then fine-tunes the dual-encoder according to the task goal. The improvements in the three aspects make it possible to effectively leverage both kinds of similarity relations for improving dense passage retrieval.

The contributions of this paper can be summarized as follows:

- We propose an approach that simultaneously learns query-centric and passage-centric similarity relations for dense passage retrieval. It is the first time that passage-centric similarity relation has been considered for this task.

- We make three major technical contributions by introducing formal formulations, generating high-quality pseudo-labeled data and designing an effective training procedure.

- Extensive experiments show that our approach significantly outperforms previous state-of-the-art models on both MSMARCO and Natural Questions datasets.

2 Related Work

Recently, dense passage retrieval has demonstrated better performance than traditional sparse retrieval methods (*e.g.,* TF-IDF and BM25). Different from sparse retrieval, dense passage retrieval represents queries and passages into low-dimensional vectors (Guu et al., 2020; Karpukhin et al., 2020), typically in a dual-encoder architecture, and uses dot product as the similarity measurement for retrieval. The existing approaches for dense passage retrieval can be divided into two categories: (1) unsupervised pre-training for retrieval (2) fine-tuning only on labeled data.

In the first category, different pre-training tasks for retrieval were proposed. Lee et al. (2019) proposed a specific approach to pre-training the retriever with an unsupervised task, namely Inverse Cloze Task (ICT), and then jointly fine-tuned the retriever and a reader on labeled data. REALM (Guu et al., 2020) proposed a new pre-training approach, which jointly trained a masked language model and a neural retriever. Different from them, our proposed approach utilizes the pseudo-labeled data via knowledge distillation in the pre-training stage, and the quality of the generated data is high (see Section 4.6).

In the second category, the existing approaches fine-tuned pre-trained language models on labeled data (Karpukhin et al., 2020; Luan et al., 2021). Both DPR (Karpukhin et al., 2020) and ME-BERT (Luan et al., 2021) used in-batch random sampling and hard negative sampling by BM25, while ANCE (Xiong et al., 2020a), NPRINC (Lu et al., 2020) and RocketQA (Qu et al., 2020) explored more sophisticated hard negative sampling approach. Izacard and Grave (2020) and Yang et al. (2020) leveraged a reader and a cross-encoder for knowledge distillation on labeled data, respectively. RocketQA found large batch size can significantly improve the retrieval performance of dual-encoders. ColBERT (Khattab and Zaharia, 2020) incorporated light-weight attention-based re-ranking while increasing the space complexity.

The existing studies mainly focus on learning the similarity relation between the queries and the passages, while ignoring the relation among passages. It makes the model difficult to discriminate the positive passages and negative passages. In this paper, we propose an approach simultaneously learn query-centric and passage-centric similarity relations.

3 Methodology

In this section, we present an approach that leverages both query-centric and **PA**ssage-centric s**I**milarity **R**elations (called **PAIR**) for dense passage retrieval.

3.1 Overview

The task of dense passage retrieval (Karpukhin et al., 2020) is described as follows. Given a query q, we aim to retrieve k most relevant passages $\{p_j\}_{j=1}^{k}$ from a large collection of M passages.

For this task, the dual-encoder architecture is widely adopted (Karpukhin et al., 2020; Qu et al., 2020), where two separate encoders $E_Q(\cdot)$ and $E_P(\cdot)$ are used to represent the query q and the passage p into d-dimensional vectors in different representation spaces. Then a dot product is performed to measure the similarity between q and p based on their embeddings:

$$s(q,p) = E_Q(q)^\top \cdot E_P(p). \tag{1}$$

Previous studies mainly capture the query-centric similarity relation. As shown in Figure 1, passage-centric similarity relation reflects important evidence for improving the retrieval performance. Therefore, we extend the original query-centric learning framework by leveraging the passage-centric similarity relation.

To develop our approach, we need to address the issues described in Section 1, and we consider three aspects to extend. First, we design a new loss function that considers both query-centric and passage-centric similarity relations. Second, we utilize knowledge distillation to obtain large-scale and high-quality pseudo-labeled data to capture more comprehensive similarity relations. Third, we design a two-stage training procedure to effectively learn the passage-centric similarity relation and improve the final retrieval performance.

3.2 Defining the Loss Functions

Our approach considers two kinds of losses, namely query-centric loss and passage-centric loss, as shown in Figure 2. The two kinds of losses are characterized by the two different similarity relations, query-centric similarity relation and passage-centric similarity relation.

Query-centric Loss The query-centric similarity relation regards the query q as the center and pushes the negative passages p^- farther than the positive passages p^+. That is:

$$s^{(Q)}(q,p^+) > s^{(Q)}(q,p^-)\,, \tag{2}$$

where $s^{(Q)}(q,p^+)$ and $s^{(Q)}(q,p^-)$ represent the similarities for the relevant and irrelevant passages to query q, and they are defined the same as $s(q,p)$ in Eq. (1). Following (Karpukhin et al., 2020; Qu et al., 2020), we learn the query-centric similarity relation by optimizing query-centric loss that is the negative log likelihood of the positive passage:

$$L_Q = -\frac{1}{N}\sum_{\langle q,p^+\rangle} \log \frac{e^{s^{(Q)}(q,p^+)}}{e^{s^{(Q)}(q,p^+)} + \sum_{p^-} e^{s^{(Q)}(q,p^-)}}. \tag{3}$$

As shown in Figure 1, for a given query, there might exist some negative passages similar to the positive passage, making it difficult to discriminate between positive and negative passages. Hence, we further incorporate passage-centric loss to address this issue.

Passage-centric Loss The aim of learning passage-centric similarity relation is to push negative passage p^- farther from positive passage p^+, and making the similarity between positive passage p^+ and query q larger than the similarity between positive passage p^+ and negative passage

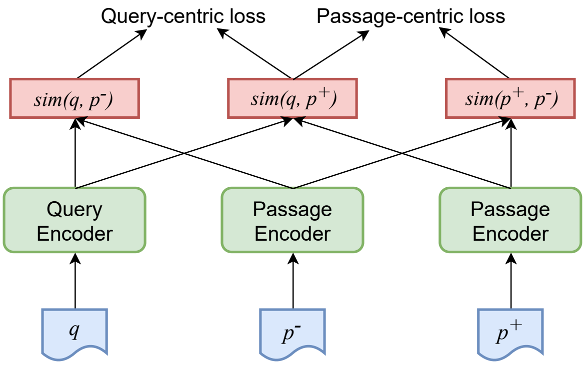

Figure 2: An illustration of the combination of query-centric loss and passage-centric loss.

p^-. Formally, we introduce the following passage-centric similarity relation:

$$s^{(P)}(p^+, q) > s^{(P)}(p^+, p^-), \tag{4}$$

where $s^{(P)}(p^+, q)$ and $s^{(P)}(p^+, p^-)$ are defined as $E_P(p^+)^\top \cdot E_Q(q)$ and $E_P(p^+)^\top \cdot E_P(p^-)$, respectively. Similarly, we learn the passage-centric similarity relation by optimizing the passage-centric loss function that is the negative log likelihood of the query:

$$L_P = -\frac{1}{N} \sum_{\langle q, p^+ \rangle} \log \frac{e^{s^{(P)}(p^+, q)}}{e^{s^{(P)}(p^+, q)} + \underline{\sum_{p^-} e^{s^{(P)}(p^+, p^-)}}}. \tag{5}$$

By comparing Eq. (3) and Eq. (5), we can observe that the difference in two kinds of loss lies in the normalization part (underlined).

The Combined Loss We present an illustrative sketch of the above two loss functions in Figure 2. Next, we propose to simultaneously learn both query-centric and passage-centric similarity relations in Eq.(2) and Eq.(4). Therefore, we combine query-centric and passage-centric loss functions defined in Eq. (3) and (5) to obtain the final loss function:

$$L = (1 - \alpha) * L_Q + \alpha * L_P, \tag{6}$$

where α is a hyper-parameter and is tuned in experiments. By considering passage-centric similarity relation, our approach will be more capable of discriminating between a positive passage and a highly similar yet irrelevant passage $\big($See Figure 1(b)$\big)$.

Dual-encoder with Shared Parameters Most of the existing studies (Eq. (2)) equip the dual-encoders with two separate encoders (E_Q and E_P) for queries and passages, respectively. In this case, different encoders may project queries and passages into two different spaces. However, to simultaneously model the query-centric similarity relation and the passage-centric similarity relation, the representations of queries and passages should be in the same space. Otherwise, the similarity between passages and the similarity between queries and passages are not comparable. Therefore, we propose using the encoders that share the same parameters and structures for both queries and passages, *i.e.,* $E_Q(\cdot)$=$E_P(\cdot)$.

3.3 Generating the Pseudo-labeled Training Data via Knowledge Distillation

By optimizing both query-centric loss and passage-centric loss, we can capture more comprehensive similarity relations. However, more similarity relation constraints require large-scale and high-quality training data for optimization. Additionally, there might be a large number of unlabeled positives even in the existing manually labeled datasets (Qu et al., 2020), and it is likely to bring false negatives when sampling hard negatives. Hence, we propose to generate pseudo-labeled training data via knowledge distillation.

Cross-encoder Teacher Model The teacher model is used to generate large-scale pseudo-labeled data. Following RocketQA (Qu et al., 2020), we adopt the cross-encoder architecture to implement the teacher, which takes as input the concatenation of query and passage and models the semantic interaction between query and passage representations. Such an architecture has been demonstrated to be more effective than the dual-encoder architecture in characterizing query-passage relevance (Yang et al., 2020). We follow Qu et al. (2020) to train the cross-encoder teacher with the labeled data.

Generating Pseudo Labels In this paper, we follow Qu et al. (2020) to obtain positives and hard negatives[2] for unlabeled queries[3]. First, we retrieve the top-*k* candidate passages of unlabeled queries from the corpus by an efficient retriever DPR (Karpukhin et al., 2020), and score them by the well-trained cross-encoder (*i.e.,* teacher model). We set two values s_{pos} and s_{neg} ($s_{pos} > s_{neg}$) as the positive and hard negative thresholds,

---

[2] Xiong et al. (2020a) and Karpukhin et al. (2020) demonstrate the importance of hard negatives.

[3] We obtain easy negatives from in-batch sampling.

Dataset	#q in train	#q in dev	#q in test	#p
MSMARCO	502,939	6,980	6.837	8,841,823
Natural Questions	58,812	6,515	3,610	21,015,324

Table 1: The detailed statistics of MSMARCO and Natural Questions. Here, "q" and "p" are the abbreviations of queries and passages, respectively.

respectively. Then, given each query, a candidate passage with a score above s_{pos} or below s_{neg} will be considered as positive or negative. Note that we also apply this on labeled corpus to obtain more positives and reliable hard negatives. Because there might be a large number of unlabeled positives even in the existing manually labeled datasets (Qu et al., 2020) and it is likely to bring false negatives in hard negative sampling.

3.4 Two-stage Training Procedure

Although passage-centric similarity relation (Eq. (5)) is able to incorporate additional relevance evidence, it is not directly related to the final task goal (*i.e.,* query-centric similarity relation). Therefore, we design a two-stage training procedure that incorporates the passage-centric loss in the pre-training stage, and then only optimize the tasks-specific loss (*i.e.,* query-centric loss) in the fine-tuning stage. We present an illustration for the two-stage training procedure in Figure 3. Next, we present the detailed training procedure.

Pre-training In the pre-training stage, we train the dual-encoder by optimizing the loss function L in Eq. (6) (*i.e.,* a combination of query-centric loss and passage-centric loss). The pseudo-labeled data from unlabeled corpus is adopted as the pre-training data (Section 3.3).

Fine-tuning In the fine-tuning stage, we only fine-tune the dual-encoder (pre-trained in the first stage) according to the query-centric loss L_Q in Eq. (3). In this way, our approach focuses on learning the task-specific loss, yielding better retrieval performance. In this stage, we use both ground-truth labels and pseudo labels derived from the labeled corpus for training.

4 Experiments

In this section, we first describe the experimental settings, then report the main experimental results, ablation study and detailed analysis.

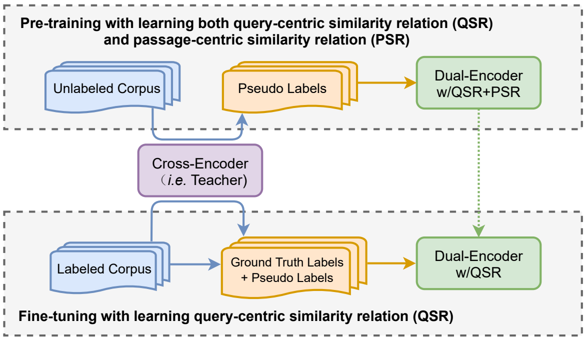

Figure 3: Overview of the proposed two-stage method.

4.1 Experimental Settings

Datasets This paper focuses on the passage retrieval task. We conduct experiments on two public datasets: MSMARCO (Nguyen et al., 2016) and Natural Questions (Kwiatkowski et al., 2019). The statistics of the datasets are listed in Table 1. *MSMARCO* was originally designed for multiple passage machine reading comprehension, and its queries were sampled from Bing search logs. Based on the queries and passages in MSMARCO Question Answering, a dataset for passage retrieval and ranking was created, namely MSMARCO Passage Ranking. *Natural Questions (NQ)* was originally introduced as a dataset for open-domain QA. The queries were collected from Google search logs. DPR (Karpukhin et al., 2020) selected the queries that had short answers, and processed all the Wikipedia articles as the collection of passages. In our experiments, we reuse the version of NQ created by DPR.

Evaluation Metrics Following previous work, we adopt Mean Reciprocal Rank (MRR) and Recall at top k ranks (Recall@k) to evaluate the performance of passage retrieval. MRR calculates the averaged reciprocal of the rank at which the first positive passage is retrieved. Recall@k calculates the proportion of questions to which the top k retrieved passages contain positives.

tion data, we collect about 1.8 million unlabeled queries from Yahoo! Answers[4], ORCAS (Craswell et al., 2020), SQuAD (Rajpurkar et al.), TriviaQA (Joshi et al., 2017) and HotpotQA (Yang et al., 2018). In the pre-training stage, we reuse the passage collections from the labeled corpus (MSMARCO and NQ).

4.2 Implementation Details

We conduct experiments with the deep learning framework PaddlePaddle (Ma et al., 2019) on up to eight NVIDIA Tesla V100 GPUs (with 32G RAM).

Pre-trained LMs The dual-encoder is initialized with the parameters of ERNIE-2.0 base (Sun et al., 2020). ERNIE-2.0 has the same networks as BERT (Devlin et al., 2019), and it introduces a continual pre-training framework on multiple pretrained tasks. The cross-encoder setting follows the cross-encoder in RocketQA (Qu et al., 2020)

Hyper-parameters (a) *batch size*: Our dual-encoder is trained with a batch size of 512×1 in fine-tuning stage on NQ and 512×8 in other settings. We use the in-batch negative setting (Karpukhin et al., 2020) on NQ and cross-batch negative setting (Qu et al., 2020) on MSMARCO. (b) *training epochs*: The number of training epochs is set up to 10 for both pre-training and fine-tuning for dual-encoder. (c) *warm-up and learning rate*: The learning rate of the dual-encoder is set to 3e-5 and the rate of linear scheduling warm-up is set to 0.1. (d) *# of positives and hard negatives*: The ratio of the positive to the hard negative is set to 1:4 on dual-encoder.

Optimizers We use LAMB optimizer (You et al., 2020) to train the dual-encoder on MSMARCO, which is more suitable in cross-batch negative setting. In other settings, we always use ADAM optimizer (Kingma and Ba, 2015).

The choice of alpha α is a hyper-parameter to balance the query-centric loss and passage-centric loss (Eq. (6)). We searched for α from 0 to 1 by setting an equal interval to 0.1, and the model achieves the best performance when α is set to 0.1.

4.3 Main Experimental Results

We consider both sparse and dense passage retrievers for baselines. The sparse retrievers include the traditional retriever BM25 (Yang et al., 2017), and four traditional retrievers enhanced by neural networks, including doc2query (Nogueira et al., 2019b), DeepCT (Dai and Callan, 2019), docTTTTTquery (Nogueira et al., 2019a) and GAR (Mao et al., 2020). Both doc2query and docTTTTTquery employ neural query generation to expand documents. In contrast, GAR employs neural generation models to expand queries. Different from them, DeepCT utilizes BERT to learn the term weight. The dense passage retrievers include DPR (Karpukhin et al., 2020), DPR-E, ANCE (Xiong et al., 2020a), ME-BERT (Luan et al., 2021), NPRINC (Lu et al., 2020), ColBERT (Khattab and Zaharia, 2020) and RocketQA (Qu et al., 2020). DPR-E is our implementation of DPR using ERNIE (Sun et al., 2020)

w/o SP	74.0	83.4	88.9
w/o PT	73.0	82.8	88.5

Table 3: The ablation study and controlled experiments of different variants of PAIR on Natural Questions.

instead of BERT, to examine the effects of pre-trained LMs.

Table 2 presents the main experimental results.

(1) We can see that PAIR significantly outperforms all the baselines on both MSMARCO and NQ datasets. The major difference between our approach and baselines lies in that we incorporate both query-centric and passage-centric similarity relations, which can capture more comprehensive semantic relations. Meanwhile, we incorporate the augmented data via knowledge distillation.

(2) We notice that baseline methods use different pre-trained LMs, as shown in the second column of Table 2. In PAIR, we use the ERNIE-base. To examine the effects of ERNIE-base, we implement DPR-E by replacing BERT-base used in DPR as ERNIE-base. From Table 2, we can observe that PAIR significantly outperforms DPR-E, although they employ the same pre-trained LM.

(3) Another observation is that the dense retrievers are overall better than the sparse retrievers. Such a finding has also been reported in prior studies (Karpukhin et al., 2020; Xiong et al., 2020a; Luan et al., 2021), which indicates the effectiveness of the dense retrieval approach.

4.4 Ablation Study

In this section, we conduct ablation study to examine the effectiveness of each strategy in our proposed approach. We only report the results on the NQ, while the results on the MSMARCO are similar and omitted here due to limited space.

Here, we consider five variants based on our approach for comparison:

(a) *w/o PSR* removes the loss for passage-centric similarity relation in the pre-training stage;

(b) *w/o KD* removes the knowledge distillation for obtaining pseudo-labeled data and only uses the labeled data (MSMARCO and NQ) for both pre-training stage and fine-tuning stage;

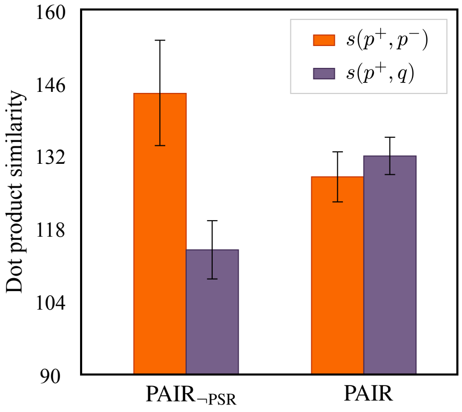

Figure 4: The comparison of PAIR and PAIR$_{\neg\text{PSR}}$ on $s(p^+, p^-)$ and $s(p^+, q)$ with standard deviation.

(c) *w/ PSR FT* adds the loss for passage-centric similarity relation in the fine-tuning stage;

(d) *w/o SP* uses separate encoders for queries and passages instead of encoders with shared parameters;

(e) *w/o PT* removes the pre-training stage.

Table 3 presents the results for the ablation study. We can observe the following findings:

- The performance drops in *w/o PSR*, demonstrating the effectiveness of learning passage-centric similarity relation;
- The performance drops in *w/o KD*, demonstrating the necessity and effectiveness of the knowledge distillation for obtaining large-scale and high-quality pseudo-labeled data, since the passage-centric loss tries to distinguish highly similar but semantically different passages;
- The performance slightly drops in *w/ PSR FT*, because passage-centric loss is not directly related to the target task (*i.e.,* query-based retrieval), which suggests that passage-centric loss should be only used in the pre-training stage;
- The performance drops in *w/o SP*, demonstrating the effectiveness of dual-encoders with shared parameters;
- The performance significantly drops in *w/o PT*, demonstrating the importance of our pre-training procedure.

4.5 Analysis on Passage-centric Similarity Relation

The previous results demonstrate the effectiveness of our proposed approach PAIR. Here, we further analyze the effect of passage-centric loss (Eq. (5)) in a more intuitive way. To examine this, we prepare two variants of our approach,

Query	Top 1 passage retrieved by PAIR (correct)	Top 1 passage retrieved by $\text{PAIR}_{\neg\text{PSR}}$ (incorrect)
Which animal is the carrier of the **H1N1** virus ?	**H1N1** strains caused a small percentage of all human flu infections in 2004–2005. Other strains of **H1N1** are endemic *in pigs* (swine influenza) and in birds (avian influenza) ...	**H5N1** is a subtype virus which can cause illness in humans and many other animal species. A bird-adapted strain of **H5N1**, called HPAIA (**H5N1**) for ...
Where is **gall bladder** situated in human body?	The **gall bladder** is a small hollow organ where bile is stored ... In humans, the pear-shaped **gall bladder** lies *beneath the liver*, although the structure and position ...	The **urinary bladder** is a hollow muscular organ in humans and some other animals that collects and stores urine from the kidneys before disposal by urination ...

Table 4: The comparison of the top-1 passages retrieved by PAIR and $\text{PAIR}_{\neg\text{PSR}}$, respectively. The **bold words** represent the main topics in queries and passages. The *italic words with wavy underline* are the right answers. The words with straight underline among passages have many words in common and may mislead the model $\text{PAIR}_{\neg\text{PSR}}$ to select the wrong passage.

namely the complete PAIR and the variant removing the passage-centric loss (Eq. (5)) denoted by $\text{PAIR}_{\neg\text{PSR}}$.

We first analyze how the passage-centric similarity relation (PSR) influences the similarity relations among query, positive passage and negative passage. Figure 4 shows the comparison of PAIR and $\text{PAIR}_{\neg\text{PSR}}$ for computing the similarities of $s(p^+, p^-)$ and $s(p^+, q)$. We obtain $s(p^+, p^-)$ and $s(p^+, q)$ by the averaging the similarity of top 100 retrieved passages for each query in the testing data of Natural Questions. We can see that before incorporating passage-centric similarity relation (PSR), $s(p^+, p^-)$ is higher than $s(p^+, q)$. As a result, the negatives are close to the positives. After incorporating PSR, $s(p^+, p^-)$ becomes lower than $s(p^+, q)$. It indicates that passage-centric loss pulls positive passages closer to queries and push them farther away from negative passages in the representation space. The comparison result is consistent with passage-level similarity relation in Eq. (4).

Next, we further present two examples in Table 4 to understand the performance difference between PAIR and $\text{PAIR}_{\neg\text{PSR}}$. In the first example, the top-1 passage retrieved by PAIR has the same topic "H1N1" as the query. In contrast, the top-1 passage retrieved by $\text{PAIR}_{\neg\text{PSR}}$ has an incorrect but highly relevant topic "H5N1". Actually, the sentences among the positive passage (retrieved by PAIR) and the negative passage (retrieved by $\text{PAIR}_{\neg\text{PSR}}$) share many common words. Such a negative passage is likely to mislead the retriever to yield incorrect rankings. Hence, these two passages should be far away from each other in the representation space. This problem cannot be well solved by only considering the query-passage similarity in existing studies. Similar observations can be find from the second example. The top-1 passage retrieved by PAIR has the same topic "gall bladder" as the query, while the top-1 passage retrieved by $\text{PAIR}_{\neg\text{PSR}}$ is about "urinary bladder". These results show that passage-centric similarity relations are particularly useful to discriminate between positive and hard negative passages (highly similar to positive passages).

Threshold	Data Quality		Retrieval Performance		
	Acc_{pos}	Acc_{neg}	R@5	R@20	R@100
$s_{pos} = 0.9$ $s_{neg} = 0.1$	**92%**	**96%**	**74.9**	**83.5**	**89.1**
$s_{pos} = 0.8$ $s_{neg} = 0.2$	90%	93%	74.5	83.4	88.9
$s_{pos} = 0.7$ $s_{neg} = 0.3$	84%	87%	73.6	**83.5**	88.6
$s_{pos} = 0.6$ $s_{neg} = 0.4$	80%	87%	73.5	83.4	88.7

Table 5: The data quality and retrieval performance in different thresholds on NQ. Acc_{pos} denotes accuracy of positives and Acc_{neg} denotes accuracy of negatives.

4.6 Analysis on Knowledge Distillation

In this section, we examine the influence of the thresholds on pseudo-labeled data via knowledge distillation, including the data quality and the retrieval performance. We conduct the analyses by using different positive thresholds s_{pos} and negative thresholds s_{neg} (See Section 3.3).

We first manually evaluate the quality of the pseudo-labeled data via knowledge distillation *w.r.t.* different threshold settings (*i.e.,* the combinations of s_{neg} and s_{pos}). For each threshold setting, we randomly select 100 queries, each of which corresponding to a positive passage and a hard-negative passage. In total, we have 4 threshold settings (as shown in Table 5) and 800 query-passage pairs. We ask two experts to manually annotate the query-passage pairs and evaluate the quality of pseudo-labeled data, the Cohen's Kappa of experts is 0.9. As shown in the first two columns of Table 5, we can observe that when $s_{pos} = 0.9$ and $s_{neg} = 0.1$, the data quality is relatively good. Additionally, when setting a low value of s_{pos} and a high value of s_{neg}, the data quality becomes worse.

The last three columns of Table 5 also present the retrieval performance *w.r.t.* different threshold settings. When choosing a low value of s_{pos} and a high value of s_{neg}, the retrieval performance drops. Hence, our approach is configured with a strict threshold setting (s_{pos} = 0.9, s_{neg} = 0.1) in experiments to achieve good performance.

5 Conclusion and Future Work

This paper presented a novel dense passage retrieval approach that leverages both query-centric and passage-centric similarity relations for capturing more comprehensive semantic relations. To implement our approach, we made three important technical contributions in the loss formulation, training data augmentation and effective training procedure. Extensive results demonstrated the effectiveness of our approach. To our knowledge, it is the first time that passage-centric similarity relation has been considered for dense passage retrieval. We believe such an idea itself is worth exploring in designing new ranking mechanism. In future work, we will design more principle ranking functions and apply current retrieval approach to downstream tasks such as question answering and passage re-ranking.

6 Ethical Impact

The technique of dense passage retrieval is effective for question answering, where the majority of questions are informational queries. Semantic crowdedness problem of passages, and term mismatch between questions and passages are typical problems, which bring barriers for the machine to accurately find the information. Our technique contributes toward the goal of asking machines to find the answer passages to natural language questions from a large collection of documents. With these advantages also come potential downsides: Wikipedia or any potential external knowledge source will probably never fully cover the breadth of user questions. The goal is still far from being achieved, and more efforts from the community is needed for us to get there.

Is Human Scoring the Best Criteria for Summary Evaluation?

Oleg Vasilyev, John Bohannon
Primer Technologies Inc.
San Francisco, California
`{oleg,john}@primer.ai`

Abstract

A summary quality measure is judged by how well it correlates with quality scores produced by human annotators. A higher correlation with human scores is considered to be a decisive indicator of a better measure. In this work we present observations that cast doubt on this view. We also show a possibility of an alternative indicator for selecting the best measure from a family of measures, a criterion that does not rely on human scores.

1 Introduction

The goal of summarization is to convey important and only important information of the text in a fluent, comprehensible and concise summary, preserving the factual consistency with the text.

There are several families of automated measures of summary quality. For example, Gabriel et al. (2020) classified the automated measures into four types: question-answering, text reconstruction, semantic similarity and lexical overlap. Each of these types has families of measures, for example SUM-QE (Xenouleas et al., 2019), APES (Eyal et al., 2019), Summa-QA (Scialom et al., 2019), QAEval (Deutsch et al., 2020) and FEQA (Durmus et al., 2020) in question-answering, BLANC (Vasilyev et al., 2020a) in text reconstruction, BERTScore (Zhang et al., 2020), MoverScore (Zhao et al., 2019) and SUPERT (Gao et al., 2020) in semantic similarity, ROUGE (Lin, 2004) and Jensen-Shannon (Louis and Nenkova, 2009) in lexical overlap.

A high correlation with human evaluation scores is currently accepted as the crucial criterion for choosing a good evaluation measure. Arguably, the factual faithfulness can be annotated objectively, with detailed classification of factual errors (Kryscinski et al., 2020; Huang et al., 2020; Vasilyev et al., 2020b; Gabriel et al., 2020). However, other summary qualities are subjective; this forces researchers to be careful in design and usage of human annotations (Bhandari et al., 2020; Fabbri et al., 2020; Iskender et al., 2021). Annotation scores depend on the types of texts and on the qualification of annotators. For example, there is a big difference in expert and crowd-sourced scores in (Fabbri et al., 2020)[1].

Annotators are biased in favor of anything that makes the scoring easier: extractiveness of the summary, and focus of the summary on the top part of the document (Ziegler et al., 2020). The annotation process itself differs from how the summary quality is assessed by a typical human reader. A human reader does not have a goal of scoring a summary, but rather uses the summary to guess the content of the text.

The contribution of this work:

1. We provide an example of a false 'improvement' of an automated evaluation measure: a dubious modification, imitating a human annotator behavior, can increase the correlation with human scores. For a contrast, we also provide an example of a true improvement that increases correlation with human scores for a good reason.
2. We explore an alternative criterion for selecting an optimal evaluation measure from a family of measures, the criterion not relying on human scores. We provide evidence that the criterion is robust across different kinds of texts and summaries.

For our demonstration we will use BLANC family of evaluation measures, because it is easily interpretable as an analogy to a human reader that uses the summary to guess the content of the text. Two families defined in (Vasilyev et al., 2020a) differ

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2184–2191
August 1–6, 2021.

by their setup. The BLANC-help family gets information from the summary by having the model read the summary when reading and reconstructing the text. The BLANC-tune family gets information from the summary by lightly tuning the model on the summary before reading and reconstructing the text. Measures in each of the families, BLANC-help and BLANC-tune, may differ by the parameters defining the setup.

2 Example of False Improvement: Limited Comparison with Text

After reading a summary, an annotator may chose not to review carefully the whole text, but to consider in detail only the parts that look most similar to the summary. We can imitate this by using only the part of the text that is most related to the given summary. In modifying BLANC this way, it is reasonable to expect that correlation with human scores will increase, but this would make a false 'improvement' of the measure.

In Appendix we provide two examples - Figures 6 and 7 - illustrating the bias that we seek to explore in this section. Each example has a summary that truly attempts to cover all important facts, and a summary that we intentionally wrote to cover only a very limited part of text. To create a falsely 'improved' measure, we seek to explore the bias of annotator giving more attention to parts of text most similar to the summary.

To create a biased BLANC, we can calculate BLANC separately for each sentence of the text, and select n sentences with the highest score. We can consider these selected sentences as the 'text' to deal with, and calculate BLANC on this 'text'. We create such *limited-text* BLANC from BLANC-help[2]. For our illustration we use average expert scores of 1600 text-summary pairs in the dataset SummEval (Fabbri et al., 2020).

Compared to BLANC, the limited text BLANC has indeed higher Spearman correlation with average expert, as shown by thin lines in Figure 1. In this and other figures through this section all p-values are below 0.05.

For Appendix examples, see results in Tables 1 and 2.

We can imagine a human expert paying more attention to several (say three or five) most 'promising' (most similar to the summary) sentences of the text. In evaluating relevance, this might be not very different from working with full text. But for other qualities (coherence, consistency, fluency) the correlation increases.

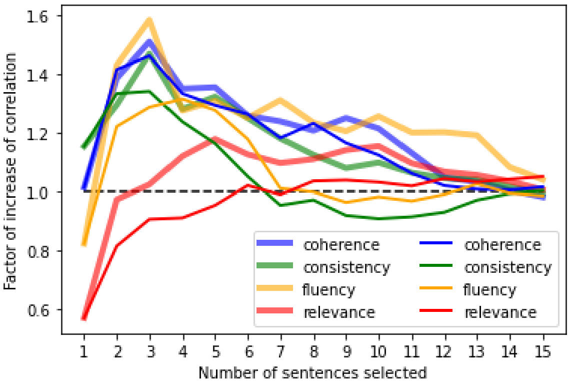

Figure 1: Factor by which Spearman correlation of BLANC with human scores increases when only part of text is used for BLANC. The text part is selected as sentences with top BLANC values (thin lines) or as contiguous sentences with highest BLANC (thick lines).

Naturally, for a human it is easier to review a contiguous piece of text rather than separated pieces, even if this might diminish legitimacy of evaluation of all qualities, including relevance. And, no surprise, BLANC for such contiguous part of text correlates with human scores even better - as shown by thick lines in Figure 1.

Figure 2 illustrates the same trends when the resulting BLANC is calculated for each selected sentence separately, and then averaged over the sentences.

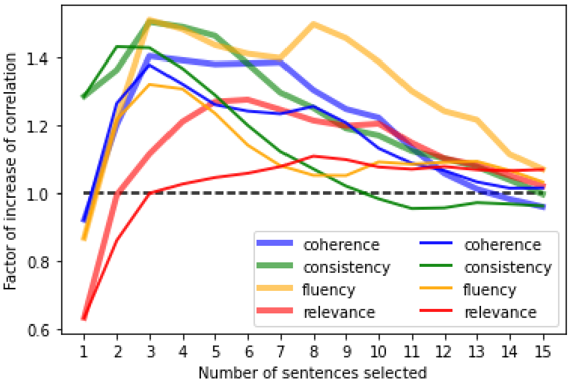

Figure 2: Factor by which Spearman correlation of BLANC with human scores increases when only part of text is used for BLANC. The text part is selected as sentences with top BLANC values (thin lines) or as contiguous sentences having highest average BLANC (thick lines). The resulting BLANC is calculated as average over BLANC of the sentences.

Figure 3 shows the increase of correlations when

---

[2] https://github.com/PrimerAI/blanc

the text is restricted not by the number of sentences but by a threshold on BLANC of a sentence.

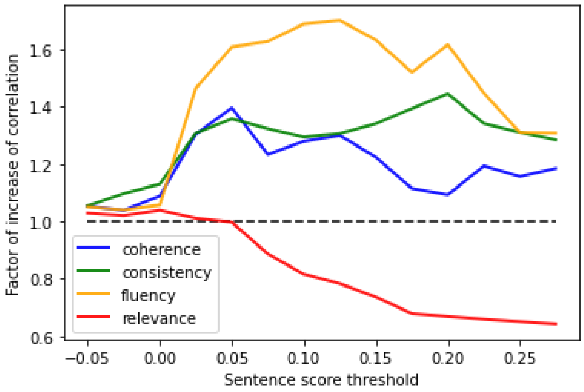

Figure 3: Factor by which Spearman correlation of BLANC with human scores increases when only part of text is used for BLANC. The text part is selected as sentences with BLANC exceeding threshold.

Selection of a part of the text is used in SUPERT multi-document evaluation measure (Gao et al., 2020) as a tool for creating 'reference' from each document and then evaluating a summary on the created references. In the context of BLANC here, the selection of a part of the text is done differently and has a clear interpretation: instead of estimating usefulness of the summary in guessing the whole text, we estimate how much the summary would help to guess only the most 'relevant' part of the text. Here 'relevant' means the part of the text for which the summary turned out to be most helpful. This is equivalent to using only the most easy (for annotator, after reading the summary) part of the text. The summary may as well relate only to a small piece of text of no importance. This means that the evaluation measure became worse, even though the correlation with human scores is stronger.

The human bias exploited by the limited-text BLANC does not necessarily manifest itself through a low inter-annotator agreement. The reported in SummEval (Fabbri et al., 2020) inter-annotator agreement of experts is 0.71, which is an acceptable value (Artstein and Poesio, 2008). While achieving a reasonable inter-annotator agreement is an important problem in human annotations, our example shows that another problem may be in the nature of the human evaluation of summary qualities, where a summary is presented to human for scoring (rather than for guessing about the text content), and the text is presented to facilitate the scoring.

3 Example of True Improvement: Learning More from Summary

In this section we provide an example of a legitimate increase of correlations with human scores, as opposed to the described in previous section false 'improvement'. We can combine BLANC-help and BLANC-tune by tuning the model on the summary (BLANC-tune), and then using the tuned model to read the summary while doing Cloze task on the text (BLANC-help).

Such *full* BLANC version is equivalent to a human that first learns the summary, and then, while guessing missed words in the text, is still looking at the summary again and again. Using both opportunities to learn from the summary makes sense, it should legitimately extract more help from the summary. The worst that may happen is that a model used by BLANC-help is already so perfect in reading the summary that its additional tuning on the summary will not improve the measure (but will not hurt either).

As expected, the full BLANC has substantially higher correlations with annotations of experts on the 1600 text-summary pairs of (Fabbri et al., 2020). Compared to BLANC-help, the Spearman correlation of full BLANC with human scores can increase by 13%-18% for coherence, 2%-3% for consistency,13%-15% for fluency, and 7%-8% for relevance, - all this depending on the number of epochs (10-20) and learning rate (1.0e-4 to 2.0e-4) of the BLANC-tune used.

4 Max-Help Criterion and its robustness

As we have seen in section 2, the correlation with human scores is not always a reliable method to select the best evaluation measure. The fact that we were able to recognize the falsity of 'improvement' in section 2 and the legitimacy of improvement in section 3 suggests that we may find a no-human criterion, at least for some setups.

In previous sections we used BLANC-help as an initial version for our modifications. As stated in Vasilyev et al. (2020b), based on the dataset introduced in there[3], BLANC-help with interval $gap = 2$ between masking locations in the text provided the highest correlations with human scores. It was noted that BLANC's average score across

---

[3] https://github.com/PrimerAI/blanc

the dataset was also the highest at this setup, implying that BLANC extracted maximal help from the summaries. Such coincidence is not a rule: the ”max-help” measure, selected for having maximal average score, is not always the same as the ”max-human” measure, selected for having maximal correlation with human scores.

The max-help criterion - selection of a measure that has highest average score - makes sense under two conditions:

1. The measure is being selected from a family of measures that have the same definition of the output score - as assessment of a usefulness of a summary. The score may be derived, for example, from how many text tokens were successfully reconstructed with help of the summary (BLANC), or from how many questions about the text were successfully answered with help of the summary (QA-based measures). The condition is that the definition is fixed for the family.
2. The average score is being measured with a large enough dataset representing the domain on which we are interested to use the measure.

The meaning of the criterion is simple: the better is the measure in extracting useful information from summaries, the better it should be in judging summaries by their usefulness. The criterion does not require human scoring. All we need is a measurement of an average score.

The max-help criterion can be credible if it does not depend too strongly on the types of texts and summaries. In order to verify this assumption, we considered four types of summaries (and the corresponding texts): (1) CNN summaries from the CNN / Daily Mail dataset (Hermann et al., 2015); (2) Daily Mail summaries from the CNN / Daily Mail dataset; (3) First two sentences from random daily news; (4) Random two sentences from random daily news.

The random daily news were selected as three random news documents per day over one year, with the summaries of the document being two first and two random sentences. We used 1000 samples for each of the four types of summaries.

We intentionally selected summaries of so different styles and quality: if the criterion selects the same best measure for so different types of summaries, then it is indeed a very robust criterion.

For BLANC-help family, we found that for all four datasets the optimal setup (accordingly to the max-help criterion) happens to be the same: $gap = 2$; minimal length of whole-word token allowed to be masked is 6 characters $L_{normal} = 6$; the word-split tokens are always masked ($L_{lead} = 1$ for first token, and $L_{follow} = 1$ for follow-up tokens).

This setup is almost the same as the parameters found in (Vasilyev et al., 2020b) to maximise correlation with human scores, except L_{normal} and L_{follow} which have low influence. The question we asked: does the ’optimal’ max-help evaluation measure remain optimal (or near-optimal) for different kinds of texts and summaries? Figure 4 provides convincing evidence for a positive answer.

Figure 4 shows the average BLANC-help value obtained with sub-optimal (different from max-help) setup. We consider a change of gap and gap_mask (number of tokens allowed to be masked at each masking location) to explore a less frequent and a more frequent masking, and a change in the token length thresholds for masking tokens. Remarkably, the average BLANC-help value drops in each case for all four datasets in a similar manner. The token length thresholds have almost no influence, making a drop just a few percents. Change in frequency of masking has a larger effect, leading to a drop 10%-20%.

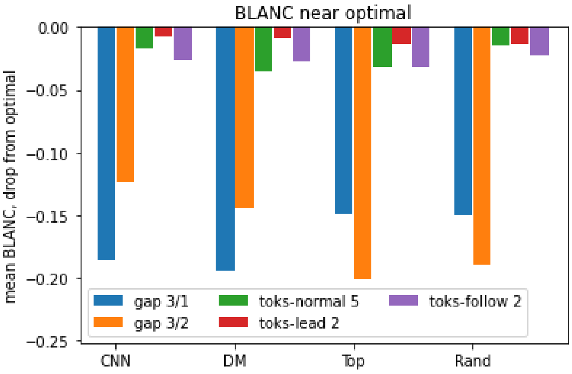

Figure 4: Drop of mean BLANC-help value when parameters differ from optimal. The drop is shown as a fraction of the optimal mean BLANC value. The summaries probed are: CNN and DM (from the CNN/Daily Mail dataset), Top and Rand (first two sentences and random two sentences from random news articles). The parameters probed are: ’gap 3/1’ is $gap = 3$ and $gap\_mask = 1$; ’gap 3/2’ is $gap = 3$ and $gap\_mask = 2$; ’toks-normal 5’ is $L_{normal} = 5$; ’toks-lead 2’ is $L_{lead} = 2$; ’toks-follow 2’ is $L_{follow} = 2$.

For BLANC-tune family, similar to BLANC-help, the max-help optimal setup is the same for all four datasets: $gap = 3$; number of tokens allowed to be masked at each masking location for inference $gap\_mask = 2$; for tuning $gap_{tune} = 4$ and $gap\_mask_{tune} = 3$; $L_{normal} = 6$; $L_{lead} = 1$; $L_{follow} = 1$; probability of replacement of a masked token by another random token at tuning $p_{replace} = 0$.

Probability $p_{replace} = 0$ differs from the value 0.1 used in the standard BERT training, but $p_{replace}$ has only weak influence on the BLANC-tune. Figure 5 shows a few examples of changes of the setup, which illustrate that the optimal measure remains optimal across all four datasets.

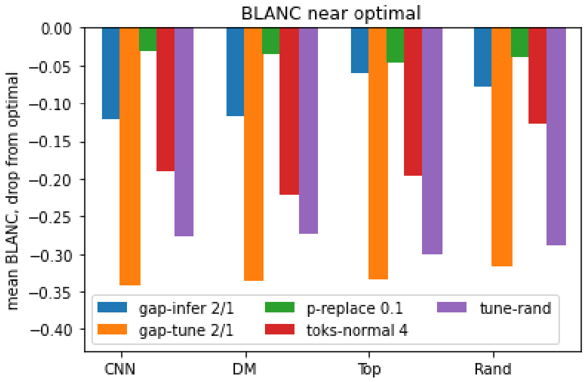

Figure 5: Drop of mean BLANC-tune value when parameters differ from optimal. The drop is shown as a fraction of the optimal mean BLANC value. The summaries probed are: CNN and DM (from the CNN/Daily Mail dataset), Top and Rand (first two sentences and random two sentences from random news articles). The parameters probed are: 'gap-infer 2/1' is $gap = 2$ and $gap\_mask = 1$; 'gap-tune 2/1' is $gap_{tune} = 2$ and $gap\_mask_{tune} = 1$; 'p-replace 0.1' is $p_{replace} = 0.1$; 'toks-normal 4' is $L_{normal} = 4$; 'tune-rand' is making tokens masking random rather than even at tuning.

The demonstrated evidence for robustness suggests that in finding an optimal measure we do not need even human summaries: we can apply the max-help criterion utilizing random sentences from the texts.

5 Conclusion

In this paper, we critically reviewed the assumption that maximal correlation with human scores defines the best evaluation measure for summarization; we provided observations supporting our scepticism. Using good interpretability of BLANC evaluation measure, we provided examples of both illegitimate 'improvement' and legitimate improvement of the correlation of BLANC scores with human scores.

We stated the motivation for an alternative criterion for choosing an optimal summary evaluation measure: the maximal average extracted usefulness of summary. We provided evidence that the criterion is robust across very different kinds of summaries, including such 'summaries' as first sentences or random sentences of the text. This means that the criterion can be applied without the need of human summaries.

While in this work we used BLANC, we think that similar observations and the same conclusions could be made using a question-answering based evaluation measure.

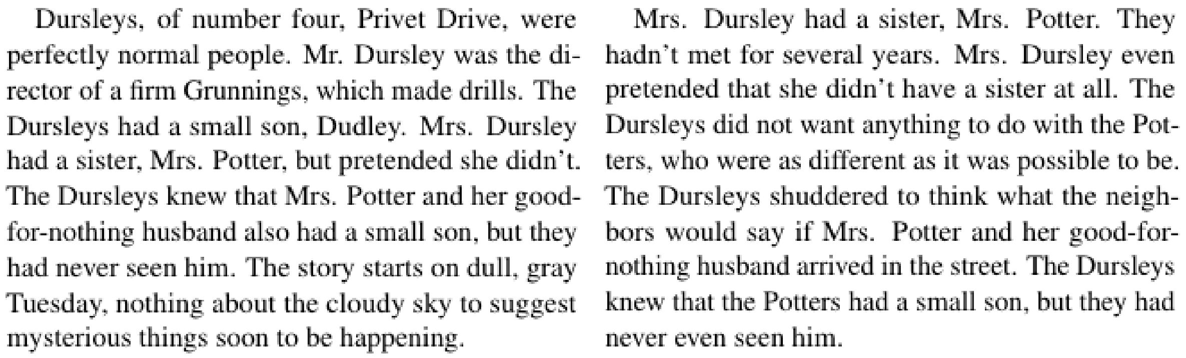
A Examples of bad judgement by falsely 'improved' measure

In Figure 6 we provide two toy summaries, each summary is supposed to summarize the first four paragraphs of 'Harry Potter' book [4]. In order to illustrate how the false improvement described in Section 2 affects ranking of summaries, we intentionally wrote one summary with 'wide coverage' (attempting to cover all the most important facts), and another summary with 'narrow coverage' (focusing on a limited part of the text).

The original BLANC, judging the summaries by how useful they are in predicting tokens of the text, gives higher score to the wide-coverage summary, - see Table 1. The falsely 'improved' BLANC - limited-text BLANC of section 2 - gives higher score to the narrow-coverage summary. It does not matter whether the small part of text covered by the second summary is important or not, the limited-text BLANC makes judgement by how well the summary covered that part of the text. In this case,

---

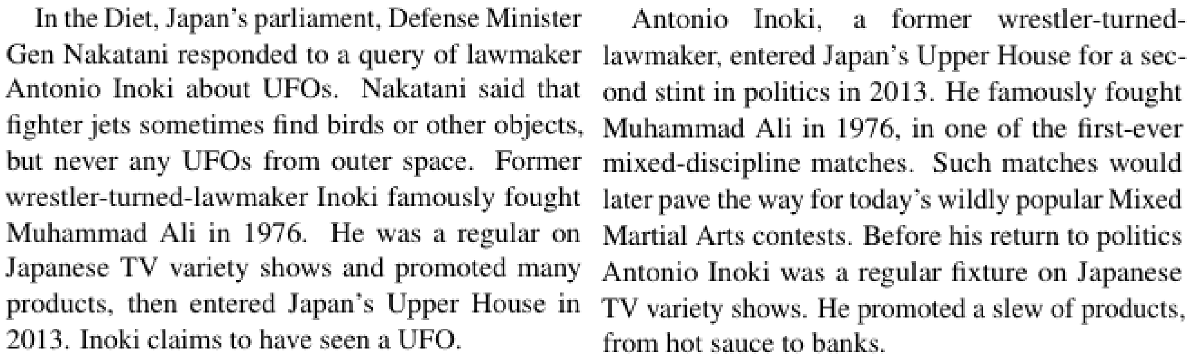
[4] J.K.Rowling (1997). *Harry Potter And the Sorcerer's Stone*. Bloomsbury



Dursleys, of number four, Privet Drive, were perfectly normal people. Mr. Dursley was the director of a firm Grunnings, which made drills. The Dursleys had a small son, Dudley. Mrs. Dursley had a sister, Mrs. Potter, but pretended she didn't. The Dursleys knew that Mrs. Potter and her good-for-nothing husband also had a small son, but they had never seen him. The story starts on dull, gray Tuesday, nothing about the cloudy sky to suggest mysterious things soon to be happening.

Mrs. Dursley had a sister, Mrs. Potter. They hadn't met for several years. Mrs. Dursley even pretended that she didn't have a sister at all. The Dursleys did not want anything to do with the Potters, who were as different as it was possible to be. The Dursleys shuddered to think what the neighbors would say if Mrs. Potter and her good-for-nothing husband arrived in the street. The Dursleys knew that the Potters had a small son, but they had never even seen him.

Figure 6: Example of a summary with a wide coverage (left) and a narrow coverage (right). Both summaries are supposed to cover first four paragraphs of 'Harry Potter And the Sorcerer's Stone' by J.K.Rowling.



In the Diet, Japan's parliament, Defense Minister Gen Nakatani responded to a query of lawmaker Antonio Inoki about UFOs. Nakatani said that fighter jets sometimes find birds or other objects, but never any UFOs from outer space. Former wrestler-turned-lawmaker Inoki famously fought Muhammad Ali in 1976. He was a regular on Japanese TV variety shows and promoted many products, then entered Japan's Upper House in 2013. Inoki claims to have seen a UFO.

Antonio Inoki, a former wrestler-turned-lawmaker, entered Japan's Upper House for a second stint in politics in 2013. He famously fought Muhammad Ali in 1976, in one of the first-ever mixed-discipline matches. Such matches would later pave the way for today's wildly popular Mixed Martial Arts contests. Before his return to politics Antonio Inoki was a regular fixture on Japanese TV variety shows. He promoted a slew of products, from hot sauce to banks.

Figure 7: Example of a summary with a wide coverage (left) and a narrow coverage (right). Both summaries are supposed to cover the same text taken from CNN/Daily Mail dataset. The text is shown in Figure 8.

BLANC	**wide**	**narrow**
Original	0.244	0.218
Limited n=4	0.539	0.584
Limited n=3	0.563	0.652
Limited n=2	0.594	0.778

Table 1: Scores of BLANC versions for wide and narrow coverage summaries of Figure 6. Top row is the original BLANC. Lower rows are for falsely 'improved' BLANC with selection of n top text sentences, as described in Section 2.

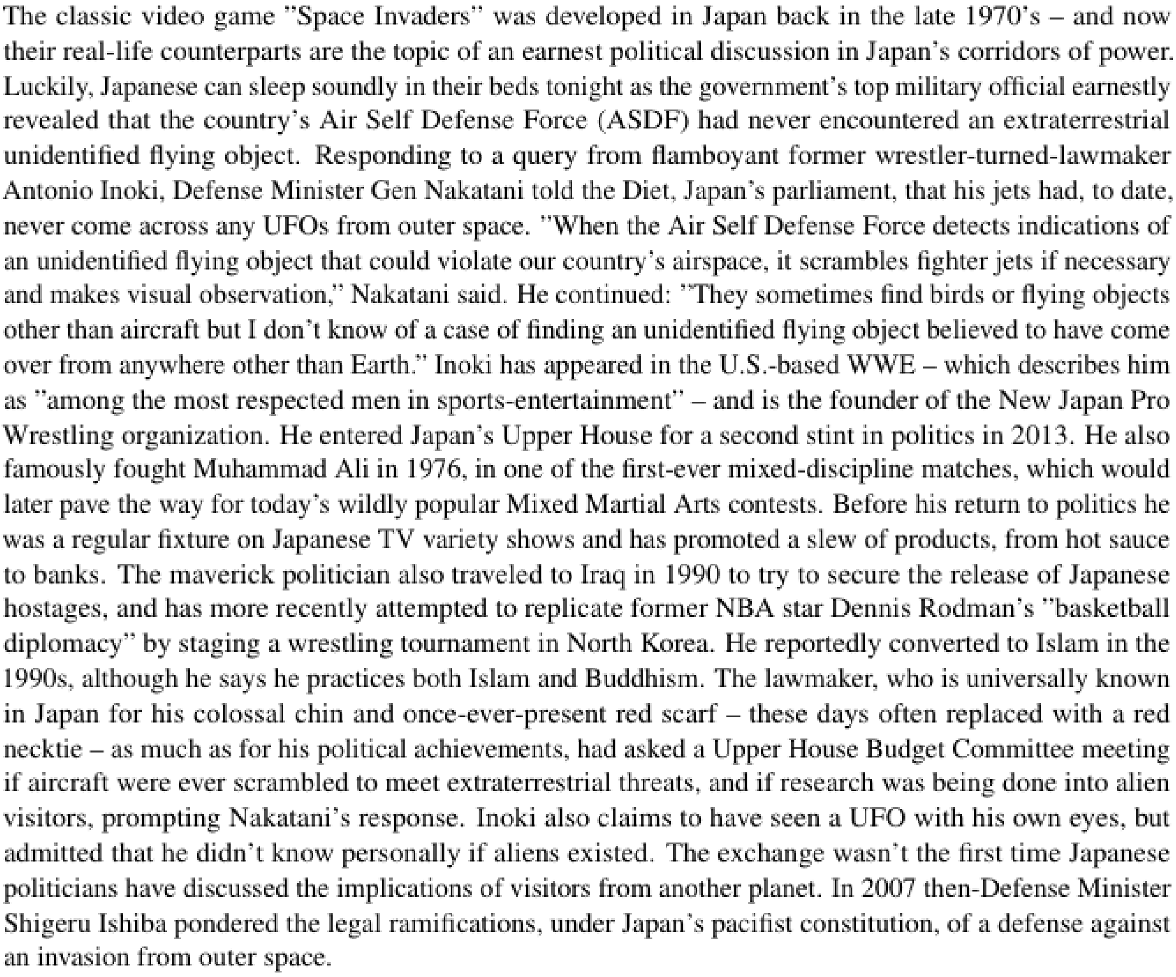
BLANC	**wide**	**narrow**
Original	0.159	0.134
Limited n=4	0.327	0.433
Limited n=3	0.365	0.516
Limited n=2	0.428	0.536

Table 2: Scores of BLANC versions for wide and narrow coverage summaries of Figure 7. Top row is the original BLANC. Lower rows are for falsely 'improved' BLANC with selection of n top text sentences, as described in Section 2.

the second summary concentrates on the attitude of the Dursleys to the Potters, and does not provide any other information.

In Figure 7 we again provide two summaries, this time we wrote them for the text shown in Figure 8, taken from SummEval dataset (Fabbri et al., 2020). Again, as shown in Table 2, the original BLANC gives higher score to the overall more useful wide-coverage summary. The falsely 'improved' limited-text BLANC gives higher score to the narrow-coverage summary which focuses only on information about Antonio Inoki and ignores his query in the parliament.

The scores by the limited-text BLANC are higher than the scores by the original BLANC. The reason is that only text sentences with highest scores are selected, and the less the number of the sentences, the higher is the average score. Naturally, for the wide-coverage summary the score increase is not as great as for the narrow-coverage summary.



The classic video game ”Space Invaders” was developed in Japan back in the late 1970's – and now their real-life counterparts are the topic of an earnest political discussion in Japan's corridors of power. Luckily, Japanese can sleep soundly in their beds tonight as the government's top military official earnestly revealed that the country's Air Self Defense Force (ASDF) had never encountered an extraterrestrial unidentified flying object. Responding to a query from flamboyant former wrestler-turned-lawmaker Antonio Inoki, Defense Minister Gen Nakatani told the Diet, Japan's parliament, that his jets had, to date, never come across any UFOs from outer space. ”When the Air Self Defense Force detects indications of an unidentified flying object that could violate our country's airspace, it scrambles fighter jets if necessary and makes visual observation," Nakatani said. He continued: ”They sometimes find birds or flying objects other than aircraft but I don't know of a case of finding an unidentified flying object believed to have come over from anywhere other than Earth." Inoki has appeared in the U.S.-based WWE – which describes him as ”among the most respected men in sports-entertainment" – and is the founder of the New Japan Pro Wrestling organization. He entered Japan's Upper House for a second stint in politics in 2013. He also famously fought Muhammad Ali in 1976, in one of the first-ever mixed-discipline matches, which would later pave the way for today's wildly popular Mixed Martial Arts contests. Before his return to politics he was a regular fixture on Japanese TV variety shows and has promoted a slew of products, from hot sauce to banks. The maverick politician also traveled to Iraq in 1990 to try to secure the release of Japanese hostages, and has more recently attempted to replicate former NBA star Dennis Rodman's ”basketball diplomacy" by staging a wrestling tournament in North Korea. He reportedly converted to Islam in the 1990s, although he says he practices both Islam and Buddhism. The lawmaker, who is universally known in Japan for his colossal chin and once-ever-present red scarf – these days often replaced with a red necktie – as much as for his political achievements, had asked a Upper House Budget Committee meeting if aircraft were ever scrambled to meet extraterrestrial threats, and if research was being done into alien visitors, prompting Nakatani's response. Inoki also claims to have seen a UFO with his own eyes, but admitted that he didn't know personally if aliens existed. The exchange wasn't the first time Japanese politicians have discussed the implications of visitors from another planet. In 2007 then-Defense Minister Shigeru Ishiba pondered the legal ramifications, under Japan's pacifist constitution, of a defense against an invasion from outer space.

Assessing Dialogue Systems with Distribution Distances

Abstract

An important aspect of developing dialogue systems is how to evaluate and compare the performance of different systems. Existing automatic evaluation metrics are based on turn-level quality evaluation and use average scores for system-level comparison. In this paper, we propose to measure the performance of a dialogue system by computing the distribution-wise distance between its generated conversations and real-world conversations. Specifically, two distribution-wise metrics, FBD and PRD, are developed and evaluated. Experiments on several dialogue corpora show that our proposed metrics correlate better with human judgments than existing metrics.

1 Introduction

Dialogue generation is a special text generation task, which has drawn booming attention in the natural language processing community. It is widely agreed that one single input query is often associated with multiple valid responses in this task, which is termed as a 1-to-n relationship between a query and its responses (Vinyals and Le, 2015; Zhou et al., 2017; Zhao et al., 2017; Liu et al., 2018; Chen et al., 2021; Chan et al., 2021; Gao et al., 2021). It increases the challenges of automatically evaluating the performance of dialogue systems.

In general, the previous evaluation metrics mainly focus on turn-level quality. For example, unsupervised word-overlapping or embedding-based metrics (Papineni et al., 2002; Lin, 2004; Mitchell and Lapata, 2008; Zhang et al., 2020) calculate the similarity or alignment between generated responses and reference responses, which is not well-suited for open-end dialogue tasks. Learned classification or regression systems (Lowe et al., 2017; Tao et al., 2018; Sellam et al., 2020; Ghazarian et al., 2019) are corpus-dependent because of requiring additional task-specific training or tuning, which run the risk of assigning lower quality to a better model in the overfitting or underfitting cases.

In this paper, we provide a new perspective that distribution distance between generated conversations and real conversations can be applied to measure the performances of dialogue systems. There are three main *contributions*: (1) We firstly propose two unsupervised distribution-wise metrics (i.e., FBD and PRD) to solve the evaluation issue in this field. (2) The experimental results show that the proposed distribution-wise metrics perform well. Particularly, FBD achieves compelling performances on most evaluation corpora, which shows a promising direction for designing evaluation metrics. (3) We collect the typical evaluation corpora and existing evaluation metrics in order to better assess the performance of dialogue systems, which could be useful for researchers in this community [1].

2 Related Work

In this section, we focus on *unsupervised* automatic evaluation metrics for dialogue system evaluation. In general, existing unsupervised metrics mainly measure *turn-level* qualities, which can be categorized into two main classes: word overlapping metrics and embedding-based metrics:

Word-overlapping Metrics Such metrics quantify the amount of word-overlap between generated response and reference responses. For example, BLEU (Papineni et al., 2002) calculates the geometric mean of the precision for n-gram. ROUGE (Lin, 2004) is a recall-oriented metric. METEOR (Banerjee and Lavie, 2005) computes the harmonic mean of precision and recall with stemming and syn-

onyms.

Embedding-based Metrics Embedding-based metrics align the generated response and the reference in latent semantic space. Some adopt the vector similarity of sentence embeddings as a quality measure. For example, Embedding Average (Foltz et al., 1998; Mitchell and Lapata, 2008) calculates sentence-level embeddings by averaging word representations. Vector Extrema (Forgues et al., 2014) computes sentence-level embeddings by taking the most extreme value for each dimension in all word vectors. Others adopt more fine-grained semantic matching. For example, Greedy Matching (Rus and Lintean, 2012) greedily matches each word in a generated response to a word in the reference response, and the final score is defined as the average of word-level similarity scores. Zhang et al. (2020) introduced a better embedding-based metric BERTScore that computes word similarity using contextual embeddings from pre-trained language models.

Our proposed methods are best placed in the literature of embedding-based metrics. However, there are two main differences from previous metrics in this field: (1) We compute the distribution distance between embedding sets as the system-level performance of a dialogue system, which does not require task-specific training/tuning; (2) We propose to extract sentence-level semantic representations directly from pre-trained language models (Devlin et al., 2019; Liu et al., 2019), where there are no operations of converting the wold-level embeddings to sentence-level embeddings.

3 Proposed Methods

Given a collect of sentence pairs $\{(\boldsymbol{x}_i, \boldsymbol{y}_i)\}^N$, we assume that the corresponding semantic representations $\{\boldsymbol{v}_i\}^N$ can be extracted in this manner:

$$\boldsymbol{v}_i = LM([\boldsymbol{x}_i, \boldsymbol{y}_i]) \tag{1}$$

where $LM(\cdot)$ refers to pre-trained language models(i.e., (Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019; Clark et al., 2020)), $[\cdot,\cdot]$ refers to the concatenation operation. Intuitively, the differences between the distribution R of real samples and the distribution G of generated samples can be applied to measure the performances of dialogue systems (i.e., $d(R, G)$). Therefore, we propose two distribution-based methods to automatically evaluate the performance of dialogue systems, which are presented in this section in detail.

3.1 Fréchet Bert Distance

Semantic representations $\{\boldsymbol{v}_i\}^N$ are extracted by a pre-trained language model, which encodes the contextual information of the sentences. The main intuition is that the distribution of semantic representations of generated sentences should be as close as possible to the distribution of semantic representations of real sentences in a successful system. To measure this, we assume that such semantic representations follow a multi-dimensional Gaussian, which can be represented by variables: *mean* and *covariance*. The difference between two Gaussians (generated and real sentence pairs) is measured by the Fréchet distance (Dowson and Landau, 1982). We call the Fréchet distance between the distribution R with mean $(\boldsymbol{\mu}_r, \boldsymbol{\Sigma}_r)$ obtained from real sentence pairs and the distribution G with mean $(\boldsymbol{\mu}_g, \boldsymbol{\Sigma}_g)$ obtained from generated sentence pairs as "Fréchet Bert Distance" (FBD), which is formulated as:

$$\begin{aligned} d_{\mathrm{FBD}}(R, G) = \|\boldsymbol{\mu}_r - \boldsymbol{\mu}_g\| + \\ \mathrm{Tr}(\boldsymbol{\Sigma}_r + \boldsymbol{\Sigma}_g - 2(\boldsymbol{\Sigma}_r\boldsymbol{\Sigma}_g)^{1/2}) \end{aligned} \tag{2}$$

Once the distribution of generated data closes to the distribution of real data, the model indeed achieves low FBD scores. Similarly, such distance (Heusel et al., 2017) has been widely verified in various Generative Adversarial Networks (GANs) in computer vision tasks (Karras et al., 2017; Zhang et al., 2018a; Park et al., 2019), which is consistent with increasing disturbances and human judgment. Surprisingly, we observed that FBD works well in evaluating open-end dialogue systems.

3.2 Precision-Recall Distance

We notice that FBD is based on the estimated Gaussian parameters $(\boldsymbol{\mu}, \boldsymbol{\Sigma})$. There is an optional strategy to get rid of estimating the parameters. Inspired by (Sajjadi et al., 2018), we apply a precision-recall-based method, named as Precision-Recall Distance (PRD), to evaluate the distance between two distributions.

The key intuition is that precision should measure how much of G can be generated by a "part" of R while recall should measure how much of R can be generated by a "part" of G. In general, (a) If R is bimodal and G only captures one of the modes, we should have perfect precision but only limited recall; (b) In the opposite case, we should have perfect recall but only limited precision; (c) If $R = G$, we should have perfect precision and recall; (d) If the supports of R and G are disjoint, we should have zero precision and recall. The BPD is formulated as:

$$d_{\text{PRD}}(R, G) = \max \left\{ \frac{2\alpha(\lambda)\beta(\lambda)}{\alpha(\lambda) + \beta(\lambda)} \middle| \lambda \in \Lambda \right\} \tag{3}$$

where $\Lambda = \{\tan(\frac{i}{m+1}\frac{\pi}{2}) | i = 1, \cdots, m\}$, $m \in \mathbb{N}$ refers to a given angular resolution, $\alpha(\lambda) = \sum_{\boldsymbol{v} \in \mathcal{V}} \min(\lambda R(\boldsymbol{v}), G(\boldsymbol{v}))$ and $\beta(\lambda) = \sum_{\boldsymbol{v} \in \mathcal{V}} \min(R(\boldsymbol{v}), \frac{G(\boldsymbol{v})}{\lambda})$ [2]. Therefore, the better dialogue systems will achieve higher PRD scores.

4 Experiments

4.1 Datasets & Systems

To verify the two proposed metrics, we conduct experiments on six public dialogue corpora.

Baseline Metrics. We mainly compare with several widely-used metrics in text generation field: a) three word-overlapping metrics: BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Denkowski and Lavie, 2014); b) four embedding-based metrics: Greedy Matching (Rus and Lintean, 2012), Embedding Average (Wieting et al., 2015), Vector Extrema (Forgues et al., 2014) and BERTScore (Zhang et al., 2020). All these metrics do not require task-specific training.

Datasets. We collect three recently released evaluation corpora which consist of dialogue query and response samples of different systems, and the corresponding human annotations:

- **Persona(M)**: USR (Mehri and Eskénazi, 2020) built an evaluation corpus based on PersonaChat (Zhang et al., 2018b), in which both four system outputs and the corresponding human evaluation scores were collected.
- **Daily(H), Convai2, and Empathetic**: GRADE (Huang et al., 2020) used three dialogue corpora, including DailyDialog (Lowe et al., 2017), Convai2 (Dinan et al., 2019) and EmpatheticDialogues (Rashkin et al., 2018), to do the evaluations and compared two dialogue models: Transformer-Ranker and Transformer-Generator collected from the ParlAI platform (Miller et al., 2017).
- **Daily(Z) and Persona(Z)**: Dialogue Evaluation (Zhao et al., 2020) used DailyDialog (Lowe et al., 2017) and PersonaChat (Zhang et al., 2018b) to build two evaluation corpora and collected outputs of six generative models (with three decoding strategies). The appropriateness of each response was obtained by human annotation.

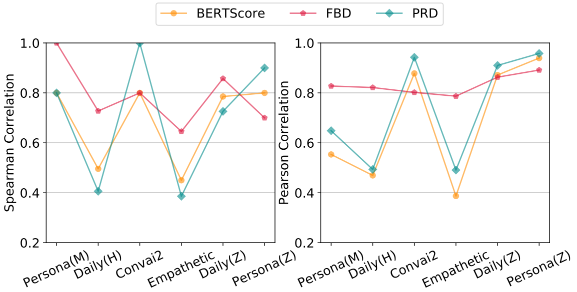

Figure 1: The comparisons between BERTScore, FBD and PRD metrics on various corpora. For each corpus, we average the performances of BERT and RoBERTa language models.

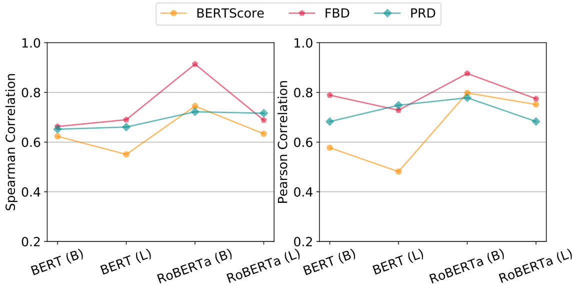

Figure 2: Comparisons between BERTScore, FBD and PRD metrics on various language models. For each model, we average the performances on all the six evaluation corpora.

$(\boldsymbol{x}_i, \boldsymbol{y}_i)$, we use the last hidden output of [CLS] as its semantics representation without tuning or training the language models. To assess the system-level performances of dialogue systems, we calculate the Spearman and Pearson correlations between the rankings of human evaluation and the rankings of evaluation metrics. If a evaluation metric is designed for *turn-level* evaluation, we average the all turn-level scores as the performance of the corresponding dialogue system.

Public Resources. All the compared evaluation corpora and evaluation metrics are available in Table 1. Once the official implementations are not available, we use the repositories with highest “stars” on GitHub. The details of each evaluation corpus, including number of samples and compared dialogue systems in each corpus, are presented in Table 2.

4.2 Results

We compute the system-level correlation between all automatic metrics and the quality ratings by using Spearman and Pearson correlation coefficients.

Model	P(M)	D(H)	C2	EM	D(Z)	P(Z)
BERT	.57±.44	.65±.39	.60±.42	.65±.39	.67±.38	.65±.38
RoBERTa	.71±.38	.68±.37	.73±.34	.68±.37	.68±.37	.71±.33

2. The reported values are mean±standard deviation.

Table 4: Comparisons of the normality on various evaluation corpora. The normality is calculated over each dimension of the extracted semantic representations.

The performances of various evaluation metrics on different public corpora are reported in Table 3. Our proposed two metrics (i.e., FBD and PRD) show comparable performances over the baseline metrics. Especially, FBD$^{\text{R}}$ achieves compelling performances on five corpora, which indicates a good ability of generalization and robustness on various corpora. In addition, most evaluation metrics are sensitive to the evaluation corpora. For example, BLEU performs well in **Convai2** but fails in **Empathetic**. Similarly, BERTScore$^{\text{B}}$ performs well in **Convai2** and **Persona(Z)** but fails in **Daily(H)** and **Empathetic**. It indicates that the selection of evaluation corpora has a great influence on assessing the performances of evaluation metrics. Hence, it's better to use multiple corpora to do the comparisons between metrics. Obviously, our proposed FBD$^{\text{R}}$ outperforms the existing evaluation metrics in the view of robustness.

In Figure 1, we compare the evaluation metrics in the perspective of various evaluation corpora, where the results of BERT and RoBERTa language models are averaged. It confirms the superiority of the FBD metric. Compared to the performance of USR (Mehri and Eskénazi, 2020) (1.000/.820 on Persona(M)), a reference-free metric that relies on task-specific training/tuning with task-specific data, the performances of our proposed methods are comparable without any training/tuning. Therefore, we believe that it's a promising direction to explore distribution-wise metrics for assessing dialogue systems in this field.

As shown in Figure 2, we average the performances of each metric on all evaluation corpora. It shows that our proposed FBD has higher performance expectations that outperform BERTScore with different language models. The large models do not show improvements in average performance compared to the base models. In general, FBD metric achieves better Spearman and Pearson correlations compared to PRD. Surprisingly, RoBERTa-based metrics, including BERTScore, the proposed FBD and PRD, perform better than the corresponding BERT-base ones. Given that our FBD metric lies on the assumption of multivariate Gaussian distribution, we hypothesize that the semantic representations extracted by RoBERTa model fit Gaussian distribution better than BERT model. To verify this point, as shown in Table 4, we use "Shapiro–Wilk test" (Razali et al., 2011) to calculate the normality in statistics, where small values lead to the rejection of normality whereas a value of one indicates normality of the data.

Table 5: Fine-grained comparisons on Daily(Z) (Zhao et al., 2020) corpus.

4.3 Fine-Grained Performances

In the evaluation corpus Daily(Z) (Zhao et al., 2020), it provides four fine-grained human evaluation scores, including *relevance*, *grammar*, *content* and *overall*, which can be used to dive more insights of different evaluation metrics.

As shown in Table 5, our proposed metric FBD$^{\text{R}}$ achieves the best performances on most evaluations in the fine-grained comparisons. It indicates the distribution-wise metric correlate better with human judgements on various aspects.

5 Conclusions

In this paper, we propose to measure the performance of a dialogue system by computing the distribution-wise difference between its generated conversations and real-world conversations. Specifically, two distribution-wise metrics, FBD and PRD, are developed on pre-trained language models. Experiments on six public dialogue corpora show that our proposed metrics correlate better with human judgments than existing metrics.

Abstract

We propose two fast neural combinatory models for constituency parsing: binary and multi-branching. Our models decompose the bottom-up parsing process into 1) classification of tags, labels, and binary orientations or chunks and 2) vector composition based on the computed orientations or chunks. These models have theoretical sub-quadratic complexity and empirical linear complexity. The binary model achieves an F1 score of 92.54 on Penn Treebank, speeding at 1327.2 sents/sec. Both the models with XLNet provide near state-of-the-art accuracies for English. Syntactic branching tendency and headedness of a language are observed during the training and inference processes for Penn Treebank, Chinese Treebank, and Keyaki Treebank (Japanese).

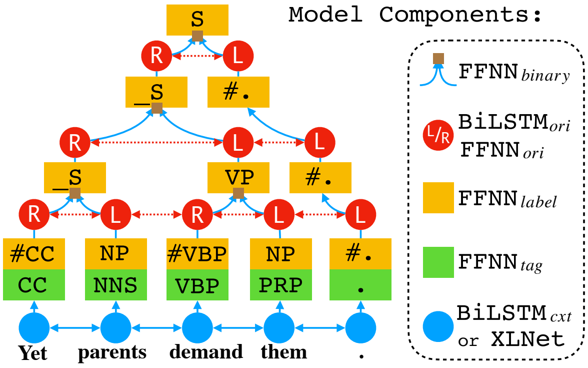

Figure 1: Parsing instance with the binary model. The bottom-up flow of word information is indicated by blue arrows and orientation flows by dotted red arrows. Binary parsing explores the internal constituents of `S`. Special labels prefixed with "#" or "_" are *sub* category placeholders caused by binarization and stratification.

1 Introduction

Transition-based and chart-based methods are two main paradigms for constituency parsing. Transition-based parsers (Dyer et al., 2016; Kitaev and Klein, 2020) build a tree with a sequence of local actions. Despite their $O(n)$ computational complexity, the locality makes them less accurate and necessitates additional grammars or lookahead features for improvement (Kuhlmann et al., 2011; Zhu et al., 2013; Liu and Zhang, 2017c). By contrast, chart-based parsers are conceptually simple and accurate when used with a CYK-style algorithm (Kitaev and Klein, 2018; Zhou and Zhao, 2019) for finding the global optima. However, their complexity is $O(n^3)$. To achieve both accuracy and simplicity (without high complexity) is a critical problem in parsing.

Recent efforts were made using neural models. In contrast to earlier symbolic approaches (Charniak, 2000; Klein and Manning, 2003), neural models are simplified by utilizing their adaptive distributed representation, thereby eliminating complicated symbolic engineering. The seq2seq model for parsing (Vinyals et al., 2015) leverages such representation to interpret the structural task as a general sequential task. With augmented data and ensemble, it outperforms the symbolic models mentioned in Petrov et al. (2006) and provides a complexity of $O(n^2)$ with the attention mechanism (Bahdanau et al., 2015). However, its performance is inferior to those of specialized neural parsers (Liu and Zhang, 2017a,b,c). Socher et al. (2013) proposed a parsing strategy for a symbolic constituent parser augmented with neural vector compositionality. It did not outperform the two paradigms in neural style probably because the neural techniques, such as contextualization, are not fully exploited. Kitaev and Klein (2020) showed that a simple transition-based model with a dynamic distributed representation, BERT (Devlin et al., 2019), nearly delivers a state-of-the-art performance.

We propose a pair of greedy combinatory parsers (i.e., neural combinators) that efficiently utilize vector compositionality with recurrent components to

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2199–2213
August 1–6, 2021.

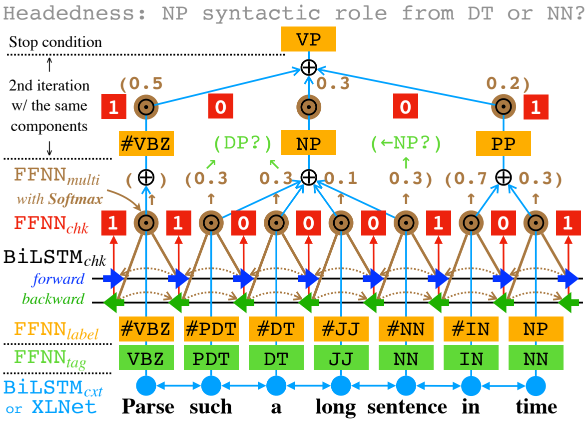

Figure 2: Multi-branching parsing uses chunks instead of orientations to form constituents. Chunks impose Softmax-normalized weights for their inputs. The unsupervised weights provide a shred of evidence for the headedness problem (Zwicky, 1985).

address the aforementioned issues. Their bottom-up parsing process is a recursive layer-wise loop of classification and vector composition, as illustrated in Figures 1 & 2. Both parsers work on multiple unfolded variable-length layers, iteratively combining vectors until one vector remains. The binary model provides either left or right orientation for each word or constituent, whereas the multi-branching model marks chunks as constituents at their boundaries. Constituent embeddings are composed based on orientations or chunks. Tagging and labeling are directly performed on all composed embeddings, creating the elements for building a tree: tags, labels, and paths. The deterministic and greedy characteristics yield two simple and fast models, and they investigate different linguistic aspects.

The contributions of our study are as follows:

- We propose two combinatory parsers[1] at $O(n)$ average-case complexity with a theoretical $O(n^2)$ upper bound. The binary parser achieves a competitive F1 score on Penn Treebank. Both models are the fastest and yet more compact than many previous models.
- We extend the proposed models with a recent pre-trained language model, XLNet (Yang et al., 2019). These models have higher speeds and are comparable to state-of-the-art parsers.
- The binary model leverages Chomsky normal form (CNF) factors as a training strategy and reflects the branching tendency of a language. The multi-branching model reveals constituent headedness (Zwicky, 1985) with an attention mechanism.

2 Previous Work

Transition-based parsers. A transducer takes sequential lexical inputs and produces sequential tree-constructing actions in $O(n)$ time. Although it can perfectly parse formal languages, complex semantics and long dependencies make it difficult to parse natural languages. Informative features (Liu and Zhang, 2017c; Kitaev and Klein, 2020; Yang and Deng, 2020), or training and decoding strategies such as dynamic oracles (Cross and Huang, 2016), reranking (Charniak and Johnson, 2005), beam search, and ensemble, can increase the accuracy. However, these make the models complex, and the paradigm fails to naturally parallelize actions.

Chart-based parsers. An exhaustive search algorithm checks every possibility in a triangular chart and finds the optimal tree globally. Recent neural chart parsers have achieved state-of-the-art accuracy (Kitaev and Klein, 2018; Zhou and Zhao, 2019; Mrini et al., 2020; Zhang et al., 2020). Despite their high accuracy, they are comparatively inefficient. Only $2n - 1$ of $O(n^2)$ scoring nodes in the chart contain true constituents; many are filler nodes. Chart parsers are often specially engineered for high-speed decoding. (e.g., using Cython)

Other parsers. Shen et al. (2018) and Nguyen et al. (2020) proposed local-and-greedy parsers in the top-down splitting style. Their models facilitate divide-and-conquer algorithms that construct the tree based on the magnitude of the splitting scores. A similar way of leveraging concurrent and greedy operations appears in an easy-first parser (Goldberg and Elhadad, 2010). Sequential labeling (Gómez-Rodríguez and Vilares, 2018; Wei et al., 2020) is a new active thread that also enables parallelism and fast decoding. Collobert (2011) designed an iterative chunking process for parsing. His work stratifies trees into levels of IOBES prefixed constituent chunking nodes. Similar to ours, his parser works from the bottom levels to higher levels. However, the complexity is fixed at $O(n^2)$ without any node combinations. All models introduced in this section do not exploit vector compositionality.

---

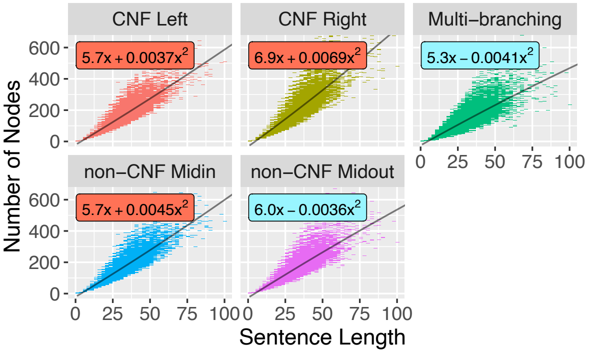

Figure 4: Linear empirical complexity in stratified PTB. Linear regression reflects insignificant $O(n^2)$ tendencies. We differentiated the quadratic terms with red or light blue colors and omitted the constant biases.

3 Neural Combinatory Parsing

3.1 Data and Complexity

Our models require stratified trees to train recurrent layers, and the binary model requires further binarization. Stratification and binarization introduce redundant relaying nodes to the trees.

Tree binarization. From the bottom-up perspective, a binary tree describes the order in which words and constituents combine with their neighbors into larger constituents, as shown in Figure 3. The orientations of the four words (i.e., right-left-right-left) determine the first combination.

After binarization, we label the relaying sub-constituents with the parent label prefixed with an underscore mark. If terminal POS tags do not immediately form constituents, we create relaying placeholders prefixed with a hash mark[2], as presented in Table 1. Unary branches were collapsed into a single node. Plus marks were used to join their labels (e.g., `SBAR+S`), and all trace branches were removed. The CNF with either a **left** or a **right** factor is commonly used. However, it is heuristically biased, and trees can be binarized using other balanced splits such as always splitting from the center to create a complete binary tree (**mid-out**) and iteratively performing **left** and **right** to create another balanced tree (**mid-in**). Finally, the orientation is extracted from the paths of these binary trees.

We binarized Penn Treebank (Marcus et al., 1993, PTB) for English, Chinese Treebank (Xue et al., 2005, CTB) for Chinese, and Keyaki Treebank[3] (Butler et al., 2012, KTB) for Japanese to present the syntactic branching tendencies in Table 2. As English is a right-branching language, its majority orientation is to the right. Even left-factoring cannot reverse the trend, but it should create a greater balance. Figure 4 shows that it is less effective to stratify PTB with a **right** factor because it enhances the tendency. The reverse tendency emerges in the KTB corpus as Japanese is a left-branching language. For Chinese, CTB does

---

[2] Multi-branching trees do not require binarization. The '**_Sub**' group disappears, but the '**#POS**' group persists.

[3] `https://github.com/ajb129/KeyakiTreebank/tree/master/treebank`

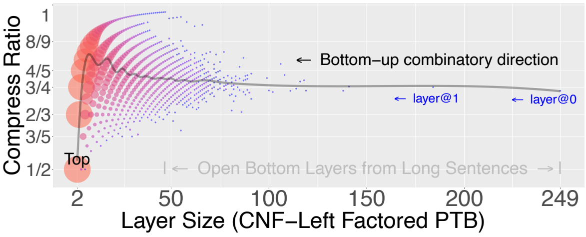

Figure 5: Layer-wise compression ratio over different sizes. The dot size was proportional to the situation count. Statistically, the ratio had a stable mean of 0.77.

not exhibit a clear branching tendency. Non-CNF factors preserve the original tendency.

Complexity. Our models are trained with stratified treebanks. The complexity for inference follows the total number of nodes in each layer of a tree. There are two ideal cases: 1) Complete balanced trees with complexity $O(n)$. They contain multiple independent phrases and enable full concurrency. 2) Trees with a single dependency core. The model reduces a constant number of nodes in each layer, resulting in $O(n^2)$ complexity.

While each parse is a mixture of many cases, the *empirical* complexity prefers the first case. Formally, the average-case complexity can be inferred as $O(n)$ with the help of a stable compression ratio $0 < C < 1$ ($C \geq 0.5$ for binary). Let m_i represent the number children of the i-th tree in a general layer; the compression ratio can be stated as $C = \frac{\sum_i 1}{\sum_i m_i}$. Our stratified treebanks give stable Cs for layers of different lengths, as shown in Figure 5. For the k-th layer of a sentence with n words, the number of nodes to compute can be expected to be $C^k \cdot n$. Based on tree height $K > 0$, the expected number of total parsing nodes is

$$\sum_{k=0}^{K} C^k \cdot n = n \cdot \sum_{k=0}^{\infty} C^k - n \cdot \sum_{k=K+1}^{\infty} C^k < \frac{n}{1 - C}.$$

The partial geometric series determines an empirically linear complexity on average.

Theoretically, the complexity has a quadratic upper bound. The general layer with

$$m_i = \begin{cases} M & \text{if } i = j \\ 1 & \text{otherwise} \end{cases}$$

entails the second case, where m_j is the only M-ary branch in each layer. The nodes shape a triangular stratified tree with an $O(n^2)$ complexity. However, this case is rare, especially for long sentences that should contain several concurrent phrases. Otherwise, regression in Figure 4 should show significant $O(n^2)$ tendencies. (See Appendix A.1 for more support and examples.)

Algorithm 1: Combinatory Parsing

```
1  Function PARSE($e_{0:n}$; $t_{0:n}$, $l^{0:k}_{0:n_k}$, $o^{0:k}_{0:n_k}$ or $c^{0:k}_{0:n_k+1}$):
2      $x^0_{0:n} \leftarrow$ BiLSTM$_{cxt}$($e_{0:n}$)
3      for $i \leftarrow 0$ to $n - 1$ do
4          $\hat{t}_i \leftarrow$ FFNN$_{tag}$($x^0_i$)
5          $L_{tag} \leftarrow$ CROSS-ENTROPY($t_i, \hat{t}_i$)
6      for $j \leftarrow 0$ to $k$ do
7          for $i \leftarrow 0$ to $n_j - 1$ do
8              $\hat{l}^j_i \leftarrow$ FFNN$_{label}$($x^j_i$)
9              $L_{label} \leftarrow$ CROSS-ENTROPY($l^j_i, \hat{l}^j_i$)
10         $x^{j+1}_{0:n_{j+1}} \leftarrow$ COMPOSE($x^j_{0:n_j}$; $o^j_{0:n_j}$ or $c^j_{0:n_j+1}$)
11     return $\hat{t}_{0:n}, \hat{l}^{0:k}_{0:n_k}$
```

Data structure. To summarize the data components of a treebank corpus, we used four tensors of indices for 1) words, 2) POS tags, 3) stratified syntactic labels, 4) stratified orientations, or 5) stratified chunks,

$$\left(x_{0:n}, t_{0:n}, l^{0:k}_{0:n_k}, o^{0:k}_{0:n_k} \text{ or } c^{0:k}_{0:n_k+1}\right)_j \in D,$$

where n is the length of the j-th sentence, k indicates the k-th layer of the stratified data, and n_k is the layer length. ":" indicates a range of a sequence.

3.2 Combinatory Parsing

Our models comprise four feedforward (FFNN) and two bidirectional LSTM (BiLSTM) networks to decompose parsing into collaborative functions, as shown in Algorithm 1. During training, we use teacher forcing. In the inference phase, the supervised signals behind all semicolons are ignored; the predicted signals serve as their substitute.

Input $e_{0:n}$ is an embedding sequence indexed by $x_{0:n}$. In lines 2–5, the model prepares a contextual sequence for the combinator and predicts the lexical tags. Lines 6–10 describe the layer-wise loop of the combinator.

The tagging and labeling functions, `FFNN`$_{tag}$ and `FFNN`$_{label}$, are 2-layer FFNNs. Their first layer is shared, creating a hidden layer necessary for projecting diversified situations in the manifold to the non-zero logits for the argmax decision. The core function `COMPOSE`[4] is either a binary Algorithm 2 or a multi-branching Algorithm 3.

---

[4] `COMPOSE` with BiLSTM cannot be parallelized to $O(1)$.

Algorithm 2: Binary Compose

```
Function COMPOSE ($x^j_{0:n_j}$; $o^j_{0:n_j}$):
    $h^j_{0:n_j} \leftarrow$ BiLSTM$_{ori}$ ($x^j_{0:n_j}$)
    for $i \leftarrow 0$ to $n_j - 1$ do
        $\hat{o}^j_i \leftarrow$ FFNN$_{ori}$ ($h^j_i$)
        $L_{ori} \leftarrow$ HINGE-LOSS ($o^j_i, \hat{o}^j_i$)
        if $i > 0$ and $\hat{o}^j_{i-1} + (1 - \hat{o}^j_i) > 0$ then
            Append BINARY ($\hat{o}^j_{i-1}, \hat{o}^j_i,\ x^j_{i-1}, x^j_i$) to $x^{j+1}$
    return $x^{j+1}_{0:n_{j+1}}$

Function BINARY ($o_L, o_R,\ x_L, x_R$):
    if $o_L + (1 - o_R) = 1$ then                // relay
        return $o_L \cdot x_L + (1 - o_R) \cdot x_R$
    else                          // vector interpolation
        $\lambda \leftarrow \sigma$ FFNN$_{binary}$ ($x_L \oplus x_R$)
        return $\lambda \odot x_L + (1 - \lambda) \odot x_R$
```

Algorithm 3: Multi-branching Compose

```
Function COMPOSE ($x^j_{0:n_j}$; $c^j_{0:n_j+1}$):
    $\vec{h}^j_{0:n_j}, \overleftarrow{h}^j_{0:n_j} \leftarrow$ BiLSTM$_{chk}$ ($x^j_{0:n_j}$)
    Pad $\vec{h}^j_{0:n_j}$ with $\vec{h}^j_{-1}$ and $\overleftarrow{h}^j_{0:n_j}$ with $\overleftarrow{h}^j_{n_j}$
    for $i \leftarrow 0$ to $n_j$ do
        $\hat{c}^j_i \leftarrow$ FFNN $_{chk}(\vec{h}^j_{i-1} \oplus \overleftarrow{h}^j_i)$
        $L_{chk} \leftarrow$ HINGE-LOSS ($c^j_i, \hat{c}^j_i$)
        if $\hat{c}^j_i = 1$ then Append $i$ to $s$          // segment
        if $i < n_j$ then
            $d^j_i \leftarrow (\vec{h}^j_i - \vec{h}^j_{i-1}) \oplus (\overleftarrow{h}^j_i - \overleftarrow{h}^j_{i+1})$
    for $i \leftarrow 0$ to $|s| - 1$ do
        Append MULTI ($d^j_{s_i:s_{i+1}},\ x^j_{s_i:s_{i+1}}$) to $x^{j+1}$
    return $x^{j+1}_{0:n_{j+1}}$

Function MULTI ($d_{chk},\ x_{chk}$):
    $\lambda_{chk} \leftarrow Softmax($ FFNN$_{multi}$ ($d_{chk}$) )
    return $\sum_i^{chk} \lambda_i \odot x_i$
```

Binary model. In Algorithm 2, the orientation function is hinted by BiLSTM$_{ori}$. A single-layer FFNN$_{ori}$ with a threshold reduces the outputs to an integer of either 0 or 1 to indicate two possible orientations. In function BINARY, when two adjacent orientations agree as they sum to 2, their embeddings are combined by a combinatory operation. σ is the Sigmoid function, "$\oplus$" represents concatenation, and "$\odot$" represents pointwise multiplication. (See Appendix A.3 for more binary variants.)

Multi-branching model. To resemble binary interpolation, we use the Softmax function for each chunk, as described in Algorithm 3. BiLSTM$_{chk}$ is in place of BiLSTM$_{ori}$ to hint FFNN$_{chk}$ emitting chunk signals. Segment s splits $x^j_{0:n_j}$ and $d^j_{0:n_j}$ into chunks of x_{chk} and d_{chk}. FFNN$_{multi}$ and Softmax turn d_{chk} into attention λ_{chk} to interpolate vector chunk x_{chk}. Binary interpolation λ is a special case of the multi-branching λ_{chk} because Sigmoid and Softmax functions are closely related.

To obtain the final tree representation, we apply a symbolic pruner in the same bottom-up manner to remove redundant nodes, expand the collapsed nodes, and assemble the sub-trees based on the neural outputs. (See Appendix A.4.)

4 Experiments

We follow previous data splits for PTB, CTB, and KTB (See Appendix A.2). The preprocessing of data is described in Section 3.1.

For the binary model, we explored interpolated dynamic datasets by sampling two CNF factored datasets. This is because of the following: 1) The experiments with the non-CNF factors did not yield any promising results; thus, we have not reported them. 2) The language was loosely left-branched, right-branched, or did not show a noticeable tendency. Moreover, the use of a single static dataset may introduce a severe orientation bias. 3) All factors are intermediate variables and equally correct. We defined the sampling strategies with two static CNF-factored datasets at certain ratios and named each strategy in the format "L%R%" according to the ratio percentages. Our experiments mainly focus on binary model **B** because of the aforementioned property for training parsers more accurate than multi-branching model **M**.

Our parsers do not contain lexical information components (Liu and Zhang, 2017c; Kitaev and Klein, 2018). Instead, we use fastText (Bojanowski et al., 2017) because we can obtain pre-trained models easily for many languages or train new ones from scratch with the corpora at hand. We examined its influence in Section 4.2, whereas the official pre-trained embeddings are the default.

Meanwhile, pre-trained language models are useful for various tasks, including constituency parsing (Kitaev and Klein, 2018, 2020; Zhou and Zhao, 2019; Yang and Deng, 2020; Mrini et al., 2020). We chose XLNet (Yang et al., 2019) to compare with the static fastText embeddings. Specifically, either a 1-layer FFNN (/0) or an n-layer BiLSTM (/n^+) was used to convert the 768-unit output to our model size. We used a GeForce GTX 1080 Ti with 11 GB and a TITAN RTX with 24GB memory only for tuning XLNet.

The model size for vector compositionality was set at 300. The hidden sizes for labeling, orientation, and chunking were 200, 64, and 200, re-

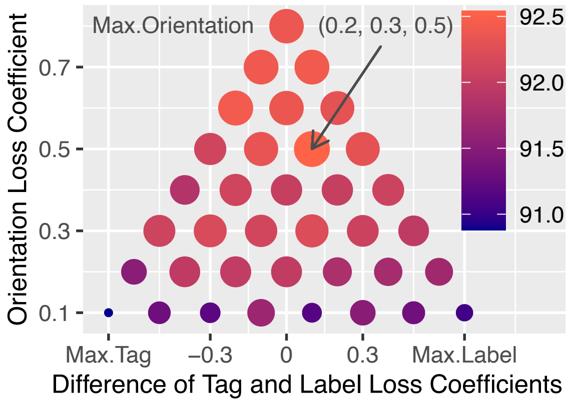

Figure 6: Grid search with an interval of 0.1 in a space of (tag, label, orientation) loss coefficients. The best was (0.2, 0.3, 0.5) indicated by an arrow.

spectively. Different numbers of layers of the `BiLSTM`$_{cxt}$ ($/n$) were explored, and the default was six layers. `HINGE-LOSS` was the default criterion for orientation while binary cross-entropy (`BCE-LOSS`) was tested. The coefficients of the three losses were explored and the default were $L = 0.2 \cdot L_{tag} + 0.3 \cdot L_{label} + 0.5 \cdot L_{ori\ (\text{or}\ chk)}$.

4.1 Overall Results

Table 3 lists the parsing accuracies and speeds of the single models in ascending order according to their F1 scores for the PTB corpus. The transition-based parsers with $O(n)$ complexity appear at the top of the table, followed by other types of models, and the chart parsers running in $O(n^3)$ time are at the bottom of the table. The models exhibited similar trends for the CTB. Shen et al. (2018) and our models belong to type O and have similar complexities. Generally, the accuracy follows the complexity, whereas the speed roughly follows the year of publication rather than complexity or type.

4.2 Comparison of Models

Models with fastText. We investigated the binary model through ablation. The impacts of fastText are presented in the upper part of Table 4. **B**/E does not require any external data beyond PTB, which is comparable to models without a pre-trained GloVe (Pennington et al., 2014).

Then, we replaced `BiLSTM`$_{ori}$ with an FFNN to examine its effect. The results are in the bottom rows. The comparison proves whether the embeddings are collaborative for the orientation signals because FFNN regards each input independently.

Finally, we used a grid search to explore the hyperparameter space of our three-loss coefficients.

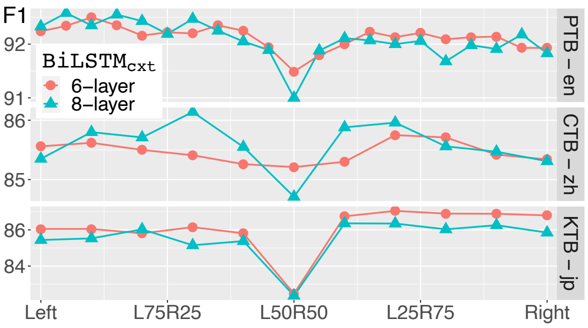

Figure 7: Probabilistic interpolations of two CNF factors to F1 scores. The capacity of `BiLSTM`$_{cxt}$ is almost saturated with 6 or 8 layers.

Figure 6 shows that the performance correlates to the orientation loss the most, but it is not overly sensitive to the hyperparameters.

Pre-trained language model. We compared the results using frozen fastText with those using frozen XLNet[5] in Table 5. The accuracy of the model increased along with the depth of `BiLSTM`$_{cxt}$, and it exhibited the most significant increase across all variants. Owing to XLNet, our complexities grew to $O(n^2)$.

We fine-tuned our models[6] and compared them with other parsers using fine-tuned language models. These are listed in Table 6.

4.3 Tree-Binarization Strategy

To reflect the branching tendency, our best single model for PTB was obtained on the dynamic L95R05 dataset. This dataset is a probabilistic interpolation between the left-factored dataset (for 95% chances) and a right-factored dataset (for 5% chances) in Figure 7. The best model for CTB appeared on the left side at L70R30, scoring 86.14, whereas the best for KTB was on the L30R70 dataset, scoring 87.05 with a 6-layer `BiLSTM`$_{cxt}$. Typically, the results for all the corpora had a minimum at L50R50. For English, the left "wing" was higher than the right; the opposite trend was observed for Japanese. For Chinese, no clear trend was obtained.

All studies described in the previous sections were conducted on the PTB L85R15 dataset.

---

[5] XLNet tokenizes words into sub-word fractions. For the frozen XLNet, using leftmost, rightmost, or averaged sub-word embeddings as the word input yielded similar results.

[6] For the fine-tuned XLNet, using either the leftmost or rightmost sub-word yielded similar results earlier. However, averaging sub-words produced F1 scores under 94.

4.4 Complexity and Speed

To test our linear speed advantage, we inflated our training data with redundant nodes to resemble the triangular chart of CYK algorithm, as depicted in Figure 8 and Table 7. The parse in the triangular treebank has the worst-case complexity of $O(n^2)$. Meanwhile, training with linearity halved the training time, reduced memory usage, and canceled the length limit for our three corpora. There is a sheer difference between linearity and squared complexity.

5 Discussion

5.1 Model Structure

Our parsers comprise a neural encoder for scoring (i.e., Algorithm 1) and a non-neural decoder for searching. The decoder is a symbolic extension of the encoder in that both run in bottom-up manner, and the decoder interprets the scores as local-and-greedy decisions. Other neural parsers also fit a similar encoder–decoder framework. However, decoders with dynamic programming often include forward and backward processes heterogeneous to

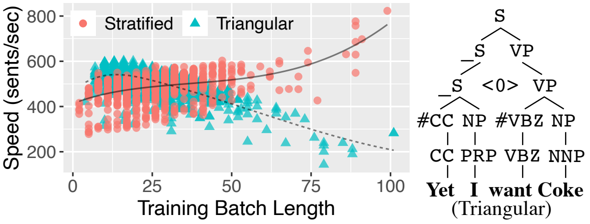

Figure 8: Linear complexity vs. squared complexity. Redundancy with placeholder "<0>" helps maintain the triangular shape.

Format	Time/150	Memory	OOM
Stratified	7.5 hours	3.3 GB	-
Triangular	15.9 hours	8.2 GB	100

Table 7: Training time and memory consumed by our two data formats. The time column indicates the time used for 150 training epochs with validations. Development F1 scores are approximately 92.4. The OOM column lists the length limit for preventing an out-of-memory error. Kitaev and Klein (2018) took 10 hours for 93 training epochs on our GeForce GTX 1080 Ti to yield their results.

their forward encoders (Kitaev and Klein, 2018, 2020). The encoder and decoder in our model and Shen et al. (2018) are more homogeneous and can be easily merged. Our parsers are bottom-up combinatory, while theirs was top-down splitting. Similar homogeneity can be found in an easy-first dependency parser (Goldberg and Elhadad, 2010).

Input component. In terms of encoder, Tables 4–6 examine the impact of $\texttt{BiLSTM}_{cxt}$ with fastText or XLNet, and the following conclusions can be drawn. 1) The top rows of Table 4 suggest that frozen fastText embeddings contain sub-word information, whereas tuning them disturbs the frozen information because the n-gram model is not part of our model. 2) Table 5 shows that the deeper the contextualization $\texttt{BiLSTM}_{cxt}$ (or XLNet), the better the results. 3) Tables 5 and 6 indicate that the tuning process for the pre-trained language models (Peters et al., 2018; Devlin et al., 2019; Yang et al., 2019) achieves a significant improvement.

Speed and size. One of our research goals was to achieve simplicity and efficiency. In terms of speed, our models parallelize more actions than transition-based parsers and have fewer computing nodes than chart parsers. In terms of size, our models contain approximately 4M parameters in addition to the 13M fastText (or 114M XLNet) pre-trained embeddings, which is fewer than those of Shen et al. (2018, 22M+) and Kitaev and Klein (2018, 26M). The recursiveness and productiveness of vector compositionality should account for the compact size.

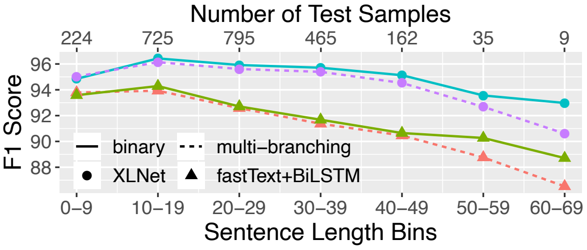

Figure 9: XLNet provides an overall improvement for all models and length bins. All models find it challenging to handle long sentences.

Vector compositionality. The performance of $\texttt{FFNN}^{\star}_{ori}$ is inferior to that of its RNN counterparts, suggesting that some information might not be encoded locally. Thus, the `COMPOSE` function should remain in a contextual form to collaboratively leverage the whole layer. However, BiRNN might still be a bottleneck for long-range orientation, as suggested in Figure 9. $\texttt{BiLSTM}_{chk}$ is a major weakness of the multi-branching model, especially for longer sentences.

5.2 Tree Binarization and Headedness

Tree binarization. Probabilistic interpolation with two CNF-factored datasets is effective for the three languages studied, as shown in Figure 7. Dynamic sampling allows the model to cover a wider range of composed vectors to improve its robustness to ambiguous orientations. Furthermore, it seems counterintuitive for human learners to obtain the best model using left-biased interpolation for a right-branching language or vice versa. However, for a neural model, balancing the frequency seems to be the key factor for improving performance (Sennrich et al., 2016; Zhao et al., 2018). The fact that the L50R50 dataset yielded the worst models also suggests that the balance should be based on a default orientation tendency. This could also be the reason why **mid-in** or **mid-out** did not improve the model.

Headedness. Figure 10 show the intermediate parses on the same sentence from our two models. They are typical examples in the output.

The binary model first combines determiners and their right neighbors rather than adjectives and nouns in noun phrases (blue spans). It also post-

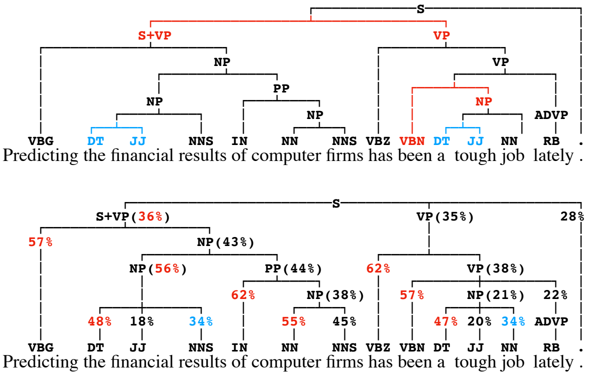

Figure 10: English internal constituents (top) and headedness (bottom) from our two models.

Parent (#)	Head child by maximum weight
NP (14.4K)	DT (4.5K); ⋆NP (4.3K); ⋆NNP (1.6K); ⋆JJ (922); ⋆NN (751); ⋆NNS (616); etc. (1.6K; 38 of 50 types with "⋆")
VP (6.8K)	VBD (1.5K); VB (1.4K); VBZ (1.0K); VBN (954); VBP (705); MD (523); VBG (387); VP (169); TO (81); etc.
PP (5.5K)	IN (5.0K); TO (397); etc.
S (3.8K)	VP (3.4K); S (194); NP (90); etc.
SBAR (1.2K)	IN (649); WHNP (395); WHPP (19); WHADVP (121); SBAR (15); etc.
ADVP (278)	RB (181); IN (30); RBR (25); etc.
QP (198)	CD (67); IN (65); RB (29); JJR (16);

Table 8: English headedness selection with our multi-branching model on PTB test set. "⋆" marks the absence of a DT child for its NP sisters. For quantifier phrases (QP), some non-quantifiers are more likely to be heads if they appear; e.g., adverbs (RB; e.g., "approximately"), prepositions (IN; e.g., "about"), and relative adjectives (JJR; e.g., "more than").

pones the combination with adjuncts such as punctuation and adverb (red spans). The high frequencies of determiners in noun phrases make them great attractors.

On the other hand, the multi-branching model places close attention on what the syntactic head is supposed to be. In the noun phrases, determiners receive the highest weight averages (red), and the nouns obtain the second (blue). This phenomenon suggests that an English noun phrase's syntactic role is mainly projected from the determiners, as discussed by Zwicky (1985). Table 8 provides more statistical support. For example, the model selects DT as an NP head if it is available; otherwise, nouns and adjectives are prominent heads. Chinese and Japanese parsers work similarly for their headedness. (See Appendix A.5.)

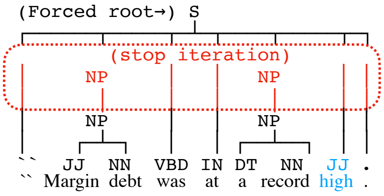

Figure 11: Failed parse from the multi-branching model. The model stops parsing and saves computations when it repeats the same chunking positions.

5.3 Error Analysis

The rate of an invalid parse is the last topic that we consider for our parsers. For the binary parser, fatal errors, such as frame-breaking orientations, appear at an early stage of training. However, the late 90% of training time contains very few errors, and our binary model is free from invalid parsing on the test set. For the multi-branching parser, it is observed that 11 out of 2,416 test parses are forests rather than parse trees when they are trained with fastText. However, the multi-branching parser with fine-tuned XLNet reduces the error count on the test set to 1.

We present a failed multi-branching parse with fastText, as shown in Figure 11. The postnominal adjective "high" is uncommon for English. Because the model did not group it with the adjacent "a record" to form an NP, the error propagated to higher layers (e.g., no PP as an adjunct to form a VP), causing the bad parse. It implies that the multi-branching model requires an appropriate predict-argument configuration to chunk.

6 Conclusion

We proposed a pair of neural combinatory constituency parsers. The binary one yields F1 scores comparable to those of recent neural parsers. The multi-branching one reveals constituency headedness. Both are simple and efficient with relatively high speeds. We also leveraged a pre-trained language model and CNF factors to increase the accuracy. We reflected the branching tendencies of three languages.

Acknowledgments

We extend special thanks to our reviewers for invaluable comments and Hayahide Yamagishi for initial discussions. This work has been partly supported by the Grant-in-Aid for Scientific Research from the Japan Society for the Promotion of Science (JSPS KAKENHI); Grant Number 19K12099.

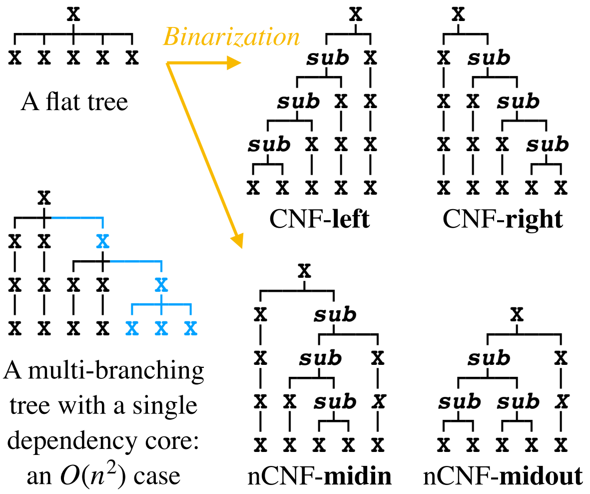

Figure 12: Examples used in the content. A flat tree is binarized with four factors. The binarization of CNF-**left**, CNF-**right**, or nCNF-**midin** creates binary trees with a single dependency core (i.e., a single *sub* thread), whose $O(n^2)$ complexity is the same with the tree without binarization in the lower left. Most nodes are relaying nodes. Meanwhile, nCNF-**midout** enables concurrent phrases with $O(n)$ complexity (i.e., multiple *sub* threads). However, the division tends to break a constituent into ungrammatical pieces, which confuses the model and does not lead to improvement.

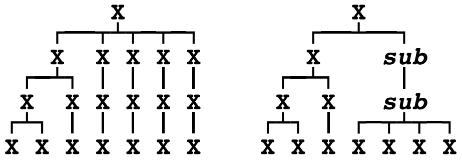

Figure 13: Adding *sub* nodes to make flat structure more efficient. Using the strategy as a new dynamic dataset also brings multi-branching model **M** a stable accuracy improvement with an F1 score of 92.36 on PTB. However, it has nothing to do with linguistic properties. We save it for a future study.

A Appendices

A.1 Compression Ratios and Linearity

Figure 12 presents examples for tree binarization and the worst case of $O(n^2)$ complexity. Figure 14 shows the overall linear data complexities in the three languages. Figures 15 & 16 and Table 9 indicate that, given a language and a factor, the compression ratio is stable and seldom affected by the sentence length.

The regressions for PTB and CTB show weak $O(n^2)$ tendencies; the quadratic coefficients can be either positive or negative. Meanwhile, KTB falls into the worst case, as shown in Figure 14. This is because KTB trees tend to have a flat structure on the right side of parses, as illustrated in Figure 17. Relaying nodes in the flat structure never combine until the final layer, creating strong $O(n^2)$ tendencies. As a result, all KTB datasets fall into the worst case, especially when binarized with the CNF-**left** factor.

A preprocess that groups the flat structure into the *sub* category can prevent considerable quadratic impacts on all datasets. All $O(n^2)$ tendencies are largely weakened across three corpora, and all linear coefficients drop significantly, as illustrated on the right of Figure 14. The preprocess cannot eradicate the worst case in KTB. However, all linear coefficients' magnitudes are at least hundreds of times larger than those of the quadratic terms. In our sub-quadratic case, 200 words lead to approximately 1.5K nodes. Meanwhile, a sentence with n words has a triangular chart with $\frac{n(n+1)}{2}$ nodes, whose quadratic coefficient is 0.5. In this case, 200 words lead to approximately 20K nodes.

A.2 Experiment Setting

The treebanks PTB and CTB have been widely used for experiments. For PTB, sections 2-21 were used for training, section 22 for development, and section 23 for testing. For CTB, articles 001-270 and 440-1151 were used for training, 301-325 for development, and 271-300 for testing. There is no widely accepted data split for the KTB corpus, except for some probabilistic divisions, because KTB contains mixed data from sources such as newswires, book digests, and Wikipedia. We randomly reserved 2,075 samples for development, 1,863 samples for testing, and the remaining 3.3 million as training samples. Few sentences in the training sets were longer than 100 words (3 of 40K in PTB; 96 of 17K in CTB; 55 of 33K in KTB). Frozen English (wiki.en.bin), Chinese (cc.zh.300.bin), and Japanese (cc.ja.300.bin) embeddings were used for PTB, CTB, and KTB, respectively[7]. We fed fastText with the PTB text to train `cbow` instead of `skipgram` embeddings for **B**/E with their default settings for 50 epochs.

The batch size was 80, and sentences longer than 100 words were excluded for the triangular data to avoid out-of-memory (OOM) errors on a single GeForce GTX 1080 Ti with 11 GB. We froze XLNet to train our model and then tuned XLNet from the 5-th epoch. We doubled the batch size at the inference phase to 160.

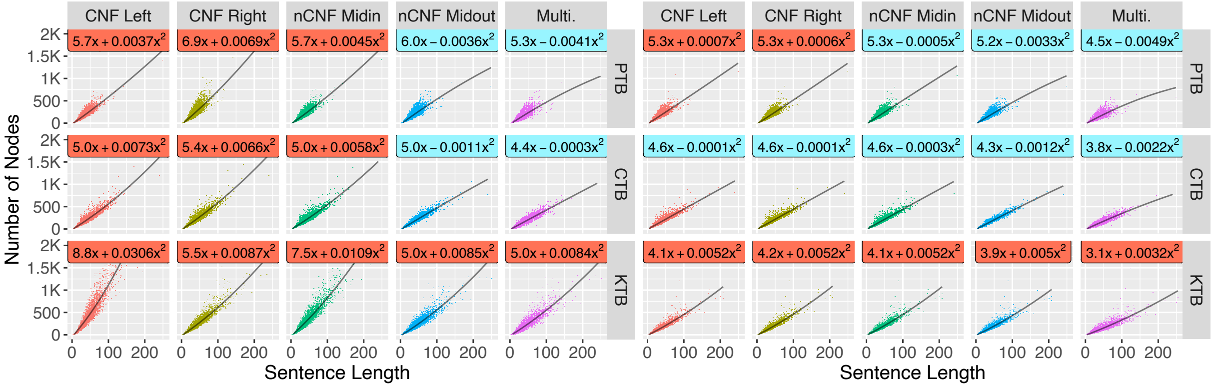

Figure 14: Left: the empirical complexities related to Figures 15 & 16. Linear regressions are shown on a light blue background when the quadratic terms are negative. Right: resultant complexities after a preprocessing that groups the flat structure into sub-constituent before stratification. (See Figure 13.)

Factor	**Left**	**Right**	**Midin**	**Midout**	**Multi.**
			All layers		
PTB	0.77 ±0.11	0.79 ±0.11	0.78 ±0.11	0.77 ±0.11	0.73 ±0.20
CTB	0.77 ±0.11	0.77 ±0.11	0.76 ±0.11	0.74 ±0.11	0.70 ±0.20
KTB	0.82 ±0.12	0.75 ±0.12	0.79 ±0.12	0.73 ±0.12	0.69 ±0.29
			Layers longer than 40		
PTB	0.78 ±0.04	0.80 ±0.04	0.77 ±0.04	0.74 ±0.04	0.69 ±0.08
CTB	0.79 ±0.04	0.80 ±0.04	0.78 ±0.04	0.77 ±0.04	0.76 ±0.07
KTB	0.90 ±0.04	0.80 ±0.05	0.86 ±0.04	0.77 ±0.06	0.84 ±0.07

Table 9: Mean and standard deviation of compression ratios of Figures 15 & 16. Longer layers have converged deviations. The last column came from the multi-branching treebanks without a binarizing factor.

We used the Adam optimizer with a default learning rate of 10^{-3}, while we opted for the XLNet's Adam hyperparameters when tuning the pre-trained XLNet (e.g., their learning rate was 10^{-5}). We adopted a warm-up period for one epoch and a linear decrease after the 15-th decrease since the last best evaluation. The recurrent dropout rate was 0.2; other dropout probabilities for FFNNs were set to 0.4. For model selection, the training process terminated when the development set did not improve above the highest score after 100 consecutive evaluations. The Evalb program[8] was used for F1 scoring.

We demonstrated score profiles for our main models in Table 10. The discrepancy in F1 scores and difference between precision and recall are relatively small on the PTB development and test sets.

Input		**Development**		**Test**	
Comp.	**M.**	**F1**	$P-R$	**F1**	$P-R$
Frozen	**B**	92.50	0.00	92.54	+0.56
fastText	**M**	92.10	−0.35	92.10	−0.03
Tuned	**B**	95.64	−0.05	92.72	+0.19
XLNet	**M**	95.34	−0.15	92.44	+0.30

Table 10: F1 scores and differences in precision and recall ($P-R$) on the PTB development and test sets.

A.3 Variants of Binary Compose

If we choose the relay instruction in line 12 of Algorithm 2, additive vector compositionality is retained (Mikolov et al., 2013) as the naïve **ADD** variant in lines 5–6 of Algorithm 4. The model can infer a full tensor tree; however, **ADD** causes the vector magnitude to increase with the tree height cumulatively. This is unwanted in the recurrent or recursive neural network.

Therefore, we examined a learnable $\texttt{FFNN}_{multi}$ with Sigmoid activation to perform gate-style interpolation in five variants **NS**, **NV**, **CS**, **CV**, and **BV** as described in lines 8–17. When a variant takes <u>n</u>o input and produces a <u>s</u>calar interpolation parameter λ, we consider this case **NS**. ("$\varnothing$" is a placeholder for no input.) Meanwhile, **CV** indicates <u>c</u>oncatenated input and <u>v</u>ectorized interpolation. **BV** is a variant that involves a <u>b</u>iaffine tensor

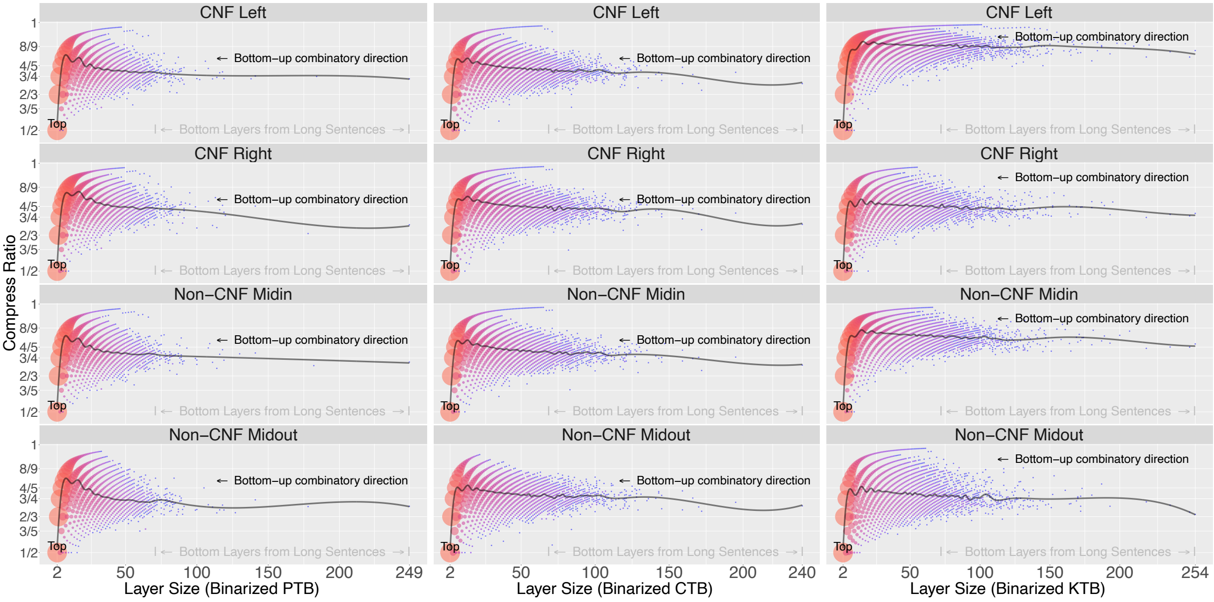

Figure 15: Binarized corpora with four factors. Curved tiers can be observed in each plot. For example, the leftmost tier is composed of $\frac{n-1}{n}$ (followed by $\frac{n-2}{n}$, $\frac{n-3}{n}$, and so on). The dots in this tier range from a high compression ratio of 0.5 to the least efficient ones in their corpus. Efficient dots are more populated, judging by their sizes and colors. All statistics yield stable means, which are also presented in Table 9.

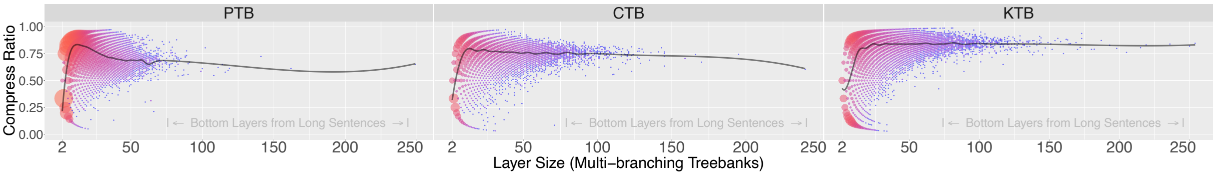

Figure 16: Multi-branching corpora. Curved tiers appear more symmetric and all statistics still yield stable means.

Algorithm 4: Binary Compose Variants

```
Function BINARY($o_L, o_R$, $x_L, x_R$; Var):
    $x \leftarrow o_L \cdot x_L + (1 - o_R) \cdot x_R$
    if $o_L + (1 - o_R) = 1$ then                    // relay
        return $x$
    else if Var is ADD then                          // ADD
        return $x$
    else
        if Var is NS or NV then                      // No input
            $\lambda \leftarrow \sigma\ \mathrm{FFNN}_{binary}(\varnothing)$
        else if Var is CS or CV then                 // Concat...
            $\lambda \leftarrow \sigma\ \mathrm{FFNN}_{binary}(x_L \oplus x_R)$
        else if Var is BV then                       // Biaffine
            $\lambda \leftarrow \sigma\ \mathrm{FFNN}_{binary}(x_L, x_R)$
        if Var is NV, CV, or BV then                 // Vector $\lambda$
            $x \leftarrow \lambda \odot x_L + (1 - \lambda) \odot x_R$
        else if Var is NS or CS then                 // Scalar $\lambda$
            $x \leftarrow \lambda \cdot x_L + (1 - \lambda) \cdot x_R$
        return $x$                                   // NS NV CS CV BV
```

operation. **CV** is our default `BINARY` variant; the experiments for these variants are presented in Table 11.

In terms of the F1 score, the most competitive variants of **CV** are **BV** and **NV**, suggesting that fine interpolation can effectively facilitate vector compositionality. The similarity in results of **CS**, **NS**, and **ADD** validate this suggestion. This indicates that vector compositionality is not as trivial as an additive function at the scalar level, and a matrix operation is sufficient. **BV** is the costliest variant with a tensor operation that runs very slowly (30 sents/sec).

Var	Specification	F1
BV	Biaffine inputs for vector λ.	92.53
CV	$x_L \oplus x_R$ as input for vector λ.	**92.54**
CS	$x_L \oplus x_R$ as input for scalar λ.	91.83
NV	No input; bias vector λ.	92.36
NS	No input; bias scalar λ.	91.95
ADD	$x_L + x_R$	91.86

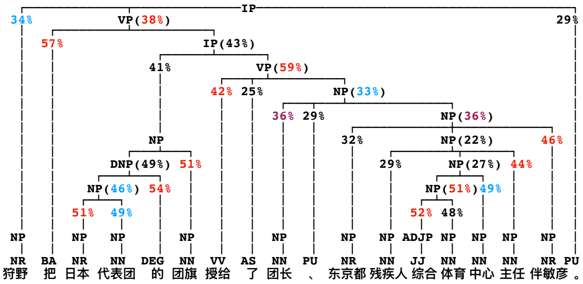
Table 11: Compositionality of the `BINARY` function.

A.4 Recovering Symbolic Tree

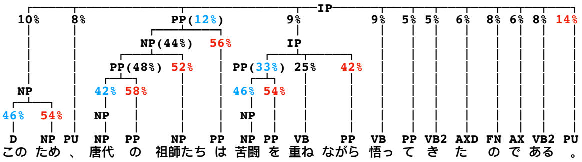
To obtain the final tree representation, we initialized the working place with leaves of words and

Algorithm 5: Recovering a Symbolic Tree

```
Function REC ($x_{0:n}$, $t_{0:n}$, $l^k_{0:n_k}$, $o^k_{0:n_k}$ or $c^k_{0:n_k+1}$):
    for $i \leftarrow 0$ to $n-1$ do
        $tree_i \leftarrow$ TREE ($t_i, x_i$)
    for $j \leftarrow 0$ to $k-2$ do
        if binary parsing then                          // BINARY
            for $i \leftarrow 0$ to $n_j - 1$ do
                if $o^j_i + (1 - o^j_{i+1}) = 2$ then
                    Combine $tree_{i:i+2}$ under $l^{j+1}_{parent\_of(i,i+1)}$
        else                                            // MULTI-BRANCHING
            foreach $chk$ in $c^j_{0:n_j+1}$ do
                Combine $tree_{chk}$ under $l^{j+1}_{parent\_of(chk)}$
    Expand unary and flatten sub labels for $tree_0$
    return $tree_0$
```



Translation: Kano awarded (授给/了) the Japanese delegation's flag to the head of the delegation (团长) and director (主任) of the Tokyo Comprehensive Sports Center for the Disabled, Toshihiko Ban.



Translation: For this reason, the Tang dynasty’s (の) ancestors (祖師たち/は-subject) have come to realize (悟っ) it through struggles (苦闘/を-object).

Figure 17: Chinese (top) and Japanese (bottom) parses from the multi-branching model.

predicted POS tags. Two symbolic rules were used to modify the labels and construct sub-trees, as described in Algorithm 5. 1) The collapsed unary branches were expanded to their original structure by splitting at the plus marks (e.g., `SBAR+S` into `SBAR` and `S`). 2) ‘the label is a *sub*’ excluded the repeated labels and relayed sub-trees. These rules enabled a single $tree_0$ as the final output.

A.5 Chinese and Japanese Headedness

Figure 17 presents two non-English parses from the multi-branching model. Both the Chinese and Japanese languages possess functional markers that receive high attention (percentage and words in red), such as the second character tagged with `BA` in Chinese, and Japanese case markers tagged with `PP`. Interestingly, the Chinese verb (i.e., the one meaning “awarded”) received the highest attention, whereas Japanese verbs (i.e., two sub-words tagged with `VB`) did not. We supposed the reason behind this is that Japanese sentences drop the `VB`s and other heads more often than Chinese. The coordinated `NP`s in the Chinese parse (i.e., two words meaning “head” and “director”) received equal attention weights.

Moreover, two trees show their branching tendencies: Chinese is **midin**-alike; Japanese is a **left**-branching language, and KTB has a large flat structure on the right.

Learning Shared Semantic Space for Speech-to-Text Translation

Abstract

Having numerous potential applications and great impact, end-to-end speech translation (ST) has long been treated as an independent task, failing to fully draw strength from the rapid advances of its sibling - text machine translation (MT). With text and audio inputs represented differently, the modality gap has rendered MT data and its end-to-end models incompatible with their ST counterparts. In observation of this obstacle, we propose to bridge this representation gap with Chimera. By projecting audio and text features to a common semantic representation, Chimera unifies MT and ST tasks and boosts the performance on ST benchmarks, MuST-C and Augmented Librispeech, to a new state-of-the-art. Specifically, Chimera obtains 27.1 BLEU on MuST-C EN-DE, improving the SOTA by a +1.9 BLEU margin. Further experimental analyses demonstrate that the shared semantic space indeed conveys common knowledge between these two tasks and thus paves a new way for augmenting training resources across modalities. [1]

1 Introduction

Speech-to-text translation (ST) takes speech input in a source language and outputs text utterance in a target language. It has many real-world applications, including automatic video captioning, simultaneous translation for international conferences, etc. Traditional ST approaches cascade automatic speech recognition (ASR) and machine translation (MT) (Sperber et al., 2017, 2019; Zhang et al., 2019; Beck et al., 2019; Cheng et al., 2019). However, cascaded models often suffer from the issues of error propagation and translation latency. As a result, there have been a series of recent attempts on end-to-end speech-to-text translation (Liu et al., 2019, 2018; Weiss et al., 2017; Bérard et al., 2018; Duong et al., 2016; Jia et al., 2019; Dong et al., 2021b; Wang et al., 2020b). The end-to-end approaches learn a single unified model, which is easier to deploy, has lower latency and could potentially reduce errors.

However, it remains a challenge for end-to-end ST to catch up with their cascaded counterparts in performance. We argue that the root cause is the gap between the two modalities, speech and text. Although they both encode human languages, they are dissimilar in both coding attributes (pitch, volume, and intonation versus words, affixes, and punctuation) and length (thousands of time frames versus tens of words). This issue is further coupled with the relatively smaller amount of parallel data for ST than for MT.

To tackle these challenges, we resort to making use of the additional available bilingual data for MT. Our hypothesis is, to better leverage MT data, an ideal model should be able to bridge the representations between speech and text. Motivated by this intuition, we propose Chimera, a text-speech shared semantic memory network. It learns a semantic memory by projecting features from both modalities into a shared semantic space. This approach unifies ST and MT workflows and thus has the advantage of leveraging massive MT corpora as a side boost in training. It can also use speech-text pairs to align the semantic memories from two modalities.

This idea of a unified text-speech representation also finds its neural basis as suggested by recent evidence from functional neuroimaging (van Atteveldt et al., 2004; Spitsyna et al., 2006; Shankweiler et al., 2008). Specifically, van Atteveldt et al. (2004); Spitsyna et al. (2006) identifies certain regions in brain that the processing stream for speech sounds and visual texts converge at. Shankweiler et al. (2008) further verifies that

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2214–2225
August 1–6, 2021.

the size of such convergence sites correlates positively with the subjects' reading skills. Coincidentally, at these convergence sites also found regions responsive to downstream activities such as lexical and semantical word recognition (Binder et al., 2003) and spontaneous generation of speech (Blank et al., 2002). The evidence establishes the pivotal role of a modality-agnostic converged representation in language activities in brain.

This intuition lacks exploration in previous studies, with only a few exceptions (Indurthi et al., 2019; Liu et al., 2020), possibly due to the difficulties aforementioned and marginal improvements.

Our results show that Chimera achieves new state-of-the-art results on all of 8 translation directions in the benchmark datasets MuST-C and Augmented LibriSpeech. Specifically, Chimera obtains a 27.1 BLEU score on MuST-C EN-DE, which surpasses the best result ever reported by up to +1.9 BLEU. We also provide results under variations and ablations and validate our model design ideas by detailed analysis, as well as visualizing the semantic space Chimera has learned.

Our work makes the following contributions. First, we propose Chimera, which is able to bridge the modality gap between speech and text. Second, we derive a novel bi-modal contrastive training task to learn an alignment between semantic memories of two modalities. Finally, Chimera achieves a new state-of-the-art performance on the MuST-C benchmark and demonstrates its efficacy in learning modality-agnostic semantic representations.

2 Related Work

End-to-end ST Since its first proof-of-concept work (Bérard et al., 2016; Duong et al., 2016), solving Speech Translation in an end-to-end manner has attracted extensive attention (Vila et al., 2018; Salesky et al., 2018, 2019; Di Gangi et al., 2019b; Bahar et al., 2019a; Di Gangi et al., 2019c; Inaguma et al., 2020). Standard training techniques such as pretraining (Weiss et al., 2017; Bérard et al., 2018; Bansal et al., 2018; Stoian et al., 2020; Wang et al., 2020a; Pino et al., 2020), multi-task training (Vydana et al., 2021; Le et al., 2020; Tang et al., 2021), meta-learning (Indurthi et al., 2019), and curriculum learning (Kano et al., 2018; Wang et al., 2020b) have been applied. As ST data are expensive to collect, Jia et al. (2019); Pino et al. (2019); Bahar et al. (2019b) augment synthesized data from ASR and MT corpora. Methods utilizing trained models, such as knowledge distillation (Liu et al., 2019) and model adaptation (Di Gangi et al., 2020), have also been shown to be effective. Among these attempts, (Indurthi et al., 2019; Le et al., 2020; Liu et al., 2020) are most related to ours, as they also attempt to train models on ASR or MT data. However, they both lack pivotal modules in model design to semantically bridge the gap between audio and text, and could thus suffer from modality mismatch in representations.

Cascaded ST The cascaded method is a more long-standing trend in ST (Sperber et al., 2017; Jan et al., 2018). To alleviate its innate problem of error propagation, Cheng et al. (2018, 2019) introduce synthetic ASR-related errors and perturbations. On the other hand, some post-processing techniques such as re-segmentation (Matusov et al., 2006), punctuation restoration (Fügen, 2008), and disfluency detection (Fitzgerald et al., 2009) are proposed to fix flaws or errors that occurred during the translation.

Cross-Lingual Techniques Techniques in multilingual tasks is also related to ours, as they aim at extracting common features out of sources from different representations (which, in this case, is language diversity) as well. However, multilingualism lacks key difficulties as observed in audio-text modality gap as discussed before. (Lu et al., 2018) and (Vazquez Carrillo et al., 2019) are early attempts by building an LSTM-based attentional interlingua. Yu et al. (2018); Yang et al. (2019) uses a similar cosine-based loss for multilingual training. Zhu et al. (2020) is probably more similar in method to ours, but Chimera is more simple in terms of model and objectives, and the memories in Chimera are additionally designed to focus on specific semantic categories.

3 Proposed Method: Text-Speech Shared Semantic Memory Network

3.1 Speech Translation Overview

An ST corpus usually consists of a set of triplet data $\mathcal{S} = \{(\mathbf{x}_i, \mathbf{z}_i, \mathbf{y}_i)\}$. Here $\mathbf{x}_i$ is the audio wave sequence, $\mathbf{z}_i$ is the transcript sequence and $\mathbf{y}_i$ is the translation sequence in the target language. As a benefit of shared semantic projection, Chimera is able to leverage large-scale MT training corpora $\mathcal{T} = \{(\mathbf{u}_i, \mathbf{v}_i)\}$, where $\mathbf{u}_i$ and $\mathbf{v}_i$ are the source and target text sequences.

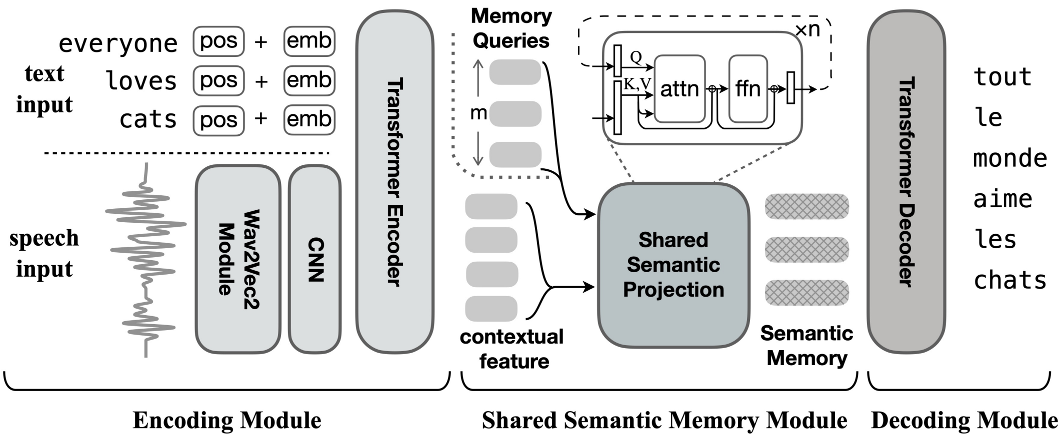

Figure 1: An overview of the proposed Chimera. The Encoder Module contains Word embedding for text input, and Wav2vec2 sub-module for speech input. The shared semantic projection Module uses its memory query to produce semantic memory with fixed-size representation from contextual features. The Decoder Module decodes translation from the semantic memory.

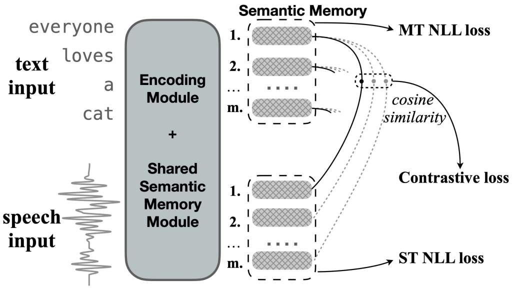

Figure 2: Besides MT and ST translation loss, we adopt a bi-modal contrastive loss to help aligning the semantic memories from text and speech. In short, among semantic memory elements from both sides of paired speech and transcript, the contrastive loss maximizes the cosine similarity between the same semantic memory element.

3.2 Chimera Architecture

Figure 1 illustrates the structure of Chimera. It consists of three major components, an encoding module, a shared semantic projection module, and a decoding module.

Encoding Module Different from that of a conventional ST model, the encoding module of Chimera accepts either speech or text as input. For text input, we use word embeddings plus positional embeddings. For speech input, we use a pretrained Wav2Vec2 (Baevski et al., 2020) to extract speech features. As the speech features can be very long, we apply an additional 1-dimensional strided CNN to reduce the length. Both speech and text branches share a common subsequent Transformer encoder (Vaswani et al., 2017). The final output of the encoding module is contextual features.

Shared Semantic Projection Module Shared semantic projection plays a pivotal role in Chimera. The contextual features of speech and text may follow different distributions and of different lengths. Ideally, the shared semantic projection computes a constant number of semantic features as its output semantic memories.

This module take the contextual features out from the encoding module as input and then output semantic memories of fixed length m. It consists of n attentional layers. It keeps a tuple of m trainable input-dependent memory queries to indicate the types of desired semantic information, which is used as the initial “memories”. Uni-modal contextual features serves as attention “keys” and “values”, while memories serves as attention “queries“. Memories are iteratively fed to the n shared semantic projection layers, with each layer output used as input to next layer. The final output is used as the semantic memory.

$$\mathbf{I}_0 = \mathbf{M}_0 \in \mathbb{R}^{m\times d} \tag{1}$$

$$\mathbf{K}_i = \mathbf{V}_i = \hat{\mathbf{H}} \in \mathbb{R}^{l\times d} \tag{2}$$

$$\mathbf{I}_{i+1} = \mathbf{O}_i = \mathrm{Attn}(\mathbf{I}_i, \mathbf{K}_i, \mathbf{V}_i) \in \mathbb{R}^{m\times d} \tag{3}$$

where $\mathbf{M}_0$, $\hat{\mathbf{H}}$, $\mathbf{I}_i$ and $\mathbf{O}_i$ denote the memory queries, contextual features, the input, and the output of each layer, respectively. l is the length of contextual features. d is the shared vector dimension. The top-most output $\mathbf{O}_n$ is finally fed into the decoding module.

Decoding Module The decoding module contains a conventional Transformer decoder. The only difference is that the input is the fixed-size $\mathbf{O}_n$, which can possibly come from either speech or text.

3.3 Training Objectives

The training objective of Chimera consists of three aspects, with their supervision signals coming from speech-to-text translation data $\{(\mathbf{x}_i, \mathbf{y}_i)\}$, text machine translation data $(\{\mathbf{u}_j, \mathbf{v}_j)\}$ and $(\{\mathbf{z}_i, \mathbf{y}_i)\}$ and the speech-transcript pairs $\{(\mathbf{x}_i, \mathbf{z}_i)\}$.

Speech-to-Text Translation Training The workflow of Chimera in Speech Translation is straightforward. The training objective is negative log-likelihood on speech-to-text translation data $\{(\mathbf{x}_i, \mathbf{y}_i)\}$ as the loss function.

$$\mathcal{L}_{\text{ST}} = -\mathbb{E}_{\mathbf{x},\mathbf{y}} \log \mathrm{P}(\mathbf{y}|\mathbf{x}) \tag{4}$$

Text Machine Translation Training Chimera is also able to train on MT corpus because of the unification of speech and text representations. Similar to ST training, the shared semantic projection module projects the contextual text features to the shared semantic space, which are then taken by the decoding module to output a translation.

$$\mathcal{L}_{\text{MT}} = -\mathbb{E}_{\mathbf{u},\mathbf{v}} \log \mathrm{P}(\mathbf{v}|\mathbf{u}) \tag{5}$$

Bi-modal Contrastive Training The motivation of Chimera design is to bridge the speech and text representations. We introduce dual-modal contrastive training to learn an alignment between representations from speech and text as illustrated in Figure 2. First, semantic memories from two inputs are computed. Then for each text semantic memory, $\mathbf{M}_i^{text}$, we compute its cosine similarities with all speech semantic memory $\{\cos(\mathbf{M}_i^{text}, \mathbf{M}_j^{speech})\}$. They are then fed into a softmax function. The loss function maximizes the item from matched pairs $(\mathbf{M}_i^{text}, \mathbf{M}_i^{speech})$. Finally, the loss is summed across all text memory items and vise versa.

$$\begin{aligned}\mathcal{L}_{\text{ctr}} = &-\mathbb{E}_{\mathbf{x},\mathbf{z}} \sum_i \ln \frac{e^{\tau \cos(\mathbf{M}_i^{\text{text}}, \mathbf{M}_i^{\text{speech}})}}{\sum_j e^{\tau \cos(\mathbf{M}_i^{\text{text}}, \mathbf{M}_j^{\text{speech}})}} \\ &-\mathbb{E}_{\mathbf{x},\mathbf{z}} \sum_j \ln \frac{e^{\tau \cos(\mathbf{M}_j^{\text{speech}}, \mathbf{M}_j^{\text{text}})}}{\sum_i e^{\tau \cos(\mathbf{M}_j^{\text{speech}}, \mathbf{M}_i^{\text{text}})}}\end{aligned} \tag{6}$$

Intuitively, the contrastive loss forces the pair $(\mathbf{M}_i^{text}, \mathbf{M}_i^{speech})$ to project semantic memories close to each other. In the meantime, the softmax function trains the model to maintain diversity among semantic memories.

The final loss is a weighted sum of each loss:

$$\mathcal{L} = \lambda_{\text{ST}}\mathcal{L}_{\text{ST}} + \lambda_{\text{MT}}\mathcal{L}_{\text{MT}} + \lambda_{\text{ctr}}\mathcal{L}_{\text{ctr}} \tag{7}$$

4 Experiments

We conduct experiments on the benchmark MuST-C and, as a validation of model design, carry out ablation studies and visualize the representations Chimera has learned.

4.1 Dataset and Preprocessing

MuST-C (Di Gangi et al., 2019a) is a multilingual speech translation corpus with triplet data sources: source audio, transcripts, and text translations. MuST-C contains translations from English (EN) to 8 languages: Dutch (NL), French (FR), German (DE), Italian (IT), Portuguese (PT), Romanian (RO), Russian (RU), and Spanish (ES). With each pair consisting of at least 385 hours of audio recordings, to the best of our knowledge, MuST-C is currently the largest speech translation dataset available for each language pair. It includes data from English TED talks with manual transcripts and translations at the sentence level. We use the dev and tst-COMMON sets as our development and test data, respectively.

Augmented LibriSpeech Dataset (En-Fr) (Kocabiyikoglu et al., 2018) is composed of aligned e-books in French and their human reading in English. It provides typical triplet data of English speech, transcript and French text. Following the setting of (Liu et al., 2019), we utilize the 100h hours of clean train set as training data, and use the original 2 hours of dev set and and 4 hours of test set.

Machine Translation Datasets After bridging the modality gap, Chimera has the potential power to utilize Machine Translation resources. Therefore we incorporate data from WMT, OpenSubtitles (Lison and Tiedemann, 2016) and OPUS100 (Zhang et al., 2020b) translation tasks. Specifically, we use WMT 2014 (Bojar et al., 2014) [2] for EN-DE, EN-FR, EN-RU and EN-ES, WMT 2016 (Bojar et al., 2016) [3] for EN-RO, and OPUS100 [4] for

EN-PT, EN-IT, and EN-NL, as pretraining corpora. We additionally evaluate OpenSubtitles as EN-DE MT data to test the impact of MT corpus selection. WMT 2014 dataset provides at least 4 million sentences of translation data in each language pair. WMT 2016 contains less, around 600k for EN-RO direction. OPUS100 has around 1M sentences for each sentence pair. OpenSubtitles provides 22M sentences for EN-DE.

Pre-processing of Data and Evaluation For speech input, the 16-bit raw wave sequences are normalized by a factor of 2^{15} to the range of $[-1, 1)$.

For text input, on each translation pair, all texts (ST transcripts and translation, and MT source and target texts) are pre-processed in the same way. Texts are case-sensitive. Punctuation is kept, split from words, and normalized. Non-print punctuation is removed. The sentences are then tokenized with Moses tokenizer [5]. We filter out samples whose number of source or target tokens is over 250 and whose ratio of source and target text lengths is outside range $[2/3, 3/2]$. For sub-wording, we use a unigram sentencepiece[6] model with a dictionary size of 10000. On each translation direction, The sentencepiece model is learned on all text data from both ST and MT corpora. The dictionary is shared across MT and ST and across source and target languages.

The performance is evaluated with BLEU (Papineni et al., 2002) using sacreBLEU [7]. We average

×	✓	24.7	34.6
×	×	25.1	34.6

Table 5: BLEU scores of Mem-16 Chimera on MuST-C tst-COMMON set without one or both of auxiliary tasks. "×" means this task is not used during fine-tuning, and "✓" means othersize. "Contrastive" is the bi-modal contrastive task. The removal of one or both of tasks greatly harms the model's performance on both language pairs.

7 consecutive checkpoints around the one of the best dev loss and adopt a beam size of 10.

4.2 Model Configuration

For text input, we use 512-dimensional word embeddings plus sinusoidal positional embeddings. For audio input, the Wav2Vec2 Module follows the base configuration in Baevski et al. (2020). It uses parameters pretrained on LibriSpeech audio data only. The 1-dimensional CNN for speech features has 2 layers with stride size 2, kernel size 5, padding 2, and hidden dimension 1024.

The shared Transformer encoder consists of 6 layers. The memory queries are 64 512-dimensional vectors. The parameters of shared semantic projection resemble a 3-layer Transformer encoder. The Transformer decoder has 6 layers. Each of these Transformer layers, except for those in the Wav2Vec2 module, has an embedding dimension of 512, a hidden dimension of 512, and 8 attention heads.

In both pretraining and fine-tuning stages, we use an Adam optimizer with $\beta_1 = 0.9, \beta_2 = 0.98$, and 4k warm-up updates. We apply an inverse square root schedule algorithm for the learning rate. In MT pretraining, the learning rate is 5e-4, the maximum number of updates is 300k, with at most 33k input tokens per batch. In ST pretraining, the learning rate is 1e-4, the maximum number of updates is 150k, with at most 16M source audio frames per batch. The loss weights λ_{ST}, λ_{MT} and λ_{ctr} are all set to 1.

We also show results on a base version of Chimera, for which the memory queries are only 16 512-dimensional vectors (codenamed "Mem-16"). Because of the training efficiency and simplicity, all ablation studies and visualizations adopted the Mem-16 configuration if not stated otherwise.

Both Chimera and Chimera Mem-16 contain around 165M parameters. The whole training process for one trial on 8 Nvidia Tesla-V100 GPUs generally takes 20 –40 hours according to the translation direction.

4.3 Benchmark Experiments

Training We train Chimera in a pretrain - fine-tune manner. In the first stage, we pretrain Chimera on MT datasets so as to leverage additional sources of training data, as well as provide a better initialization point. In the fine-tuning stage, we adopt multi-task training as described in Section3.3. In addition to the conventional ST task, Chimera is also fine-tuned on MT and bi-modal contrastive task to align inputs from speech and text.

Baselines We include as baselines the speech transformer model from (Ott et al., 2019), Espnet result from (Inaguma et al., 2020), adaptive feature selection method from (Zhang et al., 2020a), dual-decoder Transformer from (Le et al., 2020) and Modality-Agnostic Meta-Learning from (Indurthi et al., 2019) in Table 1. We also provide a series of baseline results of a simple combination of Wav2Vec2 (Baevski et al., 2020) and Transformer. It could be viewed Chimera without external MT pre-training, with still competitive but not SOTA results.

To verify the effectiveness of our training technique, we also compare with other baselines able to leverage external MT corpus in Table 3.

Results The experiment results are shown in Table 1 and 2. Our Chimera achieves state-of-the-art performance on all language pairs, even though we do

not utilize Google Translate results on Augmented Librispeech as most baselines. EN-DE results of Chimera uses WMT14+OpenSubtitles for MT pretrainng, while a detailed ablation study on the effect of MT data can be found in Section 4.4. Note that the improvement on EN-PT is not so significant as EN-DE and EN-FR. We attribute this to the data discrepancy between OPUS100 and MuST-C. A large number of sentences in OPUS100 are from movie subtitles, which are more informal, contain repeated sentences, and cover different topics from those in MuST-C public speeches.

In Table 3, under the same data condition, Chimera outperforms other techniques such as decoder pre-training and knowledge distillation (Liu et al., 2019).

4.4 Ablation Studies and Visualizations

Knowledge Shared across Tasks One potential benefit in our design is that the shared semantic space can hold common knowledge shared across ST and MT tasks. To validate this motivating idea, we analyze the model's behavior while manipulating its modules. If certain weights pretrained during the MT task also contain meaningful information for ST, fixing them should not greatly harm the model's performance.

Specifically, after MT pretraining, we fix certain modules and do not update their weights during fine-tuning. We choose to fix the weights in the shared semantic projection module, the decoding module, or both of them.

Table 4 shows the results. After freezing modules, the results on both EN-DE and EN-FR drop slightly. This demonstrates that freezing weights indeed hampers the model's ability to adapt from MT to ST dataset. But the decreased scores are still comparable to many of the best results in Table 1. This validates the effectiveness of shared semantic space, and indicates that the weights pretrained on MT are already informative enough for Chimera to still generalize sufficiently well on ST task.

Multi-task Training One advantage of bridging the modality gap is that the model can fully benefit from training on auxiliary tasks with more data, such as those mentioned in Section 3.2. To evaluate their impacts, we conduct another ablation study on EN-DE and EN-FR.. Either or both of the auxiliary tasks are not used during fine-tuning.

The results of this ablation are presented in Table 5. Here we can see a significant decrease (with, for example, p=0.020 in one-tailed Student's t-test comparing row 1 and 2) in BLEU scores when either of the auxiliary tasks is abandoned. Although

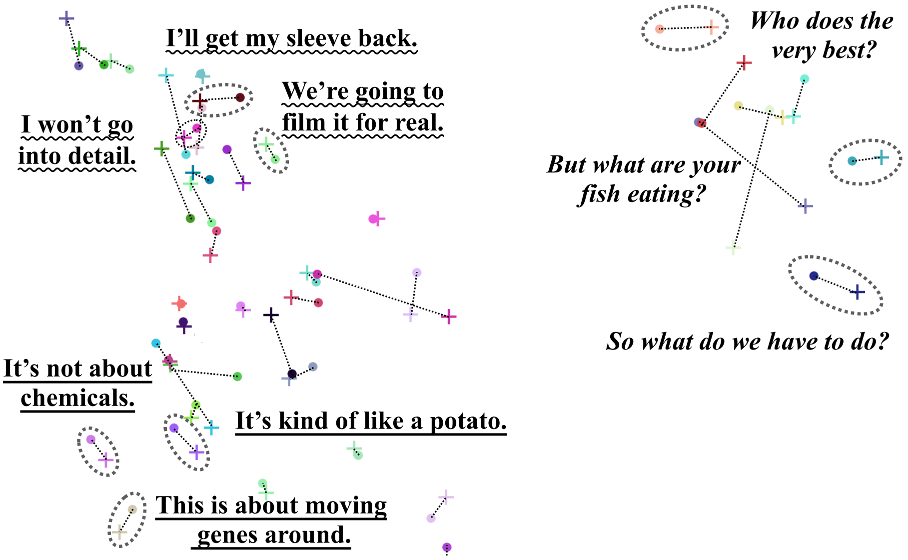

Figure 5: A visualization of one particular semantic memory in Mem-16 Chimera no different samples and modalities. "·" marks speech representations, and "+" marks text representations. Marks of the same color come from the same speech-transcript pair and are linked with dashed lines. Some of speech-transcript pairs are circled together and annotated with their transcripts. Three fonts distinguish three groups of transcripts of similar patterns.

the bi-model contrastive loss is not directly related to the ST task, a poor alignment between semantic memories of speech and text hinders Chimera from leveraging the shared knowledge across two tasks. When the MT task is removed, the drop in BLEU scores is also huge. This could be explained that during fine-tuning, the auxiliary MT task is necessary for keeping shared knowledge from being forgotten.

It is interesting to observe that abandoning both tasks produces results similar to abandoning either one of the tasks. This suggests that the two auxiliary tasks only have effects when combined with each other: only when both using MT task to maintain the pretrained parameters from forgetting, as well as using the bi-modal contrastive task to align between speech and text representations, can Chimera benefit from shared knowledge in MT pretraining.

Additional Machine Translation Data We attribute the gain in the performance of Chimera mainly to the pretraining on MT data. One evidence is the performance gain when using the larger OpenSubtitles as MT corpus for EN-DE in 1. To further probe the influence of the additional MT data, we vary the amount of MT data available during pretraining on EN-DE direction. The results are plotted in Figure 3.

As the size of additional MT dataset increases, the MuST-C BLEU score improves significantly. This confirms the importance of massive high-quality MT data for pretraining Chimera. The results also help explain the relatively inferior scores on EN-PT in Table 1 which uses the OPUS100 dataset in pretraining.

Visualization of Semantic Memories The shared semantic projection is designed to only extract semantic categories of information necessary for decoding, regardless of the input modality. In this way, it can bridge the different representations of speech and text during computation and facilitate knowledge sharing between MT and ST.

To validate this motivation, we visualize them with Principal Component Analysis (PCA) in Figure 4. Up to 100 speech-transcript paired samples are randomly chosen from the valid set. We record vector values of 16 semantic memories from Chimera Mem-16 when inputs are speeches or transcripts, and apply 2-dimensional PCA. The 16 semantic memories are distinguished by 16 colors. Every "·" corresponds to a semantic memory from speech, and each "+" is a semantic memory from the text. It is clear that the semantic memories are highly clustered, everyone of which learns a particular region. Speech and text representations are also projected close within the same region, proving the model's ability to ignore representation differences and bridge the modality gap.

To take a closer view of the structure of each semantic memory subspace, we randomly choose one

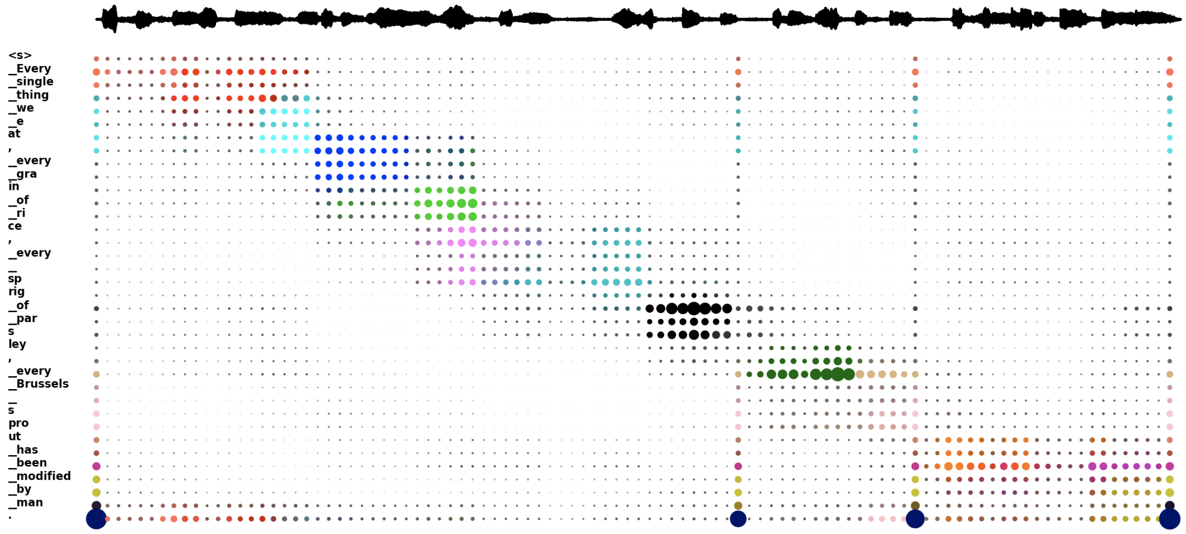

Figure 6: Visualization of the final-layer attention of $M = 16$ memories on inputs, and their alignment between each other. A pair of audio and its transcript is fed to Chimera Mem-16. The area of each dot is linear to dot product between two attention vectors. The color is a linear interpolation of M indicative colors as in Fig 4, with mixing weights linear to the Hadamard product of attention vectors. (Best viewed in color)

semantic memory and apply PCA to its corresponding cluster. The results are visualized in Figure 5. These samples come from 50 speech-transcript pairs. Each pair of speech ("·") and transcript ("+") share the same color and are linked through dashed lines.

Two interesting properties could be observed. First, paired speech and transcript inputs are again close to each other, even though they are coming from different modalities. Second, the visualized representations are organized according to their semantic or syntactic patterns. We recognize several clusters in the figure, and annotate their transcripts with different fonts. The three annotations at the upper-right corner (Italic font) are all questions; those at the upper-left corner (wavy underlined font) all follow a simple future tense; at the bottom-left corner of the figure (underlined font) is another cluster of sentences of copular verbs. This proves that the shared semantic space that Chimera has learned is well-structured, and thus validates our model design.

Visualization of Inter-Modal Attention Alignment "Attention" is the internal mechanism of Transformer based modules. In the design of Chimera, attention is used for extracting M key semantic categories of features from input. To investigate whether these extracted features is indeed semantic, we further visualized the similarity between attention on paired audio and text in Fig 6. Here the colors, which distinguish different memories attending to inputs, is clustered on sequence and distributed close to the diagonal, demonstrating an alignment between matching tokens in two modalities. Here we also observe four beaming columns, where the full stop mark in text aligns with pauses in audio. This is an indication of semantic rather than positional essence of the memories.

5 Conclusions and Future Work

In this paper, we propose Chimera, a model capable of learning a text-speech shared semantic memory network for bridging the gap between speech and text representations. Being able to leverage a large amount of external Machine Translation data, Chimera achieves new state-of-the-art performance on the MuST-C dataset on all 8 languages. Additional experiment results also demonstrate its ability to learn a well-structured shared semantic space as well as effectively share learned knowledge across MT and ST, and validate our design of auxiliary tasks.

In the future, we will focus on deriving a better task to tightly align speech and text representations. Also, the workflows of MT and ST are only partially shared in Chimera, which still requires the model to adapt to ST when switching to the fine-tuning stage. So it remains a challenge to better couple their computation graphs in future designs.

Abstract

Present language understanding methods have demonstrated extraordinary ability of recognizing patterns in texts via machine learning. However, existing methods indiscriminately use the recognized patterns in the testing phase that is inherently different from us humans who have *counterfactual thinking*, *e.g.,* to scrutinize for the hard testing samples. Inspired by this, we propose a *Counterfactual Reasoning Model*, which mimics the counterfactual thinking by learning from few counterfactual samples. In particular, we devise a *generation module* to generate representative counterfactual samples for each factual sample, and a *retrospective module* to retrospect the model prediction by comparing the counterfactual and factual samples. Extensive experiments on sentiment analysis (SA) and natural language inference (NLI) validate the effectiveness of our method.

1 Introduction

Language understanding (Ke et al., 2020) is a central theme of artificial intelligence (Chomsky, 2002), which empowers a wide spectral of applications such as sentiment evaluation (Feldman, 2013), commonsense inference (Bowman et al., 2015). The models are trained on labeled data to recognize the textual patterns closely correlated to different labels. Owing to the extraordinary representational capacity of deep neural networks, the models can well recognize the pattern and make prediction accordingly (Devlin et al., 2019). However, the cognitive ability of these data-driven models is still far from human beings due to lacking *counterfactual thinking* (Pearl, 2019).

Counterfactual thinking is a high-level cognitive ability beyond pattern recognition (Pearl, 2019). In addition to observing the patterns within factual samples, counterfactual thinking calls for comparing the fact with imaginations, so as to make better decision. For instance, given a factual sample "*What do lawyers do when they die? Lie still.*", the intuitive evaluation of its sentiment based on the textual patterns will recognize "*Lie still*" as an objective description of body posture which is *neutral*. By scrutinizing that the "still" could be intentionally postposed, we can imagine a counterfactual sample "*What do lawyers do when they die? Still lie.*" and uncover the negative sarcastic pun, whose sentiment is more accurate.

Recent work (Kaushik et al., 2019; Zeng et al., 2020) shows that incorporating counterfactual samples into model training improves the generalization ability. However, these methods follow the standard machine learning paradigm that uses the same procedure (*e.g.,* a forward propagation) to make prediction in the testing phase. That is, making decision for testing samples according to their relative positions to the model decision boundary. The indiscriminate procedure focuses on the textual patterns occurred in the testing sample and treats all testing samples equally, which easily fails on hard samples (*cf.* Figure 1). On the contrary, humans can discriminate hard samples and ponder the decision with a rational system (Daniel, 2017), which imagines counterfactual and adjusts the decision.

The key to bridge this gap lies in imitating the counterfactual thinking ability of humans, *i.e.,* learning a decision making procedure to serve for the testing phase. That is a procedure of: 1) constructing counterfactual samples for a target factual sample; 2) calling the trained language understanding model to make prediction for the counterfactual samples; and 3) comparing the counterfactual and factual samples to retrospect the model prediction. However, the procedure is non-trivial to achieve for two reasons: 1) the space of counterfactual sample is huge since any variant from the target factual

---

[*] Corresponding author.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2226–2236
August 1–6, 2021.

sample can be a counterfactual sample. It is thus challenging to search for suitable counterfactual samples that can facilitate the decision making. 2) The mechanism of how we retrospect the decision is still unclear, making it hard to be imitated.

Towards the target, we propose a *Counterfactual Reasoning Model* (CRM), which is a two-phase procedure consisting a *generation module* and a *retrospection module*. In particular, given a factual sample in the testing phase, the generation module constructs representative counterfactual samples by imagining *what would the content be if the label of the sample is* y. To imitate the unknown retrospection mechanism of humans, we build the retrospection module as a carefully designed deep neural network that separately compares the latent representation and the prediction of the factual and counterfactual samples. The proposed CRM forms a general paradigm that can be applied to most existing language understanding models without constraint on the format of the language understanding task. We select two language understanding tasks: SA and NLI, and test CRM on three representative models for each task. Extensive experiments on benchmark datasets validate the effectiveness of CRM, which achieves performance gains ranging from 5.1% to 15.6%.

The main contributions are as follow:

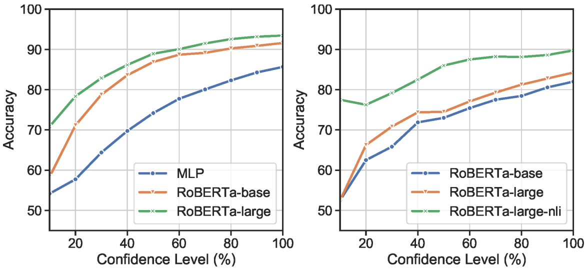
- We propose the *Counterfactual Reasoning Model* to enlighten the language understanding model with counterfactual thinking.

- We devise a generation module and a retrospection module that are task and model agnostic.

- We conduct extensive experiments, which validate the rationality and effectiveness of the proposed method.

2 Pilot Study

Decisions are usually accompanied by confidence, a feeling of being wrong or right (Boldt et al., 2019). From the perspective of model confidence, we investigate the performance of language understanding models across different testing samples. We estimate the model confidence on a sample as the widely used *Maximum Class Probability* (MCP) (Corbière et al., 2019), which is the probability over the predicted class. A lower value of MCP means less confidence and "hard" sample. According to the value of MCP, we rank the testing samples in ascending order and split them into ten groups, *i.e.,* confidence level from 1 to 10.



(a) Sentiment analysis (b) Natural language inference

Figure 1: Prediction performance of the language understanding models over testing samples at different confidence levels.

Figure 1 shows the performance of representative models over samples at different model confidence levels on the SA and NLI tasks (see Section 4.1 for model and dataset descriptions). From the figures, we can observe a clear increasing trend of classification accuracy as the confidence level increases from 1 to 10 in all cases. In other words, these models fail to predict accurately for the hard samples. It is thus essential to enhance the standard inference with a more precise decision making procedure.

3 Methodology

In this section, we first formulate the task of learning a decision making procedure for the testing phase (Section 3.1), followed by introducing the proposed CRM (Section 3.2) and the paradigm of building language understanding solutions with CRM (Section 3.3).

3.1 Problem Formulation

As discussed in the previous work (Wu et al., 2020; Li et al., 2020, 2019), language understanding tasks can be abstracted as a classification problem where the input is a text and the target is to make decision across a set of candidates of interests. We follow the problem setting with consideration of counterfactual samples (Kaushik et al., 2019; Liang et al., 2020), where the training data are twofold: 1) *factual samples* $\mathcal{T} = \{(\boldsymbol{x}, y)\}$ where $y \in [1, C]$ denotes the class or the target decision of the text; $\boldsymbol{x} \in \mathbb{R}^D$ is the latent representation of the text, which encodes the textual contents[1]. 2) *counterfactual samples*

---

[1] The input is indeed the plain text which is projected to a latent representation by an encoder (*e.g.,* a Transformer (Devlin et al., 2019)) in the cutting edge solutions. We omit the

$$\mathcal{T}^* \quad = \quad \{(\boldsymbol{x}_c^*, c) | (\boldsymbol{x}, y) \in \mathcal{T}, c \in [1, C] \& c \neq y\}$$

where $(\boldsymbol{x}_c^*, c)$ is a counterfactual sample in class c corresponds to the factual sample $(\boldsymbol{x}, y)$[2]. We assume that a classification model (*e.g.,* BERT (Devlin et al., 2019)) has been trained over the labeled data. Formally,

$$\hat{\boldsymbol{\theta}} = \min_{\boldsymbol{\theta}} \sum_{(\boldsymbol{x},y) \in \mathcal{T}/\mathcal{T}^*} l(y, f(\boldsymbol{x}|\boldsymbol{\theta})) + \alpha \|\boldsymbol{\theta}\|, \qquad (1)$$

where $\hat{\boldsymbol{\theta}}$ is the learned parameters of the model $f(\cdot)$; $l(\cdot)$ is a classification loss such as cross-entropy (Kullback, 1997), and α is a hyper-parameter to adjust the regularization.

The target is to build a decision making procedure to perform counterfactual reasoning when serving for the testing phase. Given a testing sample $\boldsymbol{x}$, the core is a policy of generating counterfactual samples and retrospecting the decision, which is formulated as:

$$\boldsymbol{y} = h\left(\boldsymbol{x}, \{\boldsymbol{x}^*\} | \boldsymbol{\eta}, \hat{\boldsymbol{\theta}}\right), \ \{\boldsymbol{x}^*\} = g\left(\boldsymbol{x} | \boldsymbol{\omega}\right),$$

$\boldsymbol{y} \in \mathbb{R}^C$ denotes the final prediction for the testing sample $\boldsymbol{x}$, which is a distribution over the classes; $\boldsymbol{x}^*$ is one of the generated counterfactual samples for $\boldsymbol{x}$. The generation module $g(\cdot)$ parameterized by $\boldsymbol{\omega}$ is expected to construct a set of representative counterfactual samples for the target factual sample, which provide signals for the retrospection module $h(\cdot)$ parameterized by $\boldsymbol{\eta}$ to retrospect the prediction $f\left(\boldsymbol{x}|\hat{\boldsymbol{\theta}}\right)$ given by the trained classification model. In particular, $h(\cdot)$ and $g(\cdot)$ will be learned from the factual and counterfactual training samples, respectively.

3.2 Counterfactual Reasoning Model

Figure 2 illustrates the process of CRM where the arrows in grey color represent the standard inference of trained classification model, and arrows in red color represent the retrospection with consideration of counterfactual samples.

3.2.1 Retrospection Module

We devise the retrospection module with one key consideration—distilling signals for making final decision by comparing both the latent representation and the prediction of the counterfactual samples with the factual sample. To achieve the target, we devise three key building blocks for retrospection, which successively perform *representation comparison*, *prediction comparison*, and *fusion* . In particular, the module first compares the representation of each counterfactual sample with the factual sample; then compares their predictions accordingly; and fuses the comparison across the counterfactual samples.

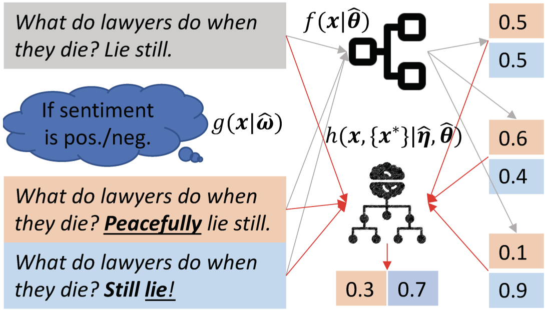


Figure 2: Illustration of the proposed CRM.

Representation comparison. Given a pair of counterfactual sample $\boldsymbol{x}^*$ and factual sample $\boldsymbol{x}$, we believe the signals meaningful for making final decision lie in the difference of the samples and how the difference affects the classification. To distill such signals, we devise the representation comparison block as $\boldsymbol{y}_\triangle = f(\boldsymbol{x} - \boldsymbol{x}^*|\hat{\boldsymbol{\theta}})$, where $\boldsymbol{y}_\triangle \in \mathcal{R}^C$ denotes the prediction of the representation difference $\boldsymbol{x} - \boldsymbol{x}^*$ given by the trained classification model. Note that we leverage the trained model to enlighten how the content difference affects the classification since the model is trained to capture the connection between the textual patterns and the classes. It should be noted that we use a duplicate of the trained classification model for the representation comparison. That is to say, the training of the retrospection module will not affect the classification model.

Prediction comparison. To retrospect the prediction $f(\boldsymbol{x}|\hat{\boldsymbol{\theta}})$, we devise a prediction comparison block to compare the predictions of each counterfactual and factual sample pair and distill patterns from $f(\boldsymbol{x}|\hat{\boldsymbol{\theta}})$, $f(\boldsymbol{x}^*|\hat{\boldsymbol{\theta}})$, and $\boldsymbol{y}_\triangle$. Inspired by the success of convolutional neural network (CNN) in capture local-region patterns, the block is devised as a CNN, which is formulated as:

$$\boldsymbol{y}^* = \text{CNN}\left(f(\boldsymbol{x}|\hat{\boldsymbol{\theta}}), f(\boldsymbol{x}^*|\hat{\boldsymbol{\theta}}), \boldsymbol{y}_\triangle\right), \qquad (2)$$

where $\boldsymbol{y}^*$ denotes the retrospected prediction when comparing to $\boldsymbol{x}^*$. In particular, a *stack layer* first stacks the three predictions as a matrix, which serves as an "image" to facilitate "observing" pat-

---

encoder for briefness since focusing on the decision making.

[2] Given the labeled factual sample, counterfactual samples can be constructed either manually (Kaushik et al., 2019) or automatically (Chen et al., 2020) by conducting minimum changes on $\boldsymbol{x}$ to swap its label from y to c

terns. Formally, $\boldsymbol{Y} = \left[f(\boldsymbol{x}|\hat{\boldsymbol{\theta}}), f(\boldsymbol{x}^*|\hat{\boldsymbol{\theta}}), \boldsymbol{y}_\triangle \right]$ where $\boldsymbol{Y} \in \mathbb{R}^{C\times 3}$. $\boldsymbol{Y}$ is then fed into an 1D convolution layer to capture the intra-class patterns across the predictions, which is formulated as:

$$\boldsymbol{H} = \sigma(\boldsymbol{Y} * \boldsymbol{F}),\ \boldsymbol{H}_{ij} = \sigma(\boldsymbol{Y}_{:i}\boldsymbol{F}_j), \tag{3}$$

where $\boldsymbol{F} \in \mathbb{R}^{3\times K}$ denotes the filters in the convolution layer, and $\sigma(\cdot)$ is an activation function such as *GELU* (Hendrycks and Gimpel, 2016). $\boldsymbol{Y}_{:i}$ and $\boldsymbol{F}_j$ represent the i-th row of $\boldsymbol{Y}$ and the j-th column of $\boldsymbol{F}$, respectively. The filter $\boldsymbol{F}_j$ can learn rules for conducting retrospection. For instance, a filter $[1, -1, 0]$ means deducting the prediction of the counterfactual sample from that of the factual sample. The output $\boldsymbol{H} \in \mathbb{R}^{C\times K}$ is then flattened as a vector and fed into a fully-connected (FC) layer to capture the inter-class patterns. Formally,

$$\boldsymbol{y}^* = \boldsymbol{W} flatten(\boldsymbol{H}) + \boldsymbol{b}, \tag{4}$$

where $\boldsymbol{W}$ and $\boldsymbol{b}$ are model parameters.

Fusion. The target is to fuse the retrospected predictions $\{\boldsymbol{y}^*\}$ into a final decision $\boldsymbol{y}$. Inspired by the success of pooling function in reading out patterns, we devise the block as $\boldsymbol{y} = pooling(\{\boldsymbol{y}^*\})$. As the fusion is performed after the pairwise comparison, we term it as *late fusion*.

Training. We update the parameters of the retrospection module by minimizing the classification loss over the factual training samples, which is:

$$\hat{\boldsymbol{\eta}} = \min_{\boldsymbol{\eta}} \sum_{(\boldsymbol{x},y)\in\mathcal{T}} l(y, \boldsymbol{y}) + \lambda\|\boldsymbol{\eta}\|. \tag{5}$$

where λ denotes the hyper-parameter to adjust the weight of the regularization term.

It should be noted that no existing research has uncovered the specific mechanism of retrospection in our brain, *i.e.,* the order of comparison and fusion is unclear. As such, we further devise two fusion strategies: *middle fusion* and *early fusion*, which performs fusion within the CNN, *i.e.,* during comparison, and before the CNN, respectively.

- *Middle fusion* performs aggregation between the convolution layer and the FC layer. This fusion first calculates the latent comparison signals $\boldsymbol{H}$ for each pair of counterfactual and factual samples according to Equation 3. The aggregated signals $pooling(\{\boldsymbol{H}\})$ are then fed into the FC layer (Equation 4) to obtain the final decision $\boldsymbol{y}$.
- *Early fusion* aggregates the counterfactual samples before performing comparison, which is formulated as $\tilde{\boldsymbol{x}}^* = pooling(\{\boldsymbol{x}^*\})$. In this way, the retrospection module is formulated as: $\boldsymbol{y} = \text{CNN}\left(f(\boldsymbol{x}|\hat{\boldsymbol{\theta}}), f(\tilde{\boldsymbol{x}}^*|\hat{\boldsymbol{\theta}}), f(\tilde{\boldsymbol{x}}^* - \boldsymbol{x}|\hat{\boldsymbol{\theta}})\right)$. For all the three fusion methods, we can use either regular pooling function without parameter or parameterized pooling function (Ying et al., 2018) to enhance the expressiveness of the retrospection module. In our experiments, using a simple mean pooling achieves a performance that is comparable to the parameterized one in most cases (*cf.* Table 3).

3.2.2 Generation Module

The target is to construct counterfactual samples that are informative for retrospecting the decision on the target factual sample $\boldsymbol{x}$. As the task involves making decision among C candidate classes, we believe that the key to generate representative counterfactual samples lies in imagining *"what would the content be if the sample belongs to class c", i.e.,* generating C counterfactual samples $\{\boldsymbol{x}_c^*\}$. With the C classes as the targets, the searching space of samples can also be largely narrowed down. Toward this end, we devise the generation module with two main considerations: 1) decomposing the factual sample $\boldsymbol{x}$ to distill contents irrelevant to the label of the sample $\boldsymbol{u} = d(\boldsymbol{x}|\boldsymbol{\omega})$; 2) injecting class c into $\boldsymbol{u}$ to form the counterfactual sample $\boldsymbol{x}_c^*$.

Decomposition. To distill $\boldsymbol{u}$, we need to recognize the connection between the content of the factual sample and each class. We thus account for class representations in the decomposition function. To align the sample space of the generation module with the retrospection module $h(\cdot)$ and the classification model $f(\cdot)$, we extract the parameters from the prediction layer of the trained classification model as the class representations. In particular, we extract the mapping matrix $\boldsymbol{W} \in \mathbb{R}^{C\times D}$ where the c-th row corresponds to class c. Note that we assume that the prediction layer has the same dimensionality as the latent representation, which is a common setting in most cutting edge language understanding models. The decomposition function is devised as a CNN to capture both the intra-dimension and inter-dimension connections between the factual sample and the classes.

- *Stack layer.* The stack layer stacks the factual sample, class representations, and the element-wise product between sample and each class, which is formulated as: $\boldsymbol{X} = [\boldsymbol{x}, \boldsymbol{W}^T, \boldsymbol{x} \odot \boldsymbol{W}^T]$. $\boldsymbol{x} \odot \boldsymbol{W}^T \in \mathbb{R}^{D\times C}$ shed lights on how closely each dimension of $\boldsymbol{x}$ connect to each class, where large absolute value indicates closer connections.

- *Convolution layer.* This layer uses 1D horizontal filters to learn patterns of deducting class relevant contents from the factual sample, which is formulated as $\boldsymbol{h} = pooling(\sigma(\boldsymbol{X} * \boldsymbol{F}^g))$. $\boldsymbol{F}^g \in \mathbb{R}^{(2C+1)\times L}$ denotes the filters where L is the total number of filters. The output $\boldsymbol{h} \in \mathbb{R}^D$ is a hidden representation.
- *FC layers.* We use two FC layers to capture the inter-dimension connections. Formally, $\boldsymbol{u} = \boldsymbol{W}^2\sigma(\boldsymbol{W}^1\boldsymbol{h} + \boldsymbol{b}^1) + \boldsymbol{b}^2$, where $\boldsymbol{W}^2 \in \mathcal{R}^{D\times M}$, $\boldsymbol{W}^1 \in \mathcal{R}^{M\times D}$, $\boldsymbol{b}^2 \in \mathcal{R}^D$, and $\boldsymbol{b}^1 \in \mathcal{R}^M$ are learnable parameters. M is a hyper-parameter to adjust the complexity of the decomposition function. Note that we can stack more layers to enhance the expressiveness of the function, whereas using two layers according to the universal approximation theorem (Hornik, 1991).

We learn the parameters of the decomposition function from the counterfactual training samples by optimizing the following objective:

$$\min_{\boldsymbol{\omega}} \sum_{(\boldsymbol{x}_c^*, c)\in\mathcal{T}^*} r(\boldsymbol{u}_c^*, \tilde{\boldsymbol{u}}_c) + \gamma l(c, f(\boldsymbol{x}_c^* - \boldsymbol{u}_c^*|\hat{\boldsymbol{\theta}})) + r(\boldsymbol{u}, \tilde{\boldsymbol{u}}_c) + \gamma l(y, f(\boldsymbol{x} - \boldsymbol{u}|\hat{\boldsymbol{\theta}})), \tag{6}$$

where $\boldsymbol{u}_c^* = d(\boldsymbol{x}_c^*|\boldsymbol{\omega})$ and $\boldsymbol{u} = d(\boldsymbol{x}|\boldsymbol{\omega})$ are the decomposition results of the counterfactual sample $\boldsymbol{x}_c^*$ and the corresponding factual sample $\boldsymbol{x}$; $\tilde{\boldsymbol{u}}_c = \frac{1}{2}(\boldsymbol{x} + \boldsymbol{x}_c^*)$ denotes the target value of the decomposition. The two terms $r(\cdot)$ and $l(\cdot)$ are Euclidean distance (Dattorro, 2010) and classification loss. By minimizing the two terms, we encourage the decomposition result: 1) to be close to the target value $\tilde{\boldsymbol{u}}_c$; and 2) if being deducted from the original sample (*e.g.,* , $\boldsymbol{x} - \boldsymbol{u}$), the classification cannot be influenced. γ is a hyper-parameter to balance the two terms.

The rationality of setting $\tilde{\boldsymbol{u}}_c = \frac{1}{2}(\boldsymbol{x} + \boldsymbol{x}_c^*)$ as the target class irrelevant content of $\boldsymbol{x}$ and $\boldsymbol{x}_c^*$ comes from the parallelogram law (Nash, 2003). Note that this pair of samples belong to two different classes where a decision boundary (a hyperplane) lies between the two classes y and c. Considering that the sample $\boldsymbol{x}$ corresponds to a vector in the hidden space, we can decompose the vector into two components that are orthogonal and parallel to the decision boundary, *i.e.,* $\boldsymbol{x}_c^* = \boldsymbol{o}_c^* + \boldsymbol{p}_c^*$ and $\boldsymbol{x} = \boldsymbol{o} + \boldsymbol{p}$. Since the two samples belong to different classes, their orthogonal components are in opposite directions and their addition will only retain the parallel components, which are irrelevant to judging the class between y and c[3].

Injection. Accordingly, given a testing sample $\boldsymbol{x}$, we can inject the orthogonal components towards class c via $\boldsymbol{x}_c^* = 2 * d(\boldsymbol{x}|\hat{\boldsymbol{\omega}}_c) - \boldsymbol{x}$, which is the imagined content of the sample if it belongs to class c. In this way, for each testing sample, we conduct the injection over all the classes and construct C counterfactual samples $\{\boldsymbol{x}_c^*\}$, which are then used in the retrospection module[4].

3.3 Learning Paradigm with CRM

The existing work (Kaushik et al., 2019; Zeng et al., 2020) for language understanding typically follows the standard learning paradigm, *i.e.,* training a classification model over labeled data. Applying the proposed CRM indeed forms a new learning paradigm for constructing language understanding solutions. Algorithm 1 illustrates the procedure of the new paradigm.

Algorithm 1 Learning paradigm with CRM

```

4 Experiments

We conduct experiments on two representative language understanding tasks, SA and NLI, to answer the following research questions:

- **RQ1:** To what extent counterfacutal reasoning improves language understanding?
- **RQ2:** How does the design of the retrospection module affect the proposed CRM?
- **RQ3:** How effective are the counterfactual samples generated by the proposed generation module?

4.1 Experiment Settings

Datasets. We adopt the same datasets in (Kaushik et al., 2019) for both tasks. The SA data are reviews

---

[3] Note that we normalize all samples to be unit vectors in the decomposition function. Moreover, inspired by (Parascandolo et al., 2018), we train a decomposition function for each class, *i.e.,* class-specific parameters $\hat{\boldsymbol{\omega}}_c$

[4] The generation module consists of C decomposition functions $d(\boldsymbol{x}|\hat{\boldsymbol{\omega}}_c)$ and the non-parametric injection function.

from IMDb, which are labeled as either positive or negative. For each factual review, the dataset contains a manually constructed counterfactual sample where the crowd workers are asked to manipulate the text to reverse the label with the constraint of no gratuitous change. NLI is a three-way classification task with two sentences as inputs and the target of detecting their relation within entailment, contradiction, and neutral. For each factual sample, four counterfactual samples are given, which are constructed by editing either the first or the second sentence with target relations different to the label of the factual sample.

Classification models. Owing to the extraordinary representational capacity of language model, fine-tuning pre-trained language model has become the emergent technique for solving language understanding tasks (Devlin et al., 2019). We select the widely used RoBERTa-base[5] and RoBERTa-large[6] for the consideration of the robustness of the RoBERTa (Liu et al., 2019) and our limited computation resources. For SA, we also test the classical Multi-Layer Perceptron (MLP) (Teney et al., 2020) with *tf-idf* text features (Schütze et al., 2008) as inputs. For NLI, we further test RoBERTa-large-nli[7], which has been fine-tuned on the large-scale MultiNLI dataset (Williams et al., 2018).

Baselines. As the proposed CRM leverages counterfactual samples, we compare CRM with three representative methods using counterfactual samples in language understanding tasks: 1) **+CF** (Kaushik et al., 2019), which uses counterfactual samples as data augmentation for model training; 2) **+GS** (Teney et al., 2020), which compares the factual and counterfactual samples in model training through regularizing their gradients; and 3) **+CL** (Liang et al., 2020), which compares the factual and counterfactual samples through a contrastive loss. Moreover, we report the performance of the testing model under *Normal Training*, *i.e.,* training over factual samples only.

Implementation. We implement the proposed CRM with PyTorch 1.7.0 based on Hugging Face Transformer[8], which is released at: https://github.com/fulifeng/Counterfactual_Reasoning_Model. In all cases, we follow the setting of +CF for training the classification model, which is a standard fine-tuning in (Liu et al., 2019). We then use *adam* (Kingma and Ba, 2014) with learning rate of 0.001 to optimize the retrospection module and the generation module. For the retrospection module, we set the number of filters in the convolution layer K as 10, the weight for regularization λ as 0. As to the generation module, we set the number of convolution filters as 10, the size of the hidden layer M as 256, and the weight for balancing Euclidean distance and classification loss γ as 15. We report the average classification accuracy over 5 different runs. For each repeat, we train the model with 20 epochs and select the model with the best performance on the validation set.

4.2 Performance Comparison (RQ1)

We first use the handcrafted counterfactual samples to demonstrate the effectiveness of counterfactual reasoning in the inference stage of language understanding model, which can be seen as using a golden standard generation module to provide counterfactual samples for the retrospection module. Note that we do not use the label of counterfactual samples in the testing set. Table 1 shows the performance of the compared methods on the two tasks. From the table, we observe that:

- +CRM largely outperforms all the baseline methods in all cases. As compared to +CF, the same classification model without CRM in the testing phase, +CRM achieves relative performance improvement up to 15.6%. The performance gain is attributed to the retrospection module, which justifies the rationality and effectiveness of incorporating counterfactual thinking into the inference stage of language understanding model. In other words, by comparing the factual sample with its counterfactual samples, the retrospection module indeed makes more accurate decisions.
- On the SA task, a huge gap (85.3 ↔ 93.4) lies in the performance of the shallow model MLP and the deep RoBERTa-base/RoBERTa-large. When applying +CRM, MLP achieves a performance that is comparable to the deep models. The result indicates that counterfactual reasoning can compensate for the disadvantages caused by the insufficient model representational capacity. In addition, the result reflects that CRM brings cognitive ability beyond recognizing textual patterns. If the retrospection module only facilitates capturing the correlation between textual patterns and classes, such simple model cannot bridge the

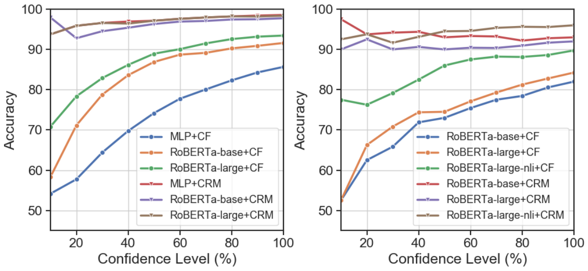
huge gap of representational capacity between MLP and RoBERTa-large.

- The performance of baseline methods are comparable to each other in most cases, *i.e.,* incorporating counterfactual samples into model training does not necessarily improve the testing performance on factual samples. This result is consistent with (Kaushik et al., 2019), which is reasonable since these methods are devised for enhancing the generalization ability, especially for the out-of-distribution testing samples, which can sacrifice the performance on normal testing samples. Besides, the result indicates that training with counterfactual samples is insufficient for achieving counterfactual thinking, which reflects the rationality of enhancing the inference paradigm with a decision making procedure.



(a) Sentiment analysis (b) Natural language inference

Figure 3: Prediction performance of +CF and +CRM over testing samples at different confidence levels.

Performance on hard samples. Furthermore, we investigate whether the proposed CRM facilitate dealing with hard samples. Recall that we split the testing samples into 10 groups according to the confidence of the classification model, *i.e.,* +CF (*cf.* Section 2). We perform group-wise comparison between +CF and +CRM. Figure 3 shows the performance of all the classification models with +CF and +CRM. From the figures, 1) we observe that the performance of +CRM is stable across different confidence levels, whereas the performance of the classification model shows a clear decreasing trend as the confidence level decreases from 10 to 1. The result indicates that the retrospection module is insensitive to the confidence of the classification model. 2) In all cases, +CRM achieves the largest performance gain at the first group with confidence level of 1, *i.e.,* the hardest group to the classification model. For instance, the improvement reaches 85.7% on the RoBERTa-base model for the NLI task. The large improvements further justifies the effectiveness of the retrospection module, *i.e.,* comparing the prediction of factual samples to counterfactual samples indeed facilitates dealing with hard samples.

RoBERTa-large	87.4±2.2	**93.8±1.9**
RoBERTa-large-nli	88.8±1.6	**94.4±1.2**

Table 2: Performance comparison of implicit modeling (end-to-end model) and explicit modeling (CRM) of counterfactual thinking.

CRM *V.S.* implicit modeling. According to the uniform approximation theorem (Hornik, 1991), the CRM can also be approximated by a deep neural network. We thus investigate whether counterfactual thinking can be learned in an implicit manner. In particular, we evaluate a model that takes both the factual sample and counterfactual samples as inputs to make prediction for the factual one. Table 2 shows the performance, where we have the following observations: 1) The implicit modeling performs much worse than the proposed CRM in most cases, which justifies the effectiveness of the retrospection module and the rationality of modeling comparison explicitly. 2) On the NLI task, RoBERTa-base+CRM outperforms RoBERTa-large (implicit), which means that the superior performance of CRM is not because of the additional model parameters introduced by the retrospection module, but the explicit comparison between factual and counterfactual samples.

4.3 In-depth Analysis

Effects of retrospection module design (RQ2). Note that the order of comparison and fusion in the retrospection mechanism of us humans is still unclear. We investigate how the fusion strategies influence the effectiveness of the proposed CRM. Table 3 shows the performance of CRM based on the early fusion (EF), late fusion (LF), and middle fusion (MF) on the NLI task. We omit the comparison on the SA task since the dataset only has one counterfactual sample for the target factual sample. For both EF and LF, we use the mean pooling as the pooling function. As to MF, we use a pooling function that is equipped with self-attention (Vaswani et al., 2017). The reasons of this setting are twofold: 1) using mean pooling will make LF and MF equivalent since the FC layer in the retrospection module is a linear mapping. Note that LF performs pooling after the FC layer, while the pooling function of MF is just before the FC layer. 2) The comparison between the LF and MF can thus shed light on whether parameterized pooling function can benefit the retrospection.

From the table, we can observe that, in most cases, CRM based on different fusion strategies achieve performance comparable to each other. It indicates that the retrospection is insensitive to the order of fusion and the comparison between counterfactual and factual samples. Considering that MF with mean pooling is equivalent to LF, we can see that the benefit of parameterized pooling function is limited. In particular, MF only performs better than LF on one of the three testing models.

Effects of generation module (RQ3). We then investigate whether the proposed generation module constructs useful counterfactual samples for retrospection. We train and test the retrospection module (using EF) with the generated samples on RoBERTa-large on the SA task. We omit the experiments of other settings for saving computation resources. In this way, the model achieves an accuracy of 94.5 which is better than +CF (93.4) but worse than +CRM with manually constructed counterfactual samples (98.2) (*cf.* Table 1). The result indicates that the generated samples indeed facilitate the retrospection while the generation quality can be further improved. Moreover, on the testing samples at confidence level of 1, using the generated samples achieves an accuracy of 81.3 which is much better than +CF (70.8) (*cf.* Figure 3). The generated samples indeed benefit the decision making over hard testing samples.

5 Related Work

Counterfactual sample. Constructing counterfactual samples has become an emergent data augmentation technique in natural language processing, which has been used in a wide spectral of language understanding tasks, including SA (Kaushik et al., 2019; Yang et al., 2020), NLI (Kaushik et al., 2019), named entity recognition (Zeng et al., 2020) question answering (Chen et al., 2020), dialogue system (Zhu et al., 2020), vision-language navigation (Fu et al., 2020). Beyond data augmentation under the standard supervised learning paradigm, a line of research explores to incorporate counterfactual samples into other learning paradigms such as adversarial training (Zhu et al., 2020; Fu et al., 2020; Teney et al., 2020) and contrastive learning (Liang et al., 2020). This work lies in an orthogonal direction that incorporates counterfactual samples into the decision making procedure of model inference.

Counterfactual inference. A line of research attempts to enable deep neural networks with counterfactual thinking by incorporating counterfactual inference (Yue et al., 2021; Wang et al., 2021; Niu et al., 2021; Tang et al., 2020; Feng et al., 2021). These methods perform counterfactual inference over the model predictions according to a pre-defined causal graph. Due to the requirement of causal graph, such methods are hard to be generalized to different tasks. Our method does not suffer from such limitation since working on the counterfactual samples which can be generated without a comprehensive causal graph.

Hard sample. A wide spectral of machine learning techniques are related to dealing with the hard samples in language understanding. For instance,

Backbone	+CF	EF	*RI*	LF	*RI*	MF	*RI*
RoBERTa-base	83.4±0.9	91.5±1.6	9.7%	**92.8±1.8**	11.3%	89.6±2.0	7.4%
RoBERTa-large	85.8±1.2	93.8±1.9	9.3%	**95.3±0.7**	11.1%	93.4±1.7	8.9%
RoBERTa-large-nli	88.2±1.0	94.4±1.2	7.1%	93.8±0.4	6.4%	**94.7±1.3**	7.4%

Table 3: Performance of the proposed CRM based on early fusion (EF), late fusion (LF), or middle fusion (MF) on the NLI task. RI represents the relative performance improvement over the +CF method.

adversarial training (Khashabi et al., 2020) enhances the model robustness against perturbations and attacks, which are hard samples for normally trained models. Debiased training (Tu et al., 2020; Utama et al., 2020) eliminates the spurious correlation or bias in training data to enhance the generalization ability and deal with out-of-distribution samples. In addition to the training phase, a few inference techniques might improve the model performance on hard samples, including posterior regularization (Srivastava et al., 2018) and causal inference (Yu et al., 2020; Niu et al., 2021). However, both techniques require domain knowledge such as prior or causal graph tailored for specific applications. On the contrary, this work provides a general paradigm that can be used for most language understanding tasks.

6 Conclusion

In this work, we pointed out the issue of standard inference of existing language understanding models. We proposed a Counterfactual Reasoning Model which empowers the trained model with a high-level cognitive ability, counterfactual thinking. By applying the proposed CRM, we formed a new paradigm for building language understanding solutions. We conducted extensive experiments, which validate the effectiveness of our proposal, especially in dealing with hard samples.

This work opens up a new research direction about the decision making procedure in testing phase. In the future, we will explore sequential decision procedure to resolve the constraint on the number of constructed counterfactual samples. In addition, we will investigate generation module for language understanding with unsupervised generative techniques (Sauer and Geiger, 2021).

Abstract

Machine Reading Comprehension (MRC) aims to extract answers to questions given a passage, which has been widely studied recently especially in open domains. However, few efforts have been made on closed-domain MRC, mainly due to the lack of large-scale training data. In this paper, we introduce a multi-target MRC task for the medical domain, whose goal is to predict answers to medical questions and the corresponding support sentences from medical information sources simultaneously, in order to ensure the high reliability of medical knowledge serving. A high-quality dataset (more than 18k samples) is manually constructed for the purpose, named Multi-task **C**hinese **Med**ical **MRC** dataset (CMedMRC), with detailed analysis conducted. We further propose a **C**hinese **med**ical **BERT** model for the task (CMedBERT), which fuses medical knowledge into pre-trained language models by the dynamic fusion mechanism of heterogeneous features and the multi-task learning strategy. Experiments show that CMedBERT consistently outperforms strong baselines by fusing context-aware and knowledge-aware token representations.[1]

1 Introduction

Machine Reading Comprehension (MRC) has become a popular task in NLP, aiming to understand a given passage and answer the relevant questions. With the wide availability of MRC datasets (Rajpurkar et al., 2016; He et al., 2018; Cui et al., 2019) and deep learning models (Yu et al., 2018; Ding et al., 2019) (including pre-trained language models such as BERT (Devlin et al., 2019)), significant progress has been made.

Despite the success, a majority of MRC research has focused on open domains. For specific domains, however, the construction of high-quality MRC datasets, together with the design of corresponding models is considerably deficient (Welbl et al., 2017, 2018). The causes behind this phenomenon are threefold. Take the medical domain as an example. i) Data annotators are required to have medical backgrounds with high standards. Hence, simple crowd-sourcing (Rajpurkar et al., 2016; Cui et al., 2019) often leads to poor annotation results. ii) Due to the domain sensitivity, people are more concerned about the reliability of the information sources where the answers are extracted, and the explainability of the answers themselves (Lee et al., 2014; Dalmer, 2017). This is fundamentally different from the task requirements of open-domain MRC. iii) From the perspective of model learning, it is difficult for pre-trained language models to understand the meaning of the questions and passages containing a lot of specialized terms (Chen et al., 2016; Bauer et al., 2018). Without the help of domain knowledge, state-of-the-art models can perform poorly. As shown in Figure 1, BERT (Devlin et al., 2019) and MC-BERT (Zhang et al., 2020) only predict part of the correct answer, i.e., “torso” and “buttocks”, instead of generating the complete answer to the medical question.

In this paper, we present a comprehensive study on Chinese medical MRC, including i) how the task is formulated, ii) the construction of the Chinese medical dataset and iii) the MRC model with rich medical knowledge injected. To meet the requirements of medical MRC, we aim to predict both the answer spans to a medical question, and the support sentence from the passage, indicating the source of the answer. The support sentences provide abundant evidence for users to learn medical knowledge, and for medical professionals to assess the trustworthiness of model output results.

Multi-task Chinese Medical MRC

Passage: <1>叠瓦癣是一种特殊的体癣, 主要由同心性毛癣菌或称叠瓦癣菌引起…<14>躯干和臀部多见，时久可扩延于四肢，甚至口唇、甲沟及头皮<15>但掌跖多不受累，也不侵犯毛发 (<1>Imbricate tinea is a special kind of body ringworm, mainly caused by the concentric trichoderma or imbricated versicolor bacterium… <14>It often occurs in the torso and buttocks. The disease can spread to the extremities after a long time. It can even spread to the lips, nail groove and scalp. <15>But the metatarsal is not affected and also do not damage the hair...)

Question: 叠瓦癣可发生在什么部位？

(What part of body can imbricate tinea happen?)

Support sentence: 14

BERT_base Answer: 躯干和臀部 (Torso and buttocks)

MC-BERT Answer: 躯干和臀部多见，时久可扩延于四肢 (It often occurs in the torso and buttocks. The disease can spread to the extrmities after a long time.)

CMedBERT Answer: 躯干和臀部多见，时久可扩延于四肢，甚至口唇、甲沟及头皮 (It often occurs in the torso and buttocks. The disease can spread to the extremities after a long time. It can even spread to the lips, nail groove and scalp.)

Medical Entities: 1. 四肢瘫 (quadriplegia) 2. 皮 (skin) 3. 甲沟炎 (paronychia) 4. 甲沟 (nail groove)

Figure 1: Dataset example. MC-BERT and BERT can only predict part of the correct answer. With medical knowledge fused, our CMedBERT model can extract the complete answer. Contents in brackets refer to English translations.

For the dataset, we construct a highly-quality Chinese medical MRC dataset, named the Multi-task Chinese Medical MRC dataset (CMedMRC). It contains 18,153 <*question, passage, answer, support sentence*> quads. Based on the analysis of CMedMRC, we summarize four special challenges for Chinese medical MRC, including *long-tail terminologies, synonym terminology, terminology combination* and *paraphrasing*. In addition, we find that comprehensive skills are required for MRC models to answer medical questions correctly. For answer extraction in CMedMRC, direct *token matching* is required for answering 31% of the questions, *co-reference resolution* for 11%, *multi-sentence reasoning* for 18% and *implicit causality* for 22%. In addition, the answers to the remaining questions (16%) are extremely difficult to extract without rich medical background knowledge.

To address the medical MRC task, we propose the multi-task dynamic heterogeneous fusion network (CMedBERT) based on the MC-BERT (Zhang et al., 2020) model and a Chinese medical knowledge base (see Appendix). The technical contributions of CMedBERT are twofold:

- **Heterogeneous Feature Fusion**: We mimic humans' approach of reading comprehension (Wang et al., 1999) by learning attentively aggregated representations of multiple entities in the passage. Different from the knowledge fusion method used by KBLSTM (Yang and Mitchell, 2017) and KT-NET (Yang et al., 2019), we propose a two-level attention and a gated-loop mechanism to replace the knowledge sentinel, so that rich knowledge representations can be better integrated into the model.
- **Multi-task Learning**: Parameters of CMedBERT are dynamically learned by capturing the relationships between the two tasks via multi-task learning. We regard the semantic similarities between support sentences and answers to questions as the task similarities.

We compare CMedBERT against six strong baselines. For answer prediction, compared to the strongest competitor, the EM (Exact Match) and F1 scores are increased by +3.88% and +1.46%, respectively. Meanwhile, the support sentence prediction task result is increased by a large margin, i.e., +7.81% of EM and +4.07% of F1.

2 Related Work

MRC Datasets and Models. Due to the popularity of the MRC task, there exist many types of MRC datasets, such as span-extraction (Rajpurkar et al., 2016; Yang et al., 2018), multiple choices (Richardson et al., 2013; Lai et al., 2017), cloze-style (Hermann et al., 2015), cross-lingual (Jing et al., 2019; Yuan et al., 2020). For specific domains, however, the number of publicly available MRC datasets remains few, including SciQ (Welbl et al., 2017), Quasar-S (Dhingra et al., 2017) and Biology (Berant et al., 2014). CLiCR (Suster and Daelemans, 2018) is a cloze-style single-task English medical MRC dataset. However, it contains a relatively small variety of medical questions, automatically generated from clinical case reports. Recently, (Li et al., 2020) propose a multi-choice Chinese medical QA dataset, retrieving text snippets as the passage and the task only chooses an existing correct option from candidate set. Our work specifically focuses on the fine-grained medical MRC tasks and deep domain knowledge reasoning, with a manually constructed high-quality dataset released.

The model architecture of MRC mostly takes advantage of neural networks to learn token representations of passages and questions jointly (Qiu et al., 2019a; Liu et al., 2019). The interaction between questions and passages is modeled based on attention mechanisms. The rapid development of

Challenges	Characteristics	Example
Lexical-Level	***Long-tail terminology***	冈上肌肌腱断裂试验是对冈上肌肌腱是否存在断裂进行检查。(*supraspinatus tendon* rupture test is to check whether the supraspinatus tendon is ruptured.)
	Synonym terminology	...本药品对过敏性鼻炎和上呼吸道感染引起的鼻充血有效，可用于感冒或鼻窦炎... (...This medicine is effective for nasal congestion caused by allergic rhinitis and *upper respiratory tract infection*, and can be used for *colds* or sinusitis...)
	Terminology combination	...糖尿病性视网膜病(diabetic retinopathy)是糖尿病性微血管病变中最重要的表现... (...*Diabetic retinopathy (DR)* is the most important manifestation of diabetic microangiopathy...)
Sentence-Level	***Paraphrasing***	***Passage***:...如果在嘴角烂了或结痂的地方进行冷敷，一方面冷敷物品不干净的话会造成感染；另一方面局部温度降低了之后，反而会延缓伤口的愈合。...(...If you apply a cold compress on a rotten or crusted corner of the mouth, on the one hand, if the cold compress is not clean, it will *cause infection*; on the other hand, when the local temperature is lowered, it will *delay the healing of the wound*...) ***Question***:为什么嘴角烂了或结痂不建议进行冷敷？(Why is it *not recommended* to apply cold compresses when the corners of the mouth are rotten or crusted?)

Table 1: Two levels of challenges in processing Chinese medical texts. The blue and underscore contents in brackets indicate why this example belongs to its corresponding "Characteristics" category. (Best viewed in color.)

deep learning leads to a variety of models, such as the QANet (Yu et al., 2018), SAN (Liu et al., 2018). Graph neural networks have been used in MRC recently by modeling the relations between entities in the passage (Ding et al., 2019) and multi-grained tokens representation (Zheng et al., 2020).

Pre-trained Language Models and Knowledge Fusion. Pre-trained language models (e.g., BERT (Devlin et al., 2019), ERNIE-THU (Zhang et al., 2019), K-BERT (Liu et al., 2020a)) have successfully improved the performance of the MRC task, which even exceed the human level in some datasets. This is because these models obtain better token representations and capture lexical and syntactic knowledge in different layers (Guan et al., 2019). For specific domain, there also have some pre-trained models (Beltagy et al., 2019; Zhang et al., 2020).

A potential drawback is that pre-trained language models of open domains only learn general representations, lacking domain-specific knowledge to deepen the understanding of entities and other nouns (Ostendorff et al., 2019) (which are often the answers in span-extraction MRC tasks). Without proper descriptions of such entities in the passage, MRC models often fail to understand and extract key information (Das et al., 2019). Hence, the explicit fusion of knowledge in MRC models is vital for learning context-aware token representations (Pan et al., 2019; Qiu et al., 2019b; Liu et al., 2020b). Instead of encoding entities appearing in both knowledge bases and passages into the MRC model only (Chen et al., 2018), our proposed model encodes all the triples from a medical KG and then employs heuristic rules to retrieve relevant entities. This practice allows the model to acquire deeper understanding of domain-specific terms.

3 The CMedMRC Dataset

In this section, we briefly describe the collection process and provide an analysis on various aspects of the CMedMRC dataset. For more dataset collection and statistical analysis of dataset details, we refer readers to the Appendix A and Appendix B.

3.1 Dataset Collection Process

The dataset collection process follows the SQuAD-style (Rajpurkar et al., 2016) rather than collecting question-answer pairs as in Google Natural Questions (Kwiatkowski et al., 2019). Our medical text corpus is collected from DXY Medical [2], an authoritative medical knowledge source in China. The general data collection process of CMedMRC consists of four major steps: passage collection, question-answer pair collection, support sentence selection and additional answer construction. Briefly speaking, during the passage collection process, we filter the corpus to generate high-quality medical passages. A group of human annotators are required to ask questions on medical knowledge and annotate the answers from these passages. The annotation results are in the form of question-answer pairs. Following SQuAD, we ask annotators to provide 2 additional answers for each question in the DEV and TEST sets.

Since people are concerned about the scientific explanation and sources of answers in the medical domain, we ask annotators to select the support sentence of their annotated answer similar to those of CoQA (Reddy et al., 2019) and QuAC (Choi et al., 2018). Finally, CMedMRC consists of three

The incidence of *thrombotic cell weakness* is more common in childhood with an incidence rate of 0.01 / 10,000...) ***Question***:血小板无力症的发病率约为多少? (What is the incidence rate of *blood platelet weakness?*) ***Answer***: 0.01/万 (0.01/10,000)	16%

Table 2: Reading comprehension skills of models required to answer questions in CMedMRC. The blue and underscore contents in brackets indicate why the sample belongs to its category. (Best viewed in color)

parts: 12,700 training samples, 3,630 development samples and 1,823 testing samples.

3.2 Quality Control

During the dataset collection process, we take the following measures to ensure the quality of the dataset. i) The knowledge source (DXY Medical) contains high-quality medical articles which are written by medical personnel and organized based on different topics in the medical domain. ii) Our annotators are all engaged in medical-related professions rather than annotators with short-term guidance only. iii) We further hire 12 medical experts to check all the collected samples rather than checking a randomly selected sample only. The experts remove out-of-domain questions and questions that are unhelpful to medical practice. In this stage, the experts are divided into two groups and cross-check their judgments.

3.3 Challenges of Understanding Texts

Due to the closed-domain property of our dataset, there are some domain-specific textual features in both passages and questions that the model needs to understand. Based on our observations of the CMedMRC, we summarize the following two major challenges. These challenges can be also regarded as key reasons why some recent state-of-the-art MRC models cannot address the medical MRC task on CMedMRC well.

Lexical-Level: i) Long-tail terminology means these medical terms occur very infrequently and are prone to Out-Of-Vocabulary (OOV) problems. ii) Synonym terminology means that some medical terms may express the same meaning, but there is a distinction between colloquial expressions and professional terms. The above two points require the model to have rich domain knowledge to solve. iii) Terminology combination means these terms are usually formed by a combination of multiple terms, while one term is the attributive of another. This does not only require the model to have domain knowledge but also poses challenges to phrase segmentation in specific domains.

Sentence-Level: Paraphrasing means some words in questions are semantically related to certain tokens in passages, but are expressed differently. Consider the last question in Table 1. When the model tries to answer the "not-recommended" question, it should focus on negative terms ("cause infection" and "delay the healing of the wound").

3.4 Reasoning Skills for MRC Models

We randomly select 100 samples from the development set to analyze what skills the model should have in order to answer the questions correctly. We divide the reasoning skills corresponding to these samples into five major categories, namely token matching, co-reference resolution, multi-sentence reasoning, implicit causality and domain knowledge. Examples are shown in Table 2. It is particularly noteworthy that the fifth type is the need of domain knowledge to answer medical questions. Consider the example:

Passage: ... The incidence of thrombotic cell weakness is most common in childhood with an incidence rate of 0.01 / 10,000...

Question: What is the incidence rate of blood platelet weakness?

Answer: 0.01/10,000.

We know that the *blood platelet* in the question refers to the *thrombotic cell* described in the passage through the medical knowledge base. It shows that the rich information of the knowledge base can help the model obtain a better understanding of domain terms to improve the MRC performance.

4 The CMedBERT Model

4.1 Task Formulation and Model Overview

For our task, the input includes a medical question Q together with the passage P. Let $\{p_1, p_2, \cdots p_m\}$ and $\{q_1, q_2, \cdots q_n\}$ represent the passage and question tokens, respectively. In the answer prediction task, the goal is to train an MRC model which extracts the answer span $\{p_i, p_{i+1}, \cdots p_j\}$ $(0 \le i \le j \le m)$ from P that correctly answers the question Q. Additionally, the model is required to predict the support sentence tokens $\{p_k, p_{k+1}, \cdots p_l\}$ $(0 \le k \le l \le m)$ from P to provide additional medical knowledge and to enhance interpretability of the extracted answers. We constrain that $\{p_k, p_{k+1}, \cdots p_l\}$ must form a complete sentence, instead of incomplete semantic units and the support sentence tokens contain the answer span. The high-level architecture of the CMedBERT model is shown in Figure 2. It mainly includes four modules: BERT encoding, knowledge embedding and retrieval, heterogeneous feature fusion and multi-task training.

4.2 BERT Encoding

This module is used to learn context-aware representations of question and the passage tokens. For each input pair (the question Q and the passage P), we treat $[\langle CLS\rangle, Q, \langle SEP\rangle, P, \langle SEP\rangle]$ as the input sequences for BERT. We denote $\{h_i\}_{i=1}^{m+n+3}$ as the hidden layer representations of tokens, where m and n are the length of passage tokens and question tokens, respectively.

4.3 Knowledge Embedding and Retrieval

In the knowledge bases, relational knowledge is stored in the form of (*subject, relation, object*) triples. In order to fuse knowledge into token representations, we first encode all entities in the knowledge base into a low-dimensional vector space. Here, we employ PTransE (Lin et al., 2015a) to learn entity representations, and denote the underlying entity embedding as e_i. Because existing medical NER tools do not have high coverage over our corpus, we consider five types of token strings as candidate entities: noun, time, location, direction and numeric. Two matching strategies are then employed to retrieve relevant entities from the knowledge base: (i) The two strings match exactly. (ii) The number of overlapped tokens is larger than a threshold. After relevant entities are retrieved, we can fuse the knowledge into contextual representations, introduced below.

4.4 Heterogeneous Feature Fusion

In this module, we fuse heterogeneous entity features retrieved from the knowledge base into the question and passage tokens representations.

Local Fusion Attention. We observe that each token is usually related to multiple entities of varying importance. Thus, we assign different weights to the entity embedding e_j corresponding to the token representation h_i using attention mechanism:

$$\alpha_{i,j} = \frac{exp(e_j^T W h_i)}{\sum_{k=1}^{K} exp(e_k^T W h_i)} \tag{1}$$

where K is the number of entities and $\alpha_{i,j}$ represents the similarity between the j^{th} entity in the retrieved entity set and the i^{th} token. $W \in \mathbb{R}^{d_2 \times d_1}$ where d_1 is the dimension of BERT's output and d_2 is the dimension of entity embeddings. After fusing, the representation of the i^{th} token is: $\bar{e}_i = \sum_{k=1}^{K} \alpha_{i,k} e_k$. However, $\bar{e}_i$ is only related to retrieved entities, not other tokens in the question-passage pair.

Global Fusion Attention. In BERT, the output of the $[CLS]$ tag represents the entire sequence information learned by transformer encoders. We use

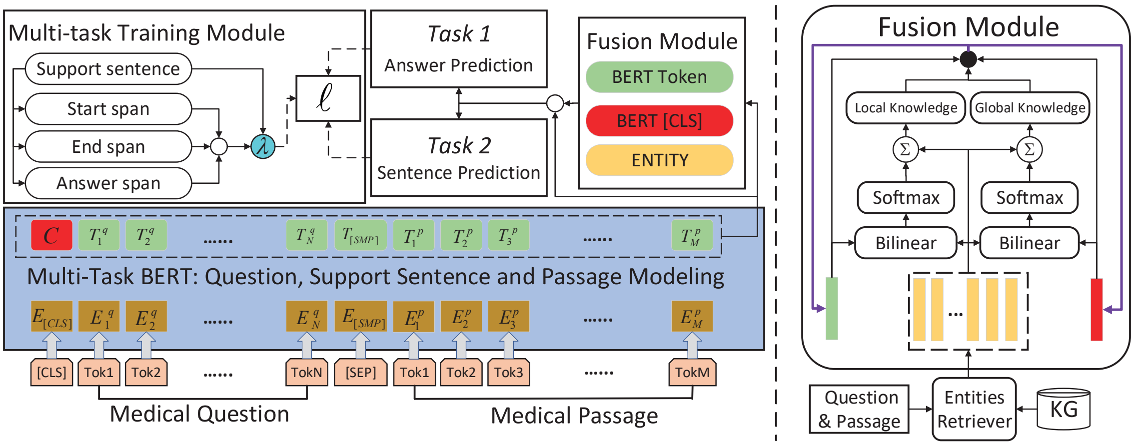

Figure 2: Model overview. The green box and the red box in the heterogeneous feature fusion layer represent the local and global token information, respectively. In the multi-task training module, the model learns the relationship between two tasks by dynamically learning the parameter λ. (Best viewed in color)

the token output $h_{[CLS]}$ to model the knowledge fusion representation of the entire entity collection that each token recalls:

$$\beta_{[CLS],j} = \frac{exp(e_j^T W h_{[CLS]})}{\sum_{k=1}^{K} exp(e_k^T W h_{[CLS]})} \qquad (2)$$

$$\hat{e}_i = \sum\nolimits_{k=1}^{K} \beta_{[CLS],k} e_k \qquad (3)$$

where $\hat{e}_i$ is the global knowledge fusion result corresponding to the i^{th} token.

Gated Loop Layer. In order to fuse local and global results into token representations, we design a gated loop layer. The information of knowledge fusion is filtered through the gating mechanism in each loop of modeling. In the initialization stage, we simply have $h_i^0 = h_i$. In the l^{th} iteration, we have the following update process:

$$G_i^\ell = \sigma(tanh(W[h_i^\ell, \bar{e}_i, \hat{e}_i])) \qquad (4)$$

$$h_i^{\ell+1} = G_i^\ell \odot h_i^\ell \qquad (5)$$

This process runs for L loops and this fusion process output is h_i^L. The loop process mimics the human's behavior of reading the passage repeatedly to find the most accurate answers.

4.5 Multi-task Training

The output layer of CMedBERT is extended from BERT. We first concatenate two types of token representations and calculate the probability of the i^{th} token being selected in the support sentence as follows:

$$o_i = \sigma(W[h_i, h_i^L]),\ p_i^{support} = \sigma(W o_i) \qquad (6)$$

We also calculate its probabilities as the starting and the ending positions of the answer span, respectively:

$$p_i^{start} = \frac{exp(w_1^T o_i)}{\sum_j exp(w_1^T o_j)},\ p_i^{end} = \frac{exp(w_2^T o_i)}{\sum_j exp(w_2^T o_j)}$$

The loss function of the answer prediction task is the negative log-likelihood of the starting and ending positions of ground-truth answer tokens:

$$\mathcal{L}_{\mathcal{A}} = -\frac{1}{N}\sum_{j=1}^{N}(logp^{start}_{y_j^{start}} + logp^{end}_{y_j^{end}}) \qquad (7)$$

For the extraction of support sentences, the loss function is defined by cross-entropy:

$$\mathcal{L}_{\mathcal{S}} = -\frac{1}{N}\sum_{j=1}^{N}\sum_{i=1}^{M}(y_j^{support} logp_i^{support}) \qquad (8)$$

where N is the number of samples and M is the length of input sequences. y_j^{start},y_j^{end} is the starting and ending positions of ground-truth of the j^{th} token. Furthermore, if the token is in the support sentence, the token label $y_j^{support}$ is set to 1, and 0 otherwise.

The representations of the support sentence are related to the positions of the answer. In order to better model the relationship between two tasks, we dynamically learn the coefficient between the loss values of two tasks. Let h_{su} and o_{sp} be self-attended, averaged pooled representations of the support sentence and the answer span. o_{st}, o_{ed} are the start and end position token representations of

Model	Answer				Support Sentence			
	Exact Match (EM)		F1		Exact Match (EM)		F1

Table 3: The results of multi-task prediction (answer and support sentence) over CMedMRC.

the answer, respectively. We have:

$$\gamma_{st}, \gamma_{ed}, \gamma_{sp} = h_{su}[o_{st}, o_{ed}, o_{sp}]^T \tag{9}$$

$$H_A = \sigma(W[\gamma_{st} o_{st}, \gamma_{ed} o_{ed}, \gamma_{sp} o_{sp}]) \tag{10}$$

where $\gamma_{st}, \gamma_{ed}, \gamma_{sp}$ are the weight coefficients between the supporting sentence and the start/end/total token representations of the answer span. The loss value coefficient of two tasks λ and the total loss $\mathcal{L}$ are as follows:

$$\lambda = max\{0, \cos(H_A, h_{su})\} \tag{11}$$

$$\mathcal{L} = \mathcal{L}_A + \lambda \mathcal{L}_S \tag{12}$$

We minimize the total loss $\mathcal{L}$ to update our model parameters in the training process.

5 Experiments and Result Analysis

5.1 Experimental Setups

We evaluate CMedBERT on CMedMRC, and compare it against six strong baselines: DrQA (Chen et al., 2017), BERT_base (Devlin et al., 2019), ERNIE (Zhang et al., 2019), KT-NET (Yang et al., 2019), MC-BERT (Zhang et al., 2020) and KMQA (Li et al., 2020). KT-NET is the first model to leverage rich knowledge to enhance pre-trained language models for MRC. MC-BERT is the first Chinese biomedical pre-trained model fine-tuned on BERT_base. We only use the encoder layer in KMQA removing the answer layer due to the different answer type.

For evaluation, we use EM (Exact Match) and F1 metrics for answer and support sentence tasks. We calculate character-level overlaps between prediction and ground truth for the Chinese language, rather than token-level overlaps for English. To assess the difficulty of solving CMedMRC tasks, we select 100 testing samples to evaluate human performance. Human scores of EM and F1 are 85.00% and 96.69% for answer prediction, respectively.

Model	Exact Match (EM)		F1	
	Dev	Test	Dev	Test
DrQA	34.50%	32.10%	56.67%	56.64%
BERT_base	62.39%	68.29%	81.48%	83.70%
ERNIE	63.18%	66.92%	81.74%	83.41%
KT-NET$^\spadesuit$	64.64%	66.26%	82.48%	83.61%
MC-BERT	63.39%	68.38%	81.86%	83.88%
KMQA	64.37%	67.48%	81.95%	83.74%
CMedBERT$^\clubsuit$	68.00%	72.11%	82.50%	85.33%
CMedBERT$^\spadesuit$	**69.83%**	**72.84%**	**83.02%**	**85.54%**
Human	-	85.00%	-	96.69%

Table 4: Result of single-task (answer prediction). $\clubsuit$ and $\spadesuit$ indicate that CMedBERT uses BERT_base and MC-BERT as the encoder, respectively.

In the implementation, we set the learning rate as 5e-5 and the batch size as 16, and the max sequence length as 512. Other BERT's hyper-parameters are the same as in Google's settings [3]. Each model is trained for 2 epochs by the Adam optimizer (Kingma and Ba, 2015). Results are presented in average with 5 random runs with different random seeds. Other implementation details are in Appendix C.

5.2 Model Results

Table 3 and Table 4 show the multi-task and single-task results on the CMedMRC development and testing sets. CMedBERT has a great improvement compared to four strong baseline models in both tasks. Specifically, our CMedBERT outperforms the state-of-the-art model by a large margin in multi-task results, with **+3.88%EM / +1.46%F1**

---

[3] `https://github.com/google-research/bert`

Model	Answer		Sentence	
	EM	F1	EM	F1
CMedBERT♠	**72.91%**	**85.64%**	**25.51%**	**52.41%**
w/o Local Att.	68.93%	83.89%	19.75%	49.45%
w/o Global Att.	71.71%	84.96%	17.59%	47.01%
w/o λ	71.91%	85.09%	21.09%	48.80%

Table 5: Ablation study of CMedBERT (testing set).

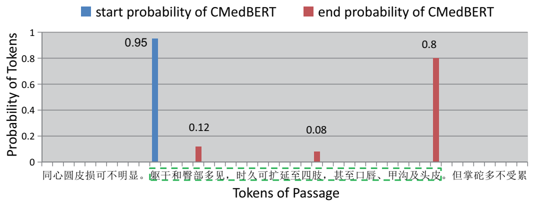
improvements, which shows the effectiveness of our model. Meanwhile, in the support sentence task, our model also has the best performance, improving (**+7.81%EM / +4.07%F1**) over the testing set. In single task evaluation, we remove the support sentence training module and the dynamic parameter for loss function module. Our model improves (**+4.46%EM / +1.66%F1**) over the best baseline model. In addition, we find that using support sentence prediction as an auxiliary task and the pre-training technique in medical domain can further improve the performance of CMedBERT.

5.3 Ablation study

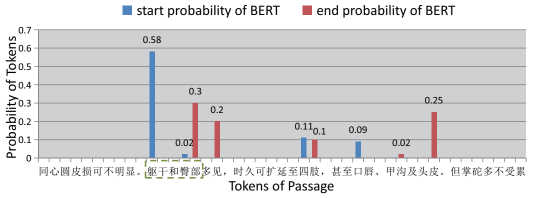
In Table 5, we choose three important model components for our ablation study and report the results over the testing set. When the dynamic parameter λ of the loss function is removed from the model, the performance of the model on two tasks is decreased by (**-1.00%EM and -0.55%F1**) and (**-4.42%EM and -3.61%F1**), respectively. Without local attention, the EM performance in the answer prediction task decreases by (**-3.98%EM and -1.75%F1**). Experiments have shown that the model performs worse without the local fusion attention than without the global fusion attention and the dynamic parameter λ. However, the performance of support sentence task is decreased significantly by (**-7.92%EM and -3.61%F1**) without global fusion attention. It shows that local fusion attention is more important for extracting answer spans, while global fusion attention plays a larger role in support sentence prediction.

5.4 Case Study

In Figure 3, we use our motivation example to conduct a case study. In BERT, we can see that the difference among the probability values of different words is small, especially when predicting the probability of ending positions. The ending position probabilities of token “部” token “皮” are **0.3** and **0.25**, leading the model to extract the wrong answer span. However, in the knowledge retrieval module of CMedBERT, multiple entities representation are fused into the context-aware latent space representation to enhance the medical text semantic understanding. Therefore, in our CMedBERT model, the starting position probability is **0.95** and the end position probability is **0.8**. In this case, the CMedBERT model can easily choose the correct range of the answer span.



(a) Tokens probabilities of **CMedBERT♠**



(b) Tokens probabilities of **BERT_base**

Figure 3: Case study. Predicted answer spans are in the green dotted box. Product of the maximum starting and ending probabilities of CMedBERT is **0.76**, with BERT to be **0.174**.

5.5 Discussion of Support Sentence Task

Compared with the answer prediction task, existing models have poor prediction results on the EM metric in the support-sentence task. In prediction results, we randomly select 100 samples for analysis. We divide the error types into the following three main types (see Appendix): i) starting position cross ii) ending position cross iii) answer substring. The most common error type is the answer substring, accounting for **46%**. In this error type, the predicted result of our model is part of the true result, which shows the model cannot predict long answers completely (Yuan et al., 2020) and reduce the accuracy of the results greatly.

6 Conclusion

In this work, we address medical MRC with a new dataset **CMedMRC** constructed. An in-depth analysis of the dataset is conducted, including statistics, characteristics, required MRC skills, etc. Moreover, we propose the **CMedBERT** model, which can help the pre-trained model better understand domain terms by retrieving entities from medical knowledge bases. Experimental results confirm the effectiveness of our model. In the future, we will explore how knowledge can improve the performance of models in the medical domain.

A Detailed Dataset Construction Process of CMedMRC

A.1 Medical Passage Curation

We use the following rules to obtain 20,000 passages from DXY as the inputs to human annotators:

- We use regular expressions to filter out images, tables, hyperlinks, etc. The English-Chinese translations of medical terms are also provided if the passages contain medical terms in English.
- We find that if we follow (Rajpurkar et al., 2016) to limit the lengths of the passages within 500 tokens, our human annotators could not ask 4 high-quality medical questions easily. Hence, our passage length limit is 1000 tokens.

A.2 Medical Question-Answer Pair Collection

We employ a group of annotators with professional medical background to generate question-answer pairs from the medical passages. Here are some general guidelines:

- We encourage our annotators to ask questions to which the answers are uniformly distributed in different positions of medical passages.
- For each medical passage, we limit the number of questions to 4.
- Each question should be strictly related to the medical domain. When creating the questions, no any part of the texts can be directly copied and pasted from the given medical passages.
- We limit the number of answer tokens to no more than 40.

A.3 Support Sentence Selection

In our dataset, we add an index to each sentence in the passages. Annotators are required to select the support sentence index and mark the range of the answer spans on the user interface.

A.4 Additional Answer Construction

To evaluate the human performance of our dataset and make our model more robust, we collect two additional answers for each question in the development and testing sets. We employ another 12 annotators for answer construction. Since our medical passage is relatively long, we show the questions and the passage contents again on the interface, together with the previously labeled support sentence indices.

Answer Type	Pct.	Example
Numeric	6%	20%
Time/Date	11%	1-3小时 (1-3 Hours)
Person	8%	儿童 (Child)
Location	5%	安徽, 云南, 湖北 (Anhui, Yunnan, Hubei)
Noun Phrase	18%	输卵管炎 (Salpingitis)
Verb Phrase	6%	清洗，干燥和粉碎 (Wash, dry and crush)
Yes/No	1%	不会感染 (Will not infect)
Description	44%	维生素缺乏 (Vitamin deficiency)
Other	1%	严重 (Severe)

Table 6: Statistical results for answer types.

	Train	Dev	Test
# Questions	12,700	3,630	1,823
Avg. tokens of passages	883.64	743.10	745.52
Avg. tokens of questions	15.40	14.85	15.23
Avg. tokens of answers	19.69	18.48	16.57
Avg. tokens of support sen.	57.50	48.19	42.70

Table 7: Statistical results of text length in our CMedMRC dataset.

B Statistical Analysis of the CMedMRC Dataset

B.1 Question and Answer Types

Due to the special characteristics of the Chinese language, the question types cannot be simply classified by prefix words of questions (Rajpurkar et al., 2016). Here, we manually define 8 common question types in the user annotation interface. The statistics of each question type are shown in Figure 4. The first seven question types usually correspond to special medical answers. For example, the *What* type refers to a question on the name of a drug or a disease, which accounts for more than half of the dataset. A third of the questions belong to the types of *How* and *Why*. The statistics of answer types are also shown in Table 6. The proportions of *Noun Phrase* and *Description* types

Error Type	Example	Percentage
Start position cross	***Ground-truth***: 当有急性炎症或者化脓时，会有剧烈疼痛；或者合并牙神经发炎时也会出现剧烈疼痛。 (*When there is acute inflammation or suppuration, there will be severe pain;* or when combined with dental nerve inflammation, there will also be severe pain) ***Prediction***: 有轻微的隐痛或胀痛；当有急性炎症或者化脓时，会有剧烈疼痛； (There is slight dull pain or pain; *when there is acute inflammation or suppuration, there will be severe pain;*)	25%
End position cross	***Ground-truth***: 以下人群高危：乙肝、丙肝病毒慢性感染者；患有类风湿关节、狼疮、硬皮病等免疫性疾病；吸烟。 ......遗传因素对本病起到一定作用。 (The following people are at high risk: people with chronic hepatitis B and C virus infections; suffering from immune diseases such as rheumatoid joints, lupus, and scleroderma; smoking. ...... *Genetic factors play a role in this disease.*) ***Prediction***: 目前认为血管炎是一种自身免疫性疾病，...... 遗传因素对本病起到一定作用。一些药物也可以引起血管炎，还有一些感染（如丙肝、乙肝、梅毒）也可以引起血管炎。 (*At present, vasculitis is considered to be an autoimmune disease, ... Genetic factors play a role in this disease.* Some drugs can also cause vasculitis, and some infections (such as hepatitis C, hepatitis B, and syphilis) can also cause vasculitis.)	21%
Answer substring	***Ground-truth***:这些药物具有抗炎、改善毛细血管通透性、减轻水肿、止痛等作用，同时对日光性皮炎有很好的治疗作用。 (These drugs have *anti-inflammatory, improve capillary permeability, reduce edema, pain relief, etc.*, and have a good therapeutic effect on solar dermatitis.) ***Prediction***:具有抗炎、改善毛细血管通透性、减轻水肿、止痛等作用 (*Anti-inflammatory, improve capillary permeability, reduce edema, relieve pain, etc.*)	46%
Other	***Ground-truth***:抗组胺药第一代的经典代表药「马来酸氯苯那敏」就是一个，它俗称扑尔敏，在多年临床应用中没有发现对胎儿有明显的致畸或其他严重危害。 (One of the classic representative drugs of the first generation of antihistamines is ”Chlorpheniramine Maleate”. It is commonly known as Chlorpheniramine. It has not been found to have obvious teratogenic or other serious harm to the fetus in many years of clinical application.) ***Prediction***:但临床上也有一些药物是经过多年验证，只要注意把握用药时间和药量，即使让孕妇吃也不会有事的 (However, there are also some drugs that have been verified for many years in clinical practice. As long as you pay attention to the time and amount of medication, it will be fine even if pregnant women take it.)	8%

Table 8: Three typical error answer types in support sentence task. The blue and underscore contents in brackets indicate why the sample belongs to its corresponding category.

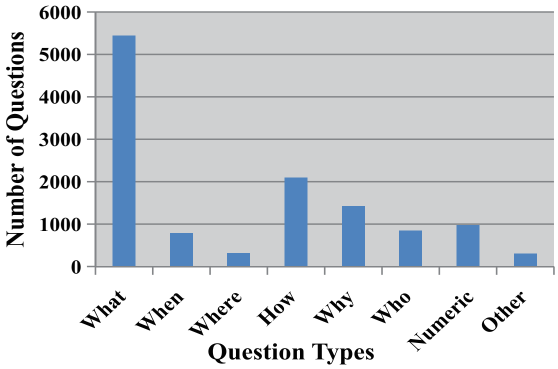

Figure 4: The number of questions that belong to each question types in CMedMRC.

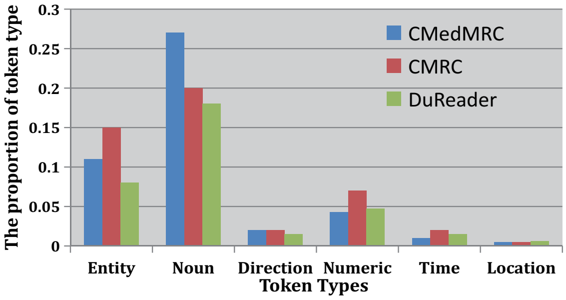

Figure 5: Proportions of entities and five frequently appearing POS tags in three Chinese MRC datasets.

are relatively large. The results are consistent with Figure 4, since most of *What* questions need to be answered with the above two answer types. Table 7 shows the text length of four input data.

B.2 Analysis of Domain Knowledge

We further analyze to what degree there exists domain knowledge in CMedMRC, in terms of medical entities and other terms. In this study, we employ the POS and NER toolkits[4] to tag medical entities and terms from 100 samples in the development set of CMedMRC. We also compare the statistics against those of two other Chinese MRC datasets, namely CMRC (Cui et al., 2019) and DuReader (He et al., 2018). The proportions of entities and five frequent POS tags in the three datasets are summarized in Figure 5. Comparing to the other two open-domain datasets, the proportion of entities in CMedMRC is very high (**11%**). In addition, the proportion of nouns (**27%**) is much higher than the other four POS tags in CMedMRC. The most likely cause is that existing models have difficulty recognizing all the medical terms, and treat them as common nouns. Among the three Chinese datasets, CMedMRC has the largest proportion (**38%**) of nouns and entities. Therefore, it is difficult for pre-trained language models to understand so many medical terms without additional medical background knowledge.

---

[4] We use jieba toolkit with additional medical term dictionaries. See `https://pypi.org/project/jieba/`.

C Experimental Settings

C.1 Medical Knowledge Base and Corpora

The underlying medical knowledge base is constructed by DXY, containing 44 relation types and over 4M relation triples. The KGs embedding trained by TransR (Lin et al., 2015b) on DXY-KG [5] containing 152,508 entities. In knowledge retrieval, the threshold of overlapped tokens is set to half of its own length. The medical pre-training corpora used in ERNIE-THU(Zhang et al., 2019) contains 5,937,695 text segments with 3,028,224,412 tokens (4.9 GB) after pre-processing.

C.2 Additional Training Details

In average, the training time for DrQA, BERT_base, MC-BERT, KT-NET, ERNIE, KMQA and CMedBERT takes 10, 16, 16, 27, 29, 28 and 25 minutes per epoch on a TiTAN RTX GPU. All the models are implemented by the PyTorch deep learning framework [6].

Abstract

Chinese spelling correction (CSC) is an important yet challenging task. Existing state-of-the-art methods either only use a pre-trained language model or incorporate phonological information as external knowledge. In this paper, we propose a novel end-to-end CSC model that integrates phonetic features into language model by leveraging the powerful pre-training and fine-tuning method. Instead of conventionally masking words with a special token in training language model, we replace words with phonetic features and their sound-alike words. We further propose an adaptive weighted objective to jointly train error detection and correction in a unified framework. Experimental results show that our model achieves significant improvements on SIGHAN datasets and outperforms the previous state-of-the-art methods.

1 Introduction

Spelling errors are common in practice and the errors will be enlarged in the downstream tasks. Therefore, Spelling correction is important to many NLP applications such as search optimization (Martins and Silva, 2004; Gao et al., 2010), machine translation (Belinkov and Bisk, 2017), part-of-speech tagging (Van Rooy and Schäfer, 2002; Sakaguchi et al., 2012), etc. Spelling correction requires a comprehensive grasp of word similarity, language modeling and reasoning, making it one of the most challenging tasks in NLP.

In this paper, we focus on Chinese spelling correction (CSC). Unlike alphabetic languages, Chinese characters cannot be typed without the help of input systems, such as Chinese Pinyin (a pronunciation-based input method) or automatic speech recognition (ASR). Thus typos of similarly pronounced characters occur quite often in Chinese text. According to Liu et al. (2010), 83% of Chinese spelling errors on the Internet results from phonologically similar characters. As illustrated in Figure 1, the character "德(de, German)" is incorrectly typed as one of its homophone[1] "的(de, of)".

Wrong:	ta 他 He	**de** 的 of	yu 语 language	shuo 说 speak	de 得	hen 很 very	hao 好 good
Correct:	ta 他 He	**de** 德 German	yu 语 language	shuo 说 speak	de 得	hen 很 very	hao 好 good
Predict without phonetic features:	ta 他 He	**ying** 英 English	yu 语 language	shuo 说 speak	de 得	hen 很 very	hao 好 good

Figure 1: An example of CSC. Each row contains three lines, Chinese pinyin, Chinese character, and gloss. The Chinese character "德(de, German) is incorrectly typed as its homophone "的(de, of)". The CSC model produces a fluent but incorrect sentence by replacing the character with "英(ying, English)", without considering the phonetic similarity.

Traditional methods of CSC firstly detect misspelled characters and generate candidates via a language model, and then use a phonetic model or rules to filter wrong candidates (Chang, 1995; Chen et al., 2013; Dong et al., 2016). To improve CSC performance, studies mainly focus on two issues: 1) how to improve the language model (Wu et al., 2010; Dong et al., 2016; Zhang et al., 2020) and 2) how to utilize external knowledge of phonological similarity (Jia et al., 2013; Yu and Li, 2014; Wang et al., 2018; Cheng et al., 2020). The language model is used to generate fluent sentences and the phonetic features can prevent the model from producing predictions whose pronunciation deviates from that of the original word. As illustrated in Fig. 1, the original *Wrong* sentence contains an incorrect word "的(de, of)". The CSC model produces a fluent but incorrect sentence by replacing "的(de,

[1] In this paper, we ignore the tone of Pinyin, and use homophone to refer to characters with the same pinyin spellings.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2250–2261
August 1–6, 2021.

of)" with "英(ying, English)". However, the pronunciations of these two words are totally different, because the model ignores phonetic features.

Recent studies tackle the issue using deep neural networks. Hong et al. (2019) used a pre-trained language model BERT (Devlin et al., 2019) to generate candidates and train a classifier with phonetic features to select the final correction. Wang et al. (2019) considered CSC as a sequence-to-sequence task and generated candidates from a confusion set [2] instead of the entire vocabulary. These methods take phonetic information as external knowledge but the discrete candidate selection obstructs the language model from learning directly via backpropagation. Zhang et al. (2020) proposed an end-to-end CSC model by modifying the mask mechanism of BERT. However, they did not use any phonological information, which is important for exploring words similarity.

In this paper, we propose a novel end-to-end model for Chinese spelling correction. The model incorporates the phonetic information into language model and leverages the pre-training and fine-tuning framework. Concretely, we first modify the learning task of pre-trained masked language model (Devlin et al., 2019). Rather than replacing characters with an indiscriminate symbol "[MASK]", we mask characters with pinyin or similar pronounced characters. This enables the language model to explore the similarity between characters and pinyin. Then we fine-tune on error correction data with a model of two networks, a detection network predicts the probability of spelling error for each word, and a correction network generates correction by fusing the word embedding and pinyin embedding with the probabilities as input. We jointly optimize the detection and correction networks in a unified framework.

The contributions of this paper are summarized as follows:

- We propose a novel end-to-end CSC model that incorporates phonetic features into language representation. The model encodes the Chinese characters and Pinyin tokens in a shared space.

- The integration of phonological information greatly facilitates CSC. Experimental results on the benchmark SIGHAN datasets show that our method significantly outperforms the previous state-of-the-art methods.

2 Related work

Earier work on CSC follows the pipeline of error detection, candidate generation, and candidate selection (Wu et al., 2010; Jia et al., 2013; Chen et al., 2013; Chiu et al., 2013; Liu et al., 2013; Xin et al., 2014; Yu and Li, 2014; Dong et al., 2016; Wang et al., 2018). These methods mainly employ unsupervised language models and rules to select candidates.

With the development of end-to-end networks, some work proposed to optimize the error correction performance directly as a sequence-labeling task with conditional random fields (CRF) (Wu et al., 2018) and recurrent neural networks (RNN) (Zheng et al., 2016; Yang et al., 2017). Wang et al. (2019) used a sequence-to-sequence framework with copy mechanism to copy the correction results directly from a prepared confusion set for the erroneous words. Cheng et al. (2020) built a graph convolution network (GCN) on top of BERT (Devlin et al., 2019) and the graph was constructed from a confusion set. Zhang et al. (2020) proposed a soft-masked BERT model that first predicts the probability of spelling error for each word, and then uses the probabilities to perform a soft-masked word embedding for correction. However, they did not use any phonetic information.

Our work is most related to Zhang et al. (2020), but with some important differences. We will further discuss this in Section 3.4.

3 Methods

Formally, the Chinese spelling correction task is to map a sequence $\mathbf{x_w} = (x_{w_1}, x_{w_2}, ..., x_{w_N})$ which may contain spelling errors to another correct sequence $\hat{\mathbf{y}} = (\hat{y}_1, \hat{y}_2, ..., \hat{y}_N)$, where both x_{w_i} and $\hat{y}_i$ $(1 \leq i \leq N)$ are Chinese characters.

We propose an end-to-end CSC model which consists of two components, detection and correction. The detection module takes $\mathbf{x_w}$ as input and predicts the probability of spelling error for each character. The correction model takes the combination of the embedding of $\mathbf{x_w}$ and its corresponding pinyin sequence $\mathbf{x_p} = (x_{p_1}, x_{p_2}, ..., x_{p_N})$ as input and predicts the correct sequence $\mathbf{y}$. We propose a method to fuse $\mathbf{x_w}$ and $\mathbf{x_p}$ embeddings using the probability of spelling error as weights.

Following the pre-train and fine-tune framework,

---

[2] Confusion set is a set of similar characters.

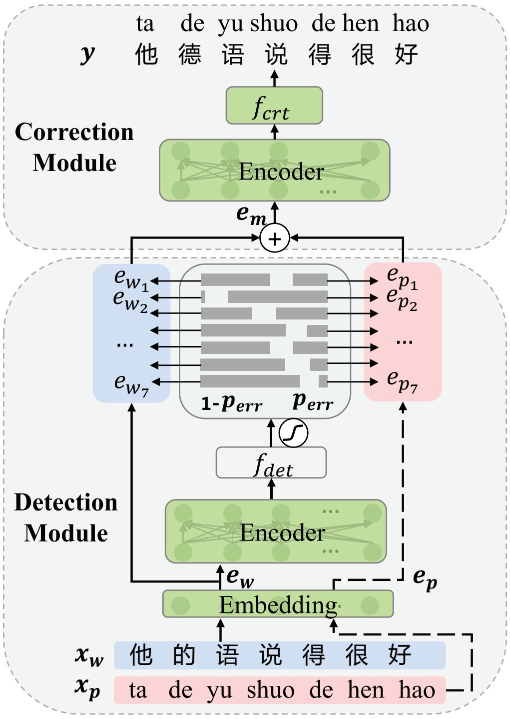

Figure 2: Illustration of our CSC model. Given the input word sequence $\mathbf{x_w}$, the detection module first predicts the probability of error $\mathbf{p_{err}}$ for all the characters. Then the correction module combines the word embedding $\mathbf{e_w}$ and pinyin embedding $\mathbf{e_p}$ to an embedding fusion $\mathbf{e_m}$ and send it to generate the final correction $\mathbf{y}$. The parameters of the Embedding, Encoder, and f_{crt} are initialized by a pre-trained language model with phonetic features. The structure and parameters of the two encoders are identical.

we first pre-train a masked language model, **MLM-phonetics**, by learning to predict characters from similarly pronounced characters and pinyin. Then in fine-tuning, we jointly optimize the the detection and correction modules.

In this section, we first introduce the model architecture (Sec. 3.1), the optimization method (Sec. 3.2) , and the pre-training of **MLM-phonetics** (Sec. 3.3), then summarize the novelty of our method (Sec. 3.4).

3.1 Model Architecture

Fig. 2 shows our model architecture, the lower is the error detection module and the upper is the correction module. Both are built upon transformer.

Detection Module Given a source sequence $\mathbf{x_w} = (x_{w_1}, x_{w_2}, ..., x_{w_N})$, the goal of the detection module is to check whether a character $x_{w_i} (1 \leq i \leq N)$ is correct or not. For this labelling problem, we use class 1 and 0 to label misspelled characters and correct characters, respectively.

We formalize the detection module as follows:

$$\mathbf{y_d} = \text{softmax}(f_{det}(E(\mathbf{e_w}))) \tag{1}$$

where $\mathbf{e_w} = (e_{w_1}, e_{w_2}, ..., e_{w_N})$ is the word embedding of $\mathbf{x_w}$, E is a pre-trained encoder and f_{det} is a fully-connected layer that maps the sentence representation to a binary sequence $\mathbf{y_d} = (y_{d_1}, y_{d_2}, ..., y_{d_N}), y_{d_i} \in \{0, 1\}$.

We use p_{err_i} to denote the probability that character x_{w_i} is erroneous:

$$p_{err_i} = p(y_{d_i} = 1 | \mathbf{x_w}; \theta_d) \tag{2}$$

where θ_d is the parameters of error detection module.

Correction Module The goal of the correction module is to generate correct characters based on the output of the detection module.

We not only use the word embeddings for input, but also use the pinyin embeddings to integrate the phonetic information. Concretely, we first generate the pinyin sequence $\mathbf{x_p}$ using the PyPinyin[3] tool, get the pinyin embedding $\mathbf{e_p}$ from the embedding layer, and fuse it with the word embedding $\mathbf{e_w}$ by linear combination:

$$\mathbf{e_m} = (1 - \mathbf{p_{err}}) \cdot \mathbf{e_w} + \mathbf{p_{err}} \cdot \mathbf{e_p} \tag{3}$$

This combination uses the spelling error probability predicted by the detection module as weights to balance the importance of the semantic feature (character embedding) and phonetic feature (pinyin embedding). We introduce two special cases: If $p_{err_i} = 0$, indicating the character x_{w_i} is detected to be correct, and the model uses only its word embedding in $\mathbf{e_m}$. If $p_{err_i} = 1$, meaning that the character is detected to be erroneous, and the model uses its pinyin embedding.

Finally, the correction results $\mathbf{y}$ is predicted through a fully-conntected layer f_{crt}:

$$\mathbf{y} = softmax(f_{crt}(E(\mathbf{e_m}))) \tag{4}$$

Note that, the parameters of the embedding, the encoder E and the correction network f_{crt} are initialized by **MLM-phonetics**. In the pre-training, **MLM-phonetics** is trained to reconstruct the correct characters from their commonly confused counterparts and their pinyin, thus it can be transformed with the fused embedding.

---

3.2 Jointly Fine-tuning

There are two objectives for our model: to train the detection parameters f_{det} and to adjust the detection and correction modules to achieve an optimal balance. We jointly optimize the detection loss $\mathcal{L}_d$ and the correction loss $\mathcal{L}_c$ that:

$$\mathcal{L}_d = \text{-} \sum_i \log p(\hat{y}_{d_i} | \mathbf{x_w}; \theta_d) \quad (5)$$

$$\mathcal{L}_c = \text{-} \sum_i p(y_{d_i} | \mathbf{x_w}; \theta_d) \cdot \log p(\hat{y}_i | \mathbf{e_m}; \theta_c) \quad (6)$$

where θ_d and θ_c is the parameter of the detection and correction module, respectively. $\hat{y}_{d_i}$ is the ground-truth detection result and y_{d_i} is the prediction by the detection module, both of them is a binary value of 0 or 1.

In particular, the correction loss is the negative log likelihood weighted by the probability of the detection result, $p(y_{d_i} | \mathbf{x_w}; \theta_d) \in (0.5, 1]$. This is to distinguish between the responsibilities of the two tasks. When the detection module gives a low-confidence prediction, that is, $p(y_{d_i} | \mathbf{x_w}; \theta_d)$ approaches 0.5, $\mathbf{e_m}$ fuses the semantic features and phonetic features with similar weights. But we hope that the detection module could provide clear judgement of right or wrong, i.e., $p(y_{d_i} | \mathbf{x_w}; \theta_d)$ approaches to 1, so that $\mathbf{e_m}$ can be dominated by either semantic features or phonetic features. In such case, the correction of error words will not be interfered by the semantic features in $\mathbf{e_m}$, and vice versa. Therefore, we penalize the low-confidence prediction given by the detection module. Concretely, when the probability of the detection result is low, $\mathcal{L}_c$ decreases and the model will focus more on optimizing $\mathcal{L}_d$. And when the detection probability is high, the model optimizes $\mathcal{L}_d$ and $\mathcal{L}_c$ at balance.

The adaptive weighting objective enables us to jointly train our model with the sum of the two loss functions:

$$\mathcal{L} = \mathcal{L}_d + \mathcal{L}_c \quad (7)$$

We compare different weighting strategies with our adaptive weighting in experiments.

3.3 Pre-training MLM-phonetics

In this section, we introduce our pre-trained language model, **MLM-phonetics**, that 1) integrates phonetic features and 2) solves the problems of using standard masked language model in our CSC architecture.

The pre-train and fine-tune framework (Devlin et al., 2019) has been proven effective in facilitating downstream NLP tasks including sentence classification, question answering, etc. But the inputs of these tasks are of identical distribution with pre-training, while the input sentences in CSC are with errors, which are different from the pre-training samples. Some work thus far side-stepped the input divergence by avoiding to input error sentences directly to pre-trained models. For example, Zhang et al. (2020) use a bidirectional-GRU for error detection before a BERT-based correction network.

In order to take advantage of the pre-training technique, we modify the pre-training task. In the pre-training of a standard mask language model (**MLM-base**), the model is trained by predicting 15% randomly selected characters which are replaced with the [MASK] token, random character, and themselves at the sampling rate of 80%, 10%, and 10%, respectively.

To avoid input divergence and integrate phonetic features, we propose two pre-training replacements: *confused-Hanzi*[4] and a *noisy-pinyin*. We use Figure 3 to illustrate these replacements:

- [MASK] replacement trains the reasoning ability of the language model by restoring masked characters only according to the context.

- *Random Hanzi* replacement trains **MLM-base** to correct words from random ones (e.g, to predict “得(de)” from “不(bu)”), which is a more difficult task compared with correcting from similarly pronounced characters. However, due to the different input distribution, this strategy is of little help to CSC.

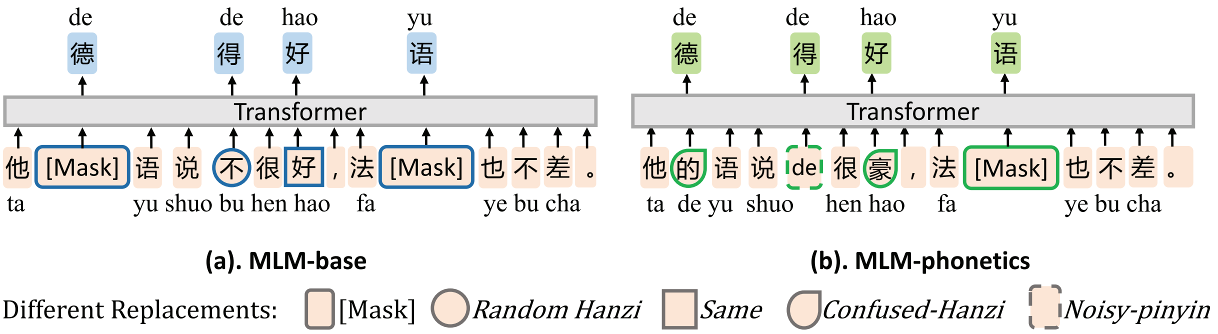
- *Same* replacement encourages **MLM-base** to copy the input characters (e.g, the replacement “好(hao)”).

- *Confused-Hanzi* replacement trains **MLM-phonetics** to correct words to their commonly confused characters in the confusion set (e.g, to predict “豪(hao)” to “好(hao)”). It provides the model a way to access samples with typo.

- *Noisy-pinyin* replacement trains **MLM-phonetics** to predict the original characters from pinyin of their commonly confused characters in the confusion set (e.g, to predict

---

[4] *Hanzi* is a transliteration meaning Chinese characters.



(a). MLM-base **(b). MLM-phonetics**

Figure 3: An example of the different replacement strategy for **MLM-base** and **MLM-phonetics**.

"得(de)" from "de"). It helps clustering similarly pronounced characters with their corresponding pinyin tokens.

The first three replacements are used for pre-training standard **MLM-base** and the last two are proposed in our method to model the similarity between characters and pinyin tokens. In the pre-training of **MLM-phonetics**, our data generator randomly chooses 20% of token positions in the training samples. If the i^{th} token is chosen, we empirically replace it with (1) the [MASK] token 40% of the time, (2) the *noisy-pinyin* of this token 30% of the time, and (3) a *confused-Hanzi* from its confusion set 30% of the time[5]. Then **MLM-phonetics** is trained to predict the original sentence from the sentence with replacements.

The two proposed pre-training tasks can smooth out the input divergence between pre-training and fine-tuning the CSC model. The *Confused-Hanzi* replacement simulates the input of the detection module and the two replacements together facilitates the pre-trained model to adapt to the fused embedding (Eq. 3).

3.4 Novelty of our method

Our method is most related to Zhang et al. (2020), but different in the following aspects.

First, our model combine the embedding of pinyin and character to prevent information loss, which is more like the human correction process that predicts correction with the pronunciation of the problematic words. On the contrary, Zhang et al. (2020) has to add residual connection before emitting the final correction, or it will forget the phonetic information of the error words after combining their embedding with [MASK].

Second, we share the pre-trained encoder in detection and correction by proposing new pre-training tasks, while Zhang et al. (2020) took an un-pre-trained bidirectional-GRU in detection to avoid the input divergence between pre-training and fine-tuning.

Third, we propose an adaptive weighting policy in jointly training the error detection and correction. This policy encourages the model to produce clear detection results, making the fused embedding dominated by either semantic features or phonetic features, which is close to the pre-training task. On the contrary, Zhang et al. (2020) proposed to linearly combine the detection and correction loss with a fixed hyper-parameter.

4 Experiments

We carry out experiments on the SIGHAN dataset, a benchmark for CSC.

4.1 Data Processing

The training set consists of two parts: 1) A pre-training corpus of 0.3 billion Chinese sentences, and 2) A CSC training corpus of 281K sentences pairs. The first corpus is used for pre-training **MLM-phonetics**, and the latter is used to fine-tune the CSC model initialized by **MLM-phonetics**.

For the pre-training corpus, we collect a variety of data, such as encyclopedia articles, news, scientific papers, and movie subtitles from a search engine. The CSC training data used in our experiments is the same as Wang et al. (2019) and Cheng et al. (2020), including three human-annotated training datasets (Wu et al., 2013; Yu et al., 2014; Tseng et al., 2015) and an automatically generated dataset with the approach proposed in Wang et al. (2018)[6].

---

[5] For multiple characters in the confusion set, select them/their pinyin randomly in the replacement.

[6] See Appendix A for training corpus detail.

Table 1: The performance on SIGHAN13, SIGHAN14, and SIGHAN15 testset. *Soft-Masked BERT** is our reproduction of *Soft-Masked BERT* using the same training data as in our method, while *Soft-Masked BERT* was trained on an in-house dataset containing 5 million sentences and their counterparts with automatically generated errors, as reported in Zhang et al. (2020), where the authors only provided their results on SIGHAN15.

4.2 Model Settings

We compare our methods with previous state-of-the-art methods:

- *FASPell* (Hong et al., 2019) first generates candidates for each character in the input sentence through a pre-trained MLM, then uses a filtering model with visual and phonetic similarity features to select the best candidate.

- *Pointer Networks* (Wang et al., 2019) uses a seq2seq system based on the constraint that each correct word is contained in the confusion set of the erroneous character.

- *Soft-Masked BERT* (Zhang et al., 2020), for each token in the sentence, linearly combines its embedding with the embedding of [MASK], and predicts the error character based on a fine-tuned masked language model.

- *SpellGCN* (Cheng et al., 2020) incorporates two similarity graphs into a pre-trained sequence-labeling model via graph convolutional network. The two graphs are derived from a confusion set and correspond to pronunciation and shape similarities.

- *ERNIE* (Sun et al., 2020) directly finetunes the standard masked language model on the CSC training data.

- **MLM-phonetics**, our proposed method uses an end-to-end system based on a pre-trained language model with phonetic features.

Pointer Network uses LSTM in both encoder and decoder. All the other methods take CSC as a sequence tagging problem with a pre-trained 12-layer Transformer as encoder. *FASPell* and *Soft-Masked BERT* use the pre-trained BERT, while *ERNIE* and **MLM-phonetics** use the pre-trained ERNIE for initialization[7]. We use the sentence-level and character-level f1-score to evaluate different systems. At the sentence-level, a prediction is considered correct only if all the errors in the sentence are detected or corrected. Therefore, sentence-level evaluation is stricter and results in lower scores. Following Cheng et al. (2020), we

---

[7] The difference between BERT and ERNIE in fine-tuning is trivial, see Appendix B for detail.

use the scripts in (Hong et al., 2019) to calculate the sentence-level results.

4.3 Overall Results

Table 1 shows the detection and correction performance on three SIGHAN test sets. All the methods provide sentence-level results except *Pointer Network*, which provides the results at the character-level.

It shows that our method, **MLM-phonetics** significantly outperforms the other systems. For example on SIGHAN15, the detection F1-score has 2.5 point improvement (77.7→80.2) and the correction F1-score has 1.6 point improvement (75.9→77.5) compared with the previous best method *SpellGCN*. Our method also achieves over 6 points improvement over *ERNIE* in correction f1-score, verifying the effectiveness of our pre-training strategy.

All the listed methods except *Pointer Networks* use pre-trained model for initialization, but only *FASPell*, *SpellGCN* and our method take phonetic information into consideration. *FASPell* uses isolated phonetic features and language model, which inevitably lead to performance decline. *SpellGCN* incorporates phonetic knowledge into the language model by building a graph convolutional network on the top of BERT. It is proven to be effective, but the graph is derived from a prepared confusion set. Therefore, the performance of the model depends on the completeness of this set. As shown in Table 1, the precision of *SpellGCN* is close to **MLM-phonetics**, but there is a significant gap in the recall. Our method, with the help of additional Pinyin tokens, integrates phonetic features in word embedding, thus increasing the generalization of the model. *Soft-Masked BERT* corrects sentences without phonetic features. Its detection and correction performance is inferior to ours. This may partly due to the lack of phonological similarity, as well as the difference in model architecture. It is also notable that the training data of our method *MLM-phonetics* is consistent with that of *Pointer Networks*, *Soft-Masked BERT**, *SpellGCN* and *ERNIE*, but *Soft-Masked BERT* and *FASPell* use different training data. See Appendix C for some case studies.

4.4 Pre-training Tasks

In order to analyze the effect of the three replacement tasks ([MASK], *Confused-Hanzi*, *Noisy-pinyin*) in the pre-training of **MLM-phonetics**, we take three models for comparison, each trained by only two of the three tasks with equal probability.

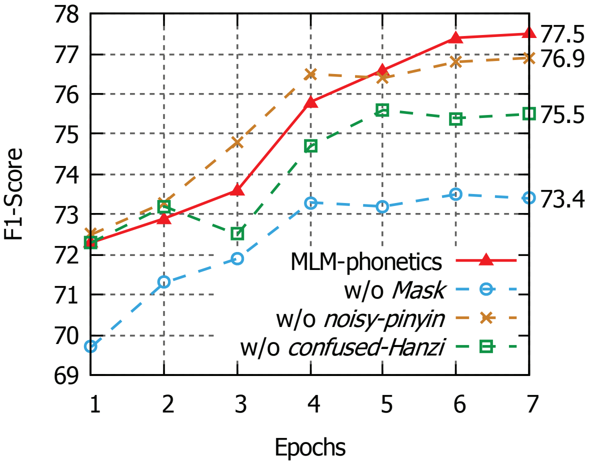

Figure 4: The Sentence-level Correction F1-score of 4 pre-trained models evaluated on SIGHAN15 testset.

During fine-tuning, the testing curves on SIGHAN15 are plotted in Figure 4. **MLM-phonetics** shows the best performance, achieving the correction f1-score of 77.5 in the 7^{th} epoch. However, it's interesting that its performance is inferior to the pre-trained model without (*w/o*) *noisy-pinyin* at the beginning. This is caused by the pre-training & fine-tuning discrepancy.

The model *w/o noisy-pinyin* only learns to predict the original characters from [MASK] and confused-Hanzi in pre-training. So the pinyin embedding has not been initialized until fine-tuning. Therefore, the pinyin embedding can be viewed as noise in the embedding fusion of the fine-tuning stage. Such embedding is close to its pre-training input distribution, thus the pre-trained model *w/o noisy-pinyin* performs good at the beginning. **MLM-phonetics**, on the contrary, is trained to reconstruct words based on either Hanzi embedding or pinyin embedding in the pre-training. But it needs to predict from a fusion of them in fine-tuning, thus it requires longer training time for adaption. As the training continues, the model benefits from the embedding fusion and finally achieves 0.6 points improvements (76.9→77.5) over the pre-trained model *w/o noisy-pinyin*.

Besides, the other two pre-trained models perform relatively low. The pre-trained model *w/o confused-Hanzi* suffers from input divergence in pre-training & fine-tuning. The model is not trained to correct words from spelling errors until the fine-tuning stage. The pre-trained model *w/o* [MASK] performs the worst, which shows the importance of

Objective		**Detection**			**Correction**		
		Prec.	**Rec.**	**F1**	**Prec.**	**Rec.**	**F1**

using [MASK] prediction to enhance the semantic comprehension.

4.5 Balance the objective of detection and correction

Next, we explore the impact of the weighting strategy that balances the two objectives in fine-tuning. In our CSC model, both the detection and correction are sequence labeling tasks. We use the detection probability to balance the two tasks, as depicted in Eq.(6). On the contrary, Zhang et al. (2020) balances the two tasks with a fixed hyper-parameter λ: $\lambda\mathcal{L}_{uc}+(1-\lambda)\mathcal{L}_d$, in which $\mathcal{L}_{uc}$ is the un-weighted negative log-likelihood of correction:

$$\mathcal{L}_{uc} = -\sum_i \log p(y_i|\mathbf{e_m};\theta_c) \tag{8}$$

The results of the two strategies are shown in Table 2. Our method is generally better than the results of using a fixed hyper-parameter for combination. Among the three systems with fixed hyper-parameters, the system with $\lambda = 0.8$ achieves the highest correction f1-score and the one with $\lambda = 0.5$ achieves the best detection f1-score. Note that the detection F1-score is evaluated based on the correction result (i.e., only the corrected characters are regarded as detected), rather than based on the prediction of the detection module. Therefore, it's not weird to find that the setting $\lambda = 0.2$ costs much on detection but its detection f1-score is the worst. This also provides us a hint that the detection and correction need to be coordinated. Setting λ to 0.2 may improve the performance of the detection module, but a poor correction module will bring down the final detection performance.

Our method, on the contrary, balances the $\mathcal{L}_c$ and $\mathcal{L}_d$ according to the confidence given by the detection module dynamically and achieves the best performance. Compared with the fixed hyper-parameter strategy with $\lambda = 0.8$, our F1 scores have 1.6 points (78.6→80.2) improvement in detection and 0.9 points (76.6→77.5) improvement in correction, indicating the effectiveness of our dynamic balance strategy in alleviating the unbalanced problem between the two tasks.

4.6 Error Analysis

To analyze the prediction errors, we collect the incorrectly predicted samples and classify them into two classes:

- *Detection Error*: the detection module produces an error prediction, i.e. $y_{d_i} \neq \hat{y}_{d_i}$.
- *Correction Error*: the detection module generates a correct prediction, but the correction module fails to generate the right character, i.e., $y_{d_i} = \hat{y}_{d_i}$ and $y_i \neq \hat{y}_i$.

We summarize the two classes on the SIGHAN15 testset and the proportion of the *Detection Error* and *Correction Error* is 83.6% and 16.4%, respectively. This reveals that most of the false predictions are *Detection Errors*.

We further explore the reason behinds the poor detection performance. Is it mainly because many errors cannot be detected (*false negative* errors), or does the detection module make incorrect predictions of errors (*false positive* errors)? We decompose the 83.6% detection errors into the two types and find that *false negative* errors and *false positive* errors account for 41.1% and 42.5% respectively. The proportions of the two error types are almost equal. A possible reason is that some homonyms are indistinguishable, such as “的”, “地”, and “得”. All of the three characters have the pronunciation of “de” and it makes sense to use any of these candidates in many sentences, phonetically or semantically. This problem has also been proposed in Cheng et al. (2020), which takes further fine-tuning to reduce the indistinguishability. In this case, the detection module produces many predictions that are different from the ground-truth results, affecting the detection performance.

5 Conclusion

In this paper, we propose a novel end-to-end framework for CSC with phonetic pre-training. Inspired by traditional pipeline systems, the model incorporates phonetic information of characters into pre-training. We first pre-train a masked language model with phonetic features to improve the model's ability to understand sentences with misspelling and model the similarity between characters and pinyin tokens. Further, we propose an end-to-end framework to integrate detection and correction in one model. Experiments on a benchmark dataset show that our model significantly outperforms the previous state-of-the-art. The CSC model with phonetic features can be used to reduce errors for speech recognition and translation systems. In the future, we are going to apply CSC to more challenging scenarios, such as streaming ASR error correction for automatic simultaneous translation, as well as variable-length correction.

A Datasets

All of our used datasets are listed in Table 3. The Pre-training corpus includes 0.3 billion sentences and the remaining four corpora contain 281K <error, correct> sentence pairs in sum[8]. The three SIGHAN datasets are human-annotated and the (Wang et al., 2018) is generated automatically with ASR and OCR technique.

Datasets		#Lines	Avg. Length	#Errors
Training Corpus				
	Pre-training corpus	0.3B	29.37	
	Wang et al. (2018)	271,329	44.4	382,704
	SIGHAN 2013	350	49.2	350
	SIGHAN 2014	6,526	49.7	10,087
	SIGHAN 2015	3,174	30	4,237
	Total	281,379	44.4	397,378
Test sets

B Difference between BERT and ERNIE

We evaluate the performance of two pre-trained models, BERT (Devlin et al., 2019) and ERNIE (Sun et al., 2020), on the SIGHAN testset. For both of them, we use the released model[9] of the base version (12 layers with the hidden size of 768).

The zero-shot performance is listed in Table 4. In this setup, we directly use the released model for error correction without fine-tuning. It shows that ERNIE has a prominent advantage over BERT in both detection and correction. This is caused by a prediction problem of BERT that for most of the time, BERT corrects the first character to be the period symbol (“。”). We guess that this is because of a Chinese data pre-processing bug of BERT, that is, when a paragraph is divided into multiple sentences, it always divides the ending period of a sentence into the beginning of the next one. Therefore, a lot of sentences incorrectly predicts the beginning character to be the period symbol.

Then we finetune the 281K CSC training data on the two pretrained models. Table 5 shows the performance of the two models is basically the same. The difference between BERT and ERNIE is +0.4, -2.0, and +1.6 on SIGHAN13, SIGHAN14, and SIGHAN15, respectively. Therefore the difference between BERT and ERNIE after fine-tuning is trivial.

	Detection			Correction		
	Prec.	**Rec.**	**F1**	**Prec.**	**Rec.**	**F1**
SIGHAN13						
BERT	4.73	4.74	4.74	3.2	3.2	3.19
ERNIE	56.0	40.9	47.3	33.3	24.3	28.1
SIGHAN14						
BERT	4.7	8.8	6.1	2.6	4.9	3.4
ERNIE	63.5	27.2	31.1	18.8	14.1	16.1
SIGHAN15						
BERT	9.4	15.6	11.7	6.3	10.4	7.8
ERNIE	55.8	33.9	42.2	30.8	18.7	23.3

Table 4: The performance of Zero-Shot BERT and ERNIE.

	Detection			Correction		
	Prec.	**Rec.**	**F1**	**Prec.**	**Rec.**	**F1**
SIGHAN13						
BERT	73.3	70.4	71.8	71.7	68.9	70.2
ERNIE	76.6	71.9	74.2	73.0	68.5	70.6
SIGHAN14						
BERT	63.3	71.0	67.0	61.3	68.7	64.8
ERNIE	63.5	69.3	66.3	60.1	65.6	62.8
SIGHAN15						
BERT	68.3	77.8	72.7	65.5	74.6	69.8
ERNIE	73.6	79.8	76.6	68.6	74.4	71.4

Table 5: The performance of pre-trained models with fine-tuning.

C Ablation Study

We compare our method with *ERNIE* and *Soft-Masked BERT* trained on identical datasets shown in Table 3. Table 6 and Table 7 show that *MLM-phonetics* performs better at generating semantically coherent and similar sounding corrections.

Table 7: Another example from the SIGHAN15 test set. Again, *MLM-phonetics* predicts phonetically similar and semantically coherent correction. But both *ERNIE* and *Soft-Masked BERT** replace “斑”(ban) with “方”(fang), which is semantically coherent but sounds greatly different.

Multi-Lingual Question Generation with Language Agnostic Language Model

Bingning Wang, Ting Yao, Weipeng Chen, Jingfang Xu and Xiaochuan Wang
Sogou Inc.
Beijing, China
`{wangbingning,yaoting}@sogou-inc.com`

Abstract

Question generation is the task of generating coherent and relevant question given context paragraph. Recently, with the development of large-scale question answering datasets such as SQuAD, the English question generation has been rapidly developed. However, for other languages such as Chinese, the available training data is limited, which hinders the development of question generation in the corresponding language. To investigate the multi-lingual question generation, in this paper, we develop a language-agnostic language model, which learns the shared representation from several languages in a single architecture. We propose an adversarial training objective to encourage the model to learn both language-specific and language-independent information. We utilize abundant monolingual text to improve the multi-lingual question generation via pre-training. With the language-agnostic language model, we achieve significant improvement in multi-lingual question generation over five languages. In addition, we propose a large-scale Chinese question generation dataset containing more than 220k human-generated questions to benefit the multi-lingual question generation research.

1 Introduction

Question Generation (QG), also known as learning to ask, has attracted a lot of research interest in recent years. QG is regarded as the dual task of machine reading comprehension (Yuan et al., 2017; Xiao et al., 2018). Rather than answering a given question, learning to ask a coherent, relevant, and non-trivial question also requires a deep understanding of the context (Davey and McBride, 1986; Graesser et al., 2010), providing a good testbed for natural language understanding.

Conventional methods for question generation rely heavily on heuristic rules, and the standalone dependency parsing tool is needed to generate handcrafted templates (Mostow and Chen, 2009; Heilman and Smith, 2010; Rus et al., 2010; Hussein et al., 2014; Dhole and Manning, 2020). In recent years, with the development of deep learning and large-scale QA datasets, more and more neural network model has been proposed, which is also referred as neural question generation. Neural QG shows great advantage compared with previous rule-based systems in terms of both fluency and diversity of the generated questions (Duan et al., 2017; Yuan et al., 2017).

However, most progress in QG is made in English. For other languages such as Hindi, the lack of large-scale QG data limits its development. Recently, multi-lingual and cross-lingual language understanding has been studied in several NLP tasks, such as question answering (Liu et al., 2019; Cui et al., 2019), summarization (Zhu et al., 2019), natural language inference (Conneau et al., 2018), etc. For QG, Kumar et al. (2019) demonstrate that for low-resource Hindi, incorporating the large-scale English SQuAD (Rajpurkar et al., 2016) dataset could boost the QG result a lot.

For multi-lingual QG, a key factor is to learn a model that could transfer knowledge across different languages. In this paper, we propose a language-agnostic language model: it consists of the specific low-level module for each language, and a shared high-level module for multi-lingual information aggregation. Separating the language model into two levels enables us to learn the language-specific information in each language and the common information shared among languages. In this way, the knowledge in multi-lingual QG could be transferred via the high-level module.

For the language-agnostic language model, however, the distributed representation of the low-level module could be easily mixed with the language information, which makes the high-level module con-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2262–2272
August 1–6, 2021.

tain some unnecessary language-specific features that are too specific to transfer across languages. Inspired by previous works on transfer learning (Chen et al., 2017; Liu et al., 2017), we propose an adversarial training objective to decouple the low-level module with the high-level module, which prevents the private and shared latent feature spaces from interfering with each other, making the high-level module language-invariant, thus achieving better transferability for different languages.

To get a better initialization for our model, we develop two self-supervised methods to pre-train our model on abundant monolingual text. We apply our model to five languages QG tasks that have human-labeled QG datasets. The experimental results demonstrate that all languages QG could benefit from the multi-lingual training. Our models surpass previous monolingual or multi-lingual QG methods by a large margin, even in zero-shot learning where we had no training data in the low-resource languages, our model achieves satisfactory results by merely trained on English dataset, which shows a promising transferability of the proposed model.

Besides, we also propose a large-scale Chinese QG dataset containing more than 220k human-labeled questions. We hope the proposed Chinese dataset could benefit the community for more comprehensive multi-lingual QG research. The codes and proposed datasets are available at `https://github.com/benywon/LALM`.

Our contributions are summarized as follow:

- We propose a novel language-agnostic language model which decouples the language specific and language independent information in QG.
- The proposed model achieves significant improvement over previous models in multi-lingual QG, and we analyze the transferability in multiple languages.
- We release a large-scale human labeled Chinese QG dataset containing more than 220k questions. To our best knowledge, this is the largest specific question generation dataset so far.

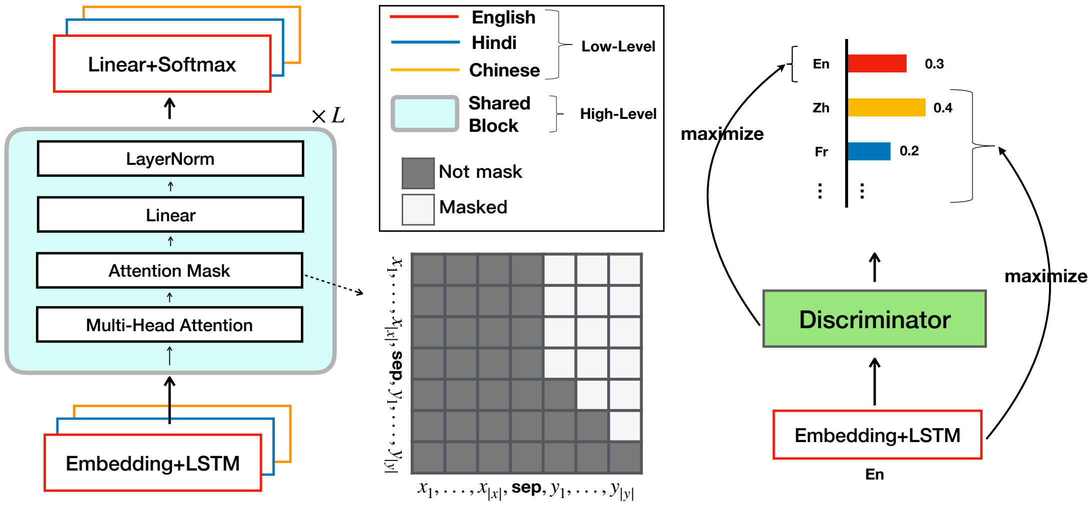
2 Related Work

Question generation has received increasing attention from the research community. Traditional QG systems are mostly rule-based, which sometimes utilizing off-the-shelf tools to get the syntactic structure, dependency relations, and semantic role of the passage (Mostow and Chen, 2009; Heilman and Smith, 2010). First, the target answers are generated using rules or semantic roles, next, low-quality questions are generated using hand-crafted rules or templates. Finally, the generated questions are ranked by features such as keyword matching degree or sentence perplexity (Hussein et al., 2014). The main drawbacks of these symbolic systems are that the rules and templates are expensive to manually create, and lack diversity.

With the development of deep learning and large-scale question answering datasets, motivated by neural machine translation, Du et al. (2017) proposed a sequence to sequence (seq2seq) architecture combined with attention mechanism, achieving a promising result on QA dataset SQuAD. Since then, many works have been proposed to extend the preliminary framework with rich features, such as named entity tags (Zhou et al., 2017) or answer position features (Duan et al., 2017), and incorporate copy mechanism to copy words from the context paragraph (Song et al., 2018). Other types of models are also introduced such as graph neural networks (Chen et al., 2019) or Transformer (Scialom et al., 2019). However, most of these works are focus on English QG and have not been validated in other languages.

Multi-Lingual language generation. Duan et al. (2019) translated documents as weakly supervised training data for zero-shot multi-lingual abstractive summarization. Chi et al. (2019) proposed a multi-lingual pre-training method that can transfer monolingual supervision signals to other pre-trained languages. Zhu et al. (2019) adopt large-scale supervised data from existing monolingual summarization datasets via translation strategy to perform multi-lingual summarization. Kumar et al. (2019) also proposed a multi-lingual question generation methods based on Transformer, they proposed a small Hindi QG dataset and improved the QG result on Hindi by training with additional English data.

Compared with the previous multi-lingual methods, our method directly separates the language-dependent module and language-independent module. We propose an adversarial decoupling module to improve the adaptive ability of the model. Besides, our model could be properly pre-trained by monolingual data, which obviates the need to construct the back-translation or pseudo-parallel data.



(a) (b) (c)

Figure 1: (a) The whole architecture of the proposed language-agnostic language model. It consists of the low-level language understanding module (Embedding+LSTM) and the high-level semantic understanding module (Transformer block), followed by a projection and softmax module. (b) The attention mask matrix M in the high-level module, $M_{i,j}$ means whether the word in position i could attend to the word in position j. The gray cells are allowed to attend and the others are masked to forbid attention. (c) The adversarial decoupling module where the discriminator tries to maximize the probability of the corresponding language while the generator (low-level module) tries to minimize it.

3 Language-agnostic Language Model

The Language-agnostic language model (LALM) consists of the low-level module and the high-level module, the whole architecture is illustrated in Figure 1(a) we describe it below.

3.1 Low-Level Module

The low-level module is built to perform the basic language understanding. In this paper, we adopt the LSTM (Hochreiter and Schmidhuber, 1997) encoder as the low-level language understanding module[1]. LSTM processes text in sequential order and embeds the language information into dense representations. We adopt the uni-directional LSTM in this paper to make the model auto-regressive.

For the language-agnostic language models, each language has its specific word embeddings and specific low-level language understanding LSTMs. This is different from some previous multi-lingual methods that a shared or aligned word embedding is utilized for different languages (Conneau et al., 2018; Lample and Conneau, 2019). Separating the language understanding module enables us to model specific linguistic characteristics in different languages. In Section 4, we will show that separating the low-level module for each language could benefit a lot for multi-lingual QG.

3.2 High-Level Module

The low-level module is built to perform the basic linguistic understanding, and the high-level module is built on top of the low-level module to perform higher-level information aggregation, which requires higher model capacity. In this paper, we use the Transformer (Vaswani et al., 2017) model as the high-level module.

The Transformer, with the core building-block called multi-head attention, has shown great advantages in representing languages in many NLP tasks. Current state-of-the-art models in natural language understanding benchmark GLEU[2] (Wang et al., 2018) are almost Transformer-based. In this paper, we focus on QG which is a sequence-to-sequence problem, so we adopt the mask operation similar with (Dong et al., 2019), which is illustrated in Figure 1(b). For a pair of sequence $(\mathbf{x}, \mathbf{y})$ where $\mathbf{x} = x_1, ..., x_{|x|}$ is the source, and $\mathbf{y} = y_1, ..., y_{|y|}$ is the target, we concatenate them together with a special token `<sep>`, forming a single sequence with length $|\mathbf{x}| + |\mathbf{y}| + 1$. We want all the positions in the source $\{1, 2, ..., |\mathbf{x}|\}$ to attend to each other so we can obtain the bi-directional representations

---

[1] In fact, we also conduct experiments on adopting other types of models as the low-level module such as Transformer or GRU, but the result is not comparable with the LSTM.

[2] `https://gluebenchmark.com/`

of the source, and all the positions in the target $\{|\mathbf{x}|+1, ..., |\mathbf{x}|+|\mathbf{y}|+1\}$ are forbidden to attend to future words:

$$M_{i,j} = \begin{cases} 0, & j \leq |\mathbf{x}| \quad \text{or} \quad j \leq i, \\ -\infty, & \text{otherwise.} \end{cases} \tag{1}$$

This attention mask operation enables us to build a causal language model that the generation of the current word only depends on its previous words. Therefore, the probability of $\mathbf{y}$ could be denoted as:

$$p(\mathbf{y}|\mathbf{x}) = \prod_{i=1}^{|y|} p(y_i|y_{<i}, \mathbf{x}) \tag{2}$$

And the loss for the whole model is the negative log likelihood of the data:

$$\mathcal{L}_{NLL} = -\mathop{\mathbb{E}}_{\mathbf{x},\mathbf{y}} \sum \log p(y_i|y_{<i}, \mathbf{x}) \tag{3}$$

3.3 Adversarial Decoupling Module

In this paper, we want the representations of the low-level module in different languages to contain no language-specific information that is interleaved with the high-level module. In this way, the high-level module could focus on the semantic understanding shared across languages. We build a *discriminator* on top of the low-level module to determine whether the output of low-level representations contains the specific language information.

The discriminator is a bi-directional LSTM taking the output of the low-level module as input and tries to predict its language. Concretely, denote the output of the low-level module is $\mathbf{S} \in \mathbb{R}^{n,d}$ where n is the sequence length (i.e. $|\mathbf{x}|+|\mathbf{y}|+1$), and d is the hidden size of the low-level module. The output of the discriminator can be represented as:

$$\begin{aligned} \mathbf{H} &= \text{bi-LSTM}(\mathbf{S}) \\ \mathbf{h} &= \text{Max-Pooling}(\mathbf{H}) \\ \hat{\mathbf{h}} &= \text{MLP}(\mathbf{h}) \\ \hat{y} &= \text{Softmax}(\hat{\mathbf{h}}) \end{aligned} \tag{4}$$

$\mathbf{h} \in \mathbb{R}^d$ is a pooled representations of the discriminator for classification. $\hat{y}$ is the language distribution in $\mathbb{R}^C$ where C is the number of languages. For the discriminator, the target is to maximize the probability of the corresponding language while the low-level module (generator) tries to minimize it. Therefore, they form an adversarial training objective that the low-level module must produce representations without discriminative language information. In this way, the discriminator acts as an adversarial decoupling module (ADM) to encourage the low-level module to generate language-agnostic representations.

The architecture of ADM is shown in Figure 1 (c), and the loss function for the discriminator and low-level module (generator) are:

$$\begin{aligned} \mathcal{L}_D &= -\log p(\hat{y}_i) \\ \mathcal{L}_G &= -\log p(1-\hat{y}_i) \end{aligned} \tag{5}$$

where $\hat{y}_i$ is the discriminator probability for the input language i. In fact, the objective of the generator is to maximize the entropy of the discriminator's output to make it *less confident* of the language.

3.4 Pre-training

Recent works on NLP and language generation have shown the great advantage of large-scale pre-training (Devlin et al., 2018; Radford et al., 2019; Lewis et al., 2019; Roberts et al., 2020). In this paper, we also pre-train our model in massive multilingual text. Since our model is a sequence to sequence architecture, we develop two self-supervised objectives for language generation pre-training:

Denoised Auto-Encoder (DAE): Most previous works on natural language generation pre-training resort to DAE to initialize the model. In DAE, a corrupted version of the original sentence is created as the source and the model should reconstruct the original sentence. In this paper, we adopt the similar noising strategy as Lewis et al. (2019): (1) *Token Masking* random tokens are sampled and replaced with a special `[MASK]` token. (2) *Token Deletion* randomly deletes several tokens in the document. (3) *Token Replacement* randomly replace some tokens with other tokens in the vocabulary. (4) *Sentence Permutation* randomly swap some tokens in the sentence.

Next Sentence Generation: One of the problems of the DAE is that the input is always the corrupted sentence, which is not the case during finetune, the pretrain-finetune discrepancy may hurt the performance of the downstream tasks (Yang et al., 2019). Similar to Kiros et al. (2015) and Dong et al. (2019), we sample a consecutive segment in the text and divide it into two parts, we treat the first parts as the source and the second part as the target. The objective is to generate the second part based on the first part.

3.5 Question Generation Fine-tuning

After pre-training, we suppose the low-level module of our model has learned the multi-lingual linguistic information. Then the fine-tuning objective is to adjust the high-level module for question generation. Therefore, in this phase, we fix the low-level module, i.e. the word embedding, LSTM, and output projection linear layer, and only update the parameter of the high-level module.

4 Experiments

4.1 Dataset

The question generation datasets are sometimes directly derived from the corresponding question answering datasets. In the current question answering application, most multi-lingual datasets are automatically derived by translating from English SQuAD (Asai et al., 2018). However, it may reduce the multi-lingual QG tasks to translation tasks if we use these datasets. Therefore, we consider four different language QG datasets that are developed by the specific language speakers.

- **English (En)** We use the SQuAD (Rajpurkar et al., 2016) as the English question generation dataset. It is a standard machine reading comprehension data consists of nearly 100k human-labeled questions from Wikipedia.
- **Korean (Ko)** We use the Korquad1.0 (Lim et al., 2019) as the Korean QG data. It consists of more than 70,000 human-generated question-answer pairs on Korean Wikipedia articles.
- **French (Fr)** We adopt the French SQuAD-style dataset (d'Hoffschmidt et al., 2020) consisting of more than 25k human-curated French questions.
- **Hindi (Hi)** HiQuAD (Kumar et al., 2019) is a specific Hindi QG dataset containing 6,555 question-answer pairs. It was derived from the Hindi storybook.

Since the size of the QG dataset except English is comparative small, so we propose a new large-scale QG dataset created by humans on **Chinese (Zh)**. First of all, we collect nearly 3.5m passages from Baike[3], a Chinese Wikipedia-like encyclopedia. To increase the diversity of the selected paragraphs, we cluster the passages based on the bag-of-words, then we use Ward (Ward Jr, 1963) algorithm to select the centroid in each cluster, which result in nearly 100k passages. We ask volunteers to ask no more than 5 questions for each paragraph. Since we did not give the specific answer candidates for each paragraph, the annotators were encouraged to ask more general and comprehensive questions. We also ask other volunteers to check the quality and remove the questions that are either unanswerable or contain grammar errors. Finally, we obtain 224,962 question-paragraph pairs. We randomly select 180k of them as the training data, 20k samples for development, and the rest 24,962 for testing. We name it LAB (**L**earning to **A**sk on **B**aike).

	QG		Pre-train
	Train	Dev/Test	Name(Size)
En	86,635	8,965/8,964	enwiki(13.6Gb)
Zh	180,000	20,000/24,962	zhwiki(1.3Gb)
Ko	60,407	5,774/3,898	kowiki(608Mb)
Fr	20,731	3,188/2,189	frwiki(4.0Gb)
Hi	4,000	1,300/1,255	hiwiki(395Mb)

Table 1: The statistics of the multi-lingual pre-training data and question generation data.

We adopt the 2020-05-20 data dumps of the Wikipedia[4] in the corresponding language as the pre-training data. The details of the training data are shown in Table 1.

4.2 Implementation Details

In all experiments, we tokenize the text with sentencepiece (Kudo and Richardson, 2018). For all languages datasets, we set the vocabulary size to 30,000. We use the Adam (Kingma and Ba, 2014) optimizer with 5k warm-up steps and linearly decay the learning rate. $\beta_1, \beta_2, \epsilon$ was set to 0.9, 0.99 and 10^{-6}, respectively. For both pre-training and fine-tuning, the max learning rate was set to 10^{-4}. The batch size was 256 during pre-training and 64 during fine-tuning. We limit the max sequence length to 512. For the adversarial decoupling module training, following previous works of generative adversarial networks (Goodfellow et al., 2014; Salimans et al., 2016), the update rate for discriminator and generator was set to 1:10. For each of the 4 noising strategies in pre-training, we set the sample probability to 0.1. Similar with Scialom et al. (2019) we do not provide the answer and direcetly generate questions based on the context. We use three types of models:

LALM$_{\text{share}}$ is the shared language-agnostic lan-

Table 2: Main result of the multi-language QG. $\text{LALM}_{\text{share}}$ is similar with previous multi-lingual model that the parameters are shared across all languages. ADM represents the model trained with adversarial decoupling module.

guage model. It is similar with the proposed model but has no specific low-level LSTM for each language. That is, the low-level and high-level parameters are both shared across different languages. The hidden size was set to 768 and the layer size was set to 12, and each layer consists of 12 heads. We set the shared vocabulary size to 100,000.

$\text{LALM}_{\text{base}}$ is the base version of our model. It has the same hidden size as $\text{LALM}_{\text{share}}$. The low-level module was single layer uni-directional LSTM with hidden size 768. $\text{LALM}_{\text{base}}$ has nearly 138m parameters, where nearly half of them are low-level language understanding parameters.

$\text{LALM}_{\text{large}}$ is the large version of our proposed model. The hidden size, layer size, and head size were set to 1024,24,16, respectively. The low-level module was two-layer uni-directional LSTMs. $\text{LALM}_{\text{large}}$ has 548m parameters, where nearly a quarter of them are low-level module's parameters.

4.3 Criterion:

Following previous works of QG (Zhou et al., 2017; Chen et al., 2019), we adopt three widely used automatic metrics for evaluation: **BLEU**, **Meteor** and **Rouge-L**, which measure the n-gram similarities between the generated questions and real questions.

4.4 Baselines

We adopt 5 baseline methods for comparison.

□ **Transformer** (Vaswani et al., 2017; Scialom et al., 2019) is the most widely used architecture in sequence-to-sequence learning. For each language, we train the correspondent Transformer model based on its training data. We set dropout ratio to 0.4 to prevent overfitting.

□ **NQG++** (Zhou et al., 2017) is a popular neural QG model based on LSTM. It is enhanced with attention and copy mechanism[5].

□ **Multi-BERT** (Devlin et al., 2018) is a multi-lingual extension to the original BERT model. It was trained on the multi-lingual wikipedia. All the language shares the same vocabulary. We adopt the way same with Rönnqvist et al. (2019) to extend BERT to language generation task.

□ **CLQG** (Kumar et al., 2019) is a cross-lingual QG method based on Transformer. It is pre-trained by denoising autoencoders along with back-translation. We use the public implementation[6] and adopt the same word tokenization as well as pre-training data as our model.

□ **XNLG** (Chi et al., 2019) is a multi-lingual language generation model that transfers monolingual supervision to all pre-trained languages. It was trained with English, Chinese and French datasets. We use their public pre-trained models[7] and fine-tune on the three QG dataset.

4.5 Multi-Lingual Question Generation

To evaluate the multi-lingual question generation ability of the proposed methods, we assemble all

QG data and train the LALM thereof. For Transformer and NQG++, we initialize the word embeddings by fasttext multilingual word embeddings (Grave et al., 2018). The result is shown in Table 2.

We can see from the table that our model excels at multi-lingual QG, achieving significant improvement over previous methods in all languages. Compared with other architectures such as Transformer, we explicitly separate the low-level and the high-level module in the proposed model and use adversarial networks to decouple them. Therefore, the shared high-level module is encouraged to learn more common representations across different languages, which is more transferable and benefits the downstream QG task a lot.

Besides, we can see that if we don't explicitly separate the low and high-level parameters (LALM$_{\text{share}}$), the result drops a lot. We hypothesis that different languages have different low-level language information, such as lexical, syntactical, etc. Embedding all language processing procedures into a single model may make the model hard to discriminate the language-specific information.

Besides, the model trained with the adversarial decoupling module achieves further improvement, the ADM may impose an implicit regularization on the low-level module to make the representations more abstract, and therefore encourage the high-level module to learn more common representations (Chen et al., 2017; Liu et al., 2017).

4.6 Human Evaluation

The automatic metrics are sometimes biased toward a specific attribute of the generated question (Hosking and Riedel, 2019). So we conduct human qualitative evaluation of the generated outputs. We consider three aspects of the generated questions: **Fluency**: Whether the generated questions are well-posed and natural, in terms of both grammar and semantic. **Answerable**: Whether the generated questions could be answered by the context paragraph. **Significance**: Whether the generated question is just a simple syntactical transformation of the paragraph sentence or trivial one that seems unlikely asked by human.

We randomly sample 50 generated questions from English and 50 from Chinese and ask three volunteers to evaluate the sample quality. The result is shown in Table 5. The result shows our proposed model is also excels at human evaluation, especially for significance, which is sometimes regarded as the most important factor in QG (Graesser et al., 2010). We also showcase some outputs of our model in Table 4. We can see that LALM could generate fluent and sound questions.

4.7 Multi-Lingual v.s. Mono-Lingual

Kumar et al. (2019) have found that in QG the performance of Hindi could be improved by training with additional English data. In this section, we evaluate whether the multi-lingual is superior to the mono-lingual QG. We focus on two aspects: **(1) Pre-training**. In contrast to the proposed multi-lingual pre-training, we adopt the mono-lingual pre-training where we only pretrain on specific languages[8] and fine-tune the QG models in the same language. **(2) Fine-tuning**. Different from the setup in Sec. 4.5 where we aggregate all languages QG data for training, we only fine-tune the model on specific language.

We experiment on English and Chinese with the LALM base model. The BLEU-4 and ROUGE-L scores are shown in Table 3. It is clear that for both pre-training and fine-tuning, the multi-lingual training improves the model a lot. Moreover, the multi-lingual plays a more important role in pre-training than in fine-tuning. We suppose that during pre-training, multiple languages perform a type of regularization on the shared high-level module, while in fine-tuning the language-dependent super-

---

[8] Therefore, we omit the adversarial decoupling module since it only takes effect on multi-lingual learning.

vision of QG is more specific, which makes transfer learning less useful.

4.8 Zero-Shot Learning

In this section, we study the zero-shot multi-lingual learning ability of our model. The previous Section demonstrates that English SQuAD could strengthen other languages a lot. So we choose SQuAD as the training data and evaluate other languages. We only update the parameters of the high-level module for SQuAD without modifying the low-level language understanding module. Therefore, the replacement of the low-level module has little influence on the whole architecture, making the zero-shot inference available. We compare the zero-shot results of LALM base model with the supervised NQG++. The result is shown in Table 7.

We can see that the zero-shot version of our LALM appears to have equaled or eclipsed the QG ability of NQG++. It is an interesting result showing our model could transfer the question generation ability of English to other languages even without supervision. However, pure zero-shot learning is still struggle to achieve a good result, the supervision from the target language is necessary.

4.9 The Effect of Pre-training

We propose the self-supervised denoised auto-encoding and next sentence generation to pre-train the model. In this section, we construct a model that does not employ the pre-training but directly fine-tuned on the target data. The LALM hidden size to 256 and layer and head numbers of 4 and 8, respectively, to prevent overfitting. The results of English, Chinese, and Hindi are shown in Table 6. The performance of our model drops a lot without pre-training. Especially, it barely performs well for the low resource Hindi data because there

are only 4,000 training instances. Nevertheless, when trained with the adversarial decoupling module, our model could achieve consistent improvement, demonstrating that the ADM is good at multi-lingual transfer learning.

5 Conclusion

In this paper, we propose a language-agnostic language model to deal with the multi-lingual question generation. The model consists of the low-level and the high-level module to explicitly represent the language-dependent and language-independent information, respectively. We operate the attention mask matrix to fit our model to the sequence to sequence learning. We propose an adversarial training mechanism to decouple the two-level modules, making the low-level module contains more abstractive representations and the high-level module language-agnostic. We also proposed a large-scale Chinese QG data containing more than 220k questions. Experiments on five languages demonstrate our model achieves significant improvements over previous methods in multi-lingual QG. For future work, we would like to apply our proposed model to other multi-lingual tasks such as summarization and question answering.

Acknowledgments

We thank the anonymous reviewers for their insightful comments. And we appereate the dedicated labeling efforts contributed by the annoators, which makes the large-scale Chinese QG datasets avaliable for the community.

Structure-Aware Pre-Training for Table-to-Text Generation

Xinyu Xing and Xiaojun Wan
Wangxuan Institute of Computer Technology, Peking University
The MOE Key Laboratory of Computational Linguistics, Peking University
`{xingxinyu,wanxiaojun}@pku.edu.cn`

Abstract

Table-to-text generation is a subtask of data-to-text generation which aims to generate naltural language text based on input table. Pre-training techniques have achieved great success on table-to-text generation. However, the pre-trained models used in previous works are typically trained on free-form natural language text while the input of table-to-text task is structured table. In this paper, we propose STTP, a pre-trained model that is trained with tables and their contexts. The STTP model can understand the structured input table and generate fluent text. Experiments on two datasets show the efficacy of our model.

1 Introduction

Data-to-text generation (Reiter and Dale, 1997) is an important natural language generation task with many practical applications, and it refers to the task of generating textual output from non-linguistic input data. The input data of the task can include tables of records, simulations of physical systems, spreadsheets, and so on. The output of the task is a natural language text. Datasets in common use include WEATHERGOV(Liang et al., 2009), ROTOWIRE(Wiseman et al., 2017), WebNLG(Gardent et al., 2017) and so on. Neural generation models with different improvements have achieved impressive results on data-to-text task. Table-to-text generation is a subtask of data-to-text generation which takes tables as input.

The pretrain-and-finetune framework, which refers to first pre-training a high capacity model on large corpora and then fine-tuning it on a downstream task, has outperformed prior state of the art on both natural language understanding task and natural language generation task. Inspired by the success of transfer learning, recently some works (Mager et al., 2020; Kale, 2020; Ribeiro et al., 2020) try to apply the pretrain-and-finetune framework on data-to-text generation. They fine-tuned the pre-trained model such as BART(Lewis et al., 2019) or T5(Raffel et al., 2019) on several downstream data-to-text tasks and achieved state-of-the-art results.

Although transfer learning has achieved great success on data-to-text generation, the pre-trained models used in previous works are typically trained on free-form natural language texts while the input of table-to-text task is structured table. The text-to-text pre-trained models learn a lot of knowledge and good language models from large amount of texts, so they work well on data-to-text generation task. But they still lack the ability to understand the structured data. So we propose a structure-aware table-to-text pre-trained model STTP which is trained with tables and their contexts for table-to-text task. STTP is built on top of the text-to-text pre-trained model BART, and it can understand the structured table and describe it with natural language text. We train our model based on BART because we hope our model can benefit from the knowledge and language model learned from large corpora. We propose three self-supervised tasks to train our model with large amount of tables and their contexts. The first self-supervised task is masked table language model (MTLM) which is like the classic MLM of BERT. The second self-supervised task is adjacent cell prediction (ACP) which refers to predict the cells around the current cell. The third self-supervised task is context reconstruction (CR) which refers to reconstructing the context of a table given the table and its broken context. The first two tasks aim to train the model to better understand the structured table, while the latter task aims to align the table and text. We use the tables extracted from WDCWebTable Corpus(Lehmberg et al., 2016) and their contexts to train our model. Experimental results on WEATHERGOV dataset and WebNLG dataset show the

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2273–2278
August 1–6, 2021.

efficacy of our model.

The main contributions of this work are:

- We propose a structure-aware table-to-text pre-trained model STTP which is trained with three self-supervised tasks.
- Experimental results on WEATHERGOV dataset and WebNLG dataset show the efficacy of our model. Code will be released at `https://github.com/XingXinyu96/STTP`.

2 Related work

Data-to-text generation task involves taking structured data as input and generating text that describes this data. Traditional approaches (Stent et al., 2004; Walker et al., 2007) deal with the task in two steps: the selection of a subset of the input data to discuss and the surface realization of a generation. More recent works combine both steps by learning content plan and surface realization jointly with end-to-end models (Wen et al., 2015; Peng et al., 2017). Although the end-to-end model has achieved good results, many models (Perez-Beltrachini and Lapata, 2018; Sha et al., 2018; Puduppully et al., 2019) consider adding content selection and content planning modules to the end-to-end framework to improve performance. A lot of other new models with different improvements (Wiseman et al., 2018; Li and Wan, 2018; Liu et al., 2018; Roberti et al., 2019; Rebuffel et al., 2020) are proposed to explore how to build an effective data-to-text generator.

Inspired by the success of the pre-trained models in other natural language generation tasks, Harkous et al. (2020), Kale (2020) and Ribeiro et al. (2020) achieve state-of-the-art results on different data-to-text benchmarks with different pre-trained models. However, the existing pre-trained models are usually designed to generate text based on text input, thus lacking the ability to understand structured inputs. Several pre-training methods designed for table-to-text task have been proposed. Deng et al. (2020) present a weakly supervised Structure-Grounded pretraining framework (STRUG) for text-to-SQL that can effectively learn to capture text-table alignment. But their model is only for text-to-SQL task and need parallel text-table data. Yin et al. (2020) propose TABERT, a pretrained model which is trained with large amount of tables with their context. Their model is also used for text-to-SQL task. Chen et al. (2020a) propose a knowledge-grounded pre-trained (KGPT) model which is trained on a massive knowledge- grounded text corpus crawled from the web. Li et al. (2020) propose two self-supervised tasks, Number Ordering and Significance Ordering, to help to learn better table representation.

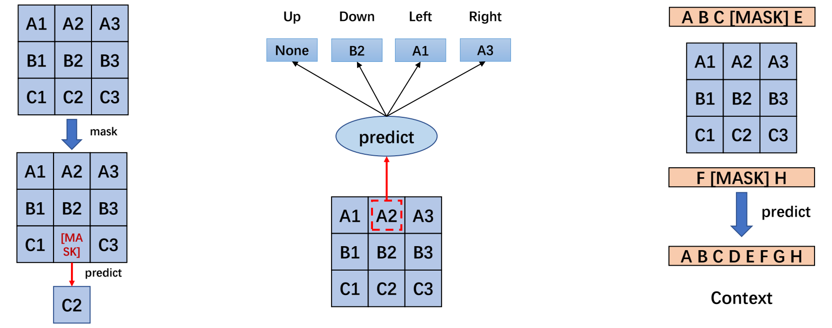
3 Approach

We use the same model architecture as BART, and add several classification layers on top of the encoder for our new self-supervised tasks. We train our model based on the text-to-text pre-trained model BART instead of training from scratch because we hope our model can benefit from the knowledge and language model BART learned from large corpus of text. The three self-supervised tasks are shown in Figure 1.

3.1 Self-Supervised Tasks

Task 1: Masked Table Language Model (MTLM). Inspired by the classic Masked Language Model proposed by BERT, we propose the Masked Table Language Model (MTLM) to learn the representation of input table. During pre-training, we treat the table as a sequence and randomly replace 15% of tokens in the table with [MASK] symbols and then the final hidden vectors corresponding to the mask tokens are fed into an output softmax over the vocabulary to predict the original tokens. In this way, our STTP model learns to understand the structured table. Although we do not explicitly consider the structure of the input table in this task, it is obvious that our model needs to understand the structure of the table to predict the masked tokens.

Task 2: Adjacent Cell Prediction (ACP). The previous MTLM task does not explicitly consider the structure of the input table, so we propose a new task Adjacent Cell Prediction (ACP) to explicitly help our model better understand the structure of the table. For a cell in a table, the surrounding cells are usually very important to understand it. So we feed the hidden vectors of a cell into several output layers to predict its top, bottom, left and right cells. In other words, we hope that the hidden vector of each cell can contain the information of other cells in the same row or column. This task requires our model to focus more on the relationship between cells in the same row or column when encoding the table. For efficiency, we only use the nearest cells in the same row or column of each cell as targets



Task 1: Masked Table Language Model (MTLM)

Task 2: Adjacent Cell Prediction (ACP)

Task 3: Context Reconstruction (CR)

Figure 1: Three Self-supervised Tasks for our STTP Model. Table is shown in blue color and context text is shown in wheat color.

for prediction.

Task 3: Context Reconstruction (CR). The previous two tasks focus on better understanding the structured table, but for table-to-text generation tasks, another important aspect is the alignment of table and text. Through the previous two tasks, our model can get a better representation of the table, then we need to generate text based on this representation which needs the alignment of table and text. If we only train the encoder with the previous two tasks and do not consider the alignment of table and text, we might get a better representation of input table but the representation is hard to understand for the well-trained decoder provided by BART. Table-text alignment data are difficult to obtain, so we use the table with text context (which is usually not strictly aligned with the table, but somewhat relevant with the table) to help our model align table and text. We randomly mask 15% tokens of the context and reconstruct the broken context with our model. There also exists a mismatch between pre-training and fine-tuning, since the input of our model is usually just a table without its context during fine-tuning. Therefore, we also train our model with a task to predict context based only on the input table. Since the table and its context are not exactly aligned, it is difficult to predict the context only from the table, but this task can help our model mitigate the mismatch problem.

3.2 Dataset for Pre-training

The first two tasks only need unsupervised tables, while the third task needs tables with context text. Yin et al. (2020) collect tables and their surrounding text from English Wikipedia and the WDCWebTable Corpus(Lehmberg et al., 2016) to train their model. The data they use is also suitable for our task. We use the preprocessing tool they provided to handle the WDCWebTable Corpus and get a lot of tables with context. Then we filter out the data with low matching degree between table and context, because such data are difficult to train for the third task. In addition, we filter out tables that contains too many numbers. Finally, we get 800k tables with context. We linearize the structure of tables to be compatible with our model. We add a special token [cell] in the middle of cells in the same row and add another special token [row] in the middle of rows of the table. When training task 3, the input of model includes both text and table, so we concatenate them together and add a special token [TABLE] between text and table.

3.3 Pre-training Procedure

We alternately train our model with the previously mentioned three self-supervised tasks. The first two tasks are only used to train the encoder while keeping the decoder frozen. The third task is divided into two subtasks in practice: one is to reconstruct the context given the table with its damaged context; the other one is to predict the context given only the table. Both of the two subtasks train the encoder and decoder at the same time. Considering that the latter subtask is very difficult because the context of a table is difficult to be predicted in many cases, we reduce the times of training it.

4 Experiment

4.1 Dataset

We perform the experiments on WEATHERGOV dataset(Liang et al., 2009) and WebNLG dataset(Gardent et al., 2017). In the WEATHERGOV dataset, the output text is a weather report, and the source data provides a structured representation of the temperature, sky conditions, etc. The WEATHERGOV dataset consists of 29, 528 scenarios, each with 36 weather records paired with a natural language weather forecast (28.7 avg. word length). The WebNLG challenge consists of mapping sets of RDF triples to text. The newest WebNLG dataset contains 16, 095 data inputs and 42, 873 data-text pairs. The average length of the output text is 22.3 words. We convert the input data into a table and then linearize the structure of table like what we do when pre-training.

4.2 Results

4.2.1 Results on WeatherGov Dataset

We use a batch size of 4 and finetune for 100 epochs over the WeatherGov Dataset. Results are presented in Table 1. As is shown in this table, seq2seq model(Mei et al., 2015) has achieved very good results, but the pre-trained model further improves the results greatly. The BLEU scores of the pre-trained models are more than 80, which indicates that the generated text is highly similar to the gold text. BART-Retrain refers to finetuning BART on both our pre-training dataset and the datasets in downstream tasks. Our STTP model outperforms the BART-Retrain model, which proves the improvements of STTP model over BART model is from the proposed training objective instead of the additional training data.

Model	BLEU	METEOR
(Mei et al., 2015)	61.01	n/a
BART-base	81.54	54.81
BART-Retrain	81.63	55.50
STTP	**82.63**	**56.35**

Table 1: Results on WeatherGov Dataset.

4.2.2 Results on WebNLG Dataset

We use a batch size of 4 and fine-tune for 16 epochs over the WebNLG Dataset. Results are presented in Table 2. The results of Seq2Seq, Seq2Seq+Delex and Seq2Seq+copy are copied from (Shimorina and Gardent, 2018). The results of GCN and KGPT-Seq are copied from (Chen et al., 2020b). As is shown in this table, all pre-trained models outperform the models without pre-training even if some of them do not explicitly consider the structure of the input data. This is due to the pre-trained models learn a lot of external knowledge and a good language model from large corpora. The structure-aware model like GCN outperforms the normal seq2seq model, which shows that structure understanding is important in this task. Our model further outperforms the BART-base model and the KGPT model, which show the efficacy of our model with new self-supervised tasks.

Model	BLEU	METEOR
Seq2Seq	54.0	37.0
Seq2Seq+Delex	56.0	39.0
Seq2Seq+Copy	61.0	42.0
GCN	60.80	42.76
KGPT-Seq	64.11	46.30
BART-BASE	62.62	43.28
BART-Retrain	62.89	43.34
STTP	**64.92**	**46.48**

Table 2: Results on WebNLG Dataset

We randomly sample 50 instances from the WebNLG dataset and perform human evaluation on them. Three graduate students are employed to rank the generated texts produced by each model in three aspects: readability (whether the generated text is fluent), accuracy (whether the information of the generated texts is consistent with that contained in the input table) and overall quality. We use Best-Worst Scaling (Louviere et al., 2015), which has been shown to produce more reliable results than ranking scales (Kiritchenko and Mohammad, 2017). Specifically, each score is computed as the percentage of times it was selected as best minus the percentage of times it was selected as worst, and ranges from -1 (unanimously worst) to +1 (unanimously best). Human evaluation results on WebNLG dataset are shown in Table 3. We can see our model outperforms KGPT model and BART-base model, which further demonstrates the efficacy of our method. Running examples are provided in the supplementary materials.

Model	Readability	Accuracy	Overall
KGPT-Seq	0.09	0.01	0.04
BART-base	-0.22	-0.10	-0.17
STTP	**0.13**	**0.09**	**0.13**

Table 3: Human Evaluation Results on WebNLG Dataset

5 Conclusion

In this paper, we propose STTP, a pre-trained model trained with tables and their contexts. STTP model has achieved great performance on two downstream tasks. In the future work, we hope to collect more data and try other self-supervised tasks to train more effective model for table-to-text task.

On the Interplay Between Fine-tuning and Composition in Transformers

Abstract

Pre-trained transformer language models have shown remarkable performance on a variety of NLP tasks. However, recent research has suggested that phrase-level representations in these models reflect heavy influences of lexical content, but lack evidence of sophisticated, compositional phrase information (Yu and Ettinger, 2020). Here we investigate the impact of fine-tuning on the capacity of contextualized embeddings to capture phrase meaning information beyond lexical content. Specifically, we fine-tune models on an adversarial paraphrase classification task with high lexical overlap, and on a sentiment classification task. After fine-tuning, we analyze phrasal representations in controlled settings following prior work. We find that fine-tuning largely fails to benefit compositionality in these representations, though training on sentiment yields a small, localized benefit for certain models. In follow-up analyses, we identify confounding cues in the paraphrase dataset that may explain the lack of composition benefits from that task, and we discuss potential factors underlying the localized benefits from sentiment training.

1 Introduction

Transformer language models like BERT (Devlin et al., 2019), GPT (Radford et al., 2018, 2019) and XLNet (Yang et al., 2019b), have improved the state-of-art in many NLP tasks since their introduction. The versatility of these pre-trained models suggests that they may acquire fairly robust linguistic knowledge and capacity for natural language "understanding". However, an emerging body of analysis demonstrates a level of superficiality in these models' handling of language (Niven and Kao, 2019; Kim and Linzen, 2020; McCoy et al., 2019; Ettinger, 2020; Yu and Ettinger, 2020).

In particular, although *composition*—a model's capacity to combine meaning units into more complex units reflecting phrase meanings—is an indispensable component of language understanding, when testing for composition in pre-trained transformer representations, Yu and Ettinger (2020) report that these representations reflect word content of phrases, but don't show signs of more sophisticated humanlike composition beyond word content. In the present paper we perform a direct follow-up of that study, asking whether models will show better evidence of composition after fine-tuning on tasks that are good candidates for requiring composition: 1) the Quora Question Pairs dataset in Paraphrase Adversaries from Word Scrambling (PAWS-QQP) (Zhang et al., 2019a), an adversarial paraphrase dataset forcing models to classify paraphrases with high lexical overlap, and 2) the Stanford Sentiment Treebank (Socher et al., 2013), a sentiment dataset with fine-grained phrase labels to promote composition. We base our analysis on the tests proposed by Yu and Ettinger (2020), which rely on alignment with human judgments of phrase pair similarities, and which leverage control of lexical overlap to target compositionality. We fine-tune and evaluate the same models and representation types tested in that paper, for optimal comparison.

We find that across the board, fine-tuning on PAWS-QQP does not improve compositionality—if anything, performance on composition metrics tends to degrade. Composition performance also remains low after training on SST, but we do see some localized improvements for certain models. Analyzing the PAWS-QQP dataset, we find reliable superficial cues to paraphrase labels (distance of word swap), explaining in part why fine-tuning on that task might fail to improve composition—and reinforcing the need for caution in interpreting difficulty of NLP tasks. We also discuss the contribution of variation in size of labeled phrases in SST, with respect to the benefits that result from fine-tuning on that task. All experimental code and

data are made available for further testing.[1]

2 Related work

Extensive work has studied the nature of learned representations in NLP models (Adi et al., 2016; Conneau et al., 2018; Ettinger et al., 2016; Durrani et al., 2020). Our work builds in particular on analysis of contextualized representations (Bacon and Regier, 2019; Tenney et al., 2019; Peters et al., 2018; Hewitt and Manning, 2019; Klafka and Ettinger, 2020; Toshniwal et al., 2020). Other work that has focused on transformers, as we do, has often focused on analyzing the attention mechanism (Vig and Belinkov, 2019; Clark et al., 2019), learned parameters (Roberts et al., 2020; Radford et al., 2019; Raffel et al., 2020) and redundancy (Dalvi et al., 2020; Voita et al., 2019; Michel et al., 2019). The evaluation that we use here follows the paradigm of classification-based probing (Kim et al., 2019; Wang et al., 2018; Zhang et al., 2019b; Yang et al., 2019a) and correlation with similarity judgments (Finkelstein et al., 2001; Gerz et al., 2016; Hill et al., 2015; Conneau and Kiela, 2018).

The current paper also builds on work subjecting trained NLP models to adversarial inputs, to highlight model weaknesses. One body of work approaches the problem by applying heuristic rules of perturbation to input sequences (Wallace et al., 2019; Jia and Liang, 2017; Zhang et al., 2019a), while another uses neural models to construct adversarial examples (Li et al., 2020, 2018) or manipulate inputs in embedding space (Jin et al., 2020). Our work also contributes to efforts to understand impacts and outcomes of the fine-tuning process (Miaschi et al., 2020; Mosbach et al., 2020; Wang et al., 2020; Perez-Mayos et al., 2021).

Phrase and sentence composition has drawn frequent attention in analysis of neural models, often focusing on analysis of internal representations and downstream task behavior (Ettinger et al., 2018; Conneau et al., 2019; Nandakumar et al., 2019; McCoy et al., 2019; Yu and Ettinger, 2020; Bhathena et al., 2020; Mu and Andreas, 2020; Andreas, 2019). Some work investigates compositionality via constructing linguistic (Keysers et al., 2019) and non-linguistic (Liška et al., 2018; Hupkes et al., 2018; Baan et al., 2019) synthetic datasets.

Most related to our work here is the finding of Yu and Ettinger (2020). They test for composition in two-word phrase representations from transformers, via similarity correlations and paraphrase detection. They find that baseline performance on these tasks is high, but once they control for amount of word overlap, performance drops dramatically, suggesting that observed correspondences rely on word content rather than phrase composition. We build directly on this work, testing whether these patterns will still hold after fine-tuning on tasks intended to encourage composition.

3 Fine-tuning Pre-trained Transformers

In response to the weaknesses observed by Yu and Ettinger (2020), we select two different datasets with promising characteristics for addressing these weaknesses. We fine-tune on these tasks, then perform layer-wise testing on contextualized representations from the fine-tuned models, comparing against results on the pre-trained models. Here we describe the two fine-tuning datasets.

3.1 PAWS: fine-tuning on high word overlap

The core of the Yu and Ettinger (2020) finding is that model performance on the selected composition tests degrades significantly when cues of lexical overlap are controlled. It stands to reason, then, that a model trained to discern meaning differences under conditions of high lexical overlap may improve on these overlap-controlled composition tests. This drives our selection of the Paraphrase Adversaries from Word Scrambling (PAWS) dataset (Zhang et al., 2019b), which consists of sentence pairs with high lexical overlap. The task is formulated as binary classification of whether two sentences are paraphrases or not. State-of-the-art models achieve only $< 40\%$ accuracy before training on the dataset (Zhang et al., 2019a). Table 1 shows examples from this dataset. Due to the high lexical overlap, we might expect that in order to achieve non-trivial accuracy on this task, models must attend to more sophisticated meaning information than simple word content.

3.2 SST: fine-tuning on hierarchical labels

Another dataset that has been associated with training and evaluation of phrasal composition is the Stanford Sentiment Treebank, which contains syntactic phrases of various lengths, together with fine-grained human-annotated sentiment labels for these phrases. Because this dataset contains annotations

of composed phrases of various sizes, we can reasonably expect that training on this dataset may foster an increased sensitivity to compositional phrase meaning. We formulate the fine-tuning task as a 5-class classification task following the setup in Socher et al. (2013). The models are trained to predict sentiment labels given phrases as input.

4 Representation evaluation

For optimal comparison of the effects of fine-tuning on the above tasks, we replicate the tests, representation types, and models reported on by Yu and Ettinger. Here we briefly describe these methods. For more details on the evaluation dataset and task setup, please refer to Yu and Ettinger (2020).

4.1 Evaluation tasks

Yu and Ettinger propose two analyses for measuring composition: similarity correlations and paraphrase classification. They focus on two-word phrases, using the BiRD bigram relatedness dataset (Asaadi et al., 2019) for similarity correlations, and the PPDB 2.0 paraphrase database (Ganitkevitch et al., 2013; Pavlick et al., 2015) for paraphrase classification. BiRD contains 3,345 bigram pairs, with source phrases paired with numerous target phrases, and human-annotated similarity scores ranging from 0 to 1. For similarity correlation, Yu and Ettinger take layer-wise correlations between these human phrase similarity scores and the cosine similarities of model representations for the same phrases. For paraphrase classification, Yu and Ettinger train a multi-layer perceptron classifier to label whether two phrase representations are paraphrases, drawing their positive phrase pairs from PPDB 2.0—which contains paraphrases with scores generated by a regression model—and randomly sampling negative pairs from the rest of the dataset. We replicate all of these procedures.

For both task types, Yu and Ettinger compare between "uncontrolled" and "controlled" tests, with the latter filtering the data to control word overlap within phrase pairs, such that amount of word overlap between two phrases can no longer be used as a cue for how similar the meanings are. It is on these controlled settings that Yu and Ettinger observe the significant drop in performance, suggesting that model representations lack the compositional knowledge to discern phrase meaning beyond word content. Below we will report results for both settings, with particular focus on controlled settings.

4.2 Representation types

Following Yu and Ettinger, for each input phrase we test as a potential representation 1) CLS token, 2) average of tokens within the phrase (Avg-Phrase), 3) average of all input tokens (Avg-All), 4) embedding of the second word of the phrase, intended to approximate the semantic head (Head-Word), and 5) SEP token. We test each of these representations at every layer of each model.[2]

5 Experimental setup

We fine-tune and analyze the same models that Yu and Ettinger test in pre-trained form: BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), DistilBERT (Sanh et al., 2019), XLNet (Yang et al., 2019b) and XLM-RoBERTa (Conneau et al., 2019). In each case, the pre-trained "base" version is used as the starting point for fine-tuning. We use the implementation of Wolf et al. (2019)[3] based on PyTorch (Paszke et al., 2019).

We fine-tune these models on the two datasets described in Section 3. The Quora Question Pairs dataset in Paraphrase Adversaries from Word Scrambling (PAWS-QQP)[4] consists of a training set with 11,988 sentence pairs, and a dev/test set with 677 sentence pairs. Tuning on PAWS-QQP is formulated as binary classification. Sentences are passed as input and models are trained to pre-

---

[2] Like Yu and Ettinger, we also test both phrase-only input (encoder input consists only of two-word phrase plus special CLS/SEP tokens), as well as inputs in which phrases are embedded in sentence contexts.

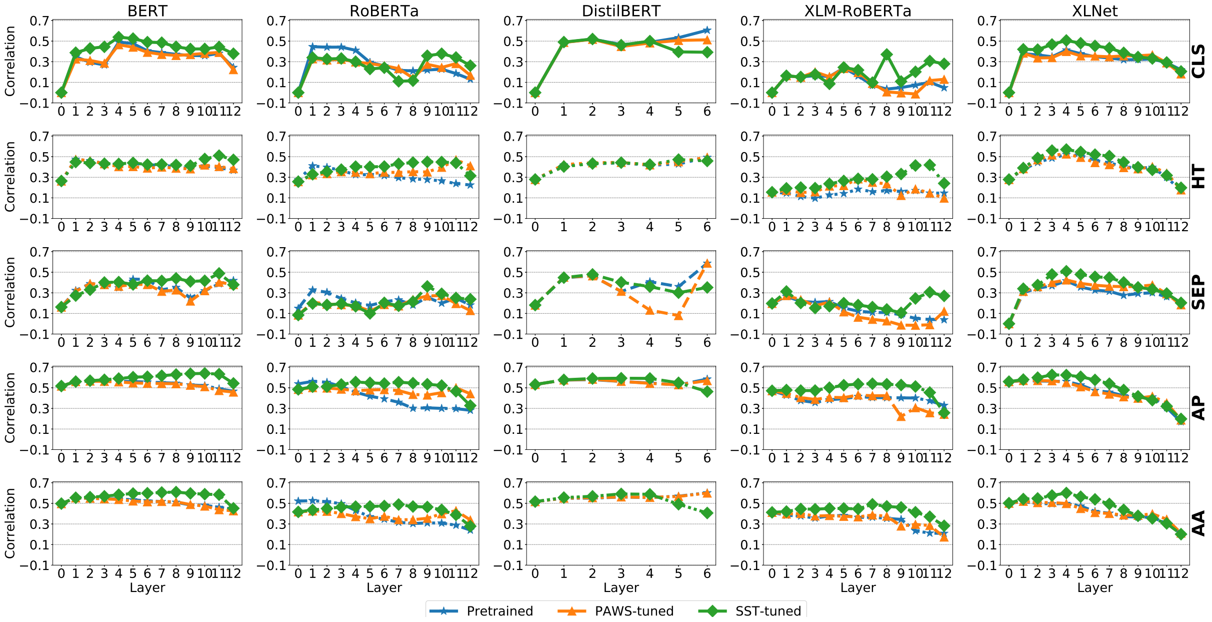

Figure 1: Similarity correlation on uncontrolled BiRD dataset, with phrase-only input. Columns correspond to models, and rows correspond to representation types ("HT" = Head-token, "AP" = Avg-Phrase and "AA" = Avg-All). For each model and representation type, the corresponding subplot shows correlations for pre-trained, PAWS-tuned and SST-tuned settings, respectively. For each subplot, X-axis corresponds to layer index, and Y-axis corresponds to correlation value. Layer 0 corresponds to input embeddings passed to the model.

dict whether the input sentences are paraphrases or not. Models are trained on the training set, and validated on the dev/test set for convergence.

The Stanford Sentiment Treebank (SST)[5] (Socher et al., 2013) contains 215,154 phrases. 15% of the data is reserved for validation. The fine-tuning task is formulated as 5-class classification on sentiment labels, where models are given phrases as input, and asked to predict sentiment. In both tasks, we use the Adam optimizer (Kingma and Ba, 2014) with default weight decay. We train the models until convergence on the validation set.

The evaluation tasks consist of correlation analysis and paraphrase classification. For correlation in the uncontrolled setting, we use the complete BiRD dataset, containing 3,345 phrase pairs.[6] For the controlled test, we filter the complete dataset following the criteria in Yu and Ettinger (2020), resulting in 410 "AB-BA" mirror-image pairs with 100% word overlap (e.g., *law school* / *school law*). For the classification tasks, we use the preprocessed data released by Yu and Ettinger (2020).[7] We collect 12,036 source-target phrase pairs from the preprocessed dataset for our uncontrolled classification setting, and for the controlled classification setting, we collect 11,772 phrase pairs with exactly 50% word overlap in each pair, following the procedure from the original paper.

6 Results after fine-tuning

6.1 Full datasets

Figure 1 presents the original results from Yu and Ettinger (2020) on pre-trained models, alongside our new results after fine-tuning, on the full BiRD dataset. Since this is prior to the control of word overlap, these correlations can be expected to reflect effects of lexical content encoding, without yet having isolated effects of composition. We find that after fine-tuning on SST, most models and representation types show small improvements in peak correlations across layers, while fine-tuning on PAWS also yields improvements in peak correlations—albeit even smaller—in models other than BERT and XLM-RoBERTa. Overall, within a given representation type, improvements are generally stronger after fine-tuning on SST than on PAWS. Between representation types, Avg-Phrase and Avg-All remain consistently at the highest correlations after fine-tuning. Additionally, we see that the decline in correlation at later layers in pre-trained BERT, RoBERTa and XLM-RoBERTa is mitigated

[7] `https://github.com/yulang/phrasal-composition-in-transformers`

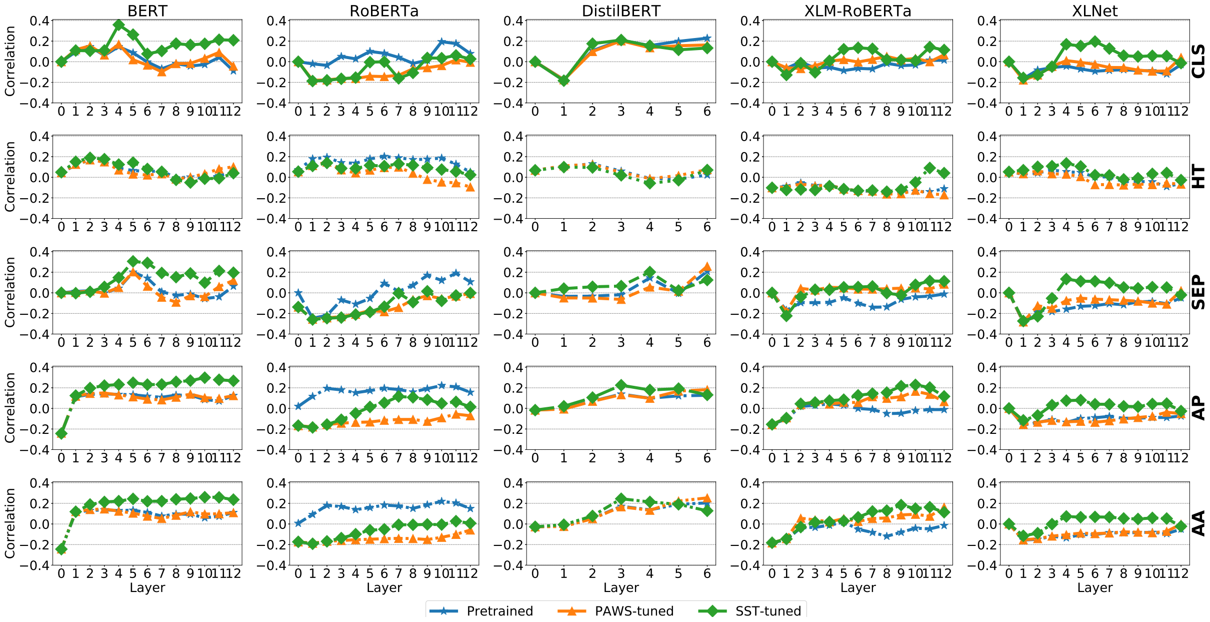

Figure 2: Similarity correlation on controlled BiRD dataset (AB-BA setting), with phrase-only input.

after fine-tuning. Model-wise, we see the most significant improvements in the RoBERTa model, for which the correlations become more consistent across layers for most representation types. As we discuss below, we take this as indication that the fine-tuning promotes more robust retention of word content information across layers, if not more robust phrasal composition.

For the sake of space, we present the plots of the uncontrolled paraphrase classification setting in Figure 7 of the Appendix. The overall improvements are even smaller than those seen in the correlations, but we do see comparable patterns in these paraphrase classification results, in particular with SST showing slightly stronger benefits than PAWS.

6.2 Controlled datasets

Above we see small benefits of fine-tuning for performance on the full, uncontrolled datasets. However, the critical question for our purposes is whether correlations also show improvements in word-overlap controlled settings, which better isolate effects of composition. Figure 2 shows correlations for all models on the controlled AB-BA (full word overlap) correlation test. Figure 3 shows the results for the controlled paraphrase classification setting, where both paraphrase and non-paraphrase pairs have exactly 50% word overlap.

The first comparison to note is between original and controlled settings, which allows us to establish the contributions of overlap information as opposed to composition. Comparing between Figure 1 and Figure 2, it is clear that fine-tuned models still show substantial reduction in correlation when overlap cues are removed. The same goes for Figure 3 (by comparison to Figure 7 of the Appendix)—we see that on the controlled dataset, accuracies hover just above chance-level performance both before and after fine-tuning, compared to over 90% accuracy on the uncontrolled dataset. This gap in performance between the original and controlled datasets mirrors the findings of Yu and Ettinger (2020), and suggests that even after fine-tuning, the majority of correspondence between model phrase representations and human meaning similarity judgments can be attributed to capturing of word content information rather than phrasal composition.

The second key comparison is between pre-trained and fine-tuned models within the overlap-controlled settings. While the prior comparison tells us that similarity correspondence is still dominated by word content effects, this second comparison can tell us whether fine-tuning shows at least some boost in meaning composition relative to pre-training. Comparing performance of pre-trained and fine-tuned models in Figure 2, we see that fine-tuning on PAWS-QQP actually slightly degrades correlations at many layers for a majority of models and representation types—with improvements largely restricted to XLM-RoBERTa and XLNet (perhaps notably, mostly in cases where pre-trained correlations are negative). This is despite the fact that models achieve strong validation performance on PAWS-QQP (as shown in Table 2), suggesting

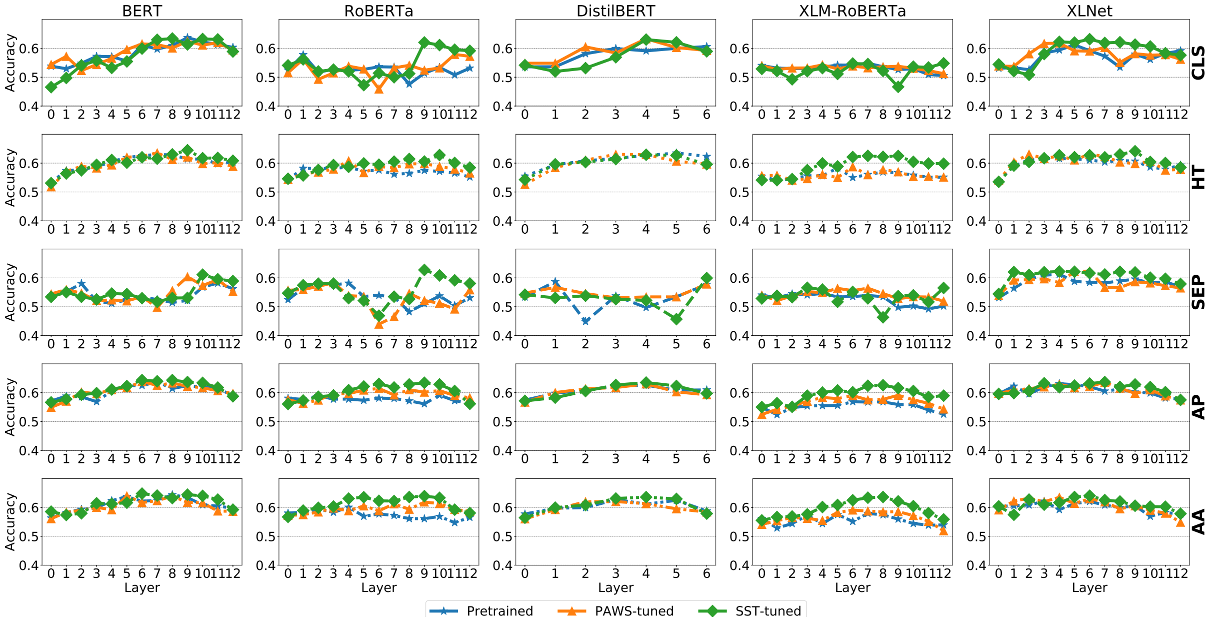

Figure 3: Paraphrase classification accuracy on controlled PPDB dataset (50% word overlap setting) with phrase-only input. Y-axis range is smaller relative to Figure 7, to make changes from pre-training more visible.

that learning this task does little to improve composition. We will explore the reasons for this below.

In Figure 3, we see that fine-tuning also does little to improve paraphrase classification accuracies in the controlled setting—though each model shows slight improvement in peak accuracy across layers and representation types (e.g., RoBERTa shows ∼3% increase in peak accuracy with SST tuning, and 2% with PAWS tuning). Even so, the best accuracies across models continue to be only marginally above chance. This, too, fails to provide evidence of any substantial composition improvement resulting from the fine-tuning process.

The story changes slightly when we turn to impacts of SST fine-tuning on correlations in Figure 2. While all correlations remain low after SST fine-tuning, we do see that correlations for BERT, XLM-RoBERTa and XLNet show some non-trivial benefits even in the controlled setting. In particular, SST tuning consistently improves correlation among all representation types in BERT (except for minor degradation in later layers for Head-token), boosting the highest correlation from ∼0.2 to ∼0.39. Between representation types, the greatest change is in the CLS token, with the most dramatic point of improvement being an abrupt correlation peak for CLS at BERT's fourth layer. We will discuss more below about this localized benefit.

A final important observation is that fine-tuning on either dataset produces clear degradation in correlations for all representation types in RoBERTa under the controlled setting, by contrast to the general improvements seen for that and other models in the uncontrolled setting. This suggests that at least for that model, fine-tuning encourages retention or enhancement of lexical information, but may degrade compositional phrase information.[8]

Model	Accuracy(%)
BERT	80.13
RoBERTa	90.81
DistilBERT	81.98
XLM-RoBERTa	91.18
XLNet	88.24
Linear CLF	71.34

Table 2: Accuracy of fine-tuned models on PAWS-QQP dev/test set. Linear CLF is a baseline classifier with relative swapping distance as the only input feature.

7 Analyzing impact of fine-tuning

The presented results suggest that despite compelling reasons to think that fine-tuning on the selected tasks may improve composition of phrase meaning, these models mostly do not exhibit noteworthy benefits from fine-tuning. In particular, fine-

---

[8] Following Yu and Ettinger (2020), in addition to phrase-only inputs we also try embedding target phrases in sentence contexts. Consistent with the findings of Yu and Ettinger (2020), we see that presence of context words does boost overall correlation and accuracy, but does not alter the general trends. Moreover, models still show relatively weak performance on controlled tasks even with context available (see Figure 8 and Figure 9 in the Appendix for details).

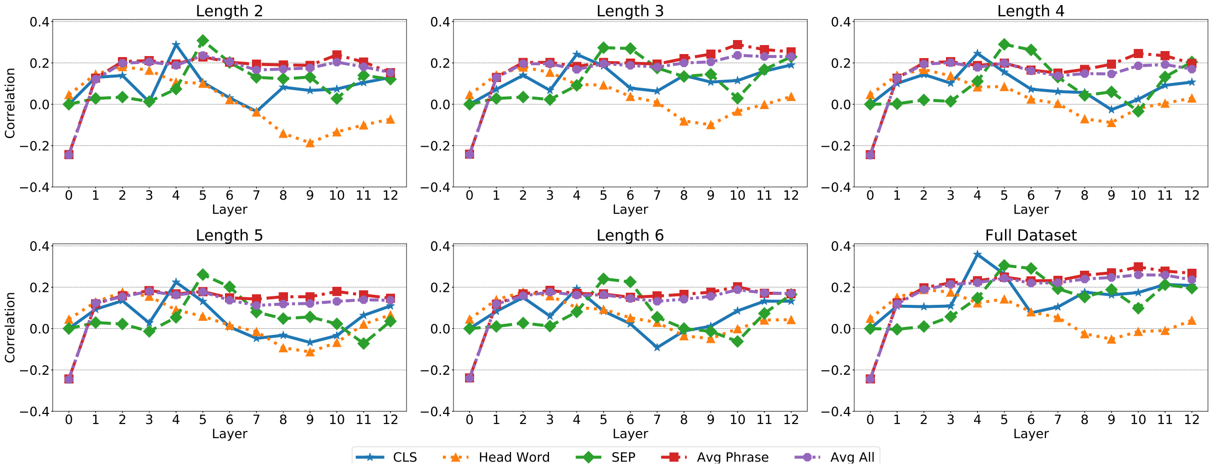

Figure 4: Layer-wise correlation of BERT fine-tuned on phrases of different lengths in SST.

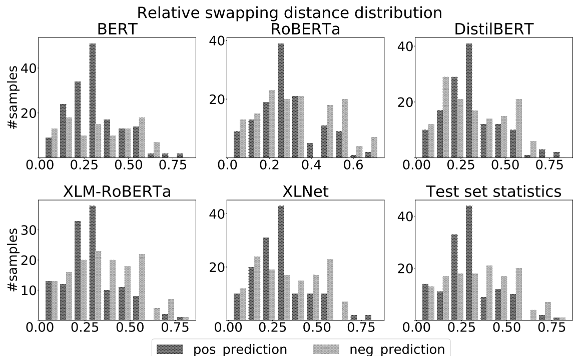

Figure 5: Distribution of positive and negative predictions made by tuned models. Last plot shows the statistics in the PAWS-QQP dev/test set. X-axis corresponds to relative swapping distance; Y-axis shows number of samples in the specific relative swapping distance bin.

tuning on the PAWS-QQP dataset often degrades performance on the controlled datasets taken to be most indicative of compositionality. As for SST, the benefits are minimal, but in localized cases like BERT's CLS token, we do see signs of improved compositionality. In this section, we conduct further analysis on the impacts of fine-tuning, and discuss why tuned models behave as they do.

7.1 Failure of PAWS-QQP

Table 2 shows accuracy of fine-tuned models on the dev/test set of PAWS-QQP.[9] It is clear that the models are learning to perform well on this dataset, but our results above indicate that this does not translate to improved composition sensitivity.

We explore the possibility that this discrepancy may be caused by trivial cues arising during the construction of the dataset, enabling models to infer paraphrase labels without needing to improve their understanding of the meaning of the sentence pair (c.f., Poliak et al., 2018; Gururangan et al., 2018). Sentence pairs in PAWS are generated via word swapping and back translation to ensure high bag-of-words overlap (Zhang et al., 2019a). We hypothesize that models may be able to achieve high performance in this task based on distance of the word swap alone, without requiring any sophisticated representation of sentence meaning.

To test this, given a sentence pair (s_1, s_2) with word counts l_1, l_2, respectively, we define "relative swapping distance" as

$$dist_{relative} = \frac{dist_{swap}}{max(l_1, l_2)}$$

where $dist_{swap}$ is defined as the index difference of the first swapping word in s_1 and s_2. For the example shown in the first row of Table 1, the first swapping word is "specific", with $dist_{swap} = 4$. Note that with this measure we focus on information from one word swap only, while some pairs in PAWS-QQP have multiple swapped words—so in reality, swapping distance information may be even stronger than our results below indicate.

In the last plot of Figure 5, we show an association between relative swapping distance and paraphrase labels in the PAWS dev/test set: sentence pairs with small swapping distance tend to be positive samples, while large swapping distance associates with negative labels. The other plots in Figure 5 show distribution of positive and negative predictions generated by each fine-tuned model with respect to relative swapping distance. We see a similar pattern, with models tending to generate negative labels when swapping distance is larger.

---

[9] The performance of BERT in the table is different from previous work mainly due to the fact that models in Zhang et al. (2019a) are tuned on concatenation of QQP and PAWS-QQP datasets rather than PAWS-QQP only.

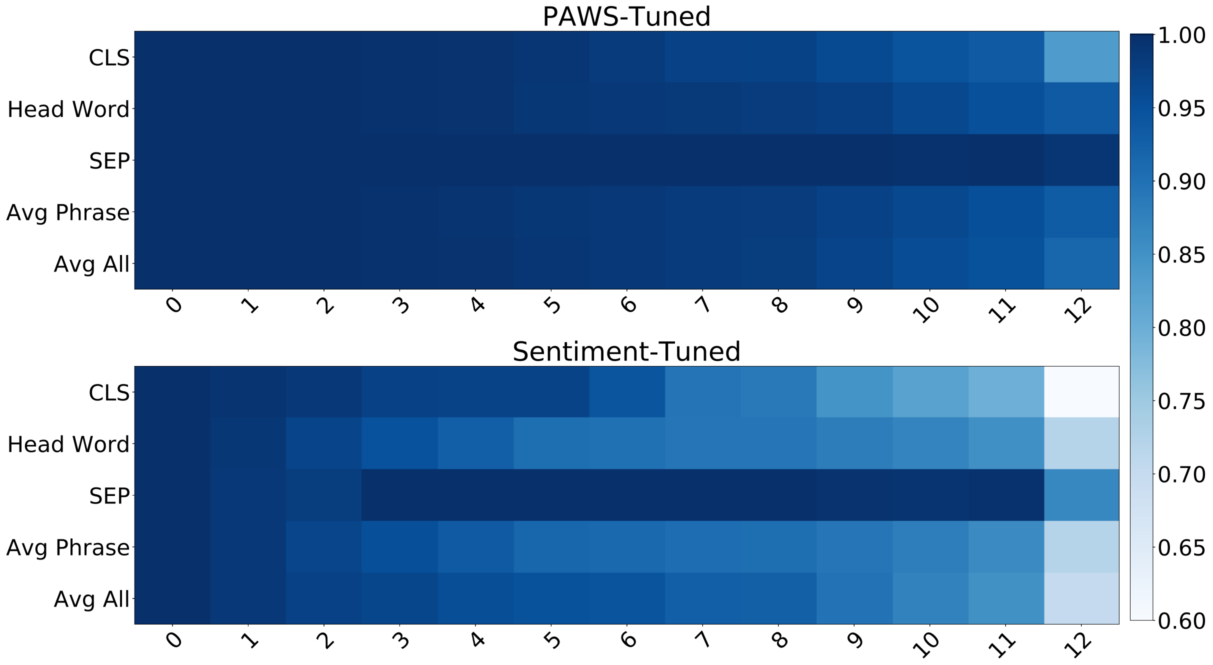

Figure 6: Average layer-wise embedding similarity between fine-tuned and pre-trained BERT. The upper half shows the comparison between PAWS-QQP tuned and pre-trained BERT. And the lower half presents Sentiment Treebank-tuned v.s. pre-trained. Embeddings are evaluated using full BiRD dataset for input.

To verify the viability of this cue, we train a simple linear classifier on PAWS-QQP, with relative swapping distance as the only input feature. The results are reported as "Linear CLF" in Table 2. Even without access to the content of the sentences, we see that this simple model is able to achieve nontrivial and comparably good classification accuracy on the dev/test set. The strong performance of the linear classifier and the distribution of predictions are consistent with the hypothesis that when we tune on PAWS-QQP, rather than forcing models to learn nuanced meaning in the absence of word overlap cues, we may instead encourage models to focus on lower-level information having little to do with the sentence meaning, further degrading their performance on the composition tasks.

7.2 Localized impacts of SST

Fine-tuning on sentiment shows a bit of a different pattern—while it mostly shows only minor changes from pre-training, and the correlations and classification accuracies remain at decidedly low levels on the controlled settings, we do see in certain models some distinctive changes in levels of similarity correlation as a result of tuning on SST. Notably, since these improvement patterns are seen in the similarity correlations but not in the classification accuracies, this suggests that these two tasks are picking up on slightly different aspects of phrasal compositionality. To investigate these effects further, we focus our attention on BERT, which shows the most distinctive improvement in correlations.

The obvious candidate for the source of the localized SST benefit is the dataset's inclusion of labeled syntactic phrases of various sizes. The benefits seen from SST tuning suggest that this may indeed encourage models to gain some finer-grained sensitivity to compositional impacts of phrase structure (at least those relevant for sentiment). To examine this further, we filter the SST dataset to subsets with phrases of the same length, from 2 to 6 words, and tune pre-trained BERT on each subset.

Figure 4 shows the correlations for BERT, fine-tuned on each phrase length, on the overlap-controlled BiRD dataset. We see that tuning on the full dataset (mixed phrase lengths) gives the strongest fourth-layer boost in CLS correlation performance—but among the size subsets, a semblance of the fourth-layer CLS peak is seen across phrase lengths, with length-2 training yielding the strongest peak, and length-6 training the smallest. This suggests an amount of size-based specialization—sentiment training on phrases of (or closer to) two words has more positive impact on similarity correlations for our two-word phrases.[10] However, we also see that phrases of

---

[10] Although subset size can potentially contribute to correlation performance, we find that subset size does not correlate

other sizes contribute non-trivially to the ultimate correlation improvement observed from training on the full dataset. This is consistent with the notion that training on diverse phrase sizes encourages fine-grained attention to compositionality, while training on phrases of similar size may have slightly more direct benefit.

Representation changes For further comparison of fine-tuning effects between tasks, we analyze changes in BERT representations at each layer before and after the fine-tuning process. Figure 6 shows the average layer-wise representation similarity between fine-tuned and pre-trained BERT given identical input. We see substantial differences between tasks in terms of representation changes: while SST fine-tuning produces significant changes across representations and layers, PAWS fine-tuning leaves representations largely unchanged (further supporting the notion that this task can be solved fairly trivially). We also see that after SST tuning, BERT's CLS token shows robust similarity to pre-trained representations until the fifth layer, followed by a rapid drop in similarity. This suggests that the fourth-layer correlation peak may be enabled in part by retention of key information from pre-training, combined with heightened phrase sensitivity from fine-tuning. We leave in-depth exploration of this dynamic for future work.

8 Discussion

The results of our experiments indicate that despite the promise of PAWS-QQP and SST tasks for improving models' phrasal composition, fine-tuning on these tasks falls far short of resolving the composition weaknesses observed by Yu and Ettinger (2020). The majority of correspondence with human judgments can still be attributed to word overlap effects—disappearing once overlap is controlled—and improvements on the controlled settings are absent, very small, or highly localized to particular models, layers and representations. This outcome aligns with the increasing body of evidence that NLP datasets often do not require of models the level of linguistic sophistication that we might hope for—and in particular, our identification of a strong spurious cue in the PAWS-QQP dataset adds to the growing number of findings emphasizing that NLP datasets often have artifacts that can inflate performance (Poliak et al., 2018; Gururangan et al., 2018; Kaushik and Lipton, 2018).

We do see a ray of promise in the small, localized benefits for certain models from tuning on SST. These improvements do not extend to all models, and are fairly small in the models that do see benefits—but as we discuss above, it appears that training on fine-grained syntactic phrase distinctions may indeed confer some enhancement of compositional meaning in phrase representations—at least when model conditions are amenable. Since sentiment information constitutes only a very limited aspect of phrase meaning, we anticipate that training on fine-grained phrase labels that reflect richer and more diverse meaning information could be a promising direction for promoting composition more robustly in these models.

9 Conclusions and future directions

We have tested effects of fine-tuning on phrase meaning composition in transformer representations. Although we select tasks with promise to address composition weaknesses and reliance on word overlap, we find that representations in the fine-tuned models show little improvement on controlled composition tests, or show only very localized improvements. Follow-up analyses suggest that the PAWS-QQP dataset contains spurious cues that undermine learning of sophisticated meaning properties when training on that task. However, results from SST tuning suggest that training on labeled phrases of various sizes could prove effective for learning composition. Future work should investigate how model properties interact with fine-tuning to produce improvements in particular models and layers—and should move toward phrase-level training with meaning-rich annotations, which we predict will be a promising direction for improving models' phrase meaning composition.

Acknowledgments

We would like to thank three anonymous reviewers for valuable feedback for improving this paper. We also thank members of the University of Chicago CompLing Lab for helpful comments and suggestions on this work. Abstract

Lifelong topic models mainly focus on in-domain text streams in which each chunk only contains documents from a single domain. To overcome data diversity of the in-domain corpus, most of the existing methods exploit the information from limited sources in a separate and heuristic manner. In this study, we develop a lifelong collaborative model (LCM) based on non-negative matrix factorization to accurately learn topics and domain-specific word embeddings. LCM particularly investigates: (1) developing a knowledge graph based on the semantic relationships among words in the lifelong learning process, so as to accumulate global context information discovered by topic models and local context information reflected by context word embeddings from previous domains, and (2) developing a subword graph based on byte pair encoding and pairwise word relationships to exploit subword information of words in the current in-domain corpus. To the best of our knowledge, we are the first to collaboratively learn topics and word embeddings via lifelong learning. Experiments on real-world in-domain text streams validate the effectiveness of our method.

1 Introduction

Lifelong learning (Silver, 2011; Mitchell et al., 2015), which accumulates and maintains the past knowledge to help future learning in an endless manner, has attracted considerable attention in topic modeling (Chen et al., 2020b; Gupta et al., 2020). Most lifelong topic models (Chen and Liu, 2014b; Chen, 2015; Wang et al., 2016) focus on the corpus that only contains text from a single domain, dubbed the in-domain corpus (Xu et al., 2018). This is because in-domain corpora are widespread in real-world applications, such as breaking news and tweets related to a specific topic (domain). The key to the success of a lifelong topic model within in-domain corpora is based on a precondition that prior topical information of previous domains can be fully exploited to guide meaningful learning in the new coming domain (Chen and Liu, 2014b). However, because the in-domain corpus is typically of limited size (Xu et al., 2018), it is insufficient for the existing methods to train coherent topics.

To alleviate the lack of global context in a corpus, one simple solution for topic models is to incorporate general-purpose pre-trained word embeddings (Das et al., 2015; Xun et al., 2016, 2017b; Dieng et al., 2020). Although the general-purpose embeddings can provide some useful information for words within the in-domain corpus, their embedding representations may not be ideal for the target domain and in some cases they may even conflict with the meanings of the words in the task domain because words often have multiple senses or meanings (Xu et al., 2018). Another solution trains topics and word embeddings jointly in the one-shot learning scenario (Xun et al., 2017a; Dieng et al., 2020). Such a unified method prevents relying on the external embedding corpus that is not always closely aligned with the domain task, because the model can learn domain-specific word embeddings by itself. Unfortunately, the aforementioned models are conducted on collected documents without the guidance of any prior knowledge. Besides, they all treat words as atomic units, which may not perform well on the in-domain corpus with relatively few words.

In light of these considerations, we aim to generate coherent topics and domain-specific word embeddings jointly by a lifelong process. On the one hand, domain-specific word embeddings tend to offer more accurate complementary information to lifelong topic modeling than pre-trained embeddings. On the other hand, we alleviate the lack of global and local context information within in-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2294–2309
August 1–6, 2021.

domain corpora by exploiting subwords (Pinter et al., 2017). Both the topical and subword information are leveraged in our knowledge-based learner to generate better domain-specific word embeddings. To achieve this, we propose a lifelong collaborative model (LCM)[1] by coordinating global context, local context, and subword information. First, our LCM maintains a knowledge graph based on word relationships to accumulate the past knowledge learned from previous domains, which exploits from both the global word-document matrix and the local word co-occurrence matrix. Second, we develop a subword graph from the current in-domain corpus to capture extra information of words. We use non-negative matrix factorization (NMF) as our framework, which is an effective method of mining latent text semantics with great flexibility in transforming prior knowledge into regulations (Lee and Seung, 1999; Chen et al., 2015, 2020b) and it gives sparseness to matrices with interpretability (Hoyer, 2004). The main contributions of this study can be summarized as follows:

- We propose a lifelong learning method to jointly generate topics and word embeddings over in-domain text streams. To the best of our knowledge, we are the first to collaboratively learn topics and domain-specific word embeddings through a lifelong process.
- We incorporate local context information and subword information into lifelong topic modeling, which can alleviate the lack of global context information when the target dataset is relatively small.
- In lifelong word embedding learning, we leverage the topical and subword information to help generate better domain-specific embeddings for down-stream learning tasks.

2 Related Work

Topic modeling (Deerwester et al., 1990; Hofmann, 1999; Blei et al., 2003) and word embedding learning (Mikolov et al., 2013a,b) are two of the most important tasks in natural language processing. The former task aims to discover the latent semantic structure of documents based on the global context, while the latter one follows the distributional hypothesis that words occurring in similar local contexts tend to have similar syntactic and semantic properties (Harris, 1954). The traditional topic and word embedding learning models are based on isolated learning, i.e., a one-shot task learning, thus they lack ability to continually learn from incrementally available data.

Lifelong Topic Modeling. A lifelong topic model (Chen and Liu, 2014b; Chen, 2015; Wang et al., 2016), as a typical example of lifelong machine learning, is gaining more and more research interests than traditional one-shot deal that conducts a topic model on collected documents just for once (Chen et al., 2020b). Lifelong topic models inherit three key characteristics in lifelong machine learning, i.e., continuous tasks, knowledge accumulation and maintenance, and a knowledge-based learner that can leverage the past knowledge to help future learning in a never-ending manner. Furthermore, lifelong topic modeling is mainly applied to in-domain corpora where each chunk only contains text from a single domain.

Based on NMF, Chen et al. (2020b) proposed a lifelong topic model named NMF-LTM. However, the above method only considers the most important 10 words under every topic while ignores other non-top words, i.e., most words in the vocabulary. This problem will be more serious if the vocabulary size is large. Besides, NMF-LTM may perform poorly for other downstream tasks, because it can only capture the information of limited words in sentences. Finally, NMF-LTM only mines word relationships from the perspective of global (topical) information, which is inadequate within in-domain corpora. Considering the limited global context in the new coming corpus, Gupta et al. (2020) incorporated general-purpose pre-trained word embeddings as complementary to topics into the knowledge base for lifelong learning. Unfortunately, the above method required that the dimension of word embeddings being equal to the number of topics and each dimension of word embeddings corresponding to a topic. This violates the complementary but different points of view, i.e., the global viewpoint and the local viewpoint, for topic models and word embedding models (Xun et al., 2017a). This model optimizes a topic-word matrix, in which each row represents the word distribution of a topic and each column represents the embedding of a word. Each dimension of the word embedding learned by this model implied the possibility of the word occurring in the corresponding topic. However, word embeddings contain many other features that cannot be captured by global (context) information, e.g., the syntactic feature.

---

[1] `https://github.com/XiaoruiQ/LCM`

Word Embedding Learning. Lifelong learning has also been adopted to train domain-specific word embeddings, which fills the gap between general-purpose embeddings trained on large-scale corpora and the topic (domain) of the down-stream task. For example, Xu et al. (2018) first developed a meta-learner to expand the new in-domain corpus by measuring the content similarity of past domains and the new domain. Then, they generated word embeddings for the new domain using the combined data. However, this method only considered the local context information from past domains, which is inadequate to capture the polysemous nature of words. As an illustration, *apple* is one of polysemous words that is topically contextualized by several domains, i.e., product line, operating system, and fruit (Gupta et al., 2020).

3 Lifelong Collaborative Model

In this section, we detail the proposed LCM for jointly learning topics and domain-specific word embeddings in a lifelong process. The topical information and local context from previous domains, and a subword graph constructed from the current in-domain corpus are exploited in LCM to guide future tasks.

3.1 Problem Formalization

Given a stream of document chunks $\left\{\mathcal{DOC}_t\right\}_{t=1}^{T}$ accumulated in an endless manner ($T = +\infty$), we aim to jointly generate topics and domain-specific word embeddings when each chunk only contains text from a single domain. At any time point, our LCM deals with the current document chunk, e.g., $\mathcal{DOC}_t$, by leveraging the past knowledge learned from the previous document chunks, i.e., $\mathcal{DOC}_1$, $\mathcal{DOC}_2$, ..., $\mathcal{DOC}_{t-1}$. Table 1 lists the notations used in this paper. We use bold uppercase letters such as $\boldsymbol{D}_t$ to represent matrices, regular uppercase letters such as M to represent scalar constants, and regular lowercase letters such as λ_v to represent scalar variables.

Notation	Description
$\boldsymbol{D}_t \in R^{M \times N}$	Word-document matrix at the current moment
$\boldsymbol{U}_t \in R^{M \times K}$	Word-topic matrix at the current moment
$\boldsymbol{V}_t \in R^{K \times N}$	Topic-document matrix at the current moment
$\boldsymbol{X}_t \in R^{M \times M}$	Word co-occurrence matrix at the current moment
$\boldsymbol{B}_t \in R^{M \times E}$	Word embedding matrix at the current moment
$\boldsymbol{C}_t \in R^{M \times E}$	Context word embedding matrix at the current moment
M	The number of words
N	The number of documents
K	The number of topics
E	The dimension of word embeddings

Table 1: Frequently used notations.

3.2 Objective Function

Figure 1 illustrates the architecture of our LCM, which processes in-domain text streams through a knowledge-based learner. Formally, the objective function of LCM is defined as follows:

$$\begin{aligned} L = &\|\boldsymbol{D}_t - \boldsymbol{U}_t\boldsymbol{V}_t\|_F^2 + \left\|\boldsymbol{X}_t - \boldsymbol{B}_t\boldsymbol{C}_t^T\right\|_F^2 \\ &+ \Upsilon(\boldsymbol{V}_t) + \Psi(\boldsymbol{U}_t) + \Phi(\boldsymbol{C}_t) + \Omega(\boldsymbol{B}_t), \\ &s.t. \quad \boldsymbol{U}_t \geq 0, \boldsymbol{V}_t \geq 0, \boldsymbol{B}_t \geq 0, \boldsymbol{C}_t \geq 0. \quad (1) \end{aligned}$$

It is noteworthy that we constrain the non-negativity of $\boldsymbol{B}_t$ and $\boldsymbol{C}_t$ to learn sparse interpretable word embeddings (Murphy et al., 2012; Luo et al., 2015), so as to capture the polysemous nature of words (Panigrahi et al., 2019). With non-negativity constraints, words are represented by limited dimensions (Murphy et al., 2012). All words that have positive values under specific dimensions may share a common characteristic, which enhances the interpretability of word embeddings and helps capture the polysemous nature.

The first term of our objective function aims to factorize the global word-document matrix $\boldsymbol{D}_t$ into the word-topic matrix $\boldsymbol{U}_t$ and the topic-document matrix $\boldsymbol{V}_t$, and the interpretability of $\boldsymbol{U}_t$ and $\boldsymbol{V}_t$ is ensured by their non-negativity. For the local context information, Levy and Goldberg (2014) have proved that the Skip-Gram model with negative sampling (SGNS) is implicitly factorizing a positive pointwise mutual information word co-occurrence matrix shifted by a constant offset. Accordingly, we use the shifted positive pointwise mutual information matrix as our word co-occurrence matrix $\boldsymbol{X}_t$ and decompose it into the word embedding matrix $\boldsymbol{B}_t$ and the context word embedding matrix $\boldsymbol{C}_t$, as presented in the second term. Given a hyperparameter λ_v, the sparsity constraint on $\boldsymbol{V}_t$ is introduced as the third term $\Upsilon(\boldsymbol{V}_t) = \lambda_v \|\boldsymbol{V}_t\|_1$. This ensures that each document covers limited topics (Chen et al., 2020b). The sparsity of topics encourages interpretable topics (Card et al., 2018), which corresponds with the tuition that a document usually focuses on several salient topics instead of covering a wide variety of topics (Lin et al., 2019). Although NMF has given sparseness to V_t, a more direct control over such properties of the representation is still needed (Hoyer, 2004). The rest terms $\Psi(\boldsymbol{U}_t)$, $\Phi(\boldsymbol{C}_t)$, and $\Omega(\boldsymbol{B}_t)$ are the constraints on matrices $\boldsymbol{U}_t$, $\boldsymbol{C}_t$, and $\boldsymbol{B}_t$, which will be described in sections 3.2.3-3.2.5, respectively.

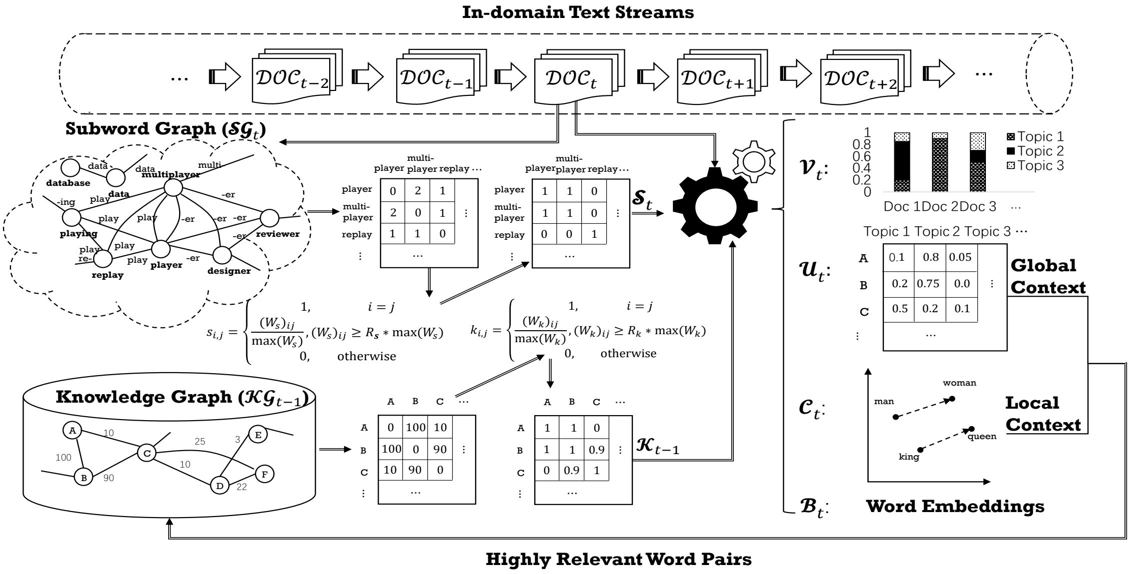

Figure 1: Lifelong Collaborative Model (LCM)

3.2.1 Knowledge Graph ($\mathcal{KG}$)

LCM uses relationships between words as the representations of our $\mathcal{KG}$ to maintain knowledge of past domains to help with the current in-domain task. $\mathcal{KG}$ accumulates the knowledge of past domains from two sources of information, i.e., the global context information mined by topic models and the local context information reflected by context word embeddings. As shown in Figure 1, the output of LCM contains the word-topic matrix $\boldsymbol{U}_t$, the topic-document matrix $\boldsymbol{V}_t$, the word embedding matrix $\boldsymbol{B}_t$, and the context word embedding matrix $\boldsymbol{C}_t$. $\mathcal{KG}$ fuels the global context and local context information with the help of $\boldsymbol{U}_t$ and $\boldsymbol{C}_t$, as follows.

For the global context information, we use the inner product to measure similarities between topic distributions of words in $\boldsymbol{U}_t$. For each word w_i in the current vocabulary of $\boldsymbol{D}_t$, we find $topT$ words w_j $(j = 1, 2, ..., T)$, whose topic distributions of all topics are most similar to w_i. Each w_j and w_i are seen as word pairs that reflect the relationship from the global context information, i.e., the topical information. After finding $topT$ related words of each word, all the word pairs are accumulated and de-duplicated. Following (Chen et al., 2020b), we set the weight of each word pair (w_i, w_j) to 1.

Regarding the local context information, we use the inner product to measure similarities between context word embeddings of words in $\boldsymbol{C}_t$. For each word w_i in the current vocabulary of $\boldsymbol{D}_t$, we find $topT$ words whose context word embeddings are most similar to this word. All word pairs represent the relationship from the perspective of local context information and their weights are set to η after de-duplication, where η adjusts the weight relationship between global context information and local context information.

Then, we accumulate the word pairs from these two sources to fuel the information of global context and local context. It is worth noting that if a word pair (w_i, w_j) appears simultaneously in the two kinds of word pairs, its weight is recorded as $1 + \eta$. De-duplication is not required here, because the relationship between two words related in both global context and local context is closer than that of two words only related in one kind of source information. We use $\mathcal{J}_t$ to denote all the related word pairs in the current in-domain corpus, and $\mathcal{J}_t$ is defined as:

$$\mathcal{J}_t = \{(W_k)_{ij}\}, \tag{2}$$

where $(W_k)_{ij}$ represents the weight of the word pair (w_i, w_j) in $\mathcal{KG}$. Finally, $\mathcal{KG}$ is updated as follows:

$$\mathcal{KG}_t = \mathcal{KG}_{t-1} + \mathcal{J}_t. \tag{3}$$

3.2.2 Subword Graph ($\mathcal{SG}$)

To incorporate subword information, LCM uses a subword graph ($\mathcal{SG}$) to store relationships between words in $\boldsymbol{D}_t$ from the perspective of subword information. The motivation of introducing $\mathcal{SG}$ is to capture more information from the structures of words themselves as the complement for global and local contexts (Bojanowski et al., 2017; Pinter et al., 2017). Many in-domain text streams contain a high proportion of rare words with low word frequencies, e.g., proper nouns in specific domains, which cannot be adequately reflected by context due to the low frequencies. Note that $\mathcal{SG}$ only mines the subword information of the current in-domain corpus since subwords are only related to domain-independent structures of words.

A typical word in English is composed by three kinds of subword units, i.e., the word root, the prefix, and the suffix[2]. Word roots and prefixes determine the meaning of words, while suffixes determine the syntactic-related part of speech. We adopt byte pair encoding (BPE) (Sennrich et al., 2016), which can implicitly match these morpheme boundaries, to conduct subword segmentation. We also compare this segmentation method with character n-gram features (Bojanowski et al., 2017) in experiments. For every word pair, the number of shared subword units between them are recorded as the weight. In the current in-domain corpus, $\mathcal{SG}_t$ is defined as:

$$\mathcal{SG}_t = \{(W_s)_{ij}\}, \tag{4}$$

where $(W_s)_{ij}$ represents the weight of the word pair (w_i, w_j) in $\mathcal{SG}_t$.

3.2.3 Constraint on U_t

Before introducing $\Psi(\boldsymbol{U}_t)$, we first construct the word-word relationship matrix $\boldsymbol{K}_{t-1} \in R^{M\times M}$ from $\mathcal{KG}_{t-1}$ to represent the closeness of relationships between words. In $\mathcal{KG}_{t-1}$, we select all of the word pairs in which both of the two words occurred in the current vocabulary of $\boldsymbol{D}_t$. Only these words contribute to the current in-domain task on $\boldsymbol{D}_t$, and all diagonal elements of $\boldsymbol{K}_{t-1}$ are 1. R_k, which represents the threshold ratio for $\mathcal{KG}$, is used to select the "close" relationships between words. For two words w_i and w_j, if the corresponding pair (w_i, w_j) occurred in the selected word pairs in $\boldsymbol{D}_t$ mentioned above, the value of k_{ij} will be determined by the threshold ratio R_k. If the weight of (w_i, w_j), i.e., $(W_k)_{ij}$, is greater than or equal to the max weight of all the word pairs in $\boldsymbol{D}_t$ multiplied by R_k, then $k_{ij} = \frac{(W_k)_{ij}}{max(W_k)}$. If it is less than the max weight multiplied by R_k or w_i and w_j are not connected in $\mathcal{KG}_{t-1}$, then $k_{ij} = 0$. In the above, R_k helps to select word pairs with relatively large weights. Although wrong connections between some word pairs are kept in our $\mathcal{KG}$, the weights of them cannot be large enough, because the max weight of $\mathcal{KG}$ becomes larger and larger over time. These pairs will not be chosen to participate in constraints of matrices. In summary, $\boldsymbol{K}_{t-1}$ is calculated as follows:

$$k_{ij} = \begin{cases} 1, & i = j \\ \dfrac{(W_k)_{ij}}{max(W_k)}, & (W_k)_{ij} \geq R_k max(W_k) \\ 0, & otherwise. \end{cases} \tag{5}$$

The word-word relationship regularization based on $\mathcal{KG}$ for $\Psi(\boldsymbol{U}_t)$ holds that the topic distributions of words that are closely related in $\mathcal{KG}$ would be more similar than those have no connection in $\mathcal{KG}$. We use the Graph Laplacian (Dai et al., 2020) as the first part of $\Psi(\boldsymbol{U}_t)$ to depict that under each topic in $\boldsymbol{U}_t$, the closer two words are connected in $\mathcal{KG}$, the closer their probabilities are. The second part of $\Psi(\boldsymbol{U}_t)$ is the diversity regularization to reduce the overlapping of topics, i.e., to improve the topic uniqueness (Nan et al., 2019). Accordingly, $\Psi(\boldsymbol{U}_t)$ is defined as follows:

$$\begin{aligned}\Psi(\boldsymbol{U}_t) =& \lambda_{u1} tr(\boldsymbol{U}_t^T \boldsymbol{H}_{t-1} \boldsymbol{U}_t) \\ &+ \lambda_{u2} \left\| \boldsymbol{U}_t^T \boldsymbol{U}_t - \boldsymbol{I}_K \right\|_F^2 .\end{aligned} \tag{6}$$

In the above, λ_{u1} and λ_{u2} are hyperparameters. $\boldsymbol{H}_{t-1} = diag(\boldsymbol{K}_{t-1} \cdot \mathbf{1}) - \boldsymbol{K}_{t-1}$ represents the Graph Laplacian of $\boldsymbol{K}_{t-1}$, where $\mathbf{1}$ represents a column vector in which all of the elements are 1, and $diag(\boldsymbol{K}_{t-1} \cdot \mathbf{1})$ represents the matrix with the vector $\boldsymbol{K}_{t-1} \cdot \mathbf{1}$ as diagonal elements. $\boldsymbol{I}_K$ is an identity matrix of order $K \times K$.

3.2.4 Constraint on C_t

$\mathcal{KG}$, which fuels the information of global context and local context from previous domains, is constructed with the help of $\boldsymbol{U}_t$ and $\boldsymbol{C}_t$. It also contributes to both the two matrices on their constraints. For $\Phi(\boldsymbol{C}_t)$, we use $\boldsymbol{K}_{t-1}$ to introduce the word-word relationship regularization. It depicts that context embeddings of words that are closely related in $\mathcal{KG}$ would be more similar than those have less connection in $\mathcal{KG}$. Specifically, under each dimension in $\boldsymbol{C}_t$, the closer two words are connected in $\mathcal{KG}$, the closer their representations are. $\Phi(\boldsymbol{C}_t)$ is calculated as follows:

$$\Phi(\boldsymbol{C}_t) = \lambda_c tr(\boldsymbol{C}_t^T \boldsymbol{H}_{t-1} \boldsymbol{C}_t), \tag{7}$$

where λ_c is a hyperparameter.

---

[2] `https://en.wikipedia.org/wiki/Root_(linguistics)`

3.2.5 Constraint on $\boldsymbol{B}_t$

The first part of $\Omega(\boldsymbol{B}_t)$ is similar to the word-word relationship regularization for $\Psi(\boldsymbol{U}_t)$ and $\Phi(\boldsymbol{C}_t)$. It holds that embeddings of words that are closely related in $\mathcal{SG}$ would be more similar than those have less connection in $\mathcal{SG}$. We also use the Graph Laplacian to depict that under each dimension in $\boldsymbol{B}_t$, the closer two words are connected in $\mathcal{SG}$, the closer their representations are. A word-word relationship matrix $\boldsymbol{S}_t \in R^{M \times M}$ is constructed from $\mathcal{SG}_t$, as follows:

$$s_{ij} = \begin{cases} 1, & i = j \\ \dfrac{(W_s)_{ij}}{max(W_s)}, & (W_s)_{ij} \geq R_s max(W_s) \\ 0, & otherwise, \end{cases} \tag{8}$$

where $(W_s)_{ij}$ represents the weight of pair (w_i, w_j) in SG_t, and R_s denotes the threshold ratio of SG. R_s helps exclude and ignore wrong connections in $\mathcal{SG}$. In addition, the cooperation of $\mathcal{KG}$ and $\mathcal{SG}$ can further reduce the influence of unimportant edges. For example, a connection that is only selected by R_k may not be as important as the connection that is selected by both of R_k and R_s simultaneously.

The second part is a sparsity constraint on $\boldsymbol{B}_t$, which depicts that each word only has features of a limited number, because we aim to learn sparse representations so that the generated domain-specific word embeddings are more interpretable.

Finally, $\Omega(\boldsymbol{B}_t)$ is defined as follows:

$$\Omega(\boldsymbol{B}_t) = \lambda_{b1} tr(\boldsymbol{B}_t^T \boldsymbol{N}_t \boldsymbol{B}_t) + \lambda_{b2} \left\| \boldsymbol{B}_t \right\|_1, \tag{9}$$

where λ_{b1} and λ_{b2} are hyperparameters. $\boldsymbol{N}_t = diag(\boldsymbol{S}_t \cdot \mathbf{1}) - \boldsymbol{S}_t$ is the Graph Laplacian of $\boldsymbol{S}_t$.

3.3 Alternately Iterative Algorithm

We develop an alternately iterative algorithm to achieve a good compromise between ease of implementation and speed. Take $\boldsymbol{B}_t$ as an example, we first calculate the derivative of the objective function L on $\boldsymbol{B}_t$ as follows:

$$\begin{aligned} \frac{\partial L}{\partial \boldsymbol{B}_t} = & -2\boldsymbol{X}_t\boldsymbol{C}_t + 2\boldsymbol{B}_t\boldsymbol{C}_t^T\boldsymbol{C}_t \\ & + 2\lambda_{b1} diag(\boldsymbol{S}_t \cdot \mathbf{1})\boldsymbol{B}_t - 2\lambda_{b1}\boldsymbol{S}_t\boldsymbol{B}_t \\ & + \lambda_{b2} \cdot \mathbf{1} \cdot \mathbf{1}^T. \end{aligned} \tag{10}$$

Based on the derivative of L on $\boldsymbol{B}_t$, the updating rule for $\boldsymbol{B}_t$ is given below:

$$\boldsymbol{B}_t \leftarrow \boldsymbol{B}_t \circ \frac{\boldsymbol{X}_t\boldsymbol{C}_t + \lambda_{b1}\boldsymbol{S}_t\boldsymbol{B}_t}{\boldsymbol{B}_t\boldsymbol{C}_t^T\boldsymbol{C}_t + J(\boldsymbol{B}_t)}, \tag{11}$$

where $J(\boldsymbol{B}_t) = \lambda_{b1} diag(\boldsymbol{S}_t \cdot \mathbf{1})\boldsymbol{B}_t + \frac{\lambda_{b2}}{2} \cdot \mathbf{1} \cdot \mathbf{1}^T$. Note that $\boldsymbol{U}_t$, $\boldsymbol{V}_t$, $\boldsymbol{C}_t$, and $\boldsymbol{B}_t$ always satisfy the non-negativity because they are updated in this multiplication form. Due to the limited space, we provide the updating rules for matrices $\boldsymbol{U}_t$, $\boldsymbol{V}_t$, and $\boldsymbol{C}_t$, the parameter inference process, the theoretical proof of the algorithmic convergence, and the time complexity analysis in Appendices A-D.

3.4 Model Scalability

Our model has a good scalability due to the "divide-and-conquer" strategy. First, we partition the large corpus into several small document chunks that belong to different domains, and we only decompose matrices of one chunk at any time. Second, we use sparse matrices to store $\mathcal{KG}$ and $\mathcal{SG}$, thus they are scalable and can be processed fast. Third, when facing a large single domain corpus in text streams, we can partition it into small sub-domain corpora and process one corpus at each time.

4 Experiments

4.1 Dataset

We evaluate our LCM on the real-world Amazon Review dataset[3] (McAuley et al., 2015; He and McAuley, 2016) from 28 departments (i.e., the first-level category). Following (Xu et al., 2018), we consider all the reviews under each second-level category as a domain. Each domain has several third-level categories, which will be used for all down-stream tasks and model evaluation. We randomly select 9 in-domain corpora to carry out experiments. Table 2 summarizes the characteristics of the selected 9 corpora, i.e., domain names, numbers of reviews and labels, the average text lengths, and vocabulary sizes. The selected corpora are preprocessed by eliminating stop-words and words with frequency (in the total reviews from 9 domains) lower than 15. Also, reviews with less than 20 words are removed.

Note that we choose the above dataset instead of other datasets for lifelong topic modeling (Gupta et al., 2020) since we focus on in-domain corpora with rare overlaps, in which, documents share few common information. For completeness, we also shuffle these 7 training domains randomly and show the results under different permutations in Appendix E.

---

Table 2: Dataset statistics.

4.2 Experimental Setting

We simulate an endless lifelong learning process using the 9 corpora. Word-word relationships in the knowledge graph are gradually accumulated on the first 7 domains. With the help of this knowledge graph, we conduct experiments on the last 2 domains and compare the model performance on both lifelong topic modeling and domain-specific word embedding learning.

We randomly select 5% reviews from "Cult Movies (CM)" for validation. To build the knowledge graph for the validation set, 5% reviews from the first 7 corpora are sampled and reviews from these 8 small-scale in-domain corpora also construct a stream of document chunks. The idea of grid search (Fayed and Atiya, 2019) is used to select the best parameters for each metric. We provide our hyperparameters search space for grid search in Appendix F. The remaining 95% reviews of the first 7 domains construct the training set. All reviews from "Science Education (SE)" and the remaining 95% documents from CM are used as the testing set.

4.3 Baselines

For lifelong topic modeling, we compare our method with the following baselines: LDA-LTM[4] (Chen and Liu, 2014b), NMF-LTM (Chen et al., 2020b), and LNTM[5] (Gupta et al., 2020). For word embedding learning, we adopt FastText[6] (Bojanowski et al., 2017), L-DEM (Xu et al., 2018), SPINE[7] (Subramanian et al., 2018), and Word2Sense[8] (Panigrahi et al., 2019). To the best of our knowledge, L-DEM is the only work focuses on lifelong learning of domain-specific word embedding. Following (Xu et al., 2018), we train other baselines in two ways for evaluation, i.e., only on the new in-domain corpus, and on the total document set by fusing the new corpus and all corpora from the previous domains. We implement NMF-LTM and L-DEM by Python according to the original papers. For the sake of fairness, the parameters of all baselines[9] are selected on the validation set in the same experimental setting as LCM.

4.4 Evaluation Metrics

Suggested by (Lau et al., 2014; Chen and Liu, 2014a,b; Wang et al., 2016; Isonuma et al., 2020), we use the normalized pointwise mutual information (NPMI) (Aletras and Stevenson, 2013) score, which closely matches human judgments, to measure the coherence of representative words of topics generated by lifelong topic models. Following (Chen et al., 2020b), top 20 words of each topic are used for calculation. Considering that it is important to discover discriminative topics, we also adopt the topic uniqueness (TU) score (Nan et al., 2019) to measure the diversity of topics. In addition, the sparsity score of the document-topic distribution (TS-U) and the topic-word distribution (TS-V) proposed by Lin et al. (2019) is further used to measure the topic sparsity quantitatively. Particularly, we use 1e-20 as the threshold to count the number of zero values in document-topic and topic-word distributions. Only values that are smaller than 1e-20 can be set to zero. Although several studies (Chang et al., 2009; Newman et al., 2010) stated that the perplexity is unable to reflect the real semantic coherence of topics and even negatively correlated with human judgements, we show this metric of each model for completeness.

As domain-specific dictionaries are relatively small and meanwhile may contain some uncommon words, it is inappropriate to evaluate domain-specific word embeddings in traditional ways, e.g., calculating the word similarity. Following (Xu et al., 2018), we build a down-stream text classification task to evaluate domain-specific word embeddings generated by different models. The two testing sets, i.e., SE and CM, are used for text classification with their third-level categories as classification labels. For each review, we use the average embedding of all of the words as its feature vector to train a SVM classifier (Bayot and Gonçalves, 2016; Qin and Wang, 2009). We use

accuracy to evaluate the effectiveness of word embeddings on the down-stream text classification task as in (Xu et al., 2018).

4.5 Result Comparison

4.5.1 Lifelong Topic Modeling

Table 3 shows the performance of different models on the lifelong topic discovery task, from which we can observe that LCM performs the best or the second best on each measure.

For the baselines, NMF-LTM achieves the best perplexity while almost the poorest TU. As mentioned in (Burkhardt and Kramer, 2019), there is a tradeoff between perplexity and TU in some cases, which means that models generating a lot of redundant topics may have a meaningless low perplexity. The reason of obtaining a low TU for NMF-LTM may be that it enforces documents within the same class would have more similar topic distributions, which is unsuitable to handle in-domain text streams since all documents in the in-domain corpus come from one class. This also influences its sparsity. For example, a document only has non-zero values for 10 topics while another document from the same class has non-zero values for another 10 topics. To get similar, they may both become non-zero for 20 topics. LNTM faces the same problem because it does not constrain the diversity among topics explicitly. The coherence score of LNTM is also unsatisfactory. A possible reason is that it treats word embeddings as topic distributions of words, which deteriorates the local semantic information captured by context word embeddings. LNTM entirely neglected the sparsity of document-topic and topic-word distributions, thus its TS-U and TS-V are zero.

LDA-LTM has a main difference with the other models, i.e., it does not construct the in-domain text stream based on time series, but fuses all of the previous domains together and accumulates the knowledge from this large corpus to help with the current in-domain corpus. Even though it is difficult to compare LDA-LTM with other lifelong topic models fairly, our LCM performs better than LDA-LTM in most cases, because we can exploit the information from local context and subwords.

The qualitative analysis of topics generated by these models is provided in Appendix G.

4.5.2 Word Embedding Learning

Figure 2 reports the accuracy of text classification using word embeddings with different dimensions. Note that sparse interpretable word embeddings always perform better when the embedding dimension is relatively large (Murphy et al., 2012). LCM performs the best in each testing set under each dimension, although some baselines (i.e., FastText, SPINE, and Word2Sense) are trained on the total 9 corpora and access more information without considering time series. L-DEM cannot learn high-quality embeddings because it needs a large amount of in-domain corpora to train its meta-learner, which is not accessible in most applications. Compared to FastText that incorporates subword information, our word embeddings perform better on classification in all cases. One possible reason is that the global context provides LCM with extra information. Two sparse word embedding models, i.e., SPINE and Word2Sense, overemphasize the sparsity while ignore the quality for downstream tasks. LCM balances well between sparsity and quality with the help of global context and subwords. We evaluate sparsity and interpretability of word embeddings in Appendix H.

For completeness, we also replace the SVM classifier with a neural network classifier (Chen et al., 2020a) consisting of 3 fully-connected layers. The results are shown in Appendix I.

4.5.3 Ablation Experiments

Take SE as an example, we report results of ablation experiments on NPMI, TU, and Accuracy in Table 4. "LCM-$\mathcal{KG}_{\mathcal{G}}$", "LCM-$\mathcal{KG}_{\mathcal{L}}$", and "LCM-$\mathcal{SG}$" represent LCM without the participation of global context in $\mathcal{KG}$, local context in $\mathcal{KG}$, and subwords in $\mathcal{SG}$, respectively. Deleting each part leads to performance degradation, which validates the

Figure 3: Analysis on catastrophic forgetting. The x-axis shows the names of domains. For each model, the bottom line indicates metrics in the original lifelong learning process, while the top line shows the model performance with the help of $\mathcal{KG}$ generated by 7 training sets and CM. The boxes with red and solid edges mark the better metric for each model in each domain, while boxes filled in red with underlined values mark the best metric in each domain among all models.

effectiveness of global context, local context, and subwords. Compared to the subword information, $\mathcal{KG}$ contributes more to topic discovery and the local context information plays the most important role in word embedding learning. We replace BPE of $\mathcal{SG}$ with character n-gram features (Bojanowski et al., 2017) in "LCM-$\mathcal{SG}_{\mathcal{BPE}}$", which indicates the effectiveness of BPE on capturing subwords.

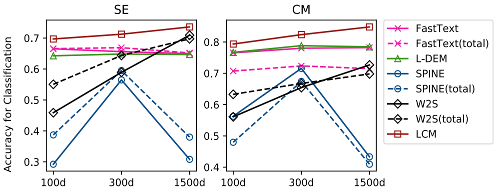

Figure 2: Classification performance comparison of SVM classifiers with word embeddings generated by different methods. Models marked with "total" are conducted on the combination of 7 training sets and the current testing set. W2S represents Word2Sense.

Method	NPMI	TU	Accuracy
LCM-$\mathcal{KG}_{\mathcal{G}}$	-0.0099	0.5790	0.7283
LCM-$\mathcal{KG}_{\mathcal{L}}$	-0.0109	0.5740	0.7244

4.5.4 Analysis on Catastrophic Forgetting

Catastrophic Forgetting (Robins, 1995; Kirkpatrick et al., 2017), which is a big challenge for lifelong topic models, will not be a serious problem for LCM. The learning process of LCM only accumulates knowledge in $\mathcal{KG}$, and the model is trained on each in-domain corpus independently by following (Chen et al., 2020b). To further investigate the ability of LCM in avoiding catastrophic forgetting, we use the final updated $\mathcal{KG}$ after CM to "go back" to help train the model on the 7 training set one by one. As LDA-LTM does not construct the in-domain text stream based on time series, we only take NMF-LTM and LNTM for comparison. In terms of NPMI and TU, Figure 3 shows that LCM has the best ability to alleviate catastrophic forgetting. For all domains, the latest $\mathcal{KG}$ will not have a significant negative impact on LCM (i.e., the catastrophic forgetting is limited), and sometimes it even helps with the new task. For example, both NMF-LTM and LCM achieve better NPMI scores with the latest $\mathcal{KG}$ in "SIM Cards & Prepaid Minutes". One possible reason is that later domains provide valuable information through $\mathcal{KG}$.

5 Conclusions

In this work, we propose a lifelong collaborative model (LCM) for learning topics and domain-specific word embeddings. LCM deals with the new in-domain corpus by coordinating global and local context information from previous domains, and subword information from the current corpus. A knowledge graph based on word-word relationships is leveraged during the learning process. Experiments on real-world in-domain text streams demonstrated the superior performances of LCM. In the future, we plan to incorporate contextualized word representations into topic models (Bianchi et al., 2020, 2021) for alleviating collapsing of word senses and learning more coherent topics.

Appendices

A Updating Rules for $\boldsymbol{U}_t$, $\boldsymbol{V}_t$, and $\boldsymbol{C}_t$

First, we transform the objective function L as:

$$\begin{aligned}
L =& \left\|\boldsymbol{D}_t - \boldsymbol{U}_t\boldsymbol{V}_t\right\|_F^2 + \left\|\boldsymbol{X}_t - \boldsymbol{B}_t\boldsymbol{C}_t^T\right\|_F^2 \\
&+ \lambda_v \left\|\boldsymbol{V}_t\right\|_1 \\
&+ \lambda_{u1} tr(\boldsymbol{U}_t^T\boldsymbol{H}_{t-1}\boldsymbol{U}_t) + \lambda_{u2}\left\|\boldsymbol{U}_t^T\boldsymbol{U}_t - \boldsymbol{I}_K\right\|_F^2 \\
&+ \lambda_c tr(\boldsymbol{C}_t^T\boldsymbol{H}_{t-1}\boldsymbol{C}_t) \\
&+ \lambda_{b1} tr(\boldsymbol{B}_t^T\boldsymbol{N}_t\boldsymbol{B}_t) + \lambda_{b2}\left\|\boldsymbol{B}_t\right\|_1 \\
=& tr(\boldsymbol{D}_t^T\boldsymbol{D}_t - 2\boldsymbol{D}_t^T\boldsymbol{U}_t\boldsymbol{V}_t + \boldsymbol{V}_t^T\boldsymbol{U}_t^T\boldsymbol{U}_t\boldsymbol{V}_t) \\
&+ tr(\boldsymbol{X}_t^T\boldsymbol{X}_t - 2\boldsymbol{X}_t^T\boldsymbol{B}_t\boldsymbol{C}_t^T + \boldsymbol{C}_t\boldsymbol{B}_t^T\boldsymbol{B}_t\boldsymbol{C}_t^T) \\
&+ \lambda_v tr(\boldsymbol{1}^T\boldsymbol{V}_t\boldsymbol{1}) \\
&+ \lambda_{u1} tr\left(\boldsymbol{U}_t^T diag(\boldsymbol{W}_{t-1}\cdot\boldsymbol{1})\boldsymbol{U}_t\right) \\
&- \lambda_{u1} tr(\boldsymbol{U}_t^T\boldsymbol{W}_{t-1}\boldsymbol{U}_t) \\
&+ \lambda_{u2} tr(\boldsymbol{U}_t^T\boldsymbol{U}_t\boldsymbol{U}_t^T\boldsymbol{U}_t - 2\boldsymbol{U}_t^T\boldsymbol{U}_t) \\
&+ \lambda_c tr\left(\boldsymbol{C}_t^T diag(\boldsymbol{W}_{t-1}\cdot\boldsymbol{1})\boldsymbol{C}_t\right) \\
&- \lambda_c tr(\boldsymbol{C}_t^T\boldsymbol{W}_{t-1}\boldsymbol{C}_t) \\
&+ \lambda_{b1} tr\left(\boldsymbol{B}_t^T diag(\boldsymbol{S}_t\cdot\boldsymbol{1})\boldsymbol{B}_t\right) \\
&- \lambda_{b1} tr(\boldsymbol{B}_t^T\boldsymbol{S}_t\boldsymbol{B}_t) \\
&+ \lambda_{b2} tr(\boldsymbol{1}^T\boldsymbol{B}_t\boldsymbol{1}) + const.
\end{aligned}$$

Then, the updating rules for matrices $\boldsymbol{U}_t$, $\boldsymbol{V}_t$, and $\boldsymbol{C}_t$ can be derived as follows:

$$\begin{aligned}
\boldsymbol{U}_t &\leftarrow \boldsymbol{U}_t \circ \frac{\boldsymbol{D}_t\boldsymbol{V}_t^T + \lambda_{u1}\boldsymbol{W}_{t-1}\boldsymbol{U}_t + 2\lambda_{u2}\boldsymbol{U}_t}{\boldsymbol{U}_t\boldsymbol{V}_t\boldsymbol{V}_t^T + Z(\boldsymbol{U}_t)}, \\
\boldsymbol{V}_t &\leftarrow \boldsymbol{V}_t \circ \frac{\boldsymbol{U}_t^T\boldsymbol{D}_t}{\boldsymbol{U}_t^T\boldsymbol{U}_t\boldsymbol{V}_t + \frac{\lambda_v}{2}\cdot\boldsymbol{1}\cdot\boldsymbol{1}^T}, \\
\boldsymbol{C}_t &\leftarrow \boldsymbol{C}_t \circ \frac{\boldsymbol{X}_t^T\boldsymbol{B}_t + \lambda_c\boldsymbol{W}_{t-1}\boldsymbol{C}_t}{\boldsymbol{C}_t\boldsymbol{B}_t^T\boldsymbol{B}_t + \lambda_c diag(\boldsymbol{W}_{t-1}\cdot\boldsymbol{1})\boldsymbol{C}_t}.
\end{aligned}$$

In the above, $Z(\boldsymbol{U}_t) = \lambda_{u1} diag(\boldsymbol{W}_{t-1}\cdot\boldsymbol{1})\boldsymbol{U}_t + 2\lambda_{u2}\boldsymbol{U}_t\boldsymbol{U}_t^T\boldsymbol{U}_t$.

B Alternately Iterative Algorithm

The inference method of our LCM is shown in Algorithm 1.

C Convergence Analysis

In this section, we analyze the convergence of Algorithm 1.

Theorem C.1. *Algorithm 1 is guaranteed to converge to a locally-optimal solution.*

Algorithm 1 Alternately Iterative Algorithm

```
Input: $\{\mathcal{DOC}_t\}_{t=1}^{T}$ ($T$ can be infinite);
Output: $\{\boldsymbol{U}_t\}_{t=1}^{T}$, $\{\boldsymbol{V}_t\}_{t=1}^{T}$, $\{\boldsymbol{C}_t\}_{t=1}^{T}$, $\{\boldsymbol{B}_t\}_{t=1}^{T}$.
$\mathcal{KG}_0 = \emptyset$;
for $t$ = 1, 2, 3, ..., $T$ do
    Randomly initialize non-negative matrices $\boldsymbol{U}_t^{(0)}$, $\boldsymbol{V}_t^{(0)}$, $\boldsymbol{C}_t^{(0)}$, $\boldsymbol{B}_t^{(0)}$;
    Construct $\boldsymbol{S}_t$ from $\mathcal{SG}_t$;
    Construct $\boldsymbol{K}_{t-1}$ from $\mathcal{KG}_{t-1}$;
    Set the iteration number $i$ to 0;
    repeat
        $i = i + 1$;
        Compute $\boldsymbol{B}_t^{(i)}$, $\boldsymbol{U}_t^{(i)}$, $\boldsymbol{V}_t^{(i)}$, and $\boldsymbol{C}_t^{(i)}$;
    until convergence;
    Compute $\mathcal{KG}_t$ using Eq. (3).
end
```

First, we prove the convergence of the update rule of $\boldsymbol{B}_t$ in Eq. (11).

Definition C.1. *$G(x, z)$ is an auxiliary function for $F(x)$ if the following conditions are satisfied.*

$$G(x, z) \geq F(x), G(x, x) = F(x).$$

Lemma C.1. *If G is an auxiliary function, then F is non-increasing under the following update rule:*

$$x^{t+1} = arg\min_x G(x, x^t). \tag{12}$$

Proof.

$$F(x^{t+1}) \leq G(x^{t+1}, x^t) \leq G(x^t, x^t) = F(x^t).$$

□

If we could prove that the updating rule of $\boldsymbol{B}_t$ confirms to Eq. (12) for an appropriate auxiliary function, we would conclude that $\boldsymbol{B}_t$ converges to a local minimum.

Lemma C.2. *Let $z = (\boldsymbol{B}_t)_{ij} > 0$, $G(x, z)$ is an auxiliary function for $F(z) = L\left((\boldsymbol{B}_t)_{ij} = z\right)$.*

$$\begin{aligned}
G(x, z) =& F(z) + \frac{\partial F(z)}{\partial z}(x - z) + \frac{(x-z)^2}{z} \\
& (\boldsymbol{B}_t\boldsymbol{C}_t^T\boldsymbol{C}_t + \lambda_{b1} diag(\boldsymbol{S}_t\cdot\boldsymbol{1})\boldsymbol{B}_t \\
& + \frac{\lambda_{b2}}{2}\cdot\boldsymbol{1}\cdot\boldsymbol{1}^T)_{ij}.
\end{aligned}$$

Proof. Clearly, $G(x, x) = F(x)$. Taylor expansion of $F(x)$ is:

$$F(x) = F(z) + \frac{\partial F(z)}{\partial z}(x - z) + \frac{1}{2}\frac{\partial^2 F(z)}{\partial z^2}(x - z)^2.$$

In order to show G is an auxiliary function, we have to show $G(x,z) \geq F(x)$:

$$\frac{\left(\boldsymbol{B}_t\boldsymbol{C}_t^T\boldsymbol{C}_t + \lambda_{b1} diag(\boldsymbol{S}_t \cdot \mathbf{1})\boldsymbol{B}_t + \frac{\lambda_{b2}}{2} \cdot \mathbf{1} \cdot \mathbf{1}^T\right)_{ij}}{z} \geq \frac{1}{2}\frac{\partial^2 F(z)}{\partial z^2},$$

where $\frac{\partial^2 F(z)}{\partial^2 z} = 2(\boldsymbol{C}_t^T\boldsymbol{C}_t)_{jj} + 2\lambda_{b1}(diag(\boldsymbol{S}_t \cdot \mathbf{1}))_{ii} - 2\lambda_{b1}(\boldsymbol{S}_t)_{ii}$.

To prove the inequation, we first verify how the inequality holds on the first term:

$$\begin{aligned}
\frac{(\boldsymbol{B}_t\boldsymbol{C}_t^T\boldsymbol{C}_t)_{ij}}{(\boldsymbol{B}_t)_{ij}} =& \frac{1}{(\boldsymbol{B}_t)_{ij}}\sum_k (\boldsymbol{B}_t)_{ik}(\boldsymbol{C}_t^T\boldsymbol{C}_t)_{kj} \\
=& \frac{1}{(\boldsymbol{B}_t)_{ij}}\sum_{k=j} (\boldsymbol{B}_t)_{ik}(\boldsymbol{C}_t^T\boldsymbol{C}_t)_{kj} \\
&+ \frac{1}{(\boldsymbol{B}_t)_{ij}}\sum_{k\neq j} (\boldsymbol{B}_t)_{ik}(\boldsymbol{C}_t^T\boldsymbol{C}_t)_{kj} \\
=& \frac{1}{(\boldsymbol{B}_t)_{ij}}(\boldsymbol{B}_t)_{ij}(\boldsymbol{C}_t^T\boldsymbol{C}_t)_{jj} \\
&+ \frac{1}{(\boldsymbol{B}_t)_{ij}}\sum_{k\neq j} (\boldsymbol{B}_t)_{ik}(\boldsymbol{C}_t^T\boldsymbol{C}_t)_{kj} \\
\geq& (\boldsymbol{C}_t^T\boldsymbol{C}_t)_{jj}.
\end{aligned}$$

Similarly, we can get:

$$\lambda_{b1}\left(diag(\boldsymbol{S}_t \cdot \mathbf{1})\boldsymbol{B}_t\right)_{ij} \geq \lambda_{b1}\left(diag(\boldsymbol{S}_t \cdot \mathbf{1})\right)_{ii}.$$

Since λ_{b1}, λ_{b2}, and each element in $\boldsymbol{S}_t$ are nonnegative, we have the above inequation. This establishes that G is an auxiliary function for F. □

Proof. To show that Algorithm 1 converges (i.e., Theorem C.1), we need to show that update rule for $\boldsymbol{B}_t$ follows Eq. (12). $\frac{\partial G(x,z)}{\partial x}$ is listed as follows:

$$\begin{aligned}
\frac{\partial G(x,z)}{\partial x} =& (-2\boldsymbol{X}_t\boldsymbol{C}_t + 2\boldsymbol{B}_t\boldsymbol{C}_t^T\boldsymbol{C}_t \\
&+ 2\lambda_{b1} diag(\boldsymbol{S}_t \cdot \mathbf{1})\boldsymbol{B}_t - 2\lambda_{b1}\boldsymbol{S}_t\boldsymbol{B}_t \\
&+ \lambda_{b2} \cdot \mathbf{1} \cdot \mathbf{1}^T)_{ij} \\
&+ \frac{x-z}{z} \cdot 2(\lambda_{b1} diag(\boldsymbol{S}_t \cdot \mathbf{1})\boldsymbol{B}_t \\
&+ \boldsymbol{B}_t\boldsymbol{C}_t^T\boldsymbol{C}_t + \frac{\lambda_{b2}}{2} \cdot \mathbf{1} \cdot \mathbf{1}^T)_{ij}.
\end{aligned}$$

Solving $\frac{\partial G(x,z)}{\partial x} = 0$ for x, we get the update rule as mentioned in Eq. (11). Since G is the auxiliary function for F, the value of F is non-increasing. We can prove the convergence of update rules for $\boldsymbol{U}_t$, $\boldsymbol{V}_t$, and $\boldsymbol{C}_t$ similarly. Thus, Algorithm 1 is guaranteed to converge to a local minimum. □

D Time Complexity Analysis

In this section, we analyze the time complexity of Algorithm 1. For updating matrices $\boldsymbol{B}_t$, $\boldsymbol{U}_t$, $\boldsymbol{V}_t$, and $\boldsymbol{C}_t$, the time complexity of one iteration is $O((3E+1)M^2+(2E^2+3E)M)$, $O((3E+1)M^2+(2E^2+2E)M)$, $O(MNK+2M^2K+3MK^2+NK^2+M^2+2MK)$, and $O(3KMN+3KN)$, respectively. Thus, the time complexity of each iteration is $O(4MNK+(6E+3)M^2+(4E^2+5E)M+2M^2K+3MK^2+NK^2+2MK+3KN)$ for our method, which spends an extra time cost of $O((6E+2)M^2+(4E^2+5E)M-(2K+1)N^2)$ to learn word embeddings when compared with the previous NMF-based lifelong topic model, i.e., NMF-LTM (Chen et al., 2020b). Although the time complexity is proportional to M, we can alleviate the scalability issue simply. For example, if M (i.e., the vocabulary) of a single domain is too large, we can partition this domain into several small subdomain corpora. At each time, we only process matrices of one sub-domain, and M of each small sub-domain will not be too large.

As an illustration, it costs about 30 seconds per iteration for training LCM based on a workstation equipped with Intel(R) Xeon(R) CPU E5-2680 v3 @ 2.50 GHz, 8 cores and 128G memory. To achieve convergence, LCM costs about 1 hour to update $\boldsymbol{B}_t$, $\boldsymbol{U}_t$, $\boldsymbol{V}_t$, and $\boldsymbol{C}_t$ for all domains in order. NMF-LTM costs about half an hour accordingly.

E Different Permutations of Training Domains

We shuffle training domains randomly for 5 times, and show the results under these different permutations in Table 5, which indicates that LCM is robust to domain permutations.

F Search Space of Hyperparameters

Table 6 shows the search space of hyperparameters for grid search in our LCM. To ensure a fair comparison with NMF-LTM (Chen et al., 2020b), *topT* in LCM is set to 5. For each word, our knowledge graph selects 5 most similar words from global and local context information, respectively. In other words, each word is connected to 10 similar words, which is equivalent to NMF-LTM. Note that for the topic number, we select 50 as topic numbers for all evaluations of LCM after validation. For fair comparison, we directly choose 50 as topic numbers for baselines and this is not a hyperparameter

Permutation	Science Education (SE)				Cult Movies (CM)

Table 8: Variances of results.

of baselines. We list the best hyperparameters on the validation set for different metrics in Table 7. We provide the search space of hyperparameters for grid search in all of our baselines and their corresponding best hyperparameters in our codes.

For hyperparameters, we first varied search spaces for sensitive analysis and observed that LCM was robust to most hyperparameters. Thus, we used final search spaces in Table 6. For completeness, we also show the variances of results under different hyperparameter values in Table 8. Take some hyperparameters in CM as examples, we vary each parameter when others are fixed, and compute the variances of NPMI and Accuracy, which indicates that LCM is robust to most hyperparameters.

G Qualitative Analysis of Topics

Following (Chen et al., 2020b), we map the topics learned by LCM with ones by LDA-LTM (Chen and Liu, 2014b), LNTM (Gupta et al., 2020), and NMF-LTM (Chen et al., 2020b), respectively. Particularly, we represent each topic by its top 20 words, and compute the cosine similarity between every two topics. Take SE as an example, we randomly show 3 topics, as listed in Table 9. Irrelevant words are marked by italics.

LDA-LTM, NMF-LTM, and LCM learn topics well in most cases. However, NMF-LTM captures some high-frequency words (i.e., amazon, anatomy, anatomical) in the corpus, which are not related to the topic "Design and production of handicrafts". LDA-LTM also assigns an irrelevant word "print" to the topic "Machinery and industrial manufacturing technology", and an irrelevant word "spring" to the topic "Body structure and anatomy".

The ability of LNTM in generating cohesive topics is poor. It is noteworthy that the topics generated by LNTM seem not related to other models, because we use cosine similarity to map topics. If the cosine similarities are the same (for LNTM, it is 0 sometimes), the topics with smaller IDs will be chosen. For the sake of fairness, we also show a relatively coherent topic generated by LNTM separately in Table 10. The result of LNTM is still worse than other models, which contains 7 irrelevant words in the top 10 word list.

H Evaluating Interpretability

To evaluate the interpretability of our domain-specific word embeddings, we follow (Murphy et al., 2012) to show top 5 words for 5 randomly chosen dimensions in word embeddings generated from CM. Although there exists noisy words, the dimensions are generally semantically coherent and interpretable. We also choose one polysemous word "cell" in SE to measure the ability of our method in capturing the polysemous nature of words. We select the two highest values of the word vector learned by our LCM for "cell", and find top 5 words in these two dimensions. From Table 11, we can observe that the two dimensions focus on cells in biology and cell phones, which reflect the two different meanings of "cell".

Table 12 shows the classification accuracy and the sparsity (i.e., the proportion of zeros) of word embeddings generated by different methods, where the dimension is 1500. Compared with other models, our LCM generates domain-specific word embeddings with a good balance between sparsity and classification accuracy.

Method	Science Education		Cult Movies	
	Accuracy	Sparsity	Accuracy	Sparsity
SPINE	0.3080	0.9969	0.4332	0.9979
Word2Sense	0.7043	0.9920	0.7267	0.9920
LCM	0.7360	0.9438	0.8481	0.9099

Table 12: Classification accuracy and sparsity of word embeddings generated by different methods.

I Evaluating Word Embedding Learning Models by Neural Networks

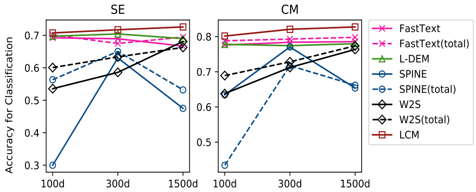

Figure 4: Classification performance comparison of neural networks with word embeddings generated by different methods.

To compare different word embedding learning models comprehensively, we replace the SVM classifier with a neural network classifier consisting of 3 fully-connected layers. As shown in Figure 4, LCM also performs the best in each testing set under each dimension.

Leveraging Argumentation Knowledge Graph for Interactive Argument Pair Identification

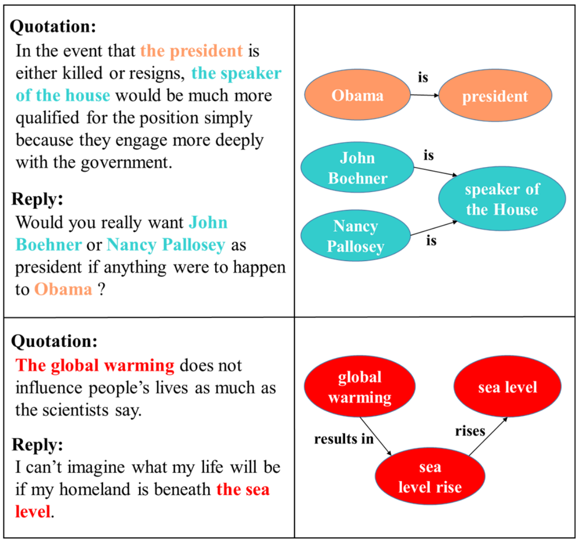
Abstract

Interactive argument pair identification is essential in the context of dialogical argumentation mining. Existing research treats it as a problem of sentence matching and largely relies on textual information to compute the similarities. However, the interaction of opinions usually involves the background of the topic and requires reasoning of knowledge, which is beyond textual information. In this paper, we propose to leverage external knowledge to enhance the identification of interactive argument pairs. We construct the argumentation knowledge graph from the discussion thread of the target topic in the online forum. The interaction between the original argument and the reply is then represented as the path of concepts in the knowledge graph. In practice, we utilize Graph Convolutional Network (GCN) to learn the concept representation in the knowledge graph and use a Transformer-based encoder to learn the representation of paths. Finally, an information alignment network is employed to capture the interaction of textual information of conceptual information (both entity-level and path-level). Experiment results indicate that our model achieves state-of-the-art performance in the benchmark dataset. Further analysis demonstrates the effectiveness of our model for enforcing knowledge reasoning through paths in the knowledge graph.

1 Introduction

Argumentation Mining aims at analyzing the semantic and logical structure of argumentative texts. Existing research covers argument structure prediction (Morio et al., 2020; Li et al., 2020), persuasiveness evaluation (Al Khatib et al., 2020; El Baff et al., 2020) and argument summarization (Bar-Haim et al., 2020b,a). Most of them focus on monological context like student essays, public speeches, etc., where only one participant is involved.



Quotation:
In the event that the president is either killed or resigns, the speaker of the house would be much more qualified for the position simply because they engage more deeply with the government.

Reply:
Would you really want John Boehner or Nancy Pallosey as president if anything were to happen to Obama ?

Quotation:
The global warming does not influence people's lives as much as the scientists say.

Reply:
I can't imagine what my life will be if my homeland is beneath the sea level.

Figure 1: Two instances of interactive argument pairs, the related concepts are colored same, and the corresponding knowledge is visualised in the right side.

Online forums such as idebate[1] and changemyview[2], enable people to exchange opinions on some specific topics freely. The user generated dataset of interactive arguments also motivates another line of research for argumentation in dialogical context (Asterhan and Schwarz, 2007). Initial researches in this filed focused on analyzing the ChangeMyView data (Tan et al., 2016; Wei et al., 2016) to summarize the key factors of persuasive arguments. Furthermore, Ji et al. (2019) and Cheng et al. (2020) propose the task of identifying and extracting interactive arguments. Ji et al. (2019) formulate this task as a problem of sentence pair scoring and computes the textual similarity

between the two arguments as the result. Such task is then further applied to other fields such as legal domain. For instance, Yuan et al. (2021) organize a challenge aimed to identify the interactive arguments from the plaintiff and the defense in a legal case. However, the interaction of argumentation is beyond text matching.

Two sample pairs of interactive arguments are shown in Figure 1. Both pairs of arguments share a limited number of overlapping tokens and fail existing models. We have two observations. Firstly, background knowledge needs to be involved. In the first sample, we need to know that ”Obama” is the ”president”, and both ”John Boehner” and ”Nancy Pallosey” are the ”speaker of the house” to understand the context. Secondly, knowledge reasoning is necessary. In the second sample, the relationship between ”global warming” and ”sea level” is implied by a series of causal effects. Furthermore, as is shown in the example, an effective way of leveraging commonsense and causal effect knowledge is to find the reasoning paths between the concept entity pairs. Therefore, we argue that retrieving and understanding the reasoning paths should be incorporated for the identification of interactive arguments.

In this paper, we propose to leverage external knowledge to enhance the automatic identification of interactive arguments via background knowledge modeling and reasoning. We start with constructing an argumentation knowledge graph following (Khatib et al., 2020) based on the context of the discussion. Then, we extract entities of each argument and link them with the external knowledge graph to obtain the concept embedding as background knowledge. Besides, we generate paths connecting each pair of entities and encode them via a transformer encoder to enforce the reasoning. Finally, we integrate the entity embeddings, path representations, and textual embedding via an information alignment network to learn the final representation of the argument pair and output a real value as the matching score. We evaluate our proposed model on a publicly available dataset and experimental results show its effectiveness compared to some state-of-the-art approaches. Further analysis of the path encoding module reveals that our model is able to perform knowledge reasoning to some extent.

Statistics	**w/o. grounding**	**w. grounding**
# of nodes	291,199	291,199
# of edges	785,036	859,534
avg. degree	2.696	2.952
# of connected components	13,805	10,035

Table 1: Basic statistics on the argumentation graph without and with concept grounding.

2 Argumentation Knowledge Graph Construction

Data Source The experimental dataset (Ji et al., 2019) in our research is constructed on top of the *CMV* dataset (Tan et al., 2016). In order to provide external knowledge for the identification of interactive arguments, we construct an argumentation knowledge graph based on the CMV dataset. *ChangeMyView* (CMV) is an online forum where users can either submit a post to elaborate their own viewpoints and invite other users to convince them of the opposite opinion or reply to others' posts to change the poster's original view. Tan et al. (2016) crawled 20,626 discussion threads with more than two posts from January 2013 to September 2015. We first extract all the concept-relation-concept triples (e_i^h, r_i, e_i^t) in the ith entry of the data source using Open Information Extraction (OpenIE). Our raw graph is thus $G = (V, E)$, where $V = \{e_i^h\}_{i=1}^n \cup \{e_i^t\}_{i=1}^n$ and $E = \{r_i\}_{i=1}^n$. The raw knowledge graph contains 291,199 nodes and 785,036 edges.

Concept Grounding In order to further improve the quality of the knowledge graph, we conduct concept grounding to align all the nodes that share common conceptual meanings. Specifically, we use *WordNet* and Wikipedia API *TagMe* (Ferragina and Scaiella, 2010) in this process. If two concepts e_i, e_j are synonyms or refer to the same entry on Wikipedia, we add a new edge r_{equal} to the graph's edge set E. After concept grounding, the size of the edge set E expands to 859,534 with the size of the node-set V remained fixed. Some basic statistics of the knowledge graph are as shown in Table 1. It indicates that concept grounding increases the number of edges in a large margin and alleviates the problem of the sparsity of the original graph.

3 Proposed Model

Given an original argument q and its context c_q, and five candidate replies $\{r_i\}_{i=1}^5$ with their corresponding contexts $\{c_i\}_{i=1}^5$, the model needs to

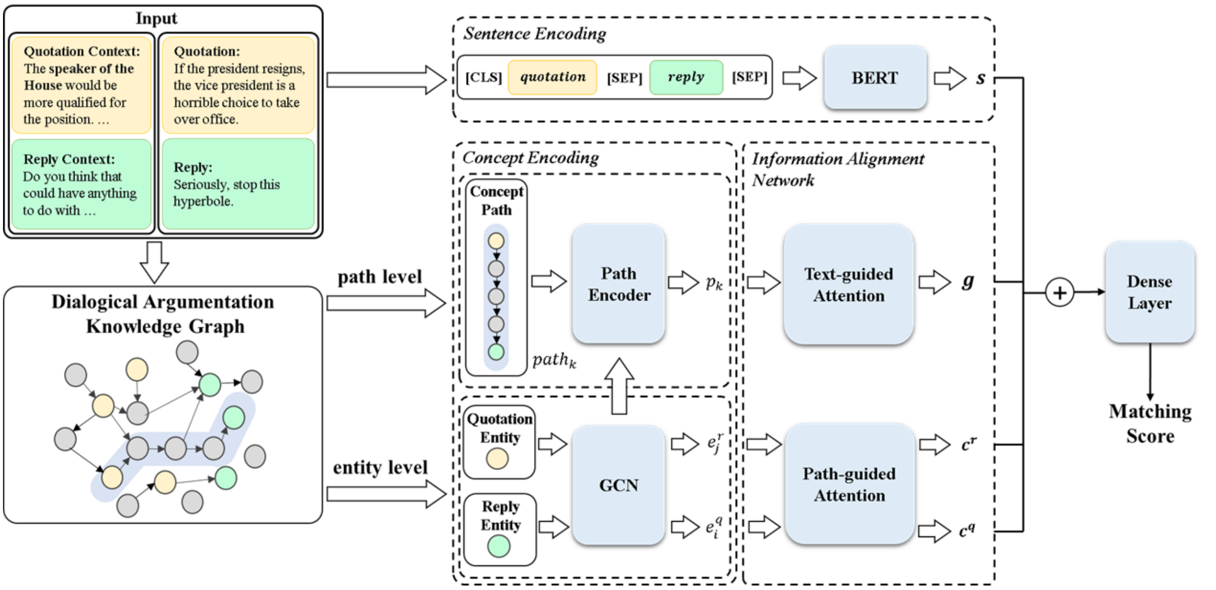

Figure 2: Illustration of the detailed architecture of our model to generate the matching feature vector, which mainly consists of three modules, a Sentence Encoder, a Concept Encoder and an Information Alignment Network. The output of these modules is then fed to a 2-layer perceptron to achieve the final matching score for the given argument pair.

identify the correct reply for q. We score each candidate pair independently and choose the reply with the highest score as the output. Moreover, in order to enable our model to conduct a reasoning process, we extract all the concept entities mentioned in the contexts from both sides, and also the concept paths that connect them. For simplicity, we will use sentence pairs to refer to the quotation and reply arguments and use concept pairs to refer to both the entities and paths in the following sections.

The full architecture of our scoring model is shown in Figure 2. It takes a sentence pair, and the concept pair extracted from its corresponding contexts as inputs and outputs a real value as its matching score. Our model mainly consists of three components, namely, sentence encoding, concept encoding, and information alignment network. We use a pre-trained language model, BERT, to learn the argument pair representation (§3.1), and encode the concept information from two levels, both entity level and path level with graph networks (§3.2). The information alignment network then integrates the sentence pair encoding and the concept encoding through a hierarchical attention mechanism to obtain the full matching features (§3.3), which are finally fed into a multi-layer perceptron (MLP) to calculate the final matching score (§3.4).

3.1 Sentence Encoding

As for the quotation and reply arguments, it is critical to use the semantic information implied in the texts. Various works have already proved the outstanding performance of pre-trained models in semantic modeling. In our work, we use the BERT model to generate the encoding s for the given argument pair by simply creating a sentence that takes the form of ”[CLS] q [SEP] r [SEP]” and taking the embedding for the ”[CLS]” token, just as suggested by previous works (Talmor et al., 2019).

3.2 Concept Encoding

For entities in the argumentation knowledge graph, we need to obtain the representation for each node. We use the BERT model with average pooling to get the initial representation for each entity. Then we encode the conceptual information in both entity-level and path-level with graph networks to enforce the background knowledge modeling and reasoning.

3.2.1 Entity Level Representation

To utilize the structural information entailed in the knowledge graph, we apply a 2-layer Graph Convolutional Network (GCN) to it. Here we adopt GCN as it has proved to be both effective and efficient in merging the node's neighbours' information into itself (Zhang et al., 2018).

Formally, let $X \in \mathbb{R}^{n \times d}$ representing the embedding matrix for all n nodes, where each node's embedding is of size d. Denote $D \in \mathbb{R}^{n \times n}$ as the diagonal degree matrix and $A \in \mathbb{R}^{n \times n}$ as the adjacency matrix of the graph G. Then the normalized symmetric adjacency matrix of the graph G can be calculated as:

$$\tilde{A} = D^{-\frac{1}{2}} A D^{-\frac{1}{2}} \tag{1}$$

By feeding the graph G into the 2-layer GCN, the final graph representation $L \in \mathbb{R}^{n \times d}$ can be calculated as:

$$L = \sigma(\tilde{A}\sigma(\tilde{A}XW_0)W_1), \tag{2}$$

where σ stands for the non-linear function (RELU), and $W_0, W_1 \in \mathbb{R}^{d \times n}$ are trainable parameters of the network.

3.2.2 Path Level Representation

To further utilize the external knowledge, we want to encode the concept path retrieved from the knowledge graph, where a path starts from a concept e_q mentioned in the original post(i.e. quotation) q, traverses through the neighbored concepts, and finally ends at a concept e_r extracted from the reply r. For each concept pair, we choose the shortest path (if exists) between them as the path connecting them.

We use the GCN output as the representation for each node that appears in the path, hence we can denote the path between the i-th concept in q (c_i^q) and the j-th concept (c_j^r) in r as $P_{ij} = (c_i^q, c_1, ...c_{m_{ij}-1}, c_j^r) \in \mathbb{R}^{m_{ij} \times d}$, where m_{ij} is the the length of the path P_{ij}.

Transformer (Vaswani et al., 2017) has been shown powerful due to its self-attention mechanism, thus, we choose it to encode the path we collected from the knowledge graph. To underline the influence of the sequence in each path, we add the path's embedding with positional embedding PE. To sum up, our path encoder generates the representation for each $Path_{ij}$ as:

$$p_{ij} = \text{Transformer\_Encoder}(P_{ij} + PE). \tag{3}$$

The output is finally fed to a fully-connected layer to fit into the size of d.

3.3 Information Alignment Network

We then align the semantic information and the conceptual information through a hierarchical attention mechanism, i.e. a text-guided attention network for paths and a path-guided attention network for entities.

3.3.1 Text-guided Attention over Paths

Note that for the given argument pair and their contexts, we already have all the paths' encoding from previous modules. We first use attention between the k-th paths p_k and semantic vector s to integrate the encoding for all the paths g:

$$\alpha_k = sW_2p_k, \tag{4}$$

$$\hat{\alpha} = \text{SoftMax}(\alpha), \tag{5}$$

$$g = \sum_k \hat{\alpha}_k p_k, \tag{6}$$

where W_2 is a parameter matrix to be learned, α and $\hat{\alpha}$ stands for the unnormalized and normalized attention weights.

3.3.2 Path-guided Attention over Concepts

Obtaining the full paths' representation g, we can further aggregate all the concepts' encoding $\{e_i\}$ of both sides using attention between them and g to generate the final representation of concepts c^q and c^r:

$$\beta_i^s = gW_3^s e_i^s, \tag{7}$$

$$\hat{\beta}^s = \text{SoftMax}(\beta^s), \tag{8}$$

$$c^s = \sum_i \hat{\beta}_i e_i^s, \tag{9}$$

where the subscript $s \in \{q, r\}$ indicates whether the concepts are from quotation or reply, W_3^q and W_3^r are parameters matrix to be learned, while $\hat{\beta}^q$ and $\hat{\beta}^r$ stand for the attention weights.

3.4 Matching Scoring

Eventually, we concatenate the textual information s, the reasoning paths information g and the concepts information c^q, c^r as the final feature and feed it to 2-layer perceptron to generate the matching score S of the given argument pair:

$$f = [s; g; c^q; c^r], \tag{10}$$

$$S = \sigma(W_S f + b_S), \tag{11}$$

where σ refers to the the rectified linear activation function (ReLU), W_S and b_S represent the weight vector and the bias respectively.

After obtaining the matching score for each argument pair, we treat the task as a sentence pair ranking problem, and use MarginRankingLoss for training:

$$L = \sum_{i=1}^{4} \max(0, \gamma - S(q, r^+) + S(q, r_i^-)), \tag{12}$$

where $S(q, r^+)$ refers to the matching score of the positive argument pair while $S(q, r_i^-)$ refers to the matching score of the i-th negative argument pair, and γ is the margin hyperparameter.

4 Experiments

In this section, we will introduce the dataset, the evaluation metrics, comparative models and experiment results.

4.1 Experiment Setup

Experimental Dataset We use the dataset constructed in (Ji et al., 2019) for evaluation. The authors find that in the *ChangeMyView* dataset (Tan et al., 2016), there exist replies that quote sentences from the original post. They extract all these *quotation-reply* pair q, r from posts in *ChangeMyView* dataset (Tan et al., 2016). For every interactive argument pair, they randomly sample four negative replies $\{r_i^{neg}\}_{i=1}^4$ along with their contexts $\{c_i^{neg}\}_{i=1}^4$ from the same discussion thread. It contains 11,565 and 1,481 instances in training set and test set respectively. Furthermore, we randomly split 10% of the training set as validation set.

Implementation Details The output dimensions for the two layers in GCN are 256 and 128 respectively, the path transformer encoder we use is stacked by 6 encoder layers. The margin γ used in MarginRankingLoss is set to 0.5. Dropout is used as 0.1 to avoid overfitting. We use Adam as our optimizer with a learning rate set to 5×10^{-6} and weight decay set to 5×10^{-6}. We run our model for 100 epochs with early stop (Caruana et al., 2000).

Models for comparison We compare the performance of some state-of-the-art models.

- **BiGRU**: This method uses a Bidirectional GRU to encode the quotation and the reply argument separately and integrates their representations into a multilayer perceptron (MLP) to get the matching score.

- **VAE** : This method uses variational auto encoder through an encoder-decoder based architecture to get the encoding of the arguments and utilizes MLP for scoring.

- **DVAE** (Rolfe, 2017): This method substitutes the above *VAE* module with a discrete variational auto encoder and adopts the former framework.

- **BERT** (Devlin et al., 2019): This method fine-tunes the pre-trained BERT model for sentence-pair classification. Note that this model is not only a baseline model but also a sub-module of our proposed model.

Note that the above models only utilize the sentences of q and r, we also extend these models to incorporate context information.

- **RNN Context**: This method uses another BiGRU module to encode the context information of each argument and concatenate it with the argument representation to get the final features.

- **Hierarchical Context** (Ji et al., 2019): This method uses a token-level CNN with an attention mechanism to achieve the sentence-level information and then integrates such sentence representation with a BiGRU layer to obtain the final context encoding.

4.2 Overall Performance

We report both precision at one(P@1) and mean reciprocal rank (*MRR*) for evaluation. The performance of all the baseline models and our proposed model is as listed in Table 2. We have the following findings.

- Among all the context-agnostic baseline models, the BERT model achieves the highest performance, and it even defeats all other models that utilize the context information, indicating that such pre-trained language model does better encode the semantic information entailed in the texts.

- Incorporating context information is crucial for identifying interactive argument pairs, as is proved by the fact that all the context-aware models significantly outperform their counterpart baseline models.

- In comparison with all the context encoding methods, hierarchical context modeling outperforms the *RNN* method. Our method outperforms the hierarchical method, which proves the effectiveness of our model.

4.3 Ablation Study

The results of the ablation study are shown in the Table 3. We can find that the Path Transformer contributes greatly to the whole framework since

Methods	P@1(%) Dev Set	P@1(%) Test Set	MRR(%) Dev Set	MRR(%) Test Set
Random Guess	20	20	45.67	45.67
BiGRU	65.92	51.52	75.22	70.57
BiGRU+RNN Context	69.29	55.98	80.51	73.20
BiGRU+Hierarchical Context	70.93	57.46	82.47	73.72
VAE+Hierarchical Context	71.28	58.61	83.82	74.66
DVAE+Hierarchical Context*	73.70	61.17	85.14	76.16
BERT	73.18	61.85	84.69	76.57
BERT+Hierarchical Context	76.81	66.85	86.38	78.51
Ours	78.33	**68.75**	87.43	**80.85**

Table 2: Performance comparison for all the models on the development dataset and the test dataset, where the sign '*' represents the former state-of-the-art model. The best result on the test set is in **bold**

Model	P@1	MRR
Sentence + Concept + Align	68.75	80.85
: BiGRU as Path Encoder	67.12	79.46
: w/o Alignment Layer	65.48	79.39
: w/o Path Transformer	64.41	77.41
: w/o Concept Encoder	61.85	76.57
: w/o Sentence Encoder	51.96	68.83

Table 3: Ablation study on our proposed framework.

the model's performance drops by over 4% in P@1. This shows that besides the textual features and the concepts that directly appear in the argument, the concepts that emerge in the reasoning path are also important when considering whether two arguments have interactive relations.

5 Further Analyses

We conduct some further analyses to have a deeper understanding of the working mechanism of concept paths. Besides, we present an error analysis and a case study.

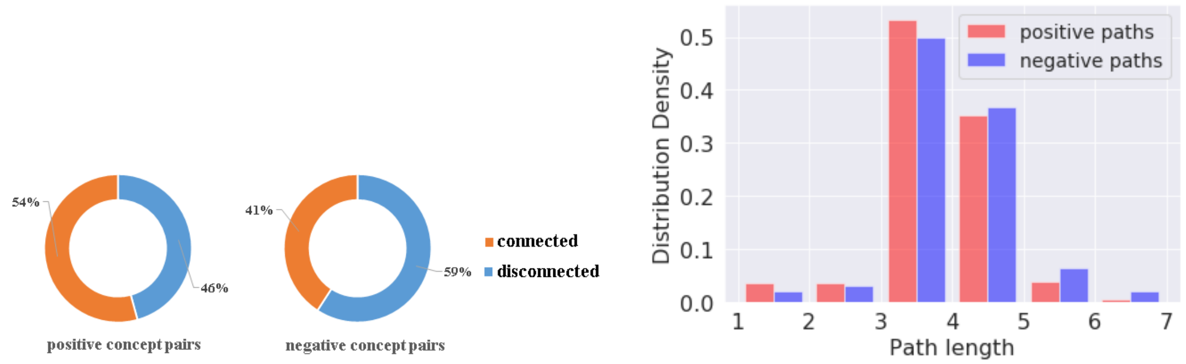
5.1 Analysis on Reasoning Path

Without ambiguity, we use positive paths and negative paths to refer to the paths that connecting the concepts in positive argument pair samples and the ones in the negative samples.

Connectivity between concept pairs First, we calculate the connectivity between each concept pair, and the results are as shown in Figure 3(a). In all the concept pairs of the two sides, the ones from a positive argument pair have a probability of 54% to form a reasoning path while the ones from a negative sample only have 41%, which conforms with the fact that an interactive argument pair mainly talk about the same topic or subject.

Path length distribution We present the distribution of the length of concept paths in Figure 3(b). The vast majority of the path lengths lie in the range from 3 to 4, while the lengths of the positive paths are generally shorter than those of the negative paths. We owe such a difference in the average length to the fact that, in positive argument pairs, the replies tend to directly use the concepts mentioned in the quotation (the reasoning path between such concept pair is hence 1). Another interpretation for the shorter average length in positive pairs is that the longer the reasoning path is, the more likely it is to become an off-topic or off-subject reply.

Path relations We further analyze the types of concept paths generated by investigating the relations appearing in the path. As discussed in the Introduction(§1), there are mainly two types of external knowledge needed to handle the interactive argument pair identification task, namely the commonsense knowledge and the causal effect knowledge. Hence, we would like to see how much proportion of these two types of knowledge occurs in the reasoning paths respectively. For common sense knowledge, we pick out the relations that contain the **be verbs** and their variants, assuming such words indicate the relation of equivalence. And as for the causal effect relations, we use a set of lexical indicators from *+/-EffectWordNet* (Choi and Wiebe, 2014), *ConnotationWordNet* (Kang et al., 2014) and *Connotation Frames* (Rashkin et al., 2016). These lexicons all evaluate the causal effect of a given predicate. The distribution of relations under



(a) The existence of reasoning paths between every concept pair in the contexts of the quotation and the reply.

(b) The distribution of path length in the positive argument pair samples and in the negative samples.

(c) The distribution of path relations in all the reasoning paths.

(d) The impact of different paths filtered by the path length on *P@1*.

Figure 3: The results of our further analysis on the reasoning paths.

such criterion is as shown in the Figure 3(c), from which we can find that near 40% of the relations belong to the common sense knowledge while 44% of the relations are of causal effect relations (31% for the positive effect and 13% for the negative effect).

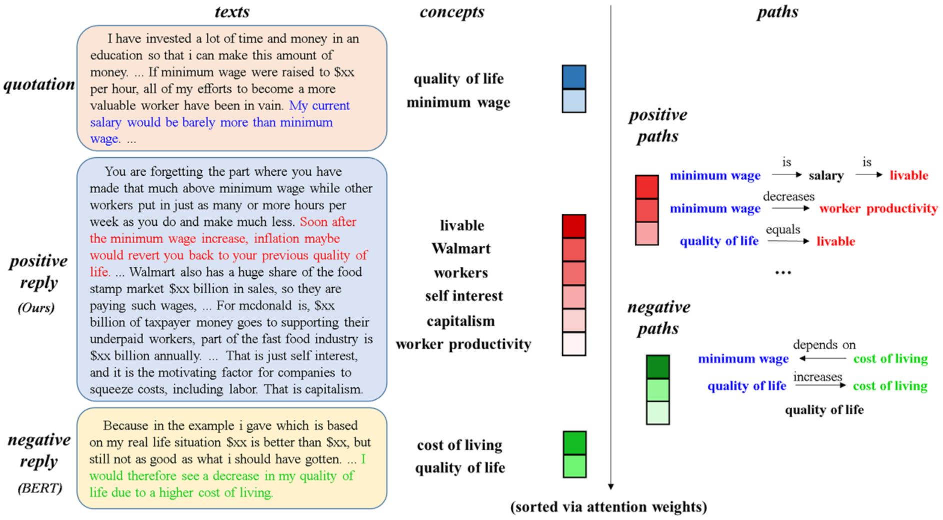
Impact of path length on model performance We show the influence of the length of the path on the performance of the model in Figure 3(d). We set a threshold on the length of the path to filter concept paths used in the model. From the results, we can find that our model's performance improves significantly when the threshold is set from 3 to 4, in which most path lengths are distributed. The performance decreases when the path length is set to 5 and 6, which means it includes some noise and hurts the performance.

5.2 Error Analysis

For the instances that our model fails to predict the interactivity, we find that the problems are mainly two-fold:

- **Concept level**: For some of the failed cases, we find that around 37% of them contain at least one reply from which no concepts can be extracted, which blocks our path-finding based reasoning process. It is also the reason why our model's performance in the ablation study is lowest when removing the semantic information (i.e. BERT encoding).

- **Semantic level**: Some other failed cases share the common features that the reply does not refer to the specific term mentioned in the quotation, but gives out a more general rebuttal, e.g. [quotation] *If the president is either killed or resigns, the vice president is a horrible choice to take over the office.* [reply] *Seriously, stop this hyperbole.* Our model cannot effectively distinguish the interactivity between them, as the reply is short and has entirely no overlapping with the quotation.



I have invested a lot of time and money in an education so that i can make this amount of money. ... If minimum wage were raised to $xx per hour, all of my efforts to become a more valuable worker have been in vain. My current salary would be barely more than minimum wage. ...

You are forgetting the part where you have made that much above minimum wage while other workers put in just as many or more hours per week as you do and make much less. Soon after the minimum wage increase, inflation maybe would revert you back to your previous quality of life. ... Walmart also has a huge share of the food stamp market $xx billion in sales, so they are paying such wages, ... For mcdonald is, $xx billion of taxpayer money goes to supporting their underpaid workers, part of the fast food industry is $xx billion annually. ... That is just self interest, and it is the motivating factor for companies to squeeze costs, including labor. That is capitalism.

Because in the example i gave which is based on my real life situation $xx is better than $xx, but still not as good as what i should have gotten. ... I would therefore see a decrease in my quality of life due to a higher cost of living.

Figure 4: Case study of an instance from the test set. Our model successfully chooses the correct reply argument from the given candidates while the BERT model gives the wrong answer. Note that the concepts and the paths are all sorted from top to bottom in terms of hierarchical attention weights.

5.3 Case study

A case study is as shown in Figure 4, where the negative reply is selected by BERT baseline. It shows that although the quotation and the negative reply share a common concept, *quality of life*, our model successfully figures out the interactive reply argument through the reasoning paths between the concepts from the two sides. All the concepts and the paths in the figure are arranged from top to bottom according to their respective attention weights. We can find that upper paths are actually highly related to the reasoning process of humans, and the irrelevant concepts such as worker productivity will automatically diminish by our hierarchical attention alignment.

6 Related Work

Dialogical argumentation mining As mentioned in Introduction(§1), our work mainly focus on dialogical argumentation mining. Among recent researches in this aspect, El Baff et al. (2020) compare content- and style-oriented classifiers on editorials to explore the effect of the writing style of editorials to the audience of different parties; Ji et al. (2019) propose the task of identifying interactive argument pairs in online debate forum such as ChangeMyView (CMV). Cheng et al. (2020) collects the text data from peer review and rebuttal process to mine the argumentative relationship entailed in such discussion; Khatib et al. (2020) constructs a monological argumentation graph by extracting knowledge from *Debatepedia.org* and use human annotation to further improve the quality of their knowledge graph. Our work obtains inspiration from the construction of Al-Khatib's knowledge graph, but adapting their method to the dialogical debating forum settings, and removing the human annotation stage to obtain an automatically generated knowledge graph.

Leveraging external knowledge in NLU Our work also lies in the general context of using external knowledge to encode sentences and paragraphs. Yang and Mitchell (2017) are among the first researches that retrieve the related entities in the external knowledge base and merge them into an LSTM encoder. Afterward, Weissenborn et al. (2017), Mihaylov and Frank (2018) and Zhang et al. (2020) mainly follows the main idea of the work to incorporate external word-level lexical knowledge to enhance the sentence embedding. Moreover, Lin et al. (2019) propose a knowledge-aware network(KagNet) that utilizes graph knowledge from *ConceptNet* to answer the commonsense questions. Compared with these methods, our work utilizes conceptual information from dialogical argumentation lexicons and conducts a reasoning process resembling human beings, which is then encoded by a path transformer, and finally aligned with the semantic information through a hierarchical attention mechanism.

7 Conclusion and Future Work

We propose a framework that imitates human's reasoning process in debating. Practically, we first construct a dialogical argumentation knowledge graph from the online debating forum ChangeMyView, by using an automatic OpenIE toolkit and conducting concept grounding with lexical resources and Wikipedia API. Then we use a path-based graph model to encode the concepts and the reasoning path between concepts from two sides of a debate and align the conceptual information with the semantic information obtained implicitly by pre-trained language model BERT. Experiments on interactive argument pair identification task show that our model can leverage the external knowledge in both effective and transparent way.

A Multi-Task Learning Framework for Multi-Target Stance Detection

Yingjie Li and Cornelia Caragea
Computer Science Department
University of Illinois at Chicago
`yli300@uic.edu`, `cornelia@uic.edu`

Abstract

Multi-target stance detection aims to identify the stance taken toward a pair of different targets from the same text, and typically, there are multiple target pairs per dataset. Existing works generally train one model for each target pair. However, they fail to learn target-specific representations and are prone to overfitting. In this paper, we propose a new training strategy under the multi-task learning setting by training one model on all target pairs, which helps the model learn more universal representations and alleviate overfitting. Moreover, in order to extract more accurate target-specific representations, we propose a multi-task learning network which can jointly train our model with a stance (dis)agreement detection task that is designed to identify agreement and disagreement between stances in paired texts. Experimental results demonstrate that our proposed model outperforms the best-performing baseline by 12.39% in macro-averaged F1-score. Our resources are publicly available on GitHub.[1]

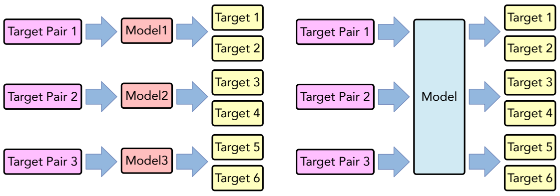
1 Introduction

Nowadays, people often take to social media to express their stances toward specific targets (e.g., various political figures). These stances in an aggregate can provide valuable information for obtaining insight into important events such as presidential elections. The common stance detection task is to determine from a piece of text whether the author of the text is in favor of, neutral or against to a specific target, which can be categorized as single-target stance detection (STSD) (Mohammad et al., 2016; Küçük and Can, 2020; ALDayel and Magdy, 2021). More recently, since people often comment on multiple target entities in the same text, a more challenging task, i.e., multi-target stance detection (MTSD), was designed to test whether a model can accurately predict the stance toward multiple targets in the same text (Sobhani et al., 2017). For example, for the tweet in Figure 1, the author aims at expressing stance toward two targets, Donald Trump and Hillary Clinton, implied by the presence of the words “beat” and “career politicians”.

Tweet: #Trump2016 can beat #HillaryClinton as he is easily beating #JebBush ;) People R sick and tired of career politicians.

Target 1:	Donald Trump	**Stance 1**:	FAVOR
Target 2:	Hillary Clinton	**Stance 2**:	AGAINST

Figure 1: An example of multi-target stance detection.



(a) (b)

Figure 2: The left figure represents the previous “Ad-hoc” training setting in which a model is trained only on a target pair. The right figure represents the proposed “Merged” training setting in which the model is trained on all target pairs.

Problem statement. Given a sentence $x = [w_1, w_2, t_1, w_3, ..., w_{l-1}, t_2, w_l]$, where t_1 and t_2 are targets, and w_i, $i = 1, ..., l$, denotes a non-target word, the goal of MTSD is to classify the stance toward these targets into one of the three classes: {FAVOR, AGAINST, NONE}.

Previous work focused on a per-target-pair training strategy, which aims to train one model for each target pair and evaluate it on the test data corresponding to that target-pair (which we call “Ad-hoc” training). The framework is illustrated in Figure 2(a). However, the model is more likely to make predictions based on specific words without

fully considering the target information, and hence, to overfit in the "Ad-hoc" training setting. To address this, as shown in Figure 2(b), we propose a "Merged" training strategy by training one model on data from all target pairs, which helps the model learn more universal representations on the whole dataset and alleviate overfitting. Furthermore, in order to extract more accurate target-specific representations, we propose a multi-task learning network which is able to jointly train our model with a stance (dis)agreement detection task that is designed to identify agreement and disagreement between stances expressed in paired-target sentences. Results show that the proposed "Merged" training setting together with identifying whether the author expresses the same stance toward two targets are beneficial to the MTSD.

Our contributions include: 1) We propose a "Merged" training strategy for MTSD and show that models fine-tuned on the pre-trained BERTweet (Nguyen et al., 2020) perform substantially better than strong baselines. Meanwhile, the decrease in performance can be widely observed in baseline results when using the "Merged" training strategy, making it a more challenging evaluation for MTSD; 2) We propose a multi-task learning network which considers the stance (dis)agreement detection task as an auxiliary task to further improve the performance of our proposed model; 3) Our proposed model outperforms the best-performing baseline by 12.39% in macro-averaged F1-score.

2 Related Work

Sobhani et al. (2017) introduced the MTSD task and presented the first dataset. They also proposed an attention-based encoder-decoder (Seq2Seq) model that predicts stance labels by focusing on important parts of a tweet. Wei et al. (2018a) proposed a dynamic memory network for detecting stance. First, target-specific attention is extracted for each target. Then, a shared external memory module that maintains useful information for targets is dynamically updated. This model achieves state-of-the-art performance on the multi-target stance dataset of Sobhani et al. (2017). We used the above two works as strong baselines for our evaluation.

Sobhani et al. (2017) and Wei et al. (2018a) deal with MTSD by training one model for each target pair and the model predicts the stance toward two targets simultaneously. However, we can also solve this task by treating it as a special case of single-target stance detection (STSD). Instead of training a model that receives two targets and a sentence as an input, we train two STSD models that receive one target and a sentence as an input, on each target pair. For the example in Figure 1, we train one STSD model for target "Donald Trump" and train another model for "Hillary Clinton" in a STSD manner.

Previous studies on STSD often employ feature engineering (Sobhani et al., 2016; Mohammad et al., 2016), Convolutional Neural Network (CNN) (Vijayaraghavan et al., 2016; Wei et al., 2016) and Recurrent Neural Network (RNN) (Zarrella and Marsh, 2016) to predict the stance for a given target. One of the major limitations is that they do not consider the target information. To address this, Augenstein et al. (2016) proposed a conditional BiLSTM encoder that learns tweet representations conditioned on the respective target. More recently, inspired by the attention mechanism (Bahdanau et al., 2015), various target-specific attention-based approaches (Du et al., 2017; Sun et al., 2018; Wei et al., 2018b; Li and Caragea, 2019, 2021) have been proposed to connect the target with the sentence representation, which is similar to aspect-based sentiment analysis (Hazarika et al., 2018; Majumder et al., 2018; Lin et al., 2019; Song et al., 2019). We compare the baseline models of STSD and MTSD with our proposed model in §4.4 using both "Ad-hoc" and "Merged" settings.

3 Approach

Previous work focused on an "Ad-hoc" training strategy, which fails to explore the potential of the training data and is unable to learn universal representations of targets. Moreover, we observe that STSD models that do not consider target information can still perform well on the multi-target dataset, which makes MTSD easier. Therefore, in order to learn more universal representations and better evaluate the performance of models on MTSD, we propose a "Merged" training strategy by training one model on all target pairs. More specifically, the model is trained on training data combined from all target pairs, and tested on each target pair separately to be compared with the results of the "Ad-hoc" strategy. Our proposed training strategy can be considered as a multi-task learning approach that helps the pre-trained language models to learn more generalized text representations by sharing the domain-specific information

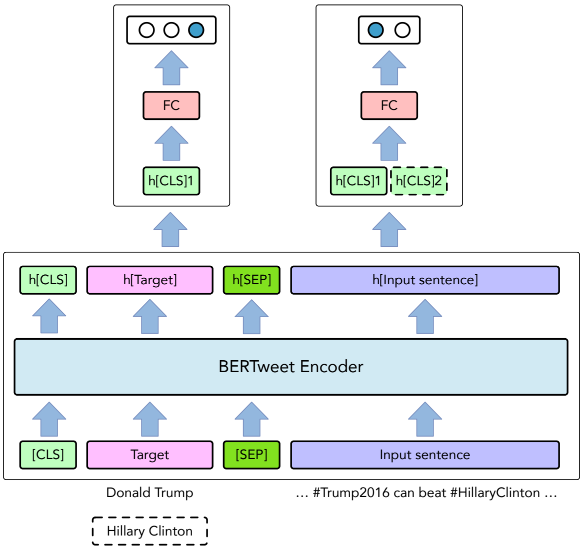

Figure 3: Model architecture.

across the related target pairs.

BERTweet (Nguyen et al., 2020) is a large-scale language model pre-trained on 850M tweets. BERTweet follows the training procedure of RoBERTa (Liu et al., 2019) and uses the same model configuration with BERT-base (Devlin et al., 2019). We fine-tune the pre-trained BERTweet on the multi-target dataset. The model architecture is shown in Figure 3. Given an input data x and a target t (t is either target 1 or target 2 in Figure 1), we formulate the input as a sequence s = $[[CLS]$ t $[SEP]$ $x]$ where $[CLS]$ encodes the sentence representation and $[SEP]$ is used to separate the target t and sentence x. We utilize the $[CLS]$ token $h_{[CLS]}$ to get the prediction $\hat{p}_1$ toward target t.

In order to learn better target-specific representations, we propose a multi-task learning network that can jointly train our model with a stance (dis)agreement detection task, which is a binary classification task where the label is 1 when the author expresses the same stance toward two targets (e.g., “FAVOR” and “FAVOR”) and 0 otherwise (e.g., “FAVOR” and “AGAINST”). More specifically, given an input data x and two targets t_1 and t_2, we formulate the inputs as $[[CLS]$ t_1 $[SEP]$ $x]$ and $[[CLS]$ t_2 $[SEP]$ $x]$. Then we leverage the representations of $[CLS]$ token of two sequences to detect whether the author of the text expresses the same stance toward two targets. The (dis)agreement class probability $\hat{p}_2$ can be computed as follows:

$$\hat{p}_2 = softmax(W_2 f(W_1 [h_{[CLS]1}; h_{[CLS]2}] \\ + b_1) + b_2)$$

Target Pair	Total	Train	Dev	Test
Trump-Clinton	1,722	1,240	177	355
Trump-Cruz	1,317	922	132	263
Clinton-Sanders	1,366	957	137	272
Total	4,455	3,119	446	890

Table 1: Distribution of instances in our dataset.

where $W_1 \in \mathbb{R}^{d_h * 2d_h}$, $W_2 \in \mathbb{R}^{2 * d_h}$, $b_1 \in \mathbb{R}^{d_h}$, $b_2 \in \mathbb{R}^2$, d_h is the size of the hidden dimension, f is an activation function, semicolon denotes vector concatenation. Note that the main task is to identify the stance toward target t_1. The target t_2 is only used in auxiliary task. Similarly, we predict the stance toward target t_2 in main task where t_1 is only used in auxiliary task.

Let D be a labeled training dataset and D_j be a mini-batch for the MTSD, and let y_1 and y_2 denote the true labels for stance detection task and (dis)agreement task, respectively. The cross-entropy loss is used to train the model. Let L_1 and L_2 be the loss of stance detection task and (dis)agreement task, respectively. Then the final loss is:

$$L = \sum_{i \in D_j} L_1(y_1^i, \hat{p}_1^i) + \alpha \sum_{i \in D_j} L_2(y_2^i, \hat{p}_2^i)$$

where i is the index of a data sample and α is a hyper-parameter to account for the importance of the auxiliary task. α is set to 0.5 in our experiments.

4 Experiments

4.1 Dataset

To test the performance of our proposed model, we use the multi-target stance dataset (Sobhani et al., 2017) of tweets annotated with stance labels with respect to two targets. This dataset contains three different target pairs: Donald Trump and Hillary Clinton, Donald Trump and Ted Cruz, Hillary Clinton and Bernie Sanders. Table 1 provides dataset statistics. Each tweet has two stance labels concerning two targets and each label has one of the values: “FAVOR”, “AGAINST” or “NONE”.

4.2 Evaluation Metrics

F_{avg}^p and macro-average of F1-score (F_{macro}) are adopted to evaluate the performance of our baseline models. First, the F1-score of label “Favor” and “Against” is calculated as follows:

$$F_{favor} = \frac{2P_{favor}R_{favor}}{P_{favor} + R_{favor}}$$

$$F_{against} = \frac{2P_{against}R_{against}}{P_{against} + R_{against}}$$

where P and R are precision and recall, respectively. After that, the F_{avg} is calculated as:

$$F_{avg} = \frac{F_{favor} + F_{against}}{2}$$

For each target pair, we compute the F_{avg} for each target and use the F^{p}_{avg}, which is calculated as the average of F_{avg} on two targets, as our evaluation metric. Moreover, we get F_{macro} by averaging F^{p}_{avg} on all target pairs.

4.3 Baseline Methods

First, we compare the proposed model with the following baselines from STSD.

BiLSTM (Schuster and Paliwal, 1997): A BiLSTM model that takes sentences as inputs without considering the target information.

CNN (Kim, 2014): The vanilla CNN that has the same input format with BiLSTM. Similarly, target information is not considered in this model.

TAN (Du et al., 2017): TAN is an attention-based LSTM that extracts target specific features.

BiCE (Augenstein et al., 2016): A BiLSTM model that uses conditional encoding for stance detection. The target information is first encoded by using a BiLSTM and the tweet is then encoded by another BiLSTM, whose state is initialised with the hidden representation of the target.

GCAE (Xue and Li, 2018): A model that is based on CNNs and gating mechanism, which is designed to block target-unrelated information.

PGCNN (Huang and Carley, 2018): Similar to GCAE, PGCNN is based on gated convolutional networks and encodes target information by generating target-sensitive filters.

The second group contains baselines from MTSD.

Seq2Seq (Sobhani et al., 2017): An attention-based encoder-decoder model that generates stance labels according to different parts of a tweet.

DMAN (Wei et al., 2018a): Using attention and memory modules to extract important information for detecting stance.

We compare the baselines of STSD and MTSD with our proposed models.

Table 2: Comparison with the baselines on the multi-target stance dataset (%). $*$: the result is from the original paper. †: the proposed models improve the best baseline at $p < 0.05$ with two-tailed t-test. ‡: the BERTweet-A improves the BERTweet at $p < 0.05$ with two-tailed t-test. F_{macro} is the average of all target pairs. Bold scores are best overall.

BERTweet We fine-tune the BERTweet model using “Merged” and “Ad-hoc” training strategies. The pre-trained BERTweet model is fine-tuned under the PyTorch framework. When fine-tuning, the batch size is 32 and maximum sequence length is 128. We use AdamW optimizer (Loshchilov and Hutter, 2019) and the learning rate is 2e-5.

BERTweet-A BERTweet is further improved by joint training with another stance detection task that identifies agreement and disagreement between stances in “Merged” and “Ad-hoc” training settings.

4.4 Results and Analysis

Main Results Table 2 shows the results of the comparison of our proposed models with the baselines mentioned above by using the proposed training strategy “Merged” and the “Ad-hoc” training strategy. We make the following observations.

First, the performance of baseline models that perform well in the “Ad-hoc” training setting drops heavily in our proposed “Merged” setting, especially for the BiLSTM and CNN. Specifically, the F_{macro} of BiLSTM and CNN drops by 10.28% and 12.64%, respectively. The results indicate that baseline models overfit the training data quite heavily

Model	Donald Trump
BERTweet-adhoc	46.75
BERTweet-merged	**52.51**†

Table 3: Performance comparison of models on the target "Donald Trump" of SemEval 2016 stance dataset (%). †: the proposed BERTweet-merged improves the BERTweet-adhoc at $p < 0.05$ with two-tailed t-test. Bold scores are best overall.

and our proposed "Merged" training strategy can serve as a better evaluation method to test whether the model learns target-specific features.

Second, different from other baselines suffering significant performance drops, BERTweet performs better in the "Merged" setting. Training all target pairs improves the F_{macro} of BERTweet from 59.51% to 67.77%, which demonstrates that BERTweet learns more universal representations with respect to targets by leveraging the data of multiple target pairs. Moreover, joint training with stance (dis)agreement detection task further improves the F_{macro} of BERTweet from 67.77% to 69.65% in the "Merged" setting. Similarly, in the "Ad-hoc" setting, the F_{macro} of BERTweet is improved from 59.51% to 60.56%, indicating that this auxiliary task is beneficial to the MTSD in both settings and helps the model put more attention on the target-related words.

Third, BERTweet-A of the "Merged" setting significantly outperforms the best-performing baseline by 12.39% in F_{macro}, showing the effectiveness of the proposed model.

Generalization Analysis To test the generalization ability of the BERTweet of the "Merged" setting (which we call BERTweet-merged), we train and validate the BERTweet-merged without auxiliary agreement task on the whole multi-target dataset and test it on the target "Donald Trump" of SemEval 2016 dataset (Mohammad et al., 2016) where an overall shift in the distribution of words and topics can be observed. Moreover, we train and validate the BERTweet-adhoc (BERTweet in "Ad-hoc" setting) on the target "Donald Trump" of multi-target dataset and test it on the same set of SemEval 2016 dataset to be compared with BERTweet-merged. The results are shown in Table 3. From the table, we can observe that BERTweet-merged significantly outperforms BERTweet-adhoc on the SemEval 2016 dataset, which indicates that the BERTweet model trained in the "Merged" setting shows better generalization ability than the BERTweet model trained in the "Ad-hoc" setting.

5 Conclusion

In this paper, we presented a comprehensive investigation into multi-target stance detection (MTSD) and proposed a more challenging task that trains a single model on data from all target pairs instead of training a model per target pair. The new training strategy can alleviate overfitting and help the model learn more universal representations by using the data of all target pairs. Moreover, we proposed to integrate a stance (dis)agreement detection module into the proposed model as an auxiliary task to gain more accurate representations of targets. Experimental results show that the proposed model outperforms the best-performing baseline by a large margin and demonstrates its effectiveness even in the face of a more challenging evaluation. Future work includes extending the proposed training strategy and (dis)agreement task to more stance detection tasks and datasets.

Abstract

Scheduled sampling is an effective method to alleviate the exposure bias problem of neural machine translation. It simulates the inference scene by randomly replacing ground-truth target input tokens with predicted ones during training. Despite its success, its critical schedule strategies are merely based on training steps, ignoring the real-time model competence, which limits its potential performance and convergence speed. To address this issue, we propose confidence-aware scheduled sampling. Specifically, we quantify real-time model competence by the confidence of model predictions, based on which we design fine-grained schedule strategies. In this way, the model is exactly exposed to predicted tokens for high-confidence positions and still ground-truth tokens for low-confidence positions. Moreover, we observe vanilla scheduled sampling suffers from degenerating into the original teacher forcing mode since most predicted tokens are the same as ground-truth tokens. Therefore, under the above confidence-aware strategy, we further expose more noisy tokens (*e.g.,* wordy and incorrect word order) instead of predicted ones for high-confidence token positions. We evaluate our approach on the Transformer and conduct experiments on large-scale WMT 2014 English-German, WMT 2014 English-French, and WMT 2019 Chinese-English. Results show that our approach significantly outperforms the Transformer and vanilla scheduled sampling on both translation quality and convergence speed.

1 Introduction

Neural Machine Translation (NMT) has made promising progress in recent years (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017). Generally, NMT models are trained to maximize the likelihood of the next token given previous golden tokens as inputs, *i.e.,* teacher forcing (Goodfellow et al., 2016). However, at the inference stage, golden tokens are unavailable. The model is exposed to an unseen data distribution generated by itself. This discrepancy between training and inference is named as the *exposure bias* problem (Ranzato et al., 2016).

Many techniques have been proposed to alleviate the exposure bias problem. To our knowledge, they mainly fall into two categories. The one is sentence-level training, which treats the sentence-level metric (*e.g.,* BLEU) as a reward, and directly maximizes the expected rewards of generated sequences (Ranzato et al., 2016; Shen et al., 2016; Rennie et al., 2017). Although intuitive, they generally suffer from slow and unstable training due to the high variance of policy gradients and the credit assignment problem (Sutton, 1984; Liu et al., 2018; Wang et al., 2018). Another category is sampling-based approaches, aiming to simulate the data distribution of reference during training. Scheduled sampling (Bengio et al., 2015) is a representative method, which samples tokens between golden references and model predictions with a scheduled probability. Zhang et al. (2019) further refine the sampling space of scheduled sampling with predictions from beam search. Mihaylova and Martins (2019) and Duckworth et al. (2019) extend scheduled sampling to the Transformer with a novel two-pass decoding architecture.

Although these sampling-based approaches have been shown effective, most of them schedule the sampling probability based on training steps. We argue this schedule strategy has two following limitations: 1) It is far from exactly reflecting the real-time model competence; 2) It is only based on training steps and equally treat all token positions, which is too coarse-grained to guide the

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2327–2337
August 1–6, 2021.

sampling selection for each target token. These two limitations yield an inadequate and inefficient schedule strategy, which hinders the potential performance and convergence speed of vanilla scheduled sampling-based approaches.

To address these issues, we propose confidence-aware scheduled sampling. Specifically, we take the model prediction confidence as the assessment of real-time model competence, based on which we design fine-grained schedule strategies. Namely, we sample predicted tokens as target inputs for high-confidence positions and still ground-truth tokens for low-confidence positions. In this way, the NMT model is exactly exposed to corresponding tokens according to its real-time competence rather than coarse-grained predefined patterns. Additionally, we observe that most predicted tokens are the same as ground-truth tokens due to teacher forcing[1], degenerating scheduled sampling to the original teacher forcing mode. Therefore, we further expose more noisy tokens (Meng et al., 2020) (*e.g.,* wordy and incorrect word order) instead of predicted ones for high-confidence token positions. Experimentally, we evaluate our approach on the Transformer (Vaswani et al., 2017) and conduct experiments on large-scale WMT 2014 English-German (EN-DE), WMT 2014 English-French (EN-FR), and WMT 2019 Chinese-English (ZH-EN).

The main contributions of this paper can be summarized as follows[2]:

- To the best of our knowledge, we are the first to propose confidence-aware scheduled sampling for NMT, which exactly samples corresponding tokens according to the real-time model competence rather than coarse-grained predefined patterns.

- We further explore to sample more noisy tokens for high-confidence token positions, preventing scheduled sampling from degenerating into the original teacher forcing mode.

- Our approach significantly outperforms the Transformer by 1.01, 1.03, 0.98 BLEU and outperforms the stronger scheduled sampling by 0.51, 0.41, and 0.58 BLEU on EN-DE, EN-FR, and ZH-EN, respectively. Our approach speeds up model convergence about 3.0× faster than the Transformer and about 1.8× faster than vanilla scheduled sampling.

- Extensive analyses indicate the effectiveness and superiority of our approach on longer sentences. Moreover, our approach can facilitate the training of the Transformer model with deeper decoder layers.

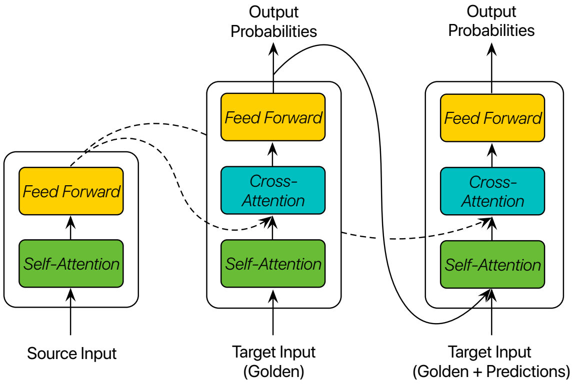

Figure 1: Scheduled sampling for the transformer with two-pass decoding (Mihaylova and Martins, 2019).

2 Background

2.1 Neural Machine Translation

Given a pair of source language $\mathbf{X} = \{x_1, x_2, \cdots, x_m\}$ with m tokens and target language $\mathbf{Y} = \{y_1, y_2, \cdots, y_n\}$ with n tokens, neural machine translation aims to model the following translation probability:

$$\begin{aligned} P(\mathbf{Y}|\mathbf{X}) &= \prod_{t=1}^{n} P(y_t|\mathbf{y}_{<t}, \mathbf{X}, \theta) \\ &= \sum_{t=1}^{n} \log P(y_t|\mathbf{y}_{<t}, \mathbf{X}, \theta) \end{aligned} \tag{1}$$

where t is the index of target tokens, $\mathbf{y}_{<t}$ is the partial translation before y_t, and θ is model parameter. In the training stage, $\mathbf{y}_{<t}$ are ground-truth tokens, and this procedure is also known as teacher forcing. The translation model is generally trained with maximum likelihood estimation (MLE).

2.2 Scheduled Sampling for the Transformer

Scheduled sampling is initially designed for Recurrent Neural Networks (Bengio et al., 2015), and further modifications are needed when applied to the Transformer (Mihaylova and Martins, 2019;

---

[1] We observe that about 70% tokens are correctly predicted in WMT14 EN-DE training data.

[2] Codes are available at `https://github.com/Adaxry/conf_aware_ss4nmt`.

Duckworth et al., 2019). As shown in Figure 1, we follow the two-pass decoding architecture. In the first pass, the model conducts the same as a standard NMT model. Its predictions are used to simulate the inference scene[3]. In the second pass, inputs of the decoder $\widetilde{\mathbf{y}}_{<t}$ are sampled from predictions of the first pass and ground-truth tokens with a certain probability. Finally, predictions of the second pass are used to calculate the cross-entropy loss, and Equation (1) is modified as follow:

$$P(\mathbf{Y}|\mathbf{X}) = \sum_{t=1}^{n} logP(y_t|\widetilde{\mathbf{y}}_{<t}, \mathbf{X}, \theta) \qquad (2)$$

Note that the two decoders are identical and share the same parameters. At inference, only the first decoder is used, that is just the standard Transformer. How to schedule the above probability of sampling tokens is the key point, which is exactly what we aim to improve in this paper.

2.3 Decay Strategies on Training Steps

Existing schedule strategies are based on training steps (Bengio et al., 2015; Zhang et al., 2019). As the number of the training step i increases, the model should be exposed to its own predictions more frequently. At the i-th training step, the probability of sampling golden tokens $f(i)$ is calculated as follow:

- Linear Decay: $f(i) = \max(\epsilon, ki + b)$, where ϵ is the minimum value, and $k < 0$ and b are respectively the slope and offset of the decay.
- Exponential Decay: $f(i) = k^i$, where $k < 1$ is the radix to adjust the sharpness of the decay.
- Inverse Sigmoid Decay: $f(i) = \frac{k}{k+e^{\frac{i}{k}}}$, where e is the mathematical constant, and $k \geq 1$ is a hyperparameter to adjust the sharpness of the decay.

We draw visible examples for different decay strategies in Figure 2.

3 Approaches

In this section, we firstly describe how to estimate model confidence at each token position. Secondly, we elaborate the fine-grained schedule strategy based on model confidence. Finally, we explore to sample more noisy tokens instead of predicted tokens for high-confidence positions.

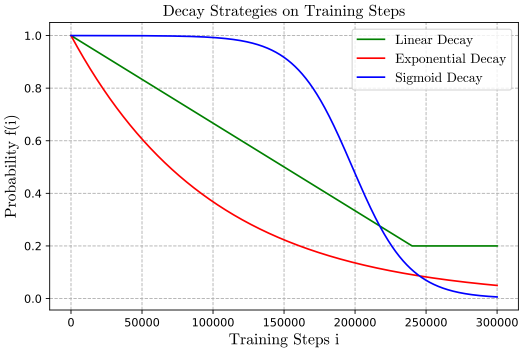

Figure 2: Examples of different decay strategies $f(i)$.

3.1 Model Confidence Estimation

We explore two approaches to estimate model confidence at each token position.

Predicted Translation Probability (PTP). Current NMT models are well-calibrated with regularization techniques in the training setting (Ott et al., 2018; Müller et al., 2019; Wang et al., 2020). Namely the predicted translation probability can directly serve as the model confidence. At the t-th target token position, we calculate the model confidence $conf(t)$ as follow:

$$conf(t) = P(y_t|\mathbf{y}_{<t}, \mathbf{X}, \theta) \qquad (3)$$

Since we base our approach on the Transformer with two-pass decoding (Mihaylova and Martins, 2019; Duckworth et al., 2019), above predicted translation probability can be directly obtained in the first-pass decoding (shown in Figure 1), causing no additional computation costs.

Monte Carlo Dropout Sampling. The model confidence can be quantified by Bayesian neural networks (Buntine and Weigend, 1991; Neal, 2012), which place distributions over the weights of neural networks. We adopt widely used Monte Carlo dropout sampling (Gal and Ghahramani, 2016; Wang et al., 2019b) to approximate Bayesian inference. Given a batch of training data and current NMT model parameterized by θ, we repeatedly conduct forward propagation K times[4]. On the k-th propagation, part of neurons $\hat{\theta}^{(k)}$ in network

---

[3] Following Goyal et al. (2017), model predictions are the weighted sum of target embeddings over output probabilities. As model predictions cause a mismatch with golden tokens, they can simulate translation errors of the inference scene.

[4] We empirically set K to 5 following Wan et al. (2020).

θ are randomly deactivated. Eventually, we obtain K sets of model parameters $\{\hat{\theta}^{(k)}\}_{k=1}^{K}$ and corresponding translation probabilities. We use the expectation or variance of translation probabilities to estimate the model confidence (Wang et al., 2019b). Intuitively, the higher expectation or, the lower variance of translation probabilities reflects higher model confidence. Formally at the t-th token position, we estimate the model confidence $conf(t)$ that calculated by the expectation of translation probabilities:

$$conf(t) = \mathbb{E}\left[P(y_t|\mathbf{y}_{<t}, \mathbf{X}, \hat{\theta}^{(k)})\right]_{k=1}^{K} \tag{4}$$

We also use the variance of translation probabilities to estimate the model confidence $conf(t)$ as an alternative:

$$conf(t) = 1 - \mathrm{Var}\left[P(y_t|\mathbf{y}_{<t}, \mathbf{X}, \theta)\right]_{k=1}^{K} \tag{5}$$

where $\mathrm{Var}[\cdot]$ denotes the variance of a distribution that calculated following the setting in (Wang et al., 2019b; Zhou et al., 2020). We will further analyze the effect of different confidence estimations in Section 4.2.

3.2 Confidence-Aware Scheduled Sampling

The confidence score $conf(t)$ quantifies whether the current NMT model is confident or hesitant on predicting the t-th target token. We take $conf(t)$ as exact and real-time information to conduct a fine-grained schedule strategy in each training iteration. Specifically, a lower $conf(t)$ indicates that the current model θ still struggles with the teacher forcing mode for the t-th target token, namely underfitting for the conditional probability $P(y_t|\mathbf{y}_{<t}, \mathbf{X}, \theta)$. Thus we should keep feeding ground-truth tokens for learning to predict the t-th target token. Conversely, a higher $conf(t)$ indicates the current model θ has learned well the basic conditional probability under teacher forcing. Thus we should empower the model with the ability to cope with the exposure bias problem. Namely, we take inevitably erroneous model predictions as target inputs for learning to predict the t-th target.

Formally, in the second-pass decoding, the above fine-grained schedule strategy is conducted at all decoding steps simultaneously:

$$y_{t-1} = \begin{cases} y_{t-1} & \text{if } conf(t) \leq t_{golden} \\ \hat{y}_{t-1} & \text{else} \end{cases} \tag{6}$$

Dataset	Size (M)	Valid / Test set
WMT14 EN-DE	4.5	newstest 2013 / 2014
WMT14 EN-FR	36	newstest 2013 / 2014
WMT19 ZH-EN	20	newstest 2018 / 2019

Table 1: Dataset statistics in our experiments.

where t_{golden} is a threshold to measure whether $conf(t)$ is high enough (*e.g.,* 0.9) to sample the predicted token $\hat{y}_{t-1}$.

3.3 Confidence-Aware Scheduled Sampling with Target Denoising

Considering predicted tokens are obtained from the teacher forcing model, most predicted tokens (*e.g.,* about 70% tokens in WMT14 EN-DE) are the same as ground-truth tokens, which degenerate the scheduled sampling to the original teacher forcing. Although previous study (Zhang et al., 2019) have proposed to address this issue by using predictions from beam search, it conducts very slowly (about 4× slower than ours) due to the autoregressive property of beam search decoding. To avoid the above degeneration problem while preserving computational efficiency, we try to add more noisy tokens instead of predicted tokens for high-confidence positions. Inspired by Meng et al. (2020), we replace ground-truth y_{t-1} with a random token y_{rand} of the current target sentence, which can simulate wordy and incorrect word order phenomena that occur at inference. Considering y_{rand} is more difficult[5] to learn than $\hat{y}_{t-1}$, we only adopt the noisy y_{rand} for higher confidence positions. Therefore, the fine-grained schedule strategy in Equation 6 is extended to:

$$y_{t-1} = \begin{cases} y_{t-1} & \text{if } conf(t) \leq t_{golden} \\ \hat{y}_{t-1} & \text{if } t_{golden} < conf(t) \leq t_{rand} \\ y_{rand} & \text{if } conf(t) > t_{rand} \end{cases} \tag{7}$$

where t_{rand} is a threshold to measure whether $conf(t)$ is high enough (*e.g.,* 0.95) to sample the random target token y_{rand}. We provide detailed selections about t_{golden} and t_{rand} in Section 4.2.

---

[5] Given a pre-trained Transformer$_{base}$ model, we respectively replace ground-truth tokens with predicted tokens $\hat{y}$ or random tokens y_{rand} with the same rate, and measure such difficulty by the increment of model perplexity. We observe that y_{rand} yields about 15% higher model perplexity than $\hat{y}$.

4 Experiments

We conduct experiments on three large-scale WMT 2014 English-German (EN-DE), WMT 2014 English-French (EN-FR), and WMT 2019 Chinese-English (ZH-EN) translation tasks. We respectively build a shared source-target vocabulary for the EN-DE and EN-FR datasets, and unshared vocabularies for the ZH-EN dataset. We apply byte-pair encoding (Sennrich et al., 2016) with 32k merge operations for all datasets. More datasets statistics are listed in Table 1.

4.1 Implementation Details

Training Setup. We train the Transformer$_{base}$ and Transformer$_{big}$ models (Vaswani et al., 2017) with the open-source THUMT (Zhang et al., 2017). All Transformer models are first trained by teacher forcing with 100k steps, and then trained with different training objects or scheduled sampling approaches for 300k steps. All experiments are conducted on 8 NVIDIA Tesla V100 GPUs, where each is allocated with a batch size of approximately 4096 tokens. We use Adam optimizer (Kingma and Ba, 2014) with 4000 warmup steps. During training and the Monte Carlo Dropout process, we set dropout (Srivastava et al., 2014) rate to 0.1 for the Transformer$_{base}$ and 0.3 for the Transformer$_{big}$.

Evaluation. We set the beam size to 4 and the length penalty to 0.6 during inference. We use *multibleu.perl* to calculate case-sensitive BLEU scores for WMT14 EN-DE and EN-FR, and use *mteval-v13a.pl* to calculate case-sensitive BLEU scores for WMT19 ZH-EN. We use the paired bootstrap resampling methods (Koehn, 2004) to compute the statistical significance of test results.

4.2 Hyperparameter Experiments

In this section, we elaborate hyperparameters settings involved in our approaches according to the performance on the validation set of WMT14 EN-DE, and share these settings for all WMT tasks.

Different Confidence Estimations. In this section, we analyze effects of different estimations for model confidence described in Section 3.1. As shown in Table 2, we observe that Monte Carlo dropout sampling based approaches (*i.e.,* expectation and variance of translation probabilities) achieve comparable or marginally better translation quality than PTP. However, since Monte Carlo dropout sampling based approaches need additional passes for forward propagation, which yields about 2.7× computation costs than the Transformer$_{base}$. On the contrary, PTP only causes marginal additional computation costs (1.3×) than the Transformer$_{base}$, as PTP can be directly obtained in the first pass decoding. Considering the trade-off between training efficiency and final performance, we use PTP to estimate model confidence by default in the following experiments.

Methods	**Training Cost**	**BLEU**	**Δ**
Transformer$_{base}$	ref.	27.10	ref.
+ PTP	1.3×	28.15	+1.05
+ Expectation	2.7×	28.15	+1.05
+ Variance	2.7×	28.20	+1.10

Table 2: BLUE scores (%) on the validation set of WMT14 EN-DE with different confidence estimations. 'Training Cost' is calculated by the total training time until models convergence on 8 NVIDIA V100 GPUs. 'PTP' refers to PTP-based confidence estimation in Equation (3). 'Expectation' and 'Variance' refers to Monte Carlo dropout sampling-based confidence estimation in Equation (4) and (5), respectively. 'ref.' is short for the reference baseline.

Thresholds Settings. There are two important hyperparameters in our approaches, namely the two threshold t_{golden} and t_{rand} that determine token selections in Equation (7). In our preliminary experiments, we observe our approach is relatively not sensitive to t_{golden}, thus we firstly fix t_{golden} to a modest value, i.e., 0.5 and analyze effects when t_{rand} ranging from 0.5 to 0.95. As the red line is shown in Figure 3, we observe that a rapid improvement in performance with the growth of t_{rand}. Therefore, we decide to set t_{rand} to 0.95 and then analyze effects when t_{golden} ranging from 0.5 to 0.95. As the blue line is shown in Figure 3, the model performance gently rises with the growth of t_{golden} and finally achieves its peak when $t_{golden} = 0.9$. Thus we finally set t_{golden} to 0.9.

4.3 Systems

Mixer. A sequence-level training algorithm for text generations by combining both REINFORCE and cross-entropy (Ranzato et al., 2016).

Minimal Risk Training. Minimal Risk Training (MRT) (Shen et al., 2016) introduces evaluation metrics (*e.g.,* BLEU) as loss functions and aims to minimize expected loss on the training data.

'Confidence' refers to the confidence-aware strategy in Equation (7). 'Denoising' refers to the target random noise y_{rand} in Equation (7). 'ref.' is short for the reference baseline.

and $t_{rand} = 0.95$.

4.4 Main Results

We list translation qualities in Table 3. For the Transformer$_{base}$ baseline, our 'Confidence-aware scheduled sampling' shows consistent improvements by 0.90, 0.98, 0.89 BLEU points on EN-DE, ZH-EN, and EN-FR, respectively. Moreover, after applying the more fine-grained strategy with target denoising, our 'Confidence-aware scheduled sampling with target denoising' achieves further improvements which are 1.01, 1.03, 0.98 BLEU points on EN-DE, ZH-EN, and EN-FR, respectively. When comparing with the stronger vanilla scheduled sampling method, 'Confidence-aware scheduled sampling with target denoising' still yields improvements by 0.51, 0.57, and 0.41 BLEU points on the above three tasks, respectively. For the more powerful Transformers$_{big}$, we also observe similar experimental conclusions as above. Specifically, 'Confidence-aware scheduled sampling with target denoising' outperforms vanilla scheduled sampling by 0.47, 0.67, and 0.42 BLEU points, respectively. In summary, experiments on strong baselines and various tasks verify the effectiveness and superiority of our approaches.

5 Analysis and Discussion

We analyze our proposals on WMT 2014 EN-DE with the Transformer$_{base}$ model.

5.1 Effects of Confidence-Aware Strategies

In this section, we rigorously validate the effectiveness of confidence-aware strategies by univariate experiments with the only difference at schedule strategy. As shown in Table 4, existing heuristic functions, *i.e.,* linear, exponential, and inverse sigmoid decay, moderately bring improvements over the Transformer$_{base}$ baseline by 0.46, 0.50, and 0.55 BLEU points, respectively. While our confidence-aware strategy that described in Equation (6) can significantly outperform the baseline by 1.05 BLEU points. We attribute the effectiveness of the confidence-aware strategy to its exact and suitable token assignments according to the real-time model competence rather than predefined patterns.

5.2 Ablation Experiments

We conduct ablation experiments to investigate the impacts of various components in our 'Confidence-aware scheduled sampling with target denoising' (described in Equation (7)) and list results in Table 5. Separately removing the confidence-aware strategy degenerates our approach into the vanilla target denoising with a uniform strategy (Meng et al., 2020), which causes a noticeable drop (0.4 BLEU), indicating the confidence-aware strategy plays a leading role for performance. On the other hand, we only observe a drop (0.15 BLEU) when removing 'Target denoising', revealing the additional noise plays a secondary role for performance. Finally, ablating both the confidence-aware strategy and 'Target denoising' degenerates our approach into the vanilla scheduled sampling. It yields a further decrease (0.51 BLEU), suggesting the confidence-aware strategy and 'Target denoising' are complementary with each other.

5.3 Different Numbers of Decoder Layers

As known in existing studies (Domhan, 2018; Wang et al., 2019a), there exists a performance bottleneck at the decoder side of NMT models. Namely, the increase in the number of decoder layers can not bring corresponding improvements for performance. He et al. (2019) attribute this bottle-

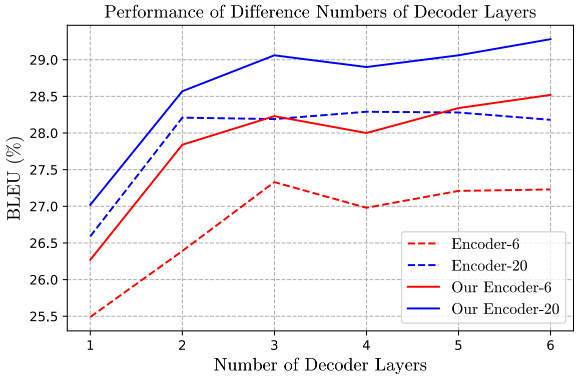

Figure 4: BLUE scores (%) on the validation set of WMT14 EN-DE with different numbers of decoder layers. Solid lines refer to our confidence-aware schedule strategy. Dashed lines refer to the Transformer$_{base}$.

neck to the fact that decoders learn an easier task than encoders.

In this paper, our fine-grained schedule strategy in Equation (7) assigns a more difficult task to the decoder. We can not help wondering whether our strategy is able to alleviate the above performance bottleneck. Firstly, we keep the number of encoders fixed to 6 (*i.e.,* Encoder-6), then apply our confidence-aware schedule strategy on the Encoder-6 Transformer$_{base}$ with the number of decoder layers ranging from 1 to 6. As shown in Figure 4, our approach (solid red line) consistently outperforms the Encoder-6 Transformer$_{base}$ (dashed red line). More importantly, the improvement of Encoder-6 Transformer$_{base}$ stops (*i.e.,* performance bottleneck) once the number of decoder exceeds 4. Despite this, we observe continuous improvement with the growth of decoder layers in our approach. Moreover, we repeat the above experiments with more powerful deep encoders (Encoder-20). We observe that the performance bottleneck for Encoder-20 Transformer$_{base}$ becomes more evident (dashed blue line). Despite this, our approaches (solid blue line) still keep improving performance with the growth of decoder layers on the stronger Encoder-20 Transformer$_{base}$.

In summary, our confidence-aware schedule strategy brings a meaningful increase in the difficulty of decoders, and the bottleneck at the decoder side is alleviated to a certain extend.

5.4 Effects on Different Sequence Lengths

Due to error accumulations, the exposure bias problem becomes more problematic with the growth of sequence lengths (Zhou et al., 2019; Zhang et al., 2020). Thus it is intuitive to verify the effectiveness of our approach over different sequence lengths. Considering the validation set of WMT14 EN-DE (3k) is too small to cover scenarios with various sentence lengths, we randomly select 10k training data with lengths from 10 to 100. As shown in Figure 5, our approach consistently outperform the Transformer$_{base}$ model at different sequence lengths. Moreover, the improvements of our approach over the Transformer$_{base}$ is gradually increasing with sentence lengths. Specifically, we observe more than 1.0 BLEU improvements when sentence lengths in $[80, 100]$.

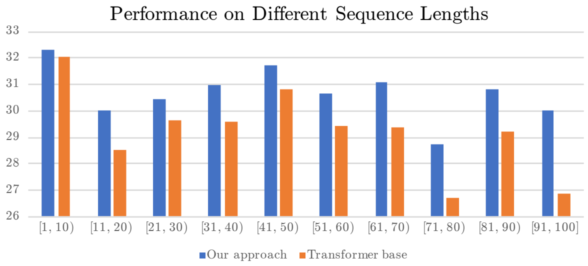

Figure 5: BLUE scores (%) on the randomly sampled WMT14 EN-DE training data with different lengths.

5.5 Model Convergence

As aforementioned, our confidence-aware scheduled sampling learns to deal with the exposure bias problem in an efficient manner, thus speeding up the model convergence. As shown in Figure 6, it costs the Transformer$_{base}$ 245k steps to converge to a local optimum (about 27.1 BLEU). To achieve the same performance, it only costs our confidence-aware scheduled sampling 80k step, namely about 3.0× speed up over the Transformer$_{base}$ and 1.8× speed up over the vanilla scheduled sampling. Since vanilla scheduled sampling randomly exposes more difficult predicted tokens for each token position, regardless of the actual model competence, its convergence speed is restricted to a certain extent. On the contrary, our approach samples predicted tokens only if the current model is capable of dealing with these more difficult inputs, mimicking the learning process of humans. Therefore, our approach is trained more efficiently.

6 Related Work

Confidence-aware Learning for NMT. As to confidence estimations for NMT, Zoph et al. (2015) frame translation as a compression game and measure the amount of information added by transla-

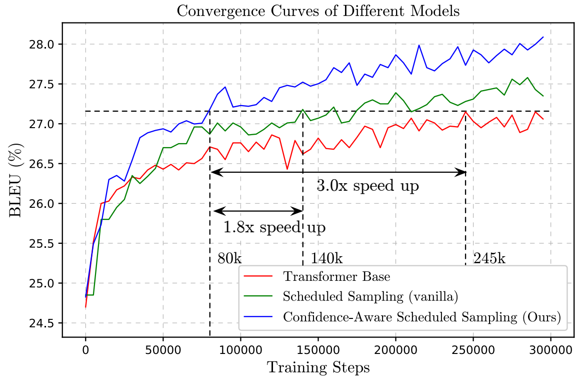

Figure 6: Convergence curves for different models. BLUE scores (%) are calculated on the validation set of WMT14 EN-DE. Our approach can achieve the same performance as the Transformer$_{base}$ with about 3.0× speed up.

tors. Wang et al. (2019b) propose to quantify the confidence of NMT model predictions based on model uncertainty, which is widely extend to select training samples (Jiao et al., 2020; Dou et al., 2020), to design confidence-aware curriculum learning (Zhou et al., 2020; Wan et al., 2020), and to augment synthetic corpora (Wei et al., 2020). Model confidence is also served as a useful metric for analyze NMT model from the perspective of fitting and search (Ott et al., 2018), visualization (Rikters et al., 2017) and calibration (Kumar and Sarawagi, 2019; Wang et al., 2020). Different from existing studies, we are the first to propose confidence-aware scheduled sampling for alleviating the exposure bias problem in NMT.

7 Conclusion

In this paper, we propose confidence-aware scheduled sampling for NMT, which exactly samples corresponding tokens according to the real-time model competence rather than human intuitions. We further explore to sample more noisy tokens for high-confidence token positions, preventing scheduled sampling from degenerating into the original teacher forcing mode. Experiments on three large-scale WMT translation tasks suggest that our approach improves vanilla scheduled sampling both translation quality and convergence speed. We elaborately analyze the effectiveness and efficiency of our approach from multiple aspects. As a result, we further observe our approaches: 1) can alleviate the performance bottleneck of decoders for NMT to a certain extend; 2) improve the translation quality of long sequences.

Acknowledgments

The research work descried in this paper has been supported by the National Key R&D Program of China (2020AAA0108001) and the National Nature Science Foundation of China (No. 61976015, 61976016, 61876198 and 61370130). Abstract

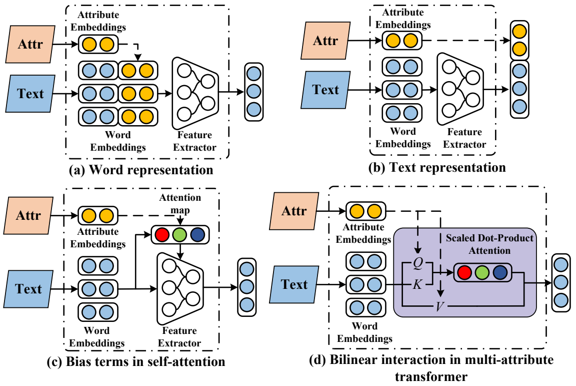
Incorporating attribute information such as user and product features into deep neural networks has been shown to be useful in sentiment analysis. Previous works typically accomplished this in two ways: concatenating multiple attributes to word/text representation or treating them as a bias to adjust attention distribution. To leverage the advantages of both methods, this paper proposes a multi-attribute BERT (MA-BERT) to incorporate external attribute knowledge. The proposed method has two advantages. First, it applies multi-attribute transformer (MA-Transformer) encoders to incorporate multiple attributes into both input representation and attention distribution. Second, the MA-Transformer is implemented as a universal layer and stacked on a BERT-based model such that it can be initialized from a pre-trained checkpoint and fine-tuned for the downstream applications without extra pretraining costs. Experiments on three benchmark datasets show that the proposed method outperformed pre-trained BERT models and other methods incorporating external attribute knowledge.



(a) Word representation

(b) Text representation

(c) Bias terms in self-attention

(d) Bilinear interaction in multi-attribute transformer

Figure 1: Different strategies to incorporate external attribute knowledge into deep neural networks.

1 Introduction

To learn a distributed text representation for sentiment classification (Pang and Lee, 2008; Liu, 2012), conventional deep neural networks, such as convolutional neural networks (CNN) (Kim, 2014) and long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997), and common integration technics, such as self-attention mechanisms (Vaswani et al., 2017; Chaudhari et al., 2019) and dynamic routing algorithms (Gong et al., 2018; Sabour et al., 2017), are usually applied to compose the vectors of constituent words. To further enhance the performance, pre-trained models (PTMs), such as BERT (Devlin et al., 2019), ALBERT (Lan et al., 2019), RoBERTa (Liu et al., 2019), and XLM-RoBERTa (Conneau et al., 2019) can be fine-tuned and transferred for sentiment analysis tasks. Practically, PTMs were first fed a large amount of unannotated data, and trained using a masked language model or next sentence prediction to learn the usage of various words and how the language is written in general. Then, the models are transferred to another task to be fed another smaller task-specific dataset.

The abovementioned methods only use features from plain texts. Incorporating attribute information such as users and products can improve sentiment analysis task performance. Previous works typically incorporated such external knowledge by concatenating these attributes into word and text representations (Tang et al., 2015), as shown in Figs. 1(a) and (b). Such methods are often introduced in shallow models to attach attribute information to modify the representation of either words or texts. However, this may lack interaction between attributes and the text since it equally aligns words to attribute features, thus the model is unable to emphasize important tokens. Several works have used attribute features as a bias term in self-attention mechanisms to model meaningful rela-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2338–2343
August 1–6, 2021.

tions between words and attributes (Wu et al., 2018; Chen et al., 2016b; Dong et al., 2017; Dou, 2017), as shown in Fig. 1(c). By using the $softmax$ function for normalization to calculate the attention score, the incorporated attribute features only impact the allocation of the attention weights. As a result, the representation of input words has not been updated, and the information of these attributes will be lost. For example, depending on individual preferences for $chili$, readers may focus on reviews talking about $spicy$, but only those who like $chili$ would consider such review recommendations useful. However, current self-attention models that learn text representations by adjusting the weights of $spicy$ may still produce the same word representation of $spicy$ for different persons, leading to confusion in distinguishing people who like $chili$ or not.

To address the above problems, this study proposes a multi-attribute BERT (MA-BERT) model which applies multi-attribute transformer (MA-Transformer) encoders to incorporate external attribute knowledge. Different from being incorporated into the attention mechanism as bias terms, multiple attributes can be injected into both attention maps and input token representations using bilinear interaction, as shown in Fig. 1(d). In addition, the MA-Transformer is implemented as a universal layer and stacked on a BERT-based model such that it can be initialized from a pre-training checkpoint and fine-tuned for downstream tasks without extra pre-training costs. Experiments are conducted on three benchmark datasets (IMDB, Yelp-2013, and Yelp-2014) for sentiment polarity classification. The results show that the proposed MA-BERT model outperformed pre-trained BERT models and other methods incorporating external attribute knowledge.

The remainder of this paper is organized as follows. Section 2 provides a detailed description of the proposed methods. The empirical experiments are reported with analysis in Section 3. Conclusions are finally drawn in Section 4.

2 Multi-Attribute BERT Model

Fig. 2 shows an overview of the MA-BERT model. It mainly consists of two parts, including a BERT-based PTM model and several MA-Transformer encoders as extra layers stacked on BERT. Both components are described in detail below.

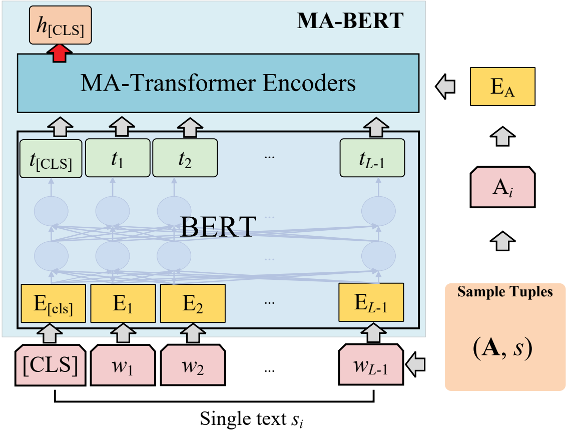


Figure 2: Overall architecture of the MA-BERT model.

2.1 BERT Encoder

By applying a word piece tokenizer (Wu et al., 2016), the input text can be denoted as a sequence of tokens, i.e., $s = \{w_0, w_1, w_2, \ldots, w_{L-1}\}$, where L is the length of the text and $w_0 =$ [CLS] is a special classification token. Moreover, its corresponding attributes are denoted as $\mathbf{A} = \{a_1, a_2, \ldots, a_M\}$, where M is the number of attributes in the text. Thus, the i-th input sample can be denoted as a tuple, i.e., $(\mathbf{A}_i, s_i)$.

To learn the hidden representation, the pre-trained language model BERT (Devlin et al., 2019) was used, achieving impressive performance for various natural language processing (NLP) tasks. We then fed the token sequence into the BERT model to obtain the representation, denoted as,

$$T = [t_0, ..., t_{L-1}] = f_{\text{BERT}}([w_0, ..., w_{L-1}]; \theta_{\text{BERT}}) \quad (1)$$

where $T \in \mathbb{R}^{L \times d_t}$ is the output representation of all tokens; θ_{BERT} is the trainable parameters of BERT, which is initialized from a pretrained checkpoint and then fine-tuned during the model training; d_t=768 is the dimensionality of the output representation.

According to Wu et al. (2018) and Wang et al. (2017), all the attributes are mapped to attribute embeddings $E_{\text{A}} = [E_{\text{A},1}, E_{\text{A},2}, \ldots, E_{\text{A},M}] \in \mathbb{R}^{M \times d_E}$, which are randomly initialized and updated in the following training phase.

Multi-Attribute Attention. To incorporate multiple attributes into the MA-Transformer, we introduce multi-attribute attention (MAA), which is expressed as,

$$Y = \text{MAA}(T, E_{\text{A}}) = [U_1, \ldots, U_M]\, W_o \quad (2)$$

$$U_m = \text{Att}(T, E_{\text{A},m}) = softmax\left(\frac{Q_m {K_m}^\top}{\sqrt{d}}\right) V_m \quad (3)$$

where U_m is the attention from m-th attribute; $W_o \in R^{(M \cdot d) \times d_t}$ is the output linear projection and d denotes the dimensionality of Q, K and V; Q, K and V are matrices that package the queries, keys and values, which are defined as,

$$Q_m = T \cdot W_{q,m} \odot E_{\mathrm{A},m} \tag{4}$$

$$K_m = T \cdot W_{k,m} \odot E_{\mathrm{A},m} \tag{5}$$

$$V_m = T \cdot W_{v,m} \odot E_{\mathrm{A},m} \tag{6}$$

where Q_m, K_m and $V_m \in \mathbb{R}^{L \times d_E}$ are bilinear transformations (Huang et al., 2019) applied on the input representation T and attribute representation $E_{\mathrm{A,m}}$. $W_{q,m}$, $W_{k,m}$ and $W_{v,m} \in \mathbb{R}^{d_t \times d_E}$ are weight matrices for query, key and value projections, and $\cdot$ and $\odot$ respectively denote the inner and the Hadamard product.

Similar to Vaswani et al. (2017), we also introduced multi-head mechanism for MA-Transformer, denoted as,

$$U_m = \bigoplus_{k=1}^{K} \mathrm{Att}(T, E^k_{\mathrm{A},m}) \in \mathbb{R}^{L \times (K \cdot d_E)} \tag{7}$$

where K is the number of heads for each attribute and $\oplus$ denotes the concatenation operator; $E^k_{\mathrm{A},m} \in \mathbb{R}^{d_E}$ is the m-th attribute representation in the k-th head, and its dimensionality should be ensured that $d_E = d_t/K$. Given that different heads can capture different relation types along with text representations, different parameters are considered for different heads.

2.2 MA-Transformer

Taking the representation of both text T and attribute $\mathbf{A}$ as input, an MA-Transformer encoder then processes the same as a standard transformer encoder (Vaswani et al., 2017) to generate $Y \in \mathbb{R}^{L \times d_t}$. Then, Y is connected by a normalization layer and a residual layer from the input representation T. The intermediate output is then passed to a two-layered feed-forward network with a rectified linear unit (ReLU) activate function. Similarly, residual and normalization layers are connected to generate the final output which is taken as the input for the next encoder.

By stacking several MA-Transformer encoders on the BERT model, the MA-BERT model generates a review representation $h_{[\mathrm{CLS}]}$ consistent with the special token [CLS]. Then, a classifier comprised of a linear projection and a $softmax$ activation (with the dimension identical to the number of classes) is used for classification.

3 Comparative Experiments

Datasets. Following the experimental settings used in Tang et al. (2015), the proposed MA-BERT model is evaluated using three benchmark datasets [1] (IMDB, Yelp-2013, and Yelp-2014). The evaluation metrics include accuracy (Acc.) and root mean squared error ($RMSE$). Higher Acc. and lower $RMSE$ scores indicate higher performance.

Implementation Details. The baseline methods can be divided into three groups. The first group includes the methods without user and product information such as **CNN** (Kim, 2014), **BiLSTM** (Hochreiter and Schmidhuber, 1997), neural sentiment classification (**NSC**) (Chen et al., 2016a) and its variant with a local attention mechanism (**NSC+LA**). For the BERT-based methods, the uncased-base-**BERT** model consisting of 12 layers of transformer encoders was implemented for comparison. **ToBERT** (Pappagari et al., 2019) was trained non-end2end using a word-to-segment strategy in a two-stage way.

The second group includes existing methods incorporating user and product information such as NSC with user (U) and product (P) information incorporated into an attention (A) mechanism (**NSC+UPA**), user product neural network (**UPNN**) (Tang et al., 2015), hierarchical model with separate user attention and product attention (**HUAPA**) (Wu et al., 2018), and the chunk-wise importance matrix model (**CHIM**) (Amplayo, 2019).

The third group includes a set of BERT-based methods incorporating user and product information using different strategies, presented in Figs. 1(a)-(c). In detail, an uncased-base-BERT model first extracted fixed feature vectors from texts. Then, the **BERT Concat (word)** model incorporates attribute features into each word vector and stacks another 6 transformer encoders as the feature extractor. Similarly, the **BERT Concat (text)** incorporates attribute features into the representation of the special token [CLS] for the classification. Finally, the **BERT Attention (bias)** applied 6 more MA-Transformers which only inject attributes into Q and K to calculate attention score instead of V in Eq. (6).

The proposed **MA-BERT** models applied 6 MA-Transformer encoders to incorporate user and product attributes, and stacking over the BERT model.

Table 1: Comparative results of different methods for sentiment classification. The **boldface** figures indicate the best results among all methods and underscored figures represent the best performance for each group of methods. All results are averaged over five runs.

Each attribute is initialized in a uniform distribution $U \sim (-0.25, 0.25)$ with the dimension of 768 (d_t) and head number of 12 (K). Thus, the dimension of each head (d_E) is set to 64. All other hyper-parameters in MA-Transformer encoders are identical with BERT-transformer encoders due to their isomorphic structure. For all models, the AdamW (Loshchilov and Hutter, 2017) optimizer was used with a base learning rate of 2e-5 in a warmup linear schedule. Early stopping (Prechelt, 1998) strategy with a patience of 3 epochs was also applied to avoid overfitting. The code for this paper is available at: `https://github.com/yoyo-yun/MA-Bert`.

Comparative Results and Discussion. Table 1 shows the comparative results of different methods for sentiment ordinal classification. For models without user and product attributes, BiLSTM outperforms CNN (UPNN w/o UP), due to its ability to encode text. Furthermore, both NSC and NSC+LA outperformed BiLSTM mainly because of its hierarchical structure.

Incorporating the user and product attributes improved performance. For example, UPNN achieved a better result than its variant without user and product attributes, i.e., CNN (UPNN w/o UP). In addition, both NSC+UPA and HUAPA introduced the user and product information as a bias to guide the hierarchical attention, and thus outperformed NSC and NSC+LA.

The proposed MA-BERT achieved the best performance on all datasets. Compared with baselines without user and product attributes, the MA-BERT can leverage implicit attribute features to boost performance. MA-BERT outperformed methods already incorporating user and product attributes (i.e., NSC+UPA, HUAPA and CHIM$_{embedding}$) because the proposed model can incorporate attribute knowledge to both the attention map and input representation.

The BERT and ToBERT models achieved improvement on all datasets against the conventional models, due to the large knowledge migration from pre-training. Unfortunately, a lack of implicit extra features resulted in performance lower than that of the proposed MA-BERT model. MA-BERT also outperformed BERT Concat (word), BERT Concat (text) and BERT Attention (bias), indicating that the proposed MA-Transformer architecture can improve existing incorporation strategies. Furthermore, the proposed MA-BERT could be initialized from the pre-trained checkpoint of BERT, thus making full use of the parameter settings without bringing additional costs for pre-training.

4 Conclusion

This paper proposes a MA-BERT model capable of incorporating multiple attributes into BERT-based PTMs for learning attribute-specific text representation. Different from existing attention models, the MA-Transformer can inject external knowledge to both attention maps and the input representation.Additionally, the proposed model could be extended to other tasks by using the MA-Transformer encoder as a universal layer and stacking it on a BERT-based model. Future work will attempt to incorporate such or similar multiple attributes into PTMs in the pre-training phases.

A Closer Look into the Robustness of Neural Dependency Parsers Using Better Adversarial Examples

Abstract

Previous work on adversarial attacks on dependency parsers has mostly focused on attack methods, as opposed to the quality of adversarial examples, which in previous work has been relatively low. To address this gap, we propose a method to generate high-quality adversarial examples with a higher number of candidate generators and stricter filters, and then verify their quality using automatic and human evaluations. We perform analysis with different parsing models and observe that: (i) injecting words not used in the training stage is an effective attack strategy; (ii) adversarial examples generated against a parser strongly depend on the parser model, the token embeddings, and even the specific instantiation of the model (i.e., a random seed). We use these insights to improve the robustness of English parsing models, relying on adversarial training and model ensembling.[1]

1 Introduction

Neural network-based models have achieved great successes in a wide range of NLP tasks. However, recent work has shown that their performance can be easily undermined with adversarial examples that would pose no confusion for humans (Zhang et al., 2020). As an increasing number of successful adversarial attackers have been developed for NLP tasks, the quality of the adversarial examples they generate has been questioned (Morris et al., 2020).

The definition of a valid successful adversarial example differs across target tasks. In semantic tasks such as sentiment analysis (Zhang et al., 2019) and textual entailment (Jin et al., 2020), a valid successful adversarial example needs to be able to alter the prediction of the target model while preserving the semantic content and fluency of the original text. In contrast, in the less explored field of attacking syntactic tasks, the syntactic structure, rather than the semantic content, must be preserved while also maintaining the fluency. Preserving the syntactic structure enables us to use the gold syntactic structure of the original sentence in the evaluation process. While preserving the fluency ensures that ungrammatical adversarial examples, which not only fool the target model but also confuse humans, will not be considered valid. Therefore in this paper, we evaluate the quality of an adversarial example in two aspects, namely the **fluency** and **syntactic structure preservation**.

Recently, Zheng et al. (2020) proposed the first dependency parser attacking algorithm based on word-substitution which depended entirely on BERT (Devlin et al., 2019) to generate candidate substitutes. The rational was that the use of the pre-trained language model will ensure fluency of the adversarial examples. However, we find that using BERT alone is far from enough to preserve fluency.

Therefore, in this paper, we propose a method to generate better adversarial examples for dependency parsing with four types of candidate generators and filters. Specifically, our method consists of three steps: (i) determining the substitution order, (ii) generating and filtering candidate substitutes for each word, (iii) searching for the best possible combination of substitutions, based on pre-computed candidates and the substitution order. We verify the superiority of the proposed method in terms of syntactic structure preservation and fluency using both automatic and human evaluations, and further show the limitation of the previous BERT-based method.

Table 1 shows adversarial examples generated by our and the method of Zheng et al. (2020), demonstrating that examples generated by our method are

more fluent, producing complicated substitutes like **emancipated**, **devising** and **eyewitnesses**. Additionally, since it is nontrivial to decode valid multi-subword tokens from BERT, the BERT-based method of Zheng et al. (2020) only generates single subwords as substitutes.

With the proposed attacking method, we evaluate the robustness of different parsing models and analyse the properties of adversarial attacks. We find that (i) the introduction of out-of-vocabulary (OOV, words not in the embedding's vocabulary) and out-of-training (OOT, words not in the training set of the parser) words in adversarial examples are two main factors that harm models' performance; (ii) adversarial examples generated against a parser strongly depend on the type of the parser, the token embeddings and even the random seed.

Adversarial training (Goodfellow et al., 2015), where adversarial examples are added in the training stage, has been commonly used in previous work (Zheng et al., 2020; Han et al., 2020) to improve a parser's robustness. Only a limited number of adversarial examples have been used in such cases, and Zheng et al. (2020) argued that overuse of them may lead to a performance drop on the clean data. However, we show that with improvement in the quality of adversarial examples produced in our method, more adversarial examples can be used in the training stage to further improve the parsing models' robustness without producing any apparent harm in their performance on the clean data. Inspired by our second finding, we propose to improve the parsers' robustness by combining models trained with different random seeds and embeddings. Such methods, which are not targeting specific types of attacks, should improve the capacity to defend against new attacks as compared to standard adversarial training.

2 Method

In this section, we first give a formal definition of a dependency parsing attack. Then we describe the proposed attacking method for dependency parsing, shown in Algorithm 1. It consists of three steps, namely ranking word importance (lines 1-4), generating candidates for substitution (line 7) and searching for the best substitute combination (lines 8-21).

2.1 Problem Definition

Given an input text space $\mathcal{X}$ containing all possible input sentences $\boldsymbol{x}$ and an output space $\mathcal{Y}$ containing all possible dependency trees of $\boldsymbol{x}$, a parser $F : \mathcal{X} \rightarrow \mathcal{Y}$ learns to map the sentence $\boldsymbol{x}$ to its corresponding tree $\boldsymbol{y}$, denoted by $F(\boldsymbol{x}) = \boldsymbol{y}$. The i-th word of $\boldsymbol{x}$ is denoted by x_i. For sentence $\boldsymbol{x}$, a valid adversarial example $\boldsymbol{x}^*$ is crafted by adding a perturbation to $\boldsymbol{x}$ so that

$$F(\boldsymbol{x}^*) \neq \boldsymbol{y}, \sigma(\boldsymbol{x}^*, \boldsymbol{x}) \leq \epsilon,$$

where σ is a constraint function and ϵ ensures that i) the perturbation is imperceptible, ii) the true dependency tree of $\boldsymbol{x}^*$ should be the same as that of $\boldsymbol{x}$. In this paper, these two constraints are ensured through the use of various filters (see Section 2.3) and are used to evaluate the quality of adversarial examples (see details on fluency and syntactic structure preservation in Section 3.3).

2.2 Word Importance Ranking

Word importance ranking in our model is based on the observation that some words have a stronger influence on model prediction than others. Such word importance is typically computed by setting each word to unknown and examining the changes in their predictions (Li et al., 2016; Ren et al., 2019).

Algorithm 1 Dependency Parsing Attack

```
Input: Sentence example $\boldsymbol{x}^{(0)} = \{x_1, x_2, \dots, x_N\}$, maximum percentage of words allowed to be modified $\gamma$
Output: Adversarial example $\boldsymbol{x}^{(i)}$
for $i = 1$ to $N$ do
    Compute word importance $I(\boldsymbol{x}^{(0)}, x_i)$ via Eq. 1
end for
Create a set $W$ of all words $x_i \in \boldsymbol{x}^{(0)}$ sorted by the descending order of their importance $I(\boldsymbol{x}^{(0)}, x_i)$.
$t = 0$
for each word $x_j$ in $W$ do
    Build candidate set $\mathcal{C}_j$ for $x_j$ following the Candidate Substitute Generating step
    Initialise valid candidate set $\mathcal{VC} \leftarrow \{\}$
    for each candidate $c_k$ in $\mathcal{C}_j$ do
        Compute the accuracy change $S(\boldsymbol{x}^{(t)}, c_k, j)$ via Eq. 3
        if $S(\boldsymbol{x}^{(t)}, c_k, j) \leq 0$ then continue end if
        Add $c_k$ to the set $\mathcal{VC}$
    end for
    if $\mathcal{VC}$ is not empty then
        $c^* = \operatorname{argmax}_{c \in \mathcal{VC}} S(\boldsymbol{x}^{(t)}, c, j)$
        $t = t + 1$
        $\boldsymbol{x}^{(t)} \leftarrow$ Replace $x_j$ in $\boldsymbol{x}^{(t-1)}$ with $c^*$
        if $t \geq \gamma \cdot N$ then return $\boldsymbol{x}^{(t)}$ end if
    end if
end for
if $t > 0$ then return $\boldsymbol{x}^{(t)}$ else return None end if
```

This helps to determine the word substituting order in the proposed method.

In this work, we use a combination of the changes found in the unlabelled attachment score (UAS) and in the labelled attachment score (LAS) to measure word importance. Specifically, the importance of a word x_i in sentence $\boldsymbol{x}$ is computed as

$$\begin{aligned} I(\boldsymbol{x}, x_i) = & \lambda_{arc} \Delta_{\text{UAS}}(\boldsymbol{x}, \hat{\boldsymbol{x}}_i) + \\ & (1 - \lambda_{arc}) \Delta_{\text{LAS}}(\boldsymbol{x}, \hat{\boldsymbol{x}}_i), \end{aligned} \quad (1)$$

where $\boldsymbol{x} = x_1 x_2 \dots x_i \dots x_N$ is the original sentence and $\hat{\boldsymbol{x}}_i = x_1 x_2 \dots \text{UNK} \dots x_N$ replaces x_i with an 'unknown' token. Here $\Delta_{\text{UAS}}(\boldsymbol{x}, \hat{\boldsymbol{x}}_i) = \text{UAS}_{F(\boldsymbol{x})} - \text{UAS}_{F(\hat{\boldsymbol{x}}_i)}$ and $\Delta_{\text{LAS}}(\boldsymbol{x}, \hat{\boldsymbol{x}}_i) = \text{LAS}_{F(\boldsymbol{x})} - \text{LAS}_{F(\hat{\boldsymbol{x}}_i)}$ are the changes in UAS and LAS respectively. λ_{arc} is a coefficient that controls the relative importance of dependency arcs and their labels.

2.3 Generation of Substitute Candidates

Generating substitute candidates is a critical step, as it significantly influences the attack success rate and the quality of generated adversarial examples. Zheng et al. (2020) relied entirely on BERT to generate candidates, but this limits the quality of the adversarial examples. To alleviate this problem, we first collect candidate substitutes from four generation methods, then apply filters to discard inappropriate substitutes, ensuring both diversity and quality of the generated candidates.

2.3.1 Generating Process

We collect substitutes from the following methods:

BERT-Based Method: We use BERT to generate candidates for each target word from its context. This method generates only single subwords.

Embedding-Based Method: Following Alzantot et al. (2018), we use word embeddings of Mrkšić et al. (2016)[2] to compute the N nearest neighbours of each target word according to their cosine similarity and use them as candidates.

Sememe-Based Method: The sememes of a word represent its core meaning (Dong and Dong, 2006). Following Zang et al. (2020), we collect the substitutes of the target word x based on the rule that one of the substitutes the senses of x^* must have the same sememe annotations as one of senses of x.

Synonym-Based Method: We use WordNet[3] to extract synonyms of each target word as candidates.

2.3.2 Filtering Process

We apply the following four types of filters to discard candidates which are likely inappropriate, either in terms of syntactic preservation or fluency.

POS Filter: We first filter out substitutes with different part-of-speech (POS) tags from the original word.[4] This filter is essential for preserving the syntactic structure of the sentence.

Word Embedding Similarity Filter: We use the word embeddings of Mrkšić et al. (2016) to compute the cosine similarity between the original word and each of the substitutes in $\mathcal{C}$ and filter out those whose similarities are less than a threshold ϵ_w.[5]

Grammar Checker Filter: We employ an off-the-shelf grammar checker[6] to filter out candidates that may introduce grammar errors. This filter helps to further ensure that the syntactic structure and fluency are preserved.

Perplexity Filter: We employ GPT-2 (Radford et al., 2019) to calculate the perplexity difference

---

[2] These embeddings are post-processed to ensure that the nearest neighbours are synonyms.

[3] `https://wordnet.princeton.edu`

[4] We use the off-the-shelf Stanford tagger. (`https://nlp.stanford.edu/software/tagger.html`)

[5] Non-synonym substitutes often reduce fluency.

[6] `https://pypi.org/project/language_tool`

between $\boldsymbol{x}$ and $\boldsymbol{x}_i^c$ for each candidate c:

$$\Delta\text{ppl}(\boldsymbol{x}, c, i) = \text{ppl}(\boldsymbol{x}_i^c) - \text{ppl}(\boldsymbol{x}), \qquad (2)$$

where $\boldsymbol{x}_i^c$ is $\boldsymbol{x}$ with its i-th word replaced by c, and filter out c whose $\Delta\text{ppl}(\boldsymbol{x}, c, i) > \epsilon_p$.

2.4 Best Substitute Searching

In this step, we greedily search for the best possible combination of substitutions, relying both on the previously created candidate lists and word substitution order. To preserve the syntactic structure of sentences, we forbid replacement of pronouns, articles, conjunctions, numerals, interjections, interrogative determiners and punctuation. Additionally, we set the maximum percentage of words allowed to be modified γ in the experiments to control the modification number.

Specifically, given a sentence $\boldsymbol{x}$, we substitute the words following the order computed in the word importance ranking step. For each target word x_i, we build an adversarial example $\boldsymbol{x}_i^c = x_1 x_2 \ldots c \ldots x_N$ for each of its substitutes c. Then we compute the accuracy change score from $\boldsymbol{x}$ to $\boldsymbol{x}_i^c$ as input to the parser:

$$\begin{aligned} S(\boldsymbol{x}, c, i) = &\lambda_{arc}\Delta_{\text{UAS}}(\boldsymbol{x}, \boldsymbol{x}_i^c) + \\ &(1 - \lambda_{arc})\Delta_{\text{LAS}}(\boldsymbol{x}, \boldsymbol{x}_i^c), \end{aligned} \qquad (3)$$

where $\Delta_{\text{UAS}}(\boldsymbol{x}, \boldsymbol{x}_i^c) = \text{UAS}_{F(\boldsymbol{x})} - \text{UAS}_{F(\boldsymbol{x}_i^c)}$ and $\Delta_{\text{LAS}}(\boldsymbol{x}, \boldsymbol{x}_i^c) = \text{LAS}_{F(\boldsymbol{x})} - \text{LAS}_{F(\boldsymbol{x}_i^c)}$ are the changes in UAS and LAS, respectively. If the percentage of modified words in the sentence exceeds a threshold γ, we stop the process. Otherwise, we search for a substitute for the next target word.

3 Experimental Setup

3.1 Target Parsers and Token Embeddings

We choose the following two strong and commonly used English parsers, one graph-based, the other transition-based, as target models, both of which achieve performance close to the state-of-the-art.

Deep Biaffine Parser (Dozat and Manning, 2017) is a graph-based parser that scores each candidate arc independently and relies on a decoding algorithm to search for the highest-scoring tree.

Stack-Pointer Parser (Ma et al., 2018) is a transition-based parser that incrementally builds the dependency tree with pre-defined operations.

We used the following four types of token embeddings to study their influence on each parsers' robustness. To focus on the influence of the embeddings, we use only the embeddings as input to the parsers:

GloVe (Pennington et al., 2014) is a frequently used static *word embedding*.

RoBERTa (Liu et al., 2019) is a pre-trained language model based on a masked language modelling object, which learns to predict a randomly masked token based on its context. It produces contextualised *word piece embeddings*.

ELECTRA (Clark et al., 2020) is a pre-trained language model based on a replaced token detection object, which learns to predict whether each token in the corrupted input has been replaced. It produces contextualised *word piece embeddings*.

ELMo (Peters et al., 2018) is a pre-trained language representation model based on *character embeddings* and bidirectional language modelling.

3.2 Datasets and Experimental Settings

We train the target parsers and evaluate the proposed method on the English Penn Treebank (PTB) dataset,[7] converted into Stanford dependencies using version 3.3.0 of the Stanford dependency converter (de Marneffe et al., 2006) (PTB-SD-3.3.0). We follow the standard PTB split, using section 2-21 for training, section 22 as a development set and 23 as a test set.

It is important to note that when converting PTB into Stanford dependencies, Zheng et al. (2020) maintained the copula (linking verbs) as a head when its complement was an adjective or noun.[8] However, since the design objective of Stanford dependency is to maximize dependencies between content words (de Marneffe et al., 2006), a more typical setting is to regard copulas as auxiliary modifiers. Therefore, we first compare with the previous method by performing this step under their settings and further conduct experiments with the typical PTB-SD-3.3.0 dataset for the convenience of follow-up research.

While training the target parsers, we adopt the hyper-parameters from their respective papers. Note that to compare with the biaffine parser, which uses first-order features, we also adopt the basic setting for the stack-pointer parser.[9] When using

---

[7] `https://catalog.ldc.upenn.edu/LDC99T42`

[8] Referred to as PTB-SD-3.3.0-COP in the rest of the paper.

[9] According to our preliminary experiments, neither second-order features nor beam search has an obvious influence on the parser robustness under our attack.

RoBERTa, ELECTRA or ELMo embeddings as input, we set the learning rate of these pre-trained models to 2e-5 and that of other parameters to 2e-2.

For the hyper-parameters of each attacking method, we set the word embedding similarity threshold $\epsilon_w = 0.7$, the candidate perplexity difference threshold $\epsilon_p = 20.0$, the arc importance coefficient $\lambda_{arc} = 0.5$ and the maximum percentage of words allowed to be modified $\gamma = 15\%$.

3.3 Evaluation Metrics

As introduced in Section 2.1, two constraints should be satisfied for an adversarial example to be valid: i) the perturbation is imperceptible, ii) the true dependency tree of x^* should be the same as that of x. For the first, we use **fluency** to measure the imperceptibility of the perturbations, and assume that in a fluent adversarial example the perturbation is imperceptible. For the second, **syntactic structure preservation** is used to measure whether an adversarial example's true dependency tree is identical to that of the original text. Both automatic and human evaluations are used for analysis.

In the automatic evaluation, GPT-2 (Radford et al., 2019) is used to compute the average perplexity of the adversarially modified PTB test set to measure the overall fluency. In the human evaluation, we ask three annotators to evaluate the quality of adversarial examples in two aspects, namely syntactic structure preservation and fluency.[10] To evaluate the preservation of the syntactic structure, we randomly collect 100 sentences along with their adversarial examples and ask the annotators to decide whether the syntactic structure is preserved in each case. For the fluency evaluation, we randomly collect 100 sentences along with the adversarial examples generated by our method and those produced by the black-box method of Zheng et al. (2020).[11] For each sentence, the annotators are asked to distinguish which example is better with regard to fluency. For both evaluations, we adopt the majority vote for the final results.

To evaluate how successful the attack is, we report the parsing results of the target models on the original and the adversarially modified (*after-attack*) PTB test set. The results are reported in terms of unlabelled attachment score (UAS) and labelled attachment score (LAS). We also report the attack success rate, namely the percentage of successfully attacked sentences. If the prediction accuracy of the modified sentence is lower than the original one, it is regarded as a successful attack.[12]

4 Results

4.1 Comparison with Previous Work

We first evaluate our attacking method on PTB-SD-3.3.0-COP and compare it with previous work (Zheng et al., 2020). Since we focus on the black-box attack in this paper, we compare with their sentence-level black-box attack against the deep biaffine parser with only word-based embeddings as input. In both their and our settings, 15% of words are allowed to be modified.

Model	**Automatic**	**Human**	
	PPL	**Fluency%**	**Syntax%**
Zheng et al.	267.96	20	75
Ours	**139.99**	**80**	**85**

Table 2: Automatic and human evaluation results on the PTB-SD-3.3.0-COP test set. PPL denotes the average perplexity. Syntax% denotes the preserved syntactic-structure rate and Fluency% the higher fluency rate.

Table 2 shows that adversarial examples generated by our method substantially outperform the previous method with regard to fluency and syntactic structure preservation. In the automatic evaluation, the average perplexity of examples generated by our method is 139.99, as compared to 267.96 of those generated by the previous work. For comparison, the average perplexity of the original PTB test set is 127.67, which is very close to ours.

In the human evaluation, results show that for 80% of the sentences, our adversarial examples have better fluency, which further confirms the effectiveness of our method. In addition, 85% of the examples we generated preserve the original syntactic structure, as compared to 75% reported by Zheng et al. (2020), showing that our method also improves the syntactic-structure preservation rate.

Table 3 shows the attack results of the two methods.[13] It is clear that with higher quality, the adversarial examples generated by our method cause

---

[10] The three human annotators are postgraduate students with a few years of research experience in syntactic parsing.

[11] We thank Zheng et al. (2020) for kindly providing us with the adversarial examples they generated.

[12] Note that Zheng et al. (2020) only considered unlabelled scores, so when comparing with these, we use the difference in UAS as the measurement of successful attacks. Conversely, in experiments on PTB-SD-3.3.0, we use the difference in LAS.

[13] We only compare UAS here since they did not report LAS in their paper.

Model	Orig-UAS	After-UAS	Succ%
Zheng et al.	95.52	88.69	51
Ours	95.45	88.95	44

Table 3: Results on the PTB-SD-3.3.0-COP test set. Orig-/After-UAS denotes the original and after-attack UAS respectively. Succ% denotes the success rate.

fewer incorrect predictions. This suggests that some of the previous attacks that were counted as successful may have used invalid adversarial examples which are either ungrammatical or which have actually changed the original syntactic structure.

Generator	BERT	Emb.	Sem.	Syn.
before	28.64	20.54	8.57	1.74
after	0.54	2.06	0.46	0.17
left%	1.89	10.04	5.32	10.03

Table 4: The average number of candidates **before** and **after** filtering generated by BERT-based (**BERT**), embedding-based (**Emb.**), sememe-based (**Sem.**) and synonym-based (**Syn.**) methods respectively. And the percentages of the **left** candidates.

To further demonstrate the limitation of the BERT-based method which the previous work used as the only candidate generator, we count the average number of candidates from our use of different generators before and after filtering. Results in Table 4 show that although the BERT-based method generates the most candidates before filtering, only 1.89% of them are left after the filters are applied. Whereas the left candidate percentage varies from 5% to 10% for the other three generators. The results further verify that the quality of candidates generated by the BERT-based method is worse than that from the embedding-based, sememe-based and synonym-based methods.

Model	After-UAS	Succ%	PPL
pos	72.21	89	326.06
pos+emb	79.87	75	286.92
pos+emb+gra	81.52	71	254.95
pos+emb+gra+ppl	88.95	44	139.99

Table 5: Ablation study of filters. **pos**, **emb**, **gra** and **ppl** stand for POS (part of speech), word embedding similarity, grammar checker and perplexity filters respectively.

To evaluate the ability of the filters, we conduct an ablation study with different combinations of these filters. Results in Table 5 show that the perplexity as well as the attack success rate decreases when more filters are applied. As expected, the greatest perplexity drop is brought by the perplexity filter.

4.2 Robustness Evaluation of Different Models

Input	Original		After-Attack		Succ%
	UAS	LAS	UAS	LAS	
			Biaffine		
G.	95.36	93.49	88.69	85.09	55.3
M.	96.29	94.51	90.70	87.67	47.5
E.	97.12	95.38	91.05	87.79	50.6
R.	97.09	95.41	92.14	89.42	46.1
			Stack-Pointer		
G.	94.93	93.05	88.26	84.64	52.6
M.	95.69	93.77	89.57	86.49	46.8
E.	96.94	95.19	90.69	87.47	50.3
R.	96.93	95.20	91.58	88.84	45.1

Table 6: Robustness evaluation results. Succ% denotes the success rate (computed based on LAS). **G.**, **M.**, **E.** and **R.** stand for GloVe, ELMo, ELECTRA and RoBERTa respectively.

We evaluate the robustness of the different parsing models introduced in Section 3.1 on PTB-SD-3.3.0 and report the results in Table 6. First of all, when applied to unperturbed sentences, the graph-based deep biaffine parser performs consistently better than the transition-based stack-pointer parser (using the same embeddings). Among the four kinds of embeddings, the word piece-level embeddings (i.e., ELECTRA and RoBERTa) achieve the highest results, while GloVe yields the lowest results.

As for the adversarially modified sentences, we find that the drop in performance is close between the two families of parsers (using the same embeddings), while the attack success rate against the Stack-Pointer parser is slightly higher. In terms of the embeddings, RoBERTa turns out to be the most robust one, which has the lowest attack success rate and achieves the highest performance on the generated adversarial examples. ELMo is also a comparatively robust embedding. We are surprised to find that although ELECTRA achieves similar performance to RoBERTa on clean input data, it performs poorly on the adversarial examples. We hypothesise that this is due to ELECTRA's training objective, i.e. learning to predict whether a token in a corrupted sentence is genuine or not. With this objective, some of our substitutes can be predicted as incorrect tokens, yielding token representations in the space not encountered by the parser in training, and hence damaging its performance. Lastly, GloVe is the most vulnerable embedding. [14]

---

[14] To evaluate the stability of the attack, for each parsing

Vocab.	**Original**				**After-Attack**				**Succ%**
	UAS	**LAS**	**OOV**	**OOT**	**UAS**	**LAS**	**OOV**	**OOT**	
50k	95.36	93.49	2	24	87.58	83.73	972	1285	59.5
400k	95.36	93.49	0	15	88.69	85.09	2	906	55.3
400k (T.)	95.36	93.49	0	8	90.06	87.26	0	0	45.5

Table 7: OOV and OOT test results. **Vocab.** stands for vocabulary size, **T.** means filtering out all the candidates that have not appeared in the training set.

4.3 Out-of-Vocabulary and Out-of-Training Words

In this section, we investigate the roles out-of-vocabulary (OOV, words not in the embedding's vocabulary) and out-of-training (OOT, words not in the training set of the parser) words play in dependency parsing attacks. We perform attacks on the Biaffine GloVe models trained with (i) 50k vocabulary (**50k**), (ii) 400k vocabulary (**400k**) and (iii) the same 400k vocabulary but where all candidates not in the training set are filtered out (**400k (T.)**).

The results are shown in Table 7, where we report the attack results along with the number of OOV and OOT words in the adversarially modified words before and after the attack. Firstly, by comparing the OOV and OOT numbers before and after the attack in the **50k** model, we find that words chosen to be replaced are often non-OOV and non-OOT, while their substitutes are often OOV and OOT. Secondly, the comparison between the **50k** and **400k** results shows that when the number of OOV words decreases, the robustness of the model increases. Therefore, it is reasonable to assume that OOV words in adversarial examples cause incorrect predictions. Thirdly, according to the **400k** and **400k (T.)** results, when the number of OOT words in adversarial examples are reduced to 0 by filtering out all the OOT candidates, the attack success rate drops substantially. Therefore, we have reason to believe that unfamiliar OOT words are another factor degrading a parser's performance.

The OOV problem mostly appears in models using word-level embeddings such as GloVe and can be alleviated by simply increasing the vocabulary size. While for the OOT problem, one potential solution is using adversarial training, where a new parser is trained with a mixture of clean training data and adversarial examples.

4.4 Adversarial Training

Previous work (Zheng et al., 2020; Han et al., 2020) used a limited number (from 2,000 sentences to half of the training data) of adversarial examples in adversarial training as (Zheng et al., 2020) argued that overuse of them may lead to a performance drop on the clean data. In this section, we investigate the adversarial training strategies on all the parsing models introduced in Section 3.1. Specifically, we generate adversarial examples for the whole PTB training set and retrain parsers on different amount of adversarial examples along with the original training set. Figure 1 shows that as the number of adversarial examples used in adversarial training increases, the robustness of the models increases accordingly. For most of the models, the increase of robustness stops between 50% and 70% of adversarial examples used.

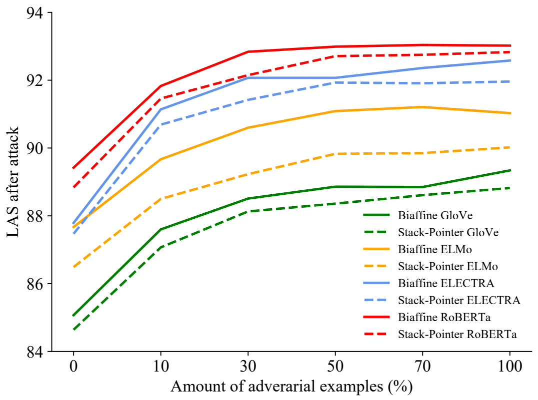

Figure 1: After-attack results with different amounts of adversarial examples used for adversarial training (best viewed in colour).

Table 8 shows the results of Biaffine parsers retrained with 100% of the adversarial examples generated for the original training set. We find that in most cases, the parsing results on the clean data are not obviously influenced although all of the adversarial examples are used. In addition, the robustness of all of the retrained models is substantially improved.

---

model in Table 6 we attack another two trained with different random seeds. The experiment shows all the results are stable across seeds.

Table 8: Adversarial training results. * denotes models with adversarial training.

4.5 Transferability

We refer to adversarial examples as transferable if, generated against one model, they succeed in fooling another one. Previously, Jin et al. (2020) found that in text classification and entailment tasks, adversarial examples are moderately transferable between models with different embeddings. In this section, we examine the following three kinds of transferabilities of adversarial examples in dependency parsing attacks: (i) **Cross Seed**: adversarial examples generated against one model are tested on another model trained with a different random seed; (ii) **Cross Parser**: adversarial examples generated against one model are tested on another from a different family of parsers; and (iii) **Cross Embedding**: adversarial examples generated against one model are tested on another trained with a different type of embedding.

Src	Cross Seed	Cross Parser	Cross Embedding			
			G.	M.	E.	R.
G.	45.0	40.3	**55.3**	27.7	27.2	25.2
M.	36.3	35.6	28.0	**47.5**	29.6	27.2
E.	34.8	40.2	27.1	28.8	**50.6**	29.2
R.	39.8	35.0	25.5	27.9	29.8	**46.1**

Table 9: Attack success rates (%) in the transferability test with Biaffine parser as the source parser. **Src** represents the source model.

Results in Table 9 and 10 show that the attack success rate always drops when adversarial examples are tested on other models, indicating that the adversarial examples strongly depend on the parser model, the token embeddings and even the specific instantiation of the model (i.e., the random seed). Among the three kinds of transferabilities, the cross seed transfer is the strongest while the cross embedding transfer is the weakest.

Src.	Cross Seed	Cross Parser	Cross Embedding			
			G.	M.	E.	R.

4.6 Cross-Seed and Cross-Embedding Ensemble

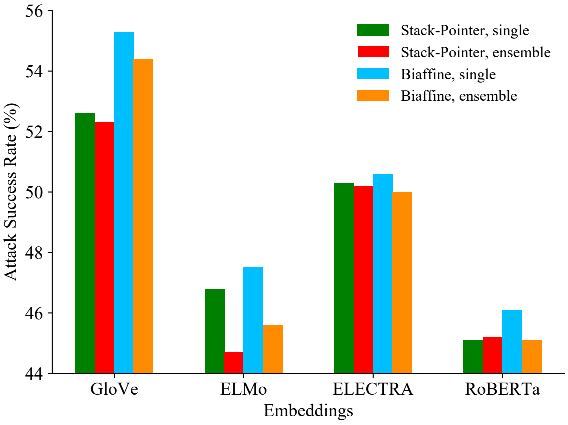

Figure 2: Attack success rates of the examples with and without cross-seed ensemble.

Based on the observations from Section 4.5, we propose to improve the robustness of parsing models using a cross-seed ensemble and cross-embedding ensemble. To ensemble multiple parsers, we simply compute the average of the probability distributions across them and use that result as the new distribution in the ensembled model.

Figure 2 shows the effect of the cross-seed ensemble, where almost all the attack success rates are dropped with such an ensemble. In addition, it is most effective with ELMo while least effective with ELECTRA and RoBERTa.

Table 11 shows the effect of using the cross-embedding ensemble, where robustness increases when more models with different token embeddings are ensembled. Moreover, contrary to adversarial training, the ensemble method is not tuned to specific types of attacks and appears robust to 'unseen' attacks, showing that it is more likely to defend against new attacks.

5 Related Work

Existing textual adversarial attacks have mostly focused on semantic tasks such as sentiment analysis (Zhang et al., 2019) and textual entailment (Jin et al., 2020). Although most of this work has applied various techniques to maintain the fluency of adversarial examples, a recent study by Morris et al. (2020) reported that quite a number of these techniques introduce grammatical errors.

In syntactic tasks, Zheng et al. (2020) recently proposed the first dependency parser attacking method which depends entirely on BERT to generate candidates. However, we show that the quality of adversarial examples generated by their method is relatively low due to the limitation of the BERT-based generator, and we propose to generate better examples by using more generators and stricter filters.

Han et al. (2020) proposed an approach to attack structured prediction models with a seq2seq model (Wang et al., 2016) and evaluated this model on dependency parsing. They used two reference parsers in addition to the victim parser to supervise the training of the adversarial example generator, and found that the three parsers produce better results when they have different inductive biases embedded to make the attack successful. This finding is quite close in spirit to our conclusion in Section 4.5. Hu et al. (2020) also put forth efforts to modify the text in syntactic tasks while preserving the original syntactic structure. However, their goal is to preserve privacy via the modification of words that could disclose sensitive information.

6 Conclusion

In this paper, we propose a method for generating high-quality adversarial examples for dependency parsing and show its effectiveness based on automatic and human evaluation. We investigate the robustness of different types of neural dependency parsers. We show that OOV and OOT words are two critical characteristics that cause a performance drop and propose to solve the OOT problem with adversarial training. We further examine three kinds of transferabilities of adversarial examples and propose to improve the robustness of parsing models by ensembling across random seeds and token embeddings.

Abstract

Stance detection determines whether the author of a text is in favor of, against or neutral to a specific target and provides valuable insights into important events such as presidential election. However, progress on stance detection has been hampered by the absence of large annotated datasets. In this paper, we present P-STANCE, a large stance detection dataset in the political domain, which contains 21,574 labeled tweets. We provide a detailed description of the newly created dataset and develop deep learning models on it. Our best model achieves a macro-average F1-score of 80.53%, which we improve further by using semi-supervised learning. Moreover, our P-STANCE dataset can facilitate research in the fields of cross-domain stance detection such as cross-target stance detection where a classifier is adapted from a different but related target. We publicly release our dataset and code.[1]

1 Introduction

Nowadays, people often express their stances toward specific targets (e.g., political events or figures, religion, or abortion) on social media. These opinions can provide valuable insights into important events, e.g., presidential election. The goal of the stance detection task is to determine whether the author of a piece of text is in favor of, against, or neutral toward a specific target (Mohammad et al., 2016b; Küçük and Can, 2020; ALDayel and Magdy, 2021). Twitter as a social platform has produced a large quantity of user-generated content, which has become a rich source for mining useful information about various topics such as presidential election. Political figures, who usually receive considerable attention and involve themselves in a large number of political events, are great targets to study stance detection. Therefore, detecting the stance expressed toward political figures on Twitter has drawn a lot of attention in the NLP community (Mohammad et al., 2016a; Sobhani et al., 2017; Darwish et al., 2017).

Even though stance detection has received a lot of attention, the annotated data are usually limited, which poses strong challenges to supervised models. Moreover, a limitation of existing datasets is that explicit mentions of targets and surface-level lexical cues that may expose the stance can be widely observed in the data (Mohammad et al., 2016a; Sobhani et al., 2017; Swami et al., 2018; Darwish et al., 2018; Conforti et al., 2020b; Lai et al., 2020), which means a model can detect the stance without extracting effective representations for the meanings of sentences (i.e., their lexical and compositional semantics). Another limitation of existing datasets, especially the datasets built on social media, is that the average length of tweets is short, which indicates that the data in these previous datasets are less informative and thus the stance can be detected more easily.

In an effort to minimize these drawbacks, we present P-STANCE, a dataset for stance detection whose primary goal is to bridge these gaps by making it possible to run large-scale evaluations that require a deeper semantic understanding. This large annotated dataset is composed of 21,574 English tweets in the political domain and each tweet is annotated with a stance toward one of three different targets: “Donald Trump,” “Joe Biden,” and “Bernie Sanders.” Examples from our dataset and their stance labels are shown in Table 1.

The main motivation of building this dataset is to provide a new benchmark for in-target stance detection where a classifier is trained and validated on the same target. However, we show additional interest in constructing a large corpus to facilitate research on cross-target stance detection where a classifier is adapted from different but related target.

August 1–6, 2021.

Target	Tweet	Stance
Donald Trump	I agree, but not convinced Barr has all the evidence for his opinion. Although, I have zero worries about POTUS being re-elected, if the evidence is compelling enough on top of the tyrannical Covid lockdowns, Im hopeful more people will wake up. #GiantRedPill #Trump	Favor
Donald Trump	Take my kids, for example. At least, I'm TOLD they're my kids. No proof. Don Jr, Ivanka and Eric were all born to an immigrant woman who WASN'T a US Citizen when they were born. They shouldn't have US Citizenship. DEPORT THEM ALL! #Trump	Against
Bernie Sanders	Air borne illnesses will only become more common with climate change. We need to immediately address this and fight for Medicare for All or this could be the new normal. #BernieSanders	Favor
Bernie Sanders	A meat tax? Paying off all medical bills? I think #bernie has truly gone off the deep end of the pander cliff. None of these socialists insane, pie-in-the-sky policies would EVER work, or even come in to fruition yet people continue to fall for it. Unbelievable. #foxandfriends	Against
Joe Biden	Robyn Seniors, National HBCU Students for Biden Co-Chair and a @FAMU_1887 student, says that she's thankful that a "woman will be Vice President in a Biden administration."	Favor
Joe Biden	The Ukrainians are smarter than our own democratic party! Shoot, my Dogs are smarter than our own democratic party!! #ImpeachmentHoax #NoQuidProQuo #Biden	Against

Table 1: Examples from our P-STANCE dataset.

More interestingly, P-Stance enables a new task in stance detection, which is cross-topic stance detection where a classifier is adapted from the same target but with different topics in the past. These tasks, which use labeled training data of a source target and aim to train a model that generalizes well to a destination target with a shifted distribution, hold great practical value.

Our contributions include the following: 1) We present P-STANCE, a large dataset for stance detection composed of 21,574 tweets sampled from over 2.8 million tweets collected from Twitter. P-STANCE is more than three times larger than the previous benchmark (Mohammad et al., 2016a) and brings additional challenges such as linguistic complexities. We provide a detailed description and a comprehensive analysis of this dataset; 2) We conduct experiments on the proposed P-STANCE dataset and establish a strong baseline based on BERTweet (Nguyen et al., 2020). BERTweet achieves a macro-average F1-score of 80.53%, which we improve further by using semi-supervised learning; 3) The union of P-STANCE and previous benchmark datasets provides more opportunities for studying other stance detection tasks, e.g., cross-target stance detection and cross-topic stance detection.

2 Related Work

The most common stance detection task on social media is target-specific stance detection (ALDayel and Magdy, 2021) which aims to identify the stance toward a set of figures or topics (Hasan and Ng, 2014; Mohammad et al., 2016a; Xu et al., 2016; Taulé et al., 2017; Swami et al., 2018; Zotova et al., 2020; Conforti et al., 2020b; Lai et al., 2020; Vamvas and Sennrich, 2020; Conforti et al., 2020a). Besides target-specific stance detection, multi-target stance detection (Sobhani et al., 2017; Darwish et al., 2017; Li and Caragea, 2021a), and claim-based stance detection (Qazvinian et al., 2011; Derczynski et al., 2015; Ferreira and Vlachos, 2016; Bar-Haim et al., 2017; Rao and Pomerleau, 2017; Derczynski et al., 2017; Gorrell et al., 2019) are other popular trends of stance detection. Multi-target stance detection aims to jointly identify the stance toward two or more targets in the same text. Unlike the target-specific stance detection and multi-target stance detection where the target is usually a prominent figure or topic, in claim-based stance detection the target is a claim, which could be an article headline or a rumor's post.

Interestingly, despite substantial progress on stance detection, large-scale annotated datasets are limited. We compare our P-STANCE dataset with some existing stance detection datasets in Table 2. We can observe that the sizes of existing stance detection datasets are smaller than ours except for the WT-WT dataset (Conforti et al., 2020b) in the financial domain. However, the average tweet length of WT-WT is much shorter when compared with our P-STANCE. Moreover, more explicit mentions of targets and lexical cues of stance appear in the sentences of WT-WT dataset. In our work, we focus on the political domain and our P-STANCE, which contains much longer sentences and less surface-level lexical cues, can serve as a new challenging benchmark for stance detection tasks.

Authors	**Target(s)**	**Source**	**Type**	**Size**

P-STANCE	Donald Trump, Joe Biden, Bernie Sanders	Twitter	Target-specific	21,574

Table 2: Comparison of English stance detection datasets.

Different from classifying the stance detection tasks by target type (i.e., one specific target, multiple targets, or a claim), we can also categorize the stance detection as in-target and cross-target stance detection by the training setting. Most previous works focused on the in-target stance detection where a classifier is trained and validated on the same target (Mohammad et al., 2016b; Zarrella and Marsh, 2016; Wei et al., 2016; Vijayaraghavan et al., 2016; Du et al., 2017; Sun et al., 2018; Wei et al., 2018; Li and Caragea, 2019, 2021b). However, sufficient annotated data are usually hard to obtain and conventional models on stance detection perform poorly on generalizing to the data of new targets, which motivates the studies of cross-target stance detection (Augenstein et al., 2016; Xu et al., 2018; Wei and Mao, 2019; Zhang et al., 2020). Most previous studies evaluated the cross-target models on the SemEval-2016 dataset (Mohammad et al., 2016a), which is a small dataset and thus may make the conclusions less convincing.

In this paper, we show that our P-STANCE dataset can be also used to evaluate the model performance of cross-target stance detection and provides opportunities for exploring more cross-target tasks by interacting with previous SemEval-2016 (Mohammad et al., 2016a) and Multi-Target stance datasets (Sobhani et al., 2017). In addition, P-STANCE enables the exploration of large-scale deep learning models including pre-trained language models, e.g., BERT (Devlin et al., 2019) and BERTweet (Nguyen et al., 2020). We fine-tune the BERT and BERTweet models on our dataset and compare them with other strong baselines.

3 Building the Dataset

In this section, we detail the creation and the particularities of P-STANCE, our large political stance detection dataset composed of 21,574 tweets collected during the 2020 U.S. presidential election.

3.1 Data Collection

We collected tweets using the Twitter streaming API. Similar to prior works (Mohammad et al., 2016a; Sobhani et al., 2017) that target presidential candidates, we focus our attention on three political figures[2] in the presidential race of 2020: "Donald Trump," "Joe Biden," and "Bernie Sanders." We used a set of query hashtags as seeds to collect target-related tweets, which can be categorized as *favor hashtags*, *against hashtags* and *neutral hashtags* (Mohammad et al., 2016a). We show examples of these query hashtags in Table 3. In total, we gathered around 2.8 million tweets for all three targets combined.

3.2 Preprocessing

To ensure the quality of this dataset, we performed several preprocessing steps: **1)** We removed tweets with less than 10, or more than 128 words. According to our observations, tweets with less than 10 words are either too easy for detecting the stance or too noisy, and tweets with more than 128 words usually contain duplicate expressions. **2)** We removed duplicates and retweets. Twitter data are noisy not only due to the creative spellings, slang

---

[2] We also tried to collect tweets about the woman politician Kamala Harris. However, we were unable to collect enough data about Harris. We will look into this in our future work.

Target	Favor Hashtag	Against Hashtag	Neutral Hashtag
Trump	#Trump2020LandSlide	#TrumpCrimeFamily	#DonaldTrump #Republican
Biden	#BidenForPresident	#SleepyJoe	#JoeBiden #Democrats
Sanders	#BernieWon	#NeverBernie	#BernieSanders #Sanders

Table 3: Examples of query hashtags.

	Trump	Biden	Sanders
#Raw collection	1,730K	429K	654K
#After preprocessing	1,221K	300K	465K

Table 4: Number of unlabeled tweets before and after preprocessing.

Setup	Trump	Biden	Sanders	Average
3-class	0.62	0.60	0.59	0.60
2-class	0.86	0.81	0.76	0.81

Table 5: Krippendorff's alpha measure of annotator agreement in 3-class and 2-class scenarios.

and URLs, but also because of the duplicate tweets. Since these duplicate data reduce our ability to build reliable models, we need to clean the dataset by removing duplicates. **3)** We kept only the tweets in English because our goal in this work is to build an English stance detection dataset. We leave multilingual stance detection as future work. After data preprocessing, the size of our corpus reduces to around 2 million examples. In Table 4, we show the number of tweets before and after preprocessing for each political figure. We will provide this large-scale repository of tweets (which we call P-STANCE-EXT) alongside P-STANCE, in hope that it will spur further research in the field of semi-supervised learning for stance detection. Finally, we sampled 10,000 tweets for each political figure, obtaining 30,000 tweets for annotation in total.

3.3 Data Annotation

We gathered stance annotations of three targets through the Amazon Mechanical Turk (AMT) crowdsourcing platform. The AMT workers were asked to annotate each tweet with "Favor," "Against," "None," or "I don't know." To ensure the annotation quality, we employed strict requirements for the annotators: **1)** Many completed tasks (>500); **2)** To reside in the USA; **3)** A high acceptance rate (>95%). Moreover, we ran the annotation process in several batches of 1000 examples. In each batch, we include 100 internally annotated examples to measure the quality of the annotators. If an annotator mislabels more than 25% of these examples, we discard the annotations of the worker completely, and relabel them. Interestingly, this process led to a considerable number of reannotations, amounting for more than 20% of the data. Each tweet was labeled by three random annotators, and disagreements in the labels were decided by the majority voting among the three annotators.

After obtaining the annotation results, we computed Krippendorff's alpha (Krippendorff, 2011) as the measure of inter-annotator agreement, as shown in Table 5. Tweets that were annotated with label "I don't know" after the majority voting were removed from the dataset. We observed that annotators had difficulties in reaching an agreement on tweets with label "None" and the average of Krippendorff's alpha values increases from 0.60 to 0.81 when we consider two classes: "Favor" and "Against". Similar to prior work (Vamvas and Sennrich, 2020), we removed the label "None" from the dataset in our experiments.

3.4 Quality Assurance and Challenges

Stance-exposing hashtags that may expose the stance directly, e.g., #NeverBernie, can be observed in the data. A model can detect the stance from these hashtags without extracting effective representations for the meanings of sentences, which makes stance detection easier. To remove the stance-exposing hashtags and ensure the data quality, we performed the following steps after the data annotation: **1)** We manually built a hashtag lexicon that contains stance-exposing hashtags for each target. Then we removed all hashtags that are appended at the end of a sentence if they are in the hashtag lexicon. The reason of only removing the appended hashtags is that a hashtag may serve as a constituent of a sentence, so it would introduce more noise if we simply remove all stance-exposing hashtags. **2)** To address the stance-exposing hashtag that is a constituent of a sentence, we replaced stance-exposing hashtags that contain the target name with a neutral hashtag, e.g., #NeverBernie → #Bernie. These steps ensure

		Trump	Biden	Sanders
Train	Favor	2,937	2,552	2,858
	Against	3,425	3,254	2,198
Val	Favor	365	328	350
	Against	430	417	284
Test	Favor	361	337	343
	Against	435	408	292
Total		7,953	7,296	6,325

Table 6: Label distribution across different targets for P-STANCE.

the high quality of our P-STANCE dataset.

In addition, P-STANCE is a challenging dataset for the following reasons: **1)** Targets in P-STANCE are referred to in a more implicit way. Consider the second example in Table 1, the target name only appears at the end of the sentence and it is hard to correctly identify the stance without any knowledge about the political figures mentioned in the content and background immigration policy. Similarly, for the third example, it is difficult to correctly identify the stance if the classifier fails to connect the target with relevant events, i.e., climate change or medicare for all residents. **2)** The average length of tweets in previous datasets is short, and there are more explicit mentions of targets and rich sentiment and emotion words that can easily reveal the stance toward the target. The average tweet length is 17 in Mohammad et al. (2016a), 21 in Sobhani et al. (2017) and 16 in Conforti et al. (2020b). However, our P-STANCE has a much longer average length of 30 and more implicit mentions of targets and context words, which indicates that our dataset is more difficult. In addition, P-STANCE covers more target-relevant events. These characteristics contribute to making P-STANCE a challenging dataset for stance detection.

3.5 Dataset Distribution

The final dataset contains 7,953 annotated tweets for "Donald Trump", 7,296 for "Joe Biden" and 6,325 for "Bernie Sanders", respectively. The label distribution of each target is shown in Table 6. Each tweet is annotated with a stance label "Favor" or "Against". We created the training, validation and testing sets following an 80/10/10 split. We note that P-STANCE is more than 3 times larger than the previous benchmark (Mohammad et al., 2016a).

4 Experimental Settings

In this section, we first introduce two benchmark datasets of stance detection in §4.1. The union of these datasets and our P-STANCE dataset provides opportunities for studying the cross-target stance detection (§5.2) and cross-topic stance detection (§5.3). Then we discuss the evaluation metrics in §4.2 and introduce the baseline methods in §4.3.

4.1 Existing Benchmark Datasets

SemEval-2016 (Mohammad et al., 2016a) and Multi-Target stance datasets (Sobhani et al., 2017) are two benchmark datasets in which political figures are chosen as the targets. SemEval-2016 contains six targets: "Atheism," "Climate Change is a Real Concern," "Feminist Movement," "Hillary Clinton," "Legalization of Abortion," and "Donald Trump." The dataset is annotated for detecting the stance toward a given target. The data distribution of SemEval-2016 is shown in Table 7.

Multi-Target stance dataset contains three sets of tweets corresponding to three target pairs: "Donald Trump and Hillary Clinton," "Donald Trump and Ted Cruz," "Hillary Clinton and Bernie Sanders" for 2016 U.S. presidential election. The task aims at detecting the stances toward two targets for each data. The data distribution of Multi-Target stance dataset is shown in Table 8. In the next section, we show how to perform various stance detection tasks with the union of these datasets and our P-STANCE dataset.

4.2 Evaluation Metrics

Similar to Mohammad et al. (2017) and Sobhani et al. (2017), F_{avg} and macro-average of F1-score (F_{macro}) are adopted to evaluate the performance of our baseline models. First, the F1-score of label "Favor" and "Against" is calculated as follows:

$$F_{favor} = \frac{2P_{favor}R_{favor}}{P_{favor} + R_{favor}} \quad (1)$$

$$F_{against} = \frac{2P_{against}R_{against}}{P_{against} + R_{against}} \quad (2)$$

where P and R are precision and recall, respectively. After that, the F_{avg} is calculated as:

$$F_{avg} = \frac{F_{favor} + F_{against}}{2} \quad (3)$$

We compute the F_{avg} for each target. F_{macro} is calculated by averaging the F_{avg} across all targets.

4.3 Baseline Methods

We run experiments with the following baselines.

Target	**#Train**	%Favor	%Against	%None	**#Test**	%Favor	%Against	%None
Atheism	513	17.93	59.26	22.81	220	14.54	72.73	12.73
Climate	395	53.67	3.80	42.53	169	72.78	6.51	20.71
Feminism	664	31.63	49.40	18.97	285	20.35	64.21	15.44
Hillary	689	17.13	57.04	25.83	295	15.25	58.31	26.44
Abortion	653	18.53	54.36	27.11	280	16.43	67.50	16.07
Trump	0	-	-	-	707	20.93	42.29	36.78

Table 7: Data distribution of SemEval-2016 dataset.

Target Pair	**Total**	**Train**	**Dev**	**Test**
Trump-Clinton	1,722	1,240	177	355
Trump-Cruz	1,317	922	132	263
Clinton-Sanders	1,366	957	137	272
Total	4,455	3,119	446	890

Table 8: Data distribution of Multi-Target dataset.

BiLSTM (Schuster and Paliwal, 1997): A BiLSTM model that takes tweets as inputs without considering the target information.

CNN (Kim, 2014): Similar to BiLSTM, the vanilla CNN only takes tweets as inputs and does not consider the target information.

TAN (Du et al., 2017): TAN is an attention-based LSTM model that extracts target specific features.

BiCE (Augenstein et al., 2016): A BiLSTM that uses conditional encoding for stance detection. The target information is first encoded by a BiLSTM, whose hidden representations are then used to initialize another BiLSTM with tweets as inputs. BiCE is also a strong baseline for cross-target stance detection.

CrossNet (Xu et al., 2018): CrossNet is another model for cross-target stance detection. It encodes the target and the tweet by using the same approach with BiCE and add an aspect attention layer to signal the core part of a stance-bearing input. CrossNet improves BiCE in many cross-target settings.

GCAE (Xue and Li, 2018): A CNN model that utilizes a gating mechanism to block target-unrelated information. GCAE is a strong baseline for aspect-based sentiment analysis and we apply it to our stance detection task.

PGCNN (Huang and Carley, 2018): Similar to GCAE, PGCNN is based on gated convolutional networks and encodes target information by generating target-sensitive filters.

BERT (Devlin et al., 2019): A pre-trained language model that predicts the stance by appending a linear classification layer to the hidden representation of $[CLS]$ token. We fine-tune the BERT-base on the stance detection task.

BERTweet (Nguyen et al., 2020): BERTweet is another pre-trained language model following the training procedure of RoBERTa (Liu et al., 2019). Similar to BERT, we fine-tune the pre-trained BERTweet to predict the stance by appending a linear classification layer to the hidden representation of the $[CLS]$ token. The pre-trained BERTweet model is fine-tuned under the PyTorch framework. The maximum sequence length is set to 128 and the batch size is 32. We use AdamW optimizer (Loshchilov and Hutter, 2019) and the learning rate is 2e-5.

5 Results

In this section, we present the set of experiments performed on various stance detection tasks on our dataset and show the results obtained by using the aforementioned baselines. Each result is the average of seven runs with different initializations.

5.1 In-Target Stance Detection

In-target stance detection is a stance detection task where a classifier is trained and validated on the same target. Most previous works adopt an "Ad-hoc" training strategy by training one model for each target and evaluate it on the test set of that target (i.e., we train three different models if there are three targets in the dataset). However, the model is more likely to predict the stance by following specific patterns without fully considering the target information and overfit. Therefore, to better evaluate the performance of baselines, we propose a "Merged" training strategy by training and validating a model on all targets and testing it on separate targets to be compared with the "Ad-hoc" setting.

Experimental results of these two different settings are shown in Table 9. First, we can observe that BERTweet performs best in both settings and significantly outperforms the second best results,

Method	Trump	Biden	Sanders	F$_{\mathrm{macro}}$	Drop
Ad-hoc					
BiLSTM	76.92	77.95	69.75	74.87	-
CNN	76.80	77.22	71.40	75.14	-
TAN	77.10	77.64	71.60	75.45	-
BiCE	77.15	77.69	71.24	75.36	-
PGCNN	76.87	76.60	72.13	75.20	-
GCAE	78.96	77.95	71.82	76.24	-
BERT	78.28	78.70	72.45	76.48	-
BERTweet	**82.48**†	**81.02**†	**78.09**†	**80.53**	-
Merged					
BiLSTM	77.18	75.47	67.43	73.36	1.51
CNN	74.79	74.11	66.68	71.86	3.28
TAN	78.30	75.26	70.67	74.74	0.71
BiCE	77.67	75.69	69.37	74.24	1.12
PGCNN	77.36	74.96	70.29	74.20	1.00
GCAE	79.00	76.32	69.93	75.08	1.16
BERT	79.19	76.02	73.59	76.27	0.21
BERTweet	**83.81**†	**79.08**†	**77.75**†	**80.21**	0.32

Table 9: Comparison of different models on the P-STANCE dataset (%). †: BERTweet model improves the best baseline at $p < 0.05$ with paired t-test. F_{macro} is the average of all target pairs. "Drop" means performance decline between two training strategies for the same model. Bold scores are best overall.

demonstrating the effectiveness of this model. Second, performance drops can be observed on all models in the "Merged" setting and models (BiLSTM and CNN) that do not consider target information suffer the most severe drops, which means our proposed training strategy can serve as a better evaluation method to test whether the model learns target-specific representations. Moreover, we can observe that both BERTweet and BERT perform well and have the minimum performance drops compared with the other baselines, which demonstrates that self-attention mechanism can better capture target-specific representations.

5.2 Cross-Target Stance Detection

Despite substantial progress on the stance detection, sufficient annotated data are usually hard to obtain and conventional models on stance detection perform poorly on generalizing to the data of new targets, which motivates the studies of cross-target stance detection. The model of cross-target stance detection is first trained and validated on a source target, and then tested on a destination target. In this subsection, we show that our P-STANCE dataset can be also used to evaluate the model performance of cross-target stance detection and provides opportunities for exploring more cross-target tasks by interacting with previous SemEval-2016 and Multi-Target stance datasets.

Target	BiCE	CrossNet	BERTweet
P-STANCE dataset			
DT → JB	55.83	56.67	**58.88**
DT → BS	51.78	50.08	**56.50**†

BS → HC	49.97	50.49	**52.81**
BS → TC	54.37	52.98	**56.91**†

Table 10: Comparison of different models for cross-target stance detection (%). The first half reports the cross-target results on our proposed P-STANCE dataset. The second half reports the cross-target results that are trained on the P-STANCE dataset and tested on the previous datasets. †: BERTweet model improves the best baseline at $p < 0.05$ with paired t-test. Bold scores are best overall.

We use five targets for our experiments: "Donald Trump" (DT), "Joe Biden" (JB), "Bernie Sanders" (BS), "Hillary Clinton" (HC), and "Ted Cruz" (TC). Experimental results of cross-target stance detection are shown in Table 10. For the first half of Table 10, only targets of P-STANCE dataset are used to evaluate the model performance. However, for the second half, targets of SemEval-2016 and Multi-Target datasets also serve as destination targets, which makes it a more challenging task since the target-related topics in 2016 are quite different from the ones in 2020. More specifically, we train and validate the model on a source target of P-STANCE dataset and test it on the data of a destination target, which is a combination of train, validation, and test sets of previous datasets. Note that we merge the data from SemEval-2016 and Multi-Target datasets if these two datasets share the same target, e.g., Hillary Clinton.

For the cross-target tasks only on the P-STANCE dataset, first, we can observe from the Table 10 that BERTweet achieves the best performance on all target configurations, demonstrating its effectiveness. Moreover, BERTweet shows greater improvement over the best baseline when training on the data of two targets. The reason is that BERTweet learns more universal representations by leveraging the data from two targets. Second, we see that CrossNet outperforms BiCE on almost all target configurations, which is consistent with the observations of previous studies (Xu et al., 2018; Zhang et al., 2020). Third, we find that models achieve better performance on JB → BS and BS → JB. One potential explanation is that targets "Joe Biden" and "Bernie Sanders" are from the same party and thus share more similar topics.

For the second half of Table 10, we observe a significant drop in performance on all models, which verifies that it is more challenging to transfer the knowledge to a destination target with more diverse topics in the past. BERTweet still achieves the best performance on almost all target configurations, making it a highly competitive model for cross-target stance detection task. Interestingly, we can observe that both BiCE, CrossNet, and BERTweet show better performance on target "Ted Cruz." A possible reason is that the data of "Ted Cruz" contain more universal expressions and topics.

5.3 Cross-Topic Stance Detection

Obtaining sufficient annotated data of specific target from most recent past is challenging. However, sometimes historical annotated data of the same target are available. Therefore, motivated by a desire to improve the models' generalization ability to transfer knowledge from historical data, we come up with a new stance detection task, named cross-topic stance detection. Specifically, in this task, the model of cross-topic stance detection is first trained on the data of a target (e.g., Donald Trump) in 2016, and then validated and tested on the data of the same target in 2020. Note that the annotated data of year 2016 are the same with the data used in §5.2. The results are shown in Table 11. Since target "Joe Biden" is absent from the previous stance detection datasets, we use targets "Donald Trump" and "Bernie Sanders" for evaluation. We can observe that BERTweet still performs best on this task and the overall model performance of cross-topic stance detection is better than that of cross-target stance detection due to the use of the same target in evaluation stage. Moreover, we see that models perform relatively poorly on target "Bernie Sanders". One possible explanation is that some topics, e.g. healthcare and climate change, appear rarely in previous datasets.

Target	BiCE	CrossNet	**BERTweet**
DT → DT	58.60	59.41	**73.58**†
BS → BS	59.04	57.66	**66.48**†

Table 11: Comparison of different models for cross-topic stance detection (%). †: BERTweet model improves the best baseline at $p < 0.05$ with paired t-test. Bold scores are best overall.

5.4 Semi-Supervised Stance Detection

During elections, there is a considerable amount of data generated by users expressing their opinions about candidates, out of which only a small amount can be annotated and used for supervised stance detection. We explore the potential of the abundant unlabeled tweets and show that we can leverage them to improve the performance of our models. To this end, we turn to semi-supervised learning, and leverage techniques such as Uncertainty-aware Self-Training (UST).

UST (Mukherjee and Awadallah, 2020) is a semi-supervised approach which uses the standard teacher-student self-training framework, but adds a few powerful changes. Concretely, UST designs different techniques which leverage the uncertainty of the teacher model to select the unlabeled set of examples in each self-training iteration. First, we train our teacher model on the labeled examples. Next, we compute uncertainty estimates of our teacher model on the set of unlabeled examples by performing a few forward passes with dropout enabled. Finally, we incorporate the uncertainty estimates into our framework as follows: **1)** We use these estimates to select the examples for which the teacher is most or least confident about. **2)** We incorporate the teacher confidence in the student loss by penalizing the student's misclassified examples in which the teacher has high confidence. We use the BERTweet model as teacher and student.

We perform various experiments to show the benefits of using a large amount of unlabeled data from P-STANCE-EXT alongside our UST model. We carry out three barely supervised experiments with various number of examples in the training set. Specifically, we experiment with 30, 50, and 100 training examples. Moreover, we also consider an experiment using the whole training set to investigate the effect of the unlabeled examples when all the training data are available. We run experiments with different training sets, and report the F1-scores obtained on the entire testing set.

We show the results of our semi-supervised ex-

Method	**Trump**	**Biden**	**Sanders**	$\mathbf{F_{macro}}$
BERTweet	82.48	81.02	78.09	80.53
UST-30	61.02	64.34	60.45	61.94
UST-50	68.42	73.24	66.12	69.26
UST-100	74.45	79.46	71.67	75.19
UST-ALL	**85.50**†	**82.22**†	**79.55**†	**82.42**

Table 12: Semi-supervised learning results. †: UST-ALL improves the BERTweet at $p < 0.05$ with paired t-test.

periments in Table 12 and make the following observations. First, UST-ALL significantly outperforms the BERTweet model by 1.89% in a macro-average F1-score when using both the labeled and unlabeled data in a semi-supervised manner. Second, with only 100 examples (2% of the available training examples), UST-100 stays within 1.6% F1-score of our best model that leverages the entire training set of target “Joe Biden.” The results indicate that the benefit of using semi-supervised approaches is two-fold. On one hand, it enables impressive performance in scarce label scenarios, while on the other hand, it still brings gains in scenarios where considerable amounts of labeled data are readily available.

6 Conclusion

In this paper, we introduced P-STANCE, an English stance detection dataset in the political domain, which is larger and more challenging compared with previous datasets for stance detection. Composed of 21,574 tweets that were collected during the 2020 USA election, P-STANCE can serve as a new benchmark for stance detection and enable future research in other stance detection tasks, e.g., cross-target stance detection and cross-topic stance detection. Experimental results show that the BERTweet model significantly outperforms other strong baselines not only on in-target stance detection, but also on cross-target and cross-topic stance detection. Moreover, the performance of BERTweet can be further improved by using semi-supervised learning. Future work includes constructing another large dataset for a more challenging task, i.e., multi-target stance detection, and studying the multilingual stance detection with the union of P-STANCE and other multilingual datasets.

Abstract

Domain Adaptation is a fundamental problem in machine learning and natural language processing. In this paper, we study the domain adaptation problem from the perspective of instance weighting. Conventional instance weighting approaches cannot learn the weights which make the model generalize well in target domain. To tackle this problem, inspired by meta-learning, we formulate the domain adaptation problem as a bi-level optimization problem, and propose a novel differentiable model-agnostic instance weighting algorithm. Our proposed approach can automatically learn the instance weights instead of using manually designed weighting metrics. To reduce the computational complexity, we adopt the second-order approximation technique during training. Experimental results[1] on three different NLP tasks (Sentiment Classification, Neural Machine Translation and Relation Extraction) illustrate the efficacy of our proposed method.

1 Introduction

Domain shift is a challenging problem which is commonly encountered in Natural Language Processing (NLP). Due to the data distribution discrepancy between source and target domain, the model trained on the data from source domain may fail to achieve satisfying performance in target domain. Therefore we face the *domain adaptation* problem. In some real-world situations, we may only focus on the performance of our model on a specific domain. To maintain the performance, we need labeled training data for supervised learning. However, we often cannot collect enough labeled training data relevant to the domain we are interested in (in-domain). Thus, we need to introduce more labeled data from other different domains (out-of-domain). We aim to leverage the general knowledge from out-of-domain dataset to enhance the in-domain performance of our model.

We consider a specific domain adaptation scenario in this work, where we have a few labeled in-domain training data and meanwhile we have sufficient labeled out-of-domain training data from other general domains.

Training on these two datasets jointly is a straightforward solution for this scenario, but not all samples from out-of-domain dataset has equal effect during the training procedure. Several studies (Koehn and Knowles, 2017) on neural machine translation (NMT) task show that, out-of-domain instances relevant to the in-domain data are beneficial while the instances irrelevant to the in-domain data may be even harmful to the translation quality. Apart from that, for sentiment classification task, some general expressions such as “I’m truly impressed by the design.” may appear in all domains. Taking them as training samples can help the model to learn general syntactic and semantic knowledge, which improves the cross-domain sentiment classification performance. But using examples like “This chair is solid.” (negative sentiment, furniture domain) may reduce the accuracy of classifying “This knife is solid.” (positive sentiment, kitchen domain), because “solid” has different meanings in these two domains. Any domain-specific expression like this would probably introduce some noise. So it is essential to find a suitable strategy to measure the importance of each training sample.

There are many instance weighting (or instance selection) methods to tackle this problem. They assign a weight to each instance and transform the loss function to a weighted-sum formula. Most of the conventional methods (Jiang and Zhai, 2007; Gretton et al., 2006, 2009; Axelrod et al., 2011; Wang et al., 2017; Zhang and Xiong, 2018; Wang et al., 2019; Dou et al., 2020) propose different

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2366–2376
August 1–6, 2021.

kinds of manually designed metrics to calculate the weights of instances. The core idea of these methods is to weight the instances according to their importance and similarity to the target domain. However, in our domain adaptation setting, the size of out-of-domain corpus is much larger than that of in-domain corpus. The weights learned by the previous methods may be biased to the out-of-domain data, which would unavoidably result in poorer performance on the in-domain data. In this paper, we seek to automatically learn the weights which make the model generalize well on the unbiased in-domain data.

Inspired by Model-Agnostic Meta-Learning (MAML) (Finn et al., 2017), we introduce another unbiased subset from in-domain data which serves as a query set. We propose a novel model-agnostic differentiable instance weighting approach named "**WIND**" (means **W**eighting **IN**stances **D**ifferentially) which is a general framework and can be applied to all tasks in our domain adaptation settings. Moreover, we hope to get rid of manually designed metrics and let the weights to be differentiable. To reduce the computational complexity, we adopt a second-order derivation approximation approach for calculating the gradient of weights. We conduct plenty of experiments on datasets from three representative NLP tasks: **sentiment classification**, **machine translation** and **relation extraction**. The results show that our proposed method substantially outperforms several strong baselines.

The contributions of our work can be summarized as follows:

- We propose a novel differentiable instance weighting algorithm for domain adaptation, which learns the weights of instances with gradient descent and does not need manually designed weighting metrics.

- We adopt a second-order approximation technique to speed up the model training.

- We conduct experiments on three typical NLP tasks: Sentiment Classification, Machine Translation and Relation Extraction. Experiment results demonstrate the effectiveness of the proposed method. Code will be released.

2 Methodology

In this section, we first formulate our domain adaptation problem and introduce some notations. Then we present the proposed gradient-based model-agnostic instance weighting framework for our setting and introduce the method to approximate the second-order derivation of query loss. Finally, we discuss some optimization details of our method.

2.1 Problem Formulation

Let $\mathcal{D}_{train}$, $\mathcal{D}_{dev}$ and $\mathcal{D}_{test}$ denote our train, development and test datasets respectively. We use $\mathcal{D}_{train}$ for model training, $\mathcal{D}_{dev}$ for hyperparameter tuning and $\mathcal{D}_{test}$ for model testing. Both $\mathcal{D}_{dev}$ and $\mathcal{D}_{test}$ are in-domain data. Differently, $\mathcal{D}_{train}$ consists of sufficient labeled out-of-domain training samples $\mathcal{D}_{out} = \{(x_i, y_i)\}_{i=1}^{m}$ and a few labeled in-domain training samples $\mathcal{D}_{in} = \{(x_i, y_i)\}_{i=1}^{n}$, where $n << m$.

How to efficiently utilize $\mathcal{D}_{in}$ is the key to better domain transfer. To tackle this problem, in this paper we first sample an *in-domain train* subset $\mathcal{D}_{it} = \{(x_i, y_i)\}_{i=1}^{n_1}$ from $\mathcal{D}_{in}$ and we assign a scalar weight w_i to each instance $(x_i, y_i) \in \mathcal{D}_{it} \cup \mathcal{D}_{out}$. We hope that during training, the model can find the optimal weight $\boldsymbol{w} = (w_1, ..., w_{n_1+m})$ by itself. For this purpose, the weight $\boldsymbol{w}$ should be differentiable and can be optimized by gradient descent. Moreover, we denote the deep neural network (DNN) as a function $f_{\boldsymbol{\theta}} : \mathcal{X} \to \mathcal{Y}$ which is parameterized by $\boldsymbol{\theta}$ and maps x_i from the input space to the label space. In our instance weighting setting, the training loss follows a weighted-sum formula:

$$\mathcal{L}_{train}(\boldsymbol{\theta}, \boldsymbol{w}) = \frac{1}{n_1 + m} \sum_{\substack{(x_i, y_i) \in \\ \mathcal{D}_{it} \cup \mathcal{D}_{out}}} w_i \ell(f_{\boldsymbol{\theta}}(x_i), y_i) \tag{1}$$

where ℓ denotes the loss function, which can be any kind of loss such as cross entropy loss for classification tasks, or label-smoothed cross entropy loss for machine translation.

Jointly optimizing $\boldsymbol{\theta}$ and $\boldsymbol{w}$ using Eq. 1 is a straightforward solution. However, due to the data distribution discrepancy of in-domain and out-of-domain datasets, learning $\boldsymbol{w}$ directly from $\mathcal{D}_{it} \cup \mathcal{D}_{out}$ by Eq. 1 may introduce bias. What we expect is that the model trained on $\boldsymbol{w}$ can be generalized to the in-domain data. In order to achieve this goal, inspired by MAML (Finn et al., 2017), we propose to sample another subset $\mathcal{D}_q = \{(x_i, y_i)\}_{i=1}^{n_2}$ named *query set* from $\mathcal{D}_{in}$. We propose to use this query set to optimize $\boldsymbol{w}$. Specifically, we aim to obtain a weight vector $\boldsymbol{w}$

which minimizes the loss on $\mathcal{D}_q$:

$$\mathcal{L}_q(\boldsymbol{\theta}) = \frac{1}{n_2} \sum_{(x_i,y_i)\in\mathcal{D}_q} \ell(f_{\boldsymbol{\theta}}(x_i), y_i) \tag{2}$$

Note that we only weight $n_1 + m$ instances from $\mathcal{D}_{it} \cup \mathcal{D}_{out}$, so $\mathcal{L}_q(\boldsymbol{\theta})$ has a standard form, not a weighted-sum form.

Given a specific $\boldsymbol{w}$, we can train a model with the loss $\mathcal{L}_{train}(\boldsymbol{\theta}, \boldsymbol{w})$ and then get the optimized parameter $\boldsymbol{\theta}^*$. We aim to minimize the loss on the query set given $\boldsymbol{\theta}^*$. Therefore, our problem can be formulated as the following bilevel optimization problem (Colson et al., 2007):

$$\begin{aligned} \min_{\boldsymbol{w}} \quad & \mathcal{L}_q(\boldsymbol{\theta}^*) \\ \text{s.t.} \quad & \boldsymbol{\theta}^* = \arg\min_{\boldsymbol{\theta}} \mathcal{L}_{train}(\boldsymbol{\theta}, \boldsymbol{w}) \end{aligned} \tag{3}$$

This bilevel formulation arises in many meta-learning or hyperparameters optimization (HPO) problems (Bergstra et al., 2013; Franceschi et al., 2018), where the optimization of the outer objective $\mathcal{L}_q$ depends on the optimization of inner objective $\mathcal{L}_{train}$. In fact, Eq. 3 is a special case of hyper-paramter optimization, because $\boldsymbol{w}$ can be viewed as special hyperparameter of our model. In Section 2.2, we will introduce our proposed algorithm to solve this nested formulation.

2.2 Optimization of Instance Weights

It is difficult to directly solve the above-mentioned bilevel optimization problem because of its high complexity of solving the inner objective. There are many gradient-based methods (Maclaurin et al., 2015; Franceschi et al., 2018) to solve this problem. However, unlike typical hyperparameters such as learning rate, the instance weight $\boldsymbol{w}$ is of high dimension. It is even harder to optimize this problem in our setting.

Inspired by the optimization techniques used in model-agnostic meta-learning (MAML) (Finn et al., 2017), we split the training procedure of each iteration into the following three steps.

2.2.1 Pseudo Update

Firstly, we sample two mini-batches of data from $\mathcal{D}_{it} \cup \mathcal{D}_{out}$ and $\mathcal{D}_q$ respectively, Then we compute the model's parameters after one step update by the gradient of $\mathcal{L}_{train}(\boldsymbol{\theta}, \boldsymbol{w})$ respect to $\boldsymbol{\theta}$:

$$\widehat{\boldsymbol{\theta}} = \boldsymbol{\theta} - \beta \cdot \nabla_{\boldsymbol{\theta}} \mathcal{L}_{train}(\boldsymbol{\theta}, \boldsymbol{w}) \tag{4}$$

where β denotes the learning rate of this step.

This step is just "pseudo update". After updating, we do not replace original parameters $\boldsymbol{\theta}$ with the adapted parameters $\widehat{\boldsymbol{\theta}}$. Instead, we store both $\boldsymbol{\theta}$ and $\widehat{\boldsymbol{\theta}}$. We will use $\widehat{\boldsymbol{\theta}}$ to calculate the gradient of $\boldsymbol{w}$ in the second step. So in our proposed algorithm, $\widehat{\boldsymbol{\theta}}$ is just an intermediate variable which will be abandoned in the end of current iteration.

2.2.2 Instance Weight Update

Then we calculate the instance weights $\boldsymbol{w}$ using $\widehat{\boldsymbol{\theta}}$. In this step, our goal is to find an optimal $\boldsymbol{w}^*$. We expect $\boldsymbol{w}^*$ to have the property that: optimizing one step by $\mathcal{L}_{train}(\boldsymbol{\theta}, \boldsymbol{w}^*)$ should result in a decrease of query loss. In other words, we expect $\boldsymbol{w}^*$ to minimize the loss on the query set after one step update:

$$\begin{aligned} \boldsymbol{w}^* &= \arg\min_{\boldsymbol{w}} \mathcal{L}_q(\widehat{\boldsymbol{\theta}}) \\ &= \arg\min_{\boldsymbol{w}} \mathcal{L}_q(\boldsymbol{\theta} - \beta \cdot \nabla_{\boldsymbol{\theta}} \mathcal{L}_{train}(\boldsymbol{\theta}, \boldsymbol{w})) \end{aligned} \tag{5}$$

Note that this is an approximation for the outer objective of Eq. 3. Theorectically, we can perform gradient descent for many steps to find $\boldsymbol{w}^*$. But it is time-consuming. So basically we optimize $\boldsymbol{w}$ with the gradient of $\mathcal{L}_q(\widehat{\boldsymbol{\theta}})$ with respect to $\boldsymbol{w}$ for only one step:

$$\widehat{\boldsymbol{w}} = \boldsymbol{w} - \gamma \cdot \nabla_{\boldsymbol{w}} \mathcal{L}_q(\widehat{\boldsymbol{\theta}}) \tag{6}$$

where γ denotes the learning rate of $\boldsymbol{w}$.

We take $\widehat{\boldsymbol{w}}$ as an approximation of $\boldsymbol{w}^*$. Using multiple gradient updates for $\boldsymbol{w}$ is a straightforward extension of this step, which will lead to more accurate approximation for $\boldsymbol{w}^*$ while increasing the computational complexity at the same time.

2.2.3 Final Update

In the previous two steps, we have an approximately optimal weights $\widehat{\boldsymbol{w}}$. We use it for actual update for $\boldsymbol{\theta}$:

$$\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} - \beta \cdot \nabla_{\boldsymbol{\theta}} \mathcal{L}_{train}(\boldsymbol{\theta}, \widehat{\boldsymbol{w}}) \tag{7}$$

Current iteration ends after this step. As mentioned before, $\widehat{\boldsymbol{\theta}}$ will be abandoned, but we can choose whether $\widehat{\boldsymbol{w}}$ to be abandoned or not. This will be further discussed in Section 2.4.3.

2.3 Second-Order Derivation Approximation

There is a fatal problem when calculating the gradient $\nabla_{\boldsymbol{w}} \mathcal{L}_q(\widehat{\boldsymbol{\theta}})$ in the instance weight update (Section 2.2.2). We apply the chain rule to Eq. 6:

$$\begin{aligned}\widehat{\boldsymbol{w}} &= \boldsymbol{w} - \gamma \cdot \nabla_{\boldsymbol{w}}\mathcal{L}_q(\widehat{\boldsymbol{\theta}}) \\ &= \boldsymbol{w} - \gamma \cdot \nabla_{\widehat{\boldsymbol{\theta}}}\mathcal{L}_q \cdot \nabla_{\boldsymbol{w}}\widehat{\boldsymbol{\theta}} \\ &= \boldsymbol{w} + \beta\gamma \cdot \nabla_{\widehat{\boldsymbol{\theta}}}\mathcal{L}_q \cdot \nabla^2_{\boldsymbol{\theta},\boldsymbol{w}}\mathcal{L}_{train}\end{aligned} \tag{8}$$

We use $|\boldsymbol{\theta}|, |\boldsymbol{w}|$ to denote the dimensions of $\boldsymbol{\theta}, \boldsymbol{w}$ respectively. The second-order derivation $\nabla^2_{\boldsymbol{\theta},\boldsymbol{w}}\mathcal{L}_{train}$ is a $|\boldsymbol{\theta}| \times |\boldsymbol{w}|$ matrix which is too huge to calculate and store. Apart from that, calculating the matrix-vector product is also expensive. Precisely calculating the results is unrealistic. Fortunately, we can adopt the approximation technique used in DARTS (Liu et al., 2018) to solve this problem. This technique uses the finite difference approximation:

$$\begin{aligned}&\nabla_{\widehat{\boldsymbol{\theta}}}\mathcal{L}_q \cdot \nabla^2_{\boldsymbol{\theta},\boldsymbol{w}}\mathcal{L}_{train} \approx \\ &\frac{\nabla_{\boldsymbol{w}}\mathcal{L}_{train}(\boldsymbol{\theta}^+, \boldsymbol{w}) - \nabla_{\boldsymbol{w}}\mathcal{L}_{train}(\boldsymbol{\theta}^-, \boldsymbol{w})}{2\epsilon}\end{aligned} \tag{9}$$

$$\begin{aligned}\boldsymbol{\theta}^+ &= \boldsymbol{\theta} + \epsilon\nabla_{\widehat{\boldsymbol{\theta}}}\mathcal{L}_q \\ \boldsymbol{\theta}^- &= \boldsymbol{\theta} - \epsilon\nabla_{\widehat{\boldsymbol{\theta}}}\mathcal{L}_q\end{aligned} \tag{10}$$

where ϵ is a small scalar. We follow Liu et al. (2018) to set $\epsilon = 0.01/\|\nabla_{\widehat{\boldsymbol{\theta}}}\mathcal{L}_q\|_2$ which is accurate enough for approximation. Let $\alpha = \beta\gamma$, we can adjust the learning rate of $\boldsymbol{w}$ by tuning α.

Calculating this approximated gradient needs only another two forward passes for $\boldsymbol{\theta}^+$ and $\boldsymbol{\theta}^-$, which greatly accelerates the training procedure. More details about the training process are described in Algorithm 1.

2.4 Optimization Details

2.4.1 Dataset Split Strategy

The data split of query set $\mathcal{D}_q$ is critical. As mentioned in Section 2.1, we randomly sample $\mathcal{D}_{it}$ and $\mathcal{D}_q$ from in-domain training set $\mathcal{D}_{in}$. If we have enough in-domain data, $\mathcal{D}_{it}$ and $\mathcal{D}_q$ should be disjoint. However, our in-domain training set is not so large, and splitting it will make it even smaller. As a result, we use $\mathcal{D}_{in} = \mathcal{D}_q = \mathcal{D}_{it}$ instead of sampling. The ablation studies about this issue are shown in Section 3.5.

2.4.2 Scaling the Weights

In this work, an extreme value of w_i may make the training unstable. It is important to scale it to an appropriate range. In practice, we use sigmoid function to normalize it into $[0, 1]$:

$$\mathcal{L}_{train} = \frac{1}{n_1 + m} \sum_{\substack{(x_i, y_i) \in \\ \mathcal{D}_{it} \cup \mathcal{D}_{out}}} \sigma(w_i)\ell(f_{\boldsymbol{\theta}}(x_i), y_i) \tag{11}$$

Algorithm 1 **WIND** (**W**eighting **IN**stances **D**ifferentially)

```
Input: In-domain training set $\mathcal{D}_{it}$, out-of-domain set $\mathcal{D}_{out}$, query set $\mathcal{D}_q$, model parameter $\boldsymbol{\theta}$
Initialize the weights $\boldsymbol{w}$ (see Section 2.4.3)
for $i = 1$ to $epochs$ do
    for $j = 1$ to $steps\_per\_epoch$ do
        Get a mini-batch $(\boldsymbol{x}_t, \boldsymbol{y}_t) \in \mathcal{D}_{it} \cup \mathcal{D}_{out}$
        Get a mini-batch $(\boldsymbol{x}_v, \boldsymbol{y}_v) \in \mathcal{D}_q$
        for $k = 1$ to $inner\_steps$ do
            Obtain $\widehat{\boldsymbol{\theta}}$ by Eq. 4
            Obtain $\widehat{\boldsymbol{w}}$ by Eq. 6 and Eq. 9
            Update $\boldsymbol{w}$ in the storage by $\widehat{\boldsymbol{w}}$
        end for
        Update $\boldsymbol{\theta}$ by Eq. 7
    end for
end for
```

2.4.3 Initialization of Instance Weight

How to initialize $\boldsymbol{w}$ is an important issue. In this paper, we assume that all the training samples from in-domain training set $\mathcal{D}_{it}$ are beneficial and should be highly weighted. For samples in D_{it}, we fix their weights to a very large number at the beginning of training, which is close to 1 after calculating by the sigmoid function. For samples in D_{out}, we initialize their weights all by zeros. During training, we do not optimize the weights of the in-domain training samples and only update the weights of the out-of-domain training samples.

Moreover, when to initialize $\boldsymbol{w}$ is another important issue. We propose two different kinds of initialization strategy. One is to initialize $\boldsymbol{w}$ at the beginning of each iteration. Another alternative is to initialize $\boldsymbol{w}$ at the beginning of the training, and update $\boldsymbol{w}$ in the storage every iteration. In practice, we choose the latter. Although the former is more easy to implement, it cannot make use of $\widehat{\boldsymbol{w}}$ from previous iterations.

3 Experiments

To evaluate the effectiveness of our proposed method introduced in Section 2 and demonstrate its model-agnostic property, we apply our method to

Dataset	Sentences
B-train ($\mathcal{D}_{in}$)	500
D,E,K ($\mathcal{D}_{out}$)	18,000
B-dev ($\mathcal{D}_{dev}$)	1,500
B-test ($\mathcal{D}_{test}$)	4,000

Table 1: Statistics of sentiment classification setting with *books* domain as the in-domain.

Dataset	Sentences
TED training ($\mathcal{D}_{in}$)	202,356
WMT14 subset ($\mathcal{D}_{out}$)	500,000
TED tst2012 ($\mathcal{D}_{dev}$)	1,700
TED tst2013 ($\mathcal{D}_{test}$)	993
TED tst2014 ($\mathcal{D}_{test}$)	1,305

Table 2: Statistics of machine translation setting.

Dataset	Docs	Relations
bc-train ($\mathcal{D}_{in}$)	10	222

Table 3: Statistics of relation extraction setting.

three different dataset settings of three tasks: Sentiment Classification, Machine Translation (MT) and Relation Extraction, respectively.

3.1 Datasets

For sentiment classification task, we conduct the experiments on the widely-used Amazon Review Dataset (Blitzer et al., 2007). This dataset contains four domain: *books* (B), *dvd* (D), *electronics* (E) and *kitchen* (K). Each domain contains the reviews of a specific category of products. We use the data processed by He et al. (2018) and collect 6000 labeled samples for each domain. We split the data of each domain into training ($\mathcal{D}_{in}$), development ($\mathcal{D}_{dev}$) and test ($\mathcal{D}_{test}$) set. In each domain adaptation setting, we choose the training data of one domain as the in-domain data ($\mathcal{D}_{in}$) and all data of other three domains as the out-of-domain data ($\mathcal{D}_{out}$). Table 1 shows an example with *books* domain as the in-domain.

For machine translation task, similar to the settings of Luong and Manning (2015); Wang et al. (2017); Zeng et al. (2019), we use the IWSLT 2016 English (EN) to German (DE) corpus (Cettolo et al., 2016) as the in-domain data. This corpus contains about 202K sentences from TED talks. For out-of-domain data, we randomly sample a subset of 500K sentences from the WMT 2014 English-German corpus. Table 2 show the statistics of the datasets.

For relation extraction task, we evaluate our method on the ACE 2005 dataset. This dataset is suitable for evaluating domain adaptation because it contains six different domains. It has been adopted by many previous works (Nguyen and Grishman, 2014; Gormley et al., 2015; Fu et al., 2017) for cross-domain relation extraction. In this work, we take *broadcast news* (bn) and *newswire* (nw) domain as out-of-domain, and split *broadcast conversation* (bc) domain into train/dev/test sets with the ratio of $1 : 1 : 4$. Table 3 shows the detailed statistics.

3.2 Implementation Details

For sentiment classification task, we use the pretrained BERT-base-uncased (Devlin et al., 2018) model provided by HuggingFace (Wolf et al., 2019) as our feature extractor. Our sentiment classifier is a one-hidden-layer MLP with ReLU as the activation function. For the optimization of model parameters $\boldsymbol{\theta}$, we use the AdamW (Loshchilov and Hutter, 2018) as the optimizer with a learning rate of $2e-5$, a warmup of 0.1 (of the total steps) and a linearly decayed learning rate scheduler. The computational cost is about 8-12 GPU hours on Tesla V100.

For machine translation, we choose a vanilla Transformer (Vaswani et al., 2017) as our backbone. We implement some baseline methods and our method via fairseq toolkit (Ott et al., 2019). We use MOSES[2] scripts to tokenize the English and German sentences, and then we apply Byte Pair Encoding (BPE) (Sennrich et al., 2015) algorithm to split the words into subwords. We limit the maximum length of the sentences to 250 subwords. We choose to share the embeddings of English and German with the vocabulary size of 32,000. We use Adam (Kingma and Ba, 2014) as the optimizer and a decayed learning rate of $7e-4$.

For relation extraction, we only focus on relation classification when the entity pairs are given for simplicity. We use the RBERT (Wu and He, 2019) model as our backbone. The configurations of optimizer and learning rate are the same as those in our sentiment classification experiments.

3.3 Baselines

We implemented the following baseline methods for comparison with our methods. It's worth noting that we don't choose some baselines (Jiang and Zhai, 2007; Wang et al., 2017) of instance weight-

- **In** A pre-trained BERT only fine-tuned on the in-domain training set.
- **Out** A pre-trained BERT only fine-tuned on the out-of-domain training set.
- **In+Out** A pre-trained BERT fine-tuned on both in-domain and out-of-domain data.
- **Ensemble** It ensembles the **in** model and the **out** model by adding their predictions. Note that this method is used as a baseline in Wang et al. (2017). Although Wang et al. (2017) conducted the experiments on machine translation, we can still adopt this method on sentiment classification task.
- **IW-Fit** It uses the weighting strategy proposed by Wang et al. (2019) for domain transfer.
- **DANN** It introduces the domain classifier and adversarial training as proposed by Ganin et al. (2016).

For machine translation, the meanings of **In**, **Out** and **In+Out** is the same as those in the sentiment classification setting. There are some other baselines for machine translation setting:

- **DM** This indicates the Discriminative Mixing method proposed by Britz et al. (2017), which adds a domain classifier to the encodings of source sentences similar to DANN (Ganin et al., 2016).
- **IDDA** This indicates Iterative Dual Domain Adaptation methods proposed by Zeng et al. (2019), which iteratively performs bidirectional translation knowledge transfer using knowledge distillation between in-domain and out-of-domain. Note that this method focuses on the performance of both domains but in this paper we only focus on in-domain performance.

For relation extraction, besides the **In**, **Out** and **In+Out** approaches, we also choose Fu et al. (2017) as our baseline. This method simply introduces DANN (Ganin et al., 2016) to cross-domain relation extraction. Note that it is implemented by convolutional neural network, we reimplement a RBERT (Wu and He, 2019) version of it.

3.4 Experiment Results

Table 4 shows the overall performance of our methods in the domain adaptation setting on the sentiment classification task. Our method achieves an absolute improvement of 0.45, 0.40, 0.52 and 0.88 points on four settings respectively in comparison to the **In+Out** baseline. Moreover, our method outperforms all the domain adaptation methods on the settings with B, D, K as the in-domain data except the E domain. Although our method does not beat all baselines on all settings, it achieves the best average performance across the four settings. On average, we achieve an improvement of 0.28 point over DANN and 0.54 point over **In+Out**.

Table 5 shows the performance for the machine translation task. We use BLEU (Papineni et al., 2002) scores to measure the performance. Our method beats all baselines on all test sets (tst2013,tst2014) and the development set (tst2012). On these three datasets, we observe an improvement of 1.17, 1.08 and 0.54 BLEU points compared to **In+Out**. On tst2013 and tst2014 test sets, we also achieve an improvement of 0.65 and 0.38 BLEU points compared to IDDA (Zeng et al., 2019) method. Table 6 further shows our method's effectiveness on the relation extraction task.

Furthermore, from the results in Tables 4, 5 and 6, we can make the following observations:

(1) In comparison to the method in (Wang et al., 2019) which uses manually designed weighting metrics, our differentiable weighting approach outperforms it in the sentiment classification task. This result demonstrates that designing the metrics manually may not be the best solution for all the tasks. Designing them requires many prior human expert knowledge which is hard to generalize well across tasks. By contrast, our method can learn instance weights with the help of meta-learning based algorithm to improve the models' in-domain generalization capability.

(2) Domain adversarial based method is a strong baseline which is surpassed only by our method in the sentiment classification task and the relation extraction task. However, it performs not so well for the machine translation task. The potential reason may be that Britz et al. (2017) introduces the domain classifier after the encoder to learn domain-invariant features of sentences from source language, but both domains share the same decoder which cannot discriminate the features encoded by the encoder. In other words, this type of method may only pay attention to the encoder and ignore the domain transfer of decoder. In contrast, our method overcomes this problem by considering weighting the loss of the whole model and thus achieves better performance.

(3) For all three tasks, adding out-of-domain corpus to the training set will improve the overall performance. We believe that adding the data of some general domains can help the model better learn domain-invariant syntactic and semantic knowledge, so it can improve the performance on the in-domain data. This is consistent with the conclusions reached by transfer learning. Interestingly, this result is contradictory to the observation of Wang et al. (2017), whose experiment results show that adding out-of-domain to in-domain data degraded machine translation performance. We suspect that there is a problem with their training strategy. The hyperparameters required under each setting may be different. Some hyperparameters that are set incorrectly (e.g. the same as **In**) may make the result of **In+Out** even worse. Another reason may be that the RNN-based sequence-to-sequence NMT system they used tends to be more sensitive to the noise while the Transformer (Vaswani et al., 2017) model we used is more robust.

All in all, as we expected, our proposed method WIND achieves the best performance under the three task settings. This illustrates the advantages of using differentiable method for data weighting.

Method	**B**	**D**	**E**	**K**
WIND+split-init	91.10	90.55	92.68	93.60
WIND+split	91.50	91.12	93.42	94.00
WIND+rand	91.17	91.03	93.33	93.95
WIND	**92.12**	**91.28**	**93.65**	**94.15**

Table 7: The comparison between different variants of our method on the sentiment classification task. Note that the results in this table are evaluated under $|\mathcal{D}_{in}| = 1,000$ setting. "+rand" means randomly initializing $\boldsymbol{w}$. "+split" means splitting $\mathcal{D}_{in}$ into disjoint $\mathcal{D}_{it}$ and $\mathcal{D}_q$. "-init" means not assigning a large number to in-domain data weights.

3.5 Ablation Study

In this part, we study the effect of the strategies mentioned in Section 2.4.1 and Section 2.4.3. The experiment results shown in Table 7 demonstrate that:

(1) Assigning the weights of in-domain instances to a large number ($1e8$) and fixing them during training can improve the accuracy. The weights of this part do not actually need to be learned. Fixing them may reduce the interference to the learning process from the out-of-domain data.

(2) Zero initialization for weights of out-of-domain instances is better than the random initialization. The underlying reason for this may be that random initialization may easily make the model stuck into a local minima.

(3) No splitting for $\mathcal{D}_{in}$ can improve the performance as well. Intuitively, this improvement comes

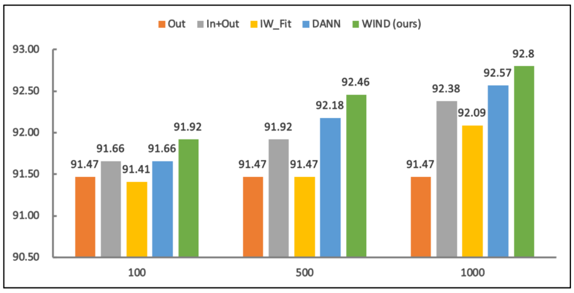

Figure 1: The effect of in-domain dataset size on the sentiment classification task.

from the increased size of in-domain training set, which enables us to make more use of the scarce in-domain training samples.

3.6 Effect of In-Domain Dataset Size

In this part, we aim to study the impact of in-domain dataset size n. Besides $n = 500$ setting, we sample another two different $\mathcal{D}_{in}$ with $n = 100$ and $n = 1000$. The rest of in-domain data is used as development set. We evaluate all three settings on the same $\mathcal{D}_{test}$ mentioned in Table 1.

Figure 1 shows the average accuracy over four domain settings when using different domain adaptation methods. We found that DANN (Ganin et al., 2016) may not perform so well when in-domain data are scarce. But our method can still achieve consistent improvements in this three dataset size settings.

4 Related Work

4.1 Domain Adaptation

Domain Adaptation is a fundamental problem in machine learning and NLP. We aim to train a well-performing model on a source domain which can be generalized to a target domain.

The basic idea for domain adaptation is to learn domain-invariant representations which generalize across the domains. To achieve this, the most prevailing method Domain Adversarial Neural Network (DANN) (Ganin et al., 2016; Qu et al., 2019; Xue et al., 2020) introduces a domain classifier and uses adversarial training to make the features unable to discriminate between source and target domains. This method has been applied to many NLP tasks. However, out-of-domain data is far more than in-domain data in our setting. DANN may cause some bias in this unbalanced dataset. Another type of methods (Fang and Xie, 2020; Li et al., 2020) propose to learn domain-general representations by contrastive learning (Chen et al., 2020a; He et al., 2019; Chen et al., 2020b). But they mainly focus on classification task and the methods are not model-agnostic frameworks.

4.2 Cross-Domain Sentiment Classification

Sentiment classification task aims to automatically classify the sentiment polarity of the given texts. Cross-domain sentiment classification aims to generalize the sentiment classifier from source domain to target domain.

Besides the domain adaptation methods introduced in Section 4.1, there are some methods which are specific for cross-domain sentiment classification. An important line of works follow the Structural Correspondence Learning (SCL) (Blitzer et al., 2006), and they design an auxiliary task called pivot prediction to transfer domain-invariant knowledge (Pan et al., 2010; Yu and Jiang, 2016; Ziser and Reichart, 2016, 2018, 2019). But the pivot words need human knowledge to select, which may be not so accurate. Recently, the pre-trained language models such as BERT (Devlin et al., 2018) have achieved state-of-the-art on many NLP tasks. DAAT (Du et al., 2020) performs a novel post-training procedure on BERT and uses adversarial training to transfer domain knowledge. But this method only works for classification task while our method is model-agnostic and does not need two-stage post-training and fine-tuning.

4.3 Meta-Learning

The goal of meta-learning is to train a model that can adapt to a new task quickly given a few new samples. In other words, meta-learning can learn the initial value of the model that is close to the optimums of many different tasks. MAML (Finn et al., 2017) is a classical method for meta-learning. Each entry of the meta-training set of MAML is a subset contains training data (support set) and test data (query set). MAML calculates the loss on the query set based on the parameters after one-step optimization on support set, and uses the gradient of this loss to update the model parameters. MAML has also been adopt for natural language understanding task before (Dou et al., 2019). Despite our domain adaptation setting is quite different from that in MAML, we can still utilize the idea of their work to help domain generation.

5 Conclusion

In this paper, we propose WIND, a differentiable instance weighting method for model-agnostic domain adaptation, which is inspired by the ideas of meta-learning to learn the weights on the in-domain query set. Experiment results on three typical NLP tasks show the efficacy of our framework.

It remains an open question how to efficiently transfer the domain knowledge. In the future, we plan to evaluate our method on more different tasks.

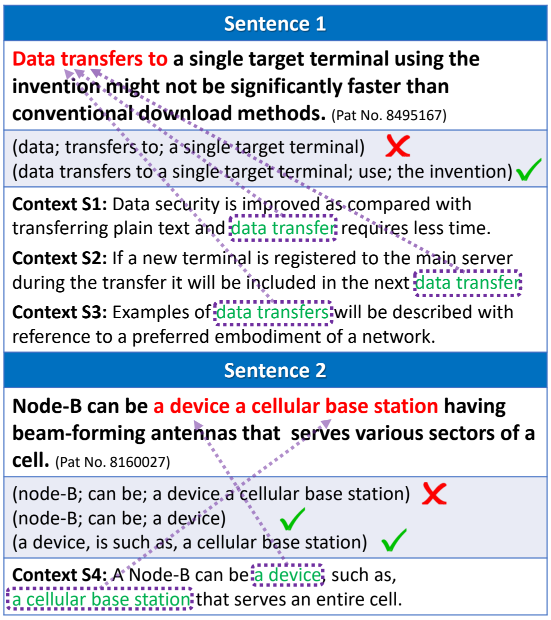
Abstract

Open Information Extraction (OpenIE) aims to extract structured relational tuples (subject, relation, object) from sentences, and plays a critical role in many NLP applications. Existing solutions perform extraction at *sentence level*, without referring to any additional contextual information. In reality, however, a sentence typically exists as part of a document rather than standalone; we often need to access relevant contextual information around the sentence before we can accurately interpret it. As there is no document-level context-aware OpenIE dataset available, we manually annotate 800 sentences from 80 documents in two domains (Healthcare and Transportation) to form a DocOIE dataset for evaluation. In addition, we propose DocIE, a document-level context-aware OpenIE model. Our experimental results demonstrate that incorporating document-level context is helpful in improving OpenIE performance. Both the DocOIE dataset and DocIE model are available online.[1]

1 Introduction

Open Information Extraction has been a critical NLP task as it can extract structured relational tuples (*subject, relation, object*) from unstructured text. The OpenIE system is fully domain-independent, and does not need input from users. It is also highly scalable and allows fast querying mechanism (Yates et al., 2007). Therefore, OpenIE has been successfully applied to a variety of downstream NLP tasks, such as knowledge base population (Martínez-Rodríguez et al., 2018; Gashteovski et al., 2020), question answering (Khot et al., 2017), and summarization (Fan et al., 2019).

Current OpenIE methods mainly focus on extracting tuples *at sentence level*. However, in many NLP scenarios, sentences exist as part of a document rather than standalone. Given a document corpus, if we simply apply existing sentence-level OpenIE models to extract tuples, we could miss some useful and critical document-level contextual information, leading to unsatisfying results. We use the two example sentences in Fig. 1 to illustrate two types of ambiguities.



Sentence 1

Data transfers to a single target terminal using the invention might not be significantly faster than conventional download methods. (Pat No. 8495167)

(data; transfers to; a single target terminal) ✗
(data transfers to a single target terminal; use; the invention) ✓

Context S1: Data security is improved as compared with transferring plain text and data transfer requires less time.

Context S2: If a new terminal is registered to the main server during the transfer it will be included in the next data transfer.

Context S3: Examples of data transfers will be described with reference to a preferred embodiment of a network.

Sentence 2

Node-B can be a device a cellular base station having beam-forming antennas that serves various sectors of a cell. (Pat No. 8160027)

(node-B; can be; a device a cellular base station) ✗
(node-B; can be; a device) ✓
(a device, is such as, a cellular base station) ✓

Context S4: A Node-B can be a device, such as, a cellular base station that serves an entire cell.

Figure 1: Example sentences with ambiguity.

Part-of-speech Ambiguity. The word "transfers" can be a verb or a noun. Accordingly, two tuples could be extracted from the first example sentence, listed in Fig. 1. This ambiguity can be resolved by the main verb of the sentence "might not be", which is far away from "transfers", and thus is not considered by many existing OpenIE systems. However, context sentences S1, S2, and S3 in the document suggest that "data transfers" shall be considered as a noun phrase throughout this document.

Syntactic Ambiguity. The second example sentence does not have an explicit clue about the re-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2377–2389
August 1–6, 2021.

lationship between “a device” and “a cellular base station”.[2] Thus, existing OpenIE systems often fail to split them, but incorrectly extract the first tuple (node-B; can be; a device a cellular base station). However, context sentence S4 includes an explicit cue to the relationship between the two terms and may thus help split them.

To minimize the aforementioned ambiguities, it is clear that we should leverage document-level context. However, all existing OpenIE datasets are generated or annotated at sentence level. These datasets include standalone sentences but not their context sentences. Hence they are not suitable for evaluating context-aware tuple extraction.

We annotate a **Doc**ument-level context-aware **O**pen **I**nformation **E**xtraction (**DocOIE**) dataset. DocOIE consists of 800 expert-annotated sentences from 80 documents, where 10 sentences are randomly sampled for annotation from each of the 80 documents. To the best of our knowledge, among all OpenIE datasets as of now, DocOIE contains the largest number of *expert-annotated* sentences.[3] More importantly, DocOIE provides document-level contexts, enabling OpenIE models to take relevant contexts for accurate tuple extraction.

Furthermore, to show that document-level context is useful for OpenIE task, we develop the **Doc**ument-level context-aware Open **I**nformation **E**xtraction (**DocIE**) model. DocIE encodes a source sentence with its contextual information by using pre-trained BERT (Devlin et al., 2019). Because contextual sentences can be much longer than the source sentence, the syntactic/semantic information in source sentence might be dominated by that of the contexts. Our proposed DocIE model differentiates the source sentence and its contexts by segment tags, and adding additional transformer encoder layers only for the source sentence.

In summary, our contributions are threefold:

- We propose a new task in OpenIE to extract relational tuples with document-level contexts.
- We introduce **DocOIE**, an expert-annotated dataset for evaluating document-level OpenIE systems. DocOIE consists of 2,122 relational tuples from 800 annotated sentences, with their document-level contexts.
- We present **DocIE**, a neural OpenIE system that can leverage document-level contexts for relational tuple extraction.

2 Related Work

OpenIE Datasets. Since introduction of OpenIE task by Yates et al. (2007), the earlier systems have been mainly evaluated by using a small number of sentences, without a standardized evaluation procedure (Niklaus et al., 2018). OIE2016 (Stanovsky and Dagan, 2016) is the first large-scale dataset constructed for OpenIE tasks and comes with a standard scoring framework. In OIE2016, the gold tuples are automatically generated from a QA-SRL dataset (He et al., 2015) according to human crafted rules. Wire57 (Lechelle et al., 2019) improves the scorer and manually annotates 57 sentences as a benchmark dataset. Considering that OIE2016 dataset is noisy, Bhardwaj et al. (2019) provide a crowdsourcing dataset named CaRB. CaRB also has 50 expert-annotated sentences and a sophisticated scoring framework.

As summarized in Table 1, the number of expert-annotated sentences in these datasets remains small. Furthermore, the sentences in these datasets do not come with contextual information. In contrast, our DocOIE dataset consists of 800 expert-annotated sentences, and comes with the source documents for accurate sentence interpretation.

OpenIE Models. TextRunner (Yates et al., 2007) is the first OpenIE system, followed by Reverb (Fader et al., 2011), OLLIE (Mausam et al., 2012), Clausie (Corro and Gemulla, 2013), CSD-IE (Bast and Haussmann, 2013), Stanford OpenIE (Angeli et al., 2015), Openie4 (Mausam, 2016), Openie5[4], NESTIE (Bhutani et al., 2016), MINIE (Gashteovski et al., 2017) and

---

[2] The missing of a comma could be a typo in the patent document. Nevertheless, not all input sentences to OpenIE system are typo free in real applications.

[3] Expert annotation means annotations are made by a person who is familiar with the OpenIE task and OpenIE models. This term is used to distinguish annotations by crowdsourcing.

[4] `github:dair-iitd/openie-standalone`

Graphene (Cetto et al., 2018). We consider them as *traditional* OpenIE models. These models extract relational tuples based on handcrafted rules or statistical methods. They usually rely on prior syntactic or semantic analysis. Consequently, any error accumulated in the prior stages deteriorates model performance.

Recently, neural OpenIE systems have been developed and showed promising results (Cui et al., 2018; Zhan and Zhao, 2020; Kolluru et al., 2020a,b). Different from the traditional models, neural OpenIE models extract tuples in an end-to-end manner, not requiring prior syntactic or semantic analysis. In principle, the traditional rule-based or statistical OpenIE models do not need training. However, neural OpenIE models need a large number of training samples to learn the extraction patterns. For instance, IMOJIE (Kolluru et al., 2020b) uses about 100,000 sentences for model training. It is unrealistic and expensive to manually annotate 100,000 sentences simply for training purpose. Therefore, a common practice in learning a neural OpenIE model is to use tuples automatically extracted by traditional systems as training data, *i.e., a bootstrapping strategy*. We consider these imperfect training labels generated via bootstrapping as pseudo labels. The pseudo labels used in (Cui et al., 2018) are by Openie4, and those in (Kolluru et al., 2020b) are from multiple OpenIE systems.

To the best of our knowledge, no OpenIE models consider document-level contexts in the tuple extraction. Nonetheless, our neural model unavoidably requires extractions of pseudo labels bootstrapped from traditional models for training. To ensure reproducibility, as part of the DocOIE dataset, we also release the document IDs that are used for generating the pseudo labels.

3 DocOIE Dataset

We now present our **Doc**ument-level context-aware **O**pen **I**nformation **E**xtraction (**DocOIE**) dataset. We first introduce the data selection and collection process, and then the annotation process by two experts. Moreover, we explain our annotation consistency measurement to indicate the high-level annotation consistency in DocOIE. In summary, DocOIE consists of two datasets: *evaluation dataset* and *training dataset*.

Evaluation dataset contains 800 expert-annotated sentences, sampled from 80 documents in two domains (healthcare and transportation). Specifically, 10 sentences are sampled for annotation from each of the 40 documents in one domain. In total, $2,122$ relational tuples are annotated in the 800 sampled sentences (refer to Table 2 for detailed statistics, and Table 5 for fine-grained analysis).

Item	#Item	Metric	Average	Min~Max
Doc	80	N_{sent}	129.85	62~218
Sent	800	L_{sent}	22.70	5~47
		N_{tuple}	2.65	1~8
Tuple	2,122	L_{sub}	3.70	1~17
		L_{rel}	3.39	1~12
		L_{obj}	3.94	0~27

Table 2: Statistics of DocOIE evaluation dataset. $N_{\{\cdot\}}$ denotes the number of units (*i.e.,* sentence or tuple); $L_{\{\cdot\}}$ denotes the length (number of words) of the unit.

Training dataset contains 2,400 documents from the two domains (healthcare and transportation); 1,200 documents in each domain. All sentences from these documents are used to bootstrap pseudo labels for neural model training.[5]

3.1 Dataset Collection

OpenIE, by definition, is to extract relational tuples in open domain. Ideally, sentences/documents in DocOIE dataset shall not be restricted to any particular document type or topical domain. However, it is challenging to include all types of documents and annotate them. In fact, all existing annotations are restricted to specific types of documents like news and Wikipedia articles (Niklaus et al., 2018).

Document Type Selection In building DocOIE, we focus on formally written documents and leave it for future work to explore other kinds of documents. We select the type of formal documents with four criteria: (i) **Adequacy:** as a document-level context-aware dataset, each document shall have a reasonable number of sentences to provide sufficient context. (ii) **Consistency:** each document shall focus on a central topic. In such a way, sentences within the same document are correlated to and consistent with each other, which helps derive proper context. (iii) **Informativeness:** a document is considered informative if it contains informative entities like technical concepts, relations,

---

[5] Only document IDs are included in DocOIE, for document collection at `http://patft.uspto.gov/`

and events. Intuitively, OpenIE models are more useful for extracting factual tuples in informative documents. (iv) **Syntactic Variety:** sentences in these documents shall vary in syntactic structures. Such variety facilitates thorough evaluation of OpenIE models under different scenarios.

Patent Document Collection After taking all factors into consideration, we choose to collect patent documents from PatFT.[6] Each patent document elaborates one specific invention in reasonable length, providing sufficient contexts to annotators. They are rich in informativeness by nature, and the documents contain rich syntactic structures.

Through PatFT search engine, patent documents can be retrieved by keywords. We have two considerations for keyword selection: (i) **Magnitude:** as part of DocOIE, a large number of documents shall be available for training neural OpenIE models. Hence, the keywords shall lead to sufficient patent documents. (ii) **Diversity:** the collected patent documents are expected to be diversified in inventors, organizations, filed date, etc., to avoid fixed patterns, hence to ensure diversity of our dataset.

As the result, we choose three broad and non-technical keywords: "healthcare", "traffic", and "transportation", to collect documents in two broad domains, *healthcare* and *transportation*. Reported in Table 3, 42,514 and 32,256 documents are collected in healthcare and transportation respectively. Documents in each domain are contributed by more than 40,000 inventors from over 8,000 cities, and the filed dates range in several decades.

Patents	Healthcare	Transportation
#Document	42,514	32,256
#Inventor	74,266	42,286
#Organization	10,888	7,919
#City	10,493	8,095
Filed year	1999~2020	1970~2020

Table 3: Properties of collected patents in healthcare and transportation domains.

We clean these documents by removing non-textual components in them. Then, by length (in number of words) the shortest 10% and longest 10% documents are removed to avoid extremely short/long documents in our dataset. The remaining documents form the corpus from which we sample (i) documents for annotation, and (ii) training documents for bootstrapping pseudo labels.

3.2 DocOIE Evaluation Dataset Selection

To ensure annotation quality and consistency, we choose to follow expert annotation scheme instead of crowdsourcing adopted in CaRB (Bhardwaj et al., 2019). As we discussed in Section 1, sentences exist as part of a document rather than standalone. To gain an accurate interpretation of a sentence, the annotator needs to read a few surrounding sentences, or even the entire document, for relevant contexts. Hence, the choices of labelling one sentence or multiple sentences per document incur different costs.

To be able to cover a reasonable number of documents and also balance the annotation workload, we choose to randomly sample 10 sentences per document from 80 documents for annotation. Recall that the average number of sentences per document is 101.78 (refer to Table 2). The 10 sentences annotated in a document can be used to evaluate context-aware OpenIE at 10 different positions in this document. In this way, our annotation covers 80 documents with considerable diversity.

In summary, we randomly selected 80 documents (40 in each domain) from the documents collected in Section 3.1. Then we randomly selected 10 sentences from each document. These 80 documents, along with 800 expert-annotated sentences form the DocOIE *evaluation dataset*.

3.3 Annotation Consistency Measurement

The annotation was performed by two OpenIE experts (both are authors of this paper) with reference to existing annotation processes (Stanovsky and Dagan, 2016; Bhardwaj et al., 2019). The dataset was annotated in three stages.

In the first stage, the two annotators practiced annotations independently on 100 sentences among the 800 sentences. Then they cross-validated the annotation results, discussed them to resolve disagreements, and updated annotation policy.

In the second stage, the two experts independently annotated another 100 sentences among the remaining 700 sentences. These two sets of annotations are used for measuring annotation consistency. Because it is not straightforward to evaluate annotation agreement by measures like Kappa coefficient, we adopted the evaluation scorer proposed by CaRB (Bhardwaj et al., 2019). The scorer performs matching at tuple level instead of lexical

---

Analysis	Healthcare	Transportation
Sentence semantic analysis (%)		
Conjunction	61.00	61.50
Terminology	60.00	42.75
Dependent Clause	29.00	41.50
Tuple semantic analysis (%)		
Negative Polarity	3.26	5.16
Possibility	12.17	8.74
Under-specificity	8.80	6.49

Table 5: Fine-grained statistical analysis for 800 annotated sentences and 2,122 tuples. Percentages refer to the respective domain: Healthcare and Transportation.

level. Specifically, we score one expert's annotations by treating the other's annotations as ground truth. Among the tuple matching strategies in CaRB, we used the default binary lenient tuple matching, to estimate the consistency between the two annotators. Reported in Table 4, the two annotators reach high-level agreement in annotations with an average F1 of 89.9%.

Based on the high-level annotation consistency, in the third stage, each expert independently annotated 300 sentences from the remaining 600 sentences. The annotations are then validated by the other expert, and annotation disagreements are resolved through discussion.

3.4 Analysis of DocOIE Evaluation Dataset

To understand the difficulty of DocOIE, we provide an analysis of the annotated sentences and tuples in DocOIE, similar to (Gashteovski et al., 2019).

Sentence-level Analysis. We evaluate the complexity of a sentence on whether it contains conjunction word, terminology mention, and dependent clause. Consider the following sentence as an example: *"Though depicted as a distinct step, it may be performed as part of the VAD or ASR processes." "VAD processes"* and *"ASR processes"* are terminology mentions. The conjunction word *"or"* in the sentence connects these two terminologies. In addition, dependent clause refers to the subordinate clause "Though depicted as a distinct step". Table 5 reports the percentages of sentences that contain at least one conjunction word, terminology mention, and dependent clause, respectively.

Tuple-level Analysis. Consider an example sentence *"They may be implemented as instructions stored on a machine-readable medium."* Two tuples can be extracted from this sentence: (1) "*they ; may be implemented as ; instructions*", and (2) "*instructions ; are stored on ; a machine-readable medium*".

We analyze a tuple on whether it is a certainty or merely a possibility. The relation "*may be implemented as*" indicates tuple (1) a possibility because of the modal verb "*may*". Then, negative polarity refers to certainty negation, which can be indicated by words such as "*not*" or "*no*". Some tuples are under-specified in either tuple subject or object. The main reason for under-specificity is the lack of co-reference information, where we need additional context to obtain a coherent meaning. In tuple (1), its subject "*they*" is under-specified because co-reference information is needed to resolve what "*they*" refers to.[7] Table 5 reports the percentages of tuples that are under each of the categories.

3.5 DocOIE Training Dataset

Besides the 80 documents for expert annotations, we further sample 2,400 documents randomly (1,200 in each domain) from the documents collected in Section 3.1 to create DocOIE training dataset. The 1,200 documents in each domain contain around 120,000 sentences, which is sufficient for pseudo label generation, required by neural OpenIE models.

4 Pseudo Label by Bootstrapping

Following the common practice (Kolluru et al., 2020b; Cui et al., 2018; Zhao et al., 2020), we generate pseudo labels by bootstrapping with traditional OpenIE models. Before we run these models on the DocOIE training dataset, we evaluate their performances on the DocOIE evaluation dataset, to select the models which can generate better quality pseudo labels.

---

[7] Co-reference is not annotated in DocOIE.

OpenIE Model	AUC	Prec	Rec	F1
Healthcare Domain				
Reverb	35.4	**79.9**	42.8	55.8
Stanford	16.5	11.0	29.7	16.1
Clausie	22.1	38.8	53.8	45.1
OpenIE4	35.4	59.5	55.1	57.2
OpenIE5	29.1	53.6	50.5	52.0
Rev+Oie4	**36.8**	75.8	47.7	**58.6**
Oie4+Rev	35.8	59.6	**55.3**	57.4
Transportation Domain				
Reverb	29.3	**79.1**	36.3	49.7
Stanford	15.7	13.2	27.8	17.9
Clausie	18.0	36.2	48.4	41.4
OpenIE4	29.2	52.8	51.2	52.0
OpenIE5	25.0	50.9	43.8	47.1
Rev+Oie4	**31.0**	74.2	42.4	**54.0**
Oie4+Rev	30.1	53.4	**52.7**	53.0

Table 6: Performance of OpenIE models on DocOIE evaluation dataset. The best scores are in boldface and second best scores are underlined.

We evaluate the models by using CaRB scorer (Bhardwaj et al., 2019). Table 6 reports the performance of five independent OpenIE models: Reverb (Fader et al., 2011), Clausie (Corro and Gemulla, 2013), Stanford OpenIE (Angeli et al., 2015), OpenIE4 (Mausam, 2016) and OpenIE5[8]. In addition to these five models, we also evaluated two combinations of Reverb and OpenIE4. With **Rev+Oie4**, Reverb is the main system and if Reverb fails to extract any tuples from a sentence, we complement the extraction by using Openie4. Similarly, **Oie4+ Rev** uses OpenIE4 as the main system, and the extractions are complemented by Reverb.

All the evaluated models show consistent performance in both domains. By F1 score, both Reverb and OpenIE4 are the best performing individual models and their combinations lead to the best and second best F1 scores in both domains. Accordingly, by applying OpenIE4, Reverb, and their combinations, the number of sentences and tuplesextracted from the DocOIE training dataset are reported in Table 7.[9] Note that, a sentence is not counted if it has no extracted tuples, which leads to the different sentence number.

OpenIE model	Healthcare #Sent	Healthcare #Tuple	Transportation #Sent	Transportation #Tuple
OpenIE4	117k	263k	111k	258k
Oie4+Rev	121k	268k	114k	262k
Reverb	103k	146k	97k	141k
Rev+Oie4	121k	181k	114k	173k

Table 7: Number of sentences and tuples extracted by Reverb, OpenIE4 and their combinations. The sentence is not included if it has no tuples extracted.

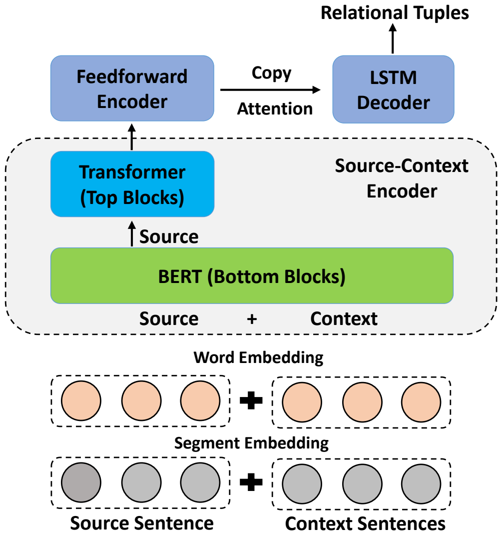

Figure 2: The architecture of DocIE.

5 DocIE Model

In this section, we present the proposed **Doc**ument-level context-aware Open **I**nformation **E**xtraction model, named **DocIE**. As shown in Fig. 2, DocIE mainly consists of two parts: source-context encoder, and encoder-decoder.

Document-level Context Formally, we denote a document as $D = \{s_1, s_2, \ldots, s_N\}$ consisting of N sentences. The source sentence s_i is the input sentence that relational tuples are extracted from. Given source sentence s_i, we regard its surrounding sentences $c_i = \{s_{i-t}, \ldots, s_{i-1}, s_{i+1}, \ldots, s_{i+t}\}$ as contextual sentences, where t represents the context window size. The larger t is, the more document-level context c_i covers.

Source-Context Encoder The source-context encoder is inspired by a recent work (Ma et al., 2020) which adopts Flat-Transformer to incorporate context into source sentence, for machine translation. In DocIE, our encoder consists of (i) bottom blocks which take the concatenation of source sen-

---

[8] `github:dair-iitd/openie-standalone`

[9] The number of sentences may vary because of different text pre-processing and sentence segmentation strategies adopted. The number of tuples extracted may vary due to different versions of OpenIE tools.

tence and context sentences as input, and (ii) top blocks which take only the representation of the source sentence from the bottom blocks as input.

In our implementation, we use BERT (Devlin et al., 2019) as the bottom blocks to perform semantic interactions between source sentence s and context c. We first project both s and c into embedding space by summing their word embedding and segment embedding, *i.e.,* $e_s = E(s) + S(s)$ and $e_c = E(c) + S(c)$. Here, E is the trainable word embedding matrix, and S is the trainable segment embedding matrix. The segment embedding is to distinguish words in source sentence from words in context sentences. They are initialized to 0 and 1 for words in source and context sentences respectively. Then we concatenate e_s with e_c as $[e_s; e_c]$ as the input to the source-context encoder.

$$h_1[s; c] = \mathrm{BERT}([\mathrm{e_s}; \mathrm{e_c}]) \tag{1}$$

BERT, with multiple layers of transformers, merges source sentence information and its contextual information. We use the last hidden state $h_1[s; c]$ of BERT as the representation of the two concatenated input sequences.

On top of the BERT blocks, we add Transformer as top blocks (Vaswani et al., 2017) to prepare the source sentence representation for the following encoder-decoder. The source sentence representation is obtained by truncating the latter (context sentences representation) $h_1[c]$ from $h_1[s; c]$. Therefore only the former (source sentence representation) $h_1[s]$ is kept.

$$h_2[s] = \mathrm{Transformer}(\mathrm{h_1[s]}) \tag{2}$$

Encoder-Decoder The encoder-decoder generation module follows CopyAttention (Cui et al., 2018) which casts OpenIE task as a sequence-to-sequence generation task with copying mechanism. The encoder-decoder framework represents a variable length input sequence in the encoder and uses it in the decoder to generate output sequence. In our encoder-decoder framework, attention mechanism (Bahdanau et al., 2015) is used to align the encoder hidden state with the decoder hidden state, jointly maximizing the log probability of output tuples, conditioned on the input sentence. Meanwhile, since tuple arguments and relation are normally sub-spans of the input sentence, additional copying mechanism (Gu et al., 2016) is applied. It helps copy words directly from the input sentence to the output tuples.

6 Experiments

We evaluate DocIE and compare its results with two baseline neural OpenIE models, CopyAttention+BERT and IMOJIE (Kolluru et al., 2020b). Kolluru et al. (2020b) report that CopyAttention+BERT is a strong baseline. Meanwhile, DocIE adopts CopyAttention (Cui et al., 2018) as its encoder-decoder module. Hence CopyAttention+BERT can be considered as the base model, from which DocIE adds context modelling.

6.1 Neural Baseline Models

We first evaluate the two neural baseline models trained with the pseudo labels listed in Table 7. The evaluation is conducted on the DocOIE evaluation dataset with CaRB scorer.

Reported in Table 8, CopyAttention+BERT outperforms IMOJIE in most settings by both measures: AUC and F1. In general, for both models, pseudo labels by Rev+Oie4 (and also Reverb) lead to better results in healthcare domain. Pseudo labels by Oie4+Rev (and also OpenIE4) generate better results in transportation domain. During our annotation of the 800 sentences, we observe that sentences in transportation domain tend to contain slightly more conjunctions (*e.g.,* multiple conjunctions in one sentence) and thus have more coordinating structures than those in healthcare. OpenIE4 system generally extracts more tuples than Reverb (refer to Table 7) and provides higher recall. Therefore, extractions in transportation domain with more conjunctions may better match the tuples extracted by OpenIE4.

Based on this set of results, in our following experiments, we use pseudo labels by Rev+Oie4 for healthcare domain, and pseudo labels by Oie4+Rev for transportation domain.

6.2 DocIE Against Baselines

In this section, we evaluate DocIE against sentence-level OpenIE systems. We refer DocIE without the top transformer layer as "DocIE w/o transformer" and DocIE as "DocIE w transformer" for clarity. The context window size of DocIE is set to 5 for healthcare domain and 4 for transportation domain.

Table 9 summarizes the experiment results. For easy comparison, the results of the best traditional OpenIE baselines (refer to Table 6) and neural OpenIE models (refer to Table 8) are replicated here. Observe that DocIE w transformer achieves the best AUC and F1 in both domains. Its variant, DocIE

Neural OpenIE	Pseudo labels	Healthcare				Transportation			
		AUC	Prec	Rec	F1	AUC	Prec	Rec	F1
CopyAttention+BERT	OpenIE4	38.6	54.4	**51.6**	52.9	38.5	54.3	**57.6**	55.9
	Oie4+Rev	40.4	57.1	50.4	53.5	38.3	55.3	56.9	**56.1**
	Reverb	43.7	77.8	46.4	58.1	36.9	70.5	42.2	52.8
	Rev+Oie4	**46.8**	**77.9**	48.6	**59.8**	**40.3**	**72.1**	43.9	54.6

	Reverb	38.5	79.2	45.6	57.9	33.2	77.3	39.2	52.0
	Rev+Oie4	**39.7**	**80.1**	46.4	**58.7**	33.0	**77.4**	39.6	52.4

Table 8: Neural baseline models trained with different pseudo labels. The best scores of *each model* are in boldface.

System	Healthcare				Transportation			
	AUC	Prec	Rec	F1	AUC	Prec	Rec	F1
Rev+Oie4	36.8	75.8	47.7	58.6	31.0	**74.2**	42.4	54.0
Oie4+Rev	35.8	59.6	**55.3**	57.4	30.1	53.4	52.7	53.0
CopyAttention+BERT	46.8	77.9	48.6	59.8	38.3	55.3	56.9	56.1
IMOJIE	39.7	**80.1**	46.4	58.7	35.8	63.5	49.2	55.5
DocIE w/o transformer	47.1	76.2	49.9	60.3	**38.5**	55.8	57.0	56.4
DocIE w transformer	**47.4**	74.4	51.3	**60.8**	**38.5**	56.0	**57.5**	**56.9**

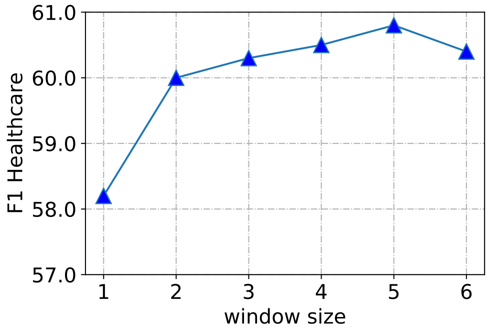
Table 9: Results of DocIE and baselines. The best scores are in boldface and second best scores are underlined.

w/o top transformer, is the second best performer and outperforms all sentence-level models.

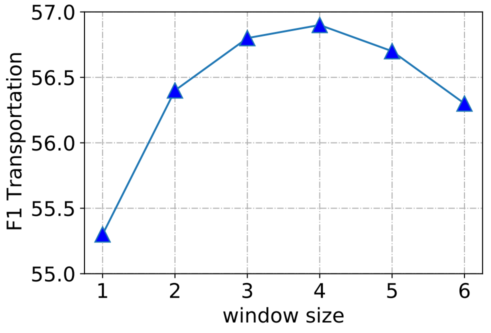
The experiment results suggest that incorporating document-level context is helpful in improving OpenIE. On the other hand, we remark that DocIE is trained by pseudo labels produced by traditional OpenIE models which do not consider document-level context. The potential of utilizing document-level context is yet to be fully realized.

6.3 Impact of Context Window Size

The setting of window size determines the number of context sentences to be considered. We evaluated the range from 1 to 6 and plot F1 scores against window size changes in Fig. 3. Observe that the optimal window size for healthcare domain is 5, and the number is 4 for transportation. Better F1 scores are observed along the increase of context sentence window, till 4 or 5. In general, 8~10 surrounding sentences (window size 4 or 5) provide sufficient context for sentence understanding. Small window size might not provide sufficient context, and a large window size might introduce noise and dominate source representation learning.



(a) Healthcare



(b) Transportation

Figure 3: F1 with varying window sizes, on both domains.

6.4 Case Study

We use the two example sentences shown in Fig. 1 as a case study, to illustrate the differences between DocIE and the sentence-level neural OpenIE baselines: CopyAttention+BERT and IMOJIE.

For Sentence 1, CopyAttention+BERT incorrectly recognizes the word "transfers" as a verb, thus extracting an incorrect tuple (data ; transfers to ; a single target terminal). IMOJIE, however, completely misses the key phrase "data transfers" and extracts an incorrect tuple (a single target terminal ; using ; the invention). Only DocIE manages to extract the correct tuple (data transfers to a single target terminal ; using ; the invention).

For Sentence 2, there is no explicit clue about the relationship between "a device" and "a cellular base". Both CopyAttention+BERT and IMOJIE treat "a device a cellular base station" as a whole and mistakenly generate a tuple (Node-B ; can be ; a device a cellular base station having beam-forming antennas). In contrast, DocIE successfully splits "a device a cellular base station" by referring to surrounding context and extracts the correct tuple (Node-B ; can be ; a device). However, DocIE fails to infer the inter-relationship between "a device" and "a cellular base". Accordingly, another correct tuple (a device ; is such as ; a cellular base station) is not extracted.

Results of the two example sentences show the improvements made by DocIE after leveraging contextual information for tuple extraction.

6.5 Error Analysis

Similar to the error analysis performed in (Kolluru et al., 2020b), we examine tuples extracted by DocIE from 50 randomly selected sentences in DocOIE. We identify the following major error types. (i) **Incompleteness:** In 28% sentences, DocIE fails to cover at least one key phrase in either arguments or relation. Missing key phrases result in incomplete information extraction. (ii) **Incorrect Boundary:** 27% extractions misinterpret the syntactic meaning of the sentence, leading to incorrect boundary of arguments and relation. (iii) **Redundant Extractions:** 15% sentences contain redundant extractions; that is, the same relational fact is extracted multiple times from a sentence or phrase. (iv) **Grammatical Errors:** 13% extractions are not grammatically correct. Most grammatical errors are contributed by the incorrect verb form used in tuple relation.

6.6 Implementation

We implement DocIE using the AllenNLP framework[10] in Pytorch 1.4. Pre-trained BERT[11] is fine-tuned at learning rate 2×10^{-5} to get contextualized word embeddings. The learning rate for the other modules is set to 1×10^{-4}. The input dimension, projection dimension, feedforward hidden dimension, number of layers, and number of attention heads of top transformer encoder are set to 768, 256, 3072, 2, and 8, respectively. The hidden dimension, and word embedding dimension of the LSTM-decoder are set to 256 and 100 respectively.

7 Conclusion

In this paper, we propose to consider document-level contextual information for OpenIE task. We contribute DocOIE, the first document-level context-aware OpenIE dataset. It consists of 800 expert-annotated sentences from 80 documents. The documents are carefully selected and the annotations are completed by experts with high-level annotation consistency.

With the help of DocOIE, we conduct evaluation of neural OpenIE models and demonstrate that incorporating document-level context is helpful in improving OpenIE performance through DocIE. As a baseline for document-level context-aware OpenIE, DocIE achieves promising results compared with all sentence-level OpenIE models. Our future works are in two main directions. One is to research on more effective context-aware OpenIE models, and the other is to investigate the possibility of not relying on pseudo labels.

DocOIE: A Document-level Context-Aware Dataset for OpenIE (Supplementary Material)

A DocOIE Annotation Agreement

This section complements Section 3.3 Annotation Consistency Measurement.

We take the sentence shown in Table 10 as an example, to demonstrate how the two experts clarified inconsistency and updated annotation policy. In blue-colored tuples, Expert A broke down a long argument *"nerve grafts in peripheral nerve tissue engineering"* into an additional tuple *(nerve grafts; are in; peripheral nerve tissue engineering)*, while Expert B chose to contain the descriptive part in this argument. After discussion, they decided to follow Expert B's practice to ensure complete argument without losing descriptive information. Meanwhile, as shown in red-colored tuples, the two experts disagreed on the inner relation of the argument "aft tissue-derived ECM modified tissue engineered nerve grafts". Expert A considered "aft tissue-derived ECM" should be modified by "tissue engineered nerve grafts" but Expert B thought "nerve grafts" shall be engineered by "aft tissue-derived ECM modified tissue". This inconsistency is resolved by referring to the relevant contexts in the document: "tissue engineered nerve grafts" is a terminological phrase and there exists an action of "ECM modification" performing on "tissue engineered nerve grafts". The annotation agreed by both experts are shown in the last row in Table 10.

B Extraction Results

Table 11 lists the tuples extracted by DocIE and the sentence-level neural OpenIE baselines: CopyAttention+BERT and IMOJIE. This table complements Section 6.4 Case Study.

Source Sentence	***The ANG meets the basic requirements for nerve grafts in peripheral nerve tissue engineering, and becomes aft tissue-derived ECM modified tissue engineered nerve grafts.***
Annotation by Expert A	(the ANG ; meets the basic requirements for ; nerve grafts) (nerve grafts ; are in ; peripheral nerve tissue engineering) (the ANG ; becomes ; tissue engineered nerve grafts) (tissue engineered nerve grafts ; is modified by ; aft tissue-derived ECM)
Annotation by Expert B	(the ANG ; meets the basic requirements for ; nerve grafts in peripheral nerve tissue engineering) (the ANG ; becomes ; aft tissue-derived ECM modified tissue engineered nerve grafts) (nerve grafts ; is engineered by ; aft tissue-derived ECM modified tissue)
Document Context	...another group is using plain ***tissue engineered nerve grafts*** (without ***ECM modification***) for repairing the sciatic nerve defects of rats....
Annotation in Agreement	(the ANG ; meets the basic requirements for ; nerve grafts in peripheral nerve tissue engineering) (the ANG ; becomes ; aft tissue-derived ECM modified tissue engineered nerve grafts) (tissue engineered nerve grafts ; is modified by ; aft tissue-derived ECM)

Table 10: An example of inconsistent annotations between two annotators, and the annotation in agreement.

Sentence 1	***In some circumstances, data transfers to a single target terminal using the invention might not be significantly faster than conventional download methods.***
Annotated tuples	(data transfers to a single target terminal ; use ; the invention) (data transfers to a single target terminal using the invention ; might not be significantly faster than ; conventional download methods)
DocIE	(data transfers to a single target terminal ; using ; the invention) (data transfers to a single target terminal using the invention ; might not be ; significantly faster than conventional download methods)

Abstract

Understanding historical events is necessary for the study of contemporary society, culture, and politics. In this work, we focus on the event extraction task (EE) to detect event trigger words and their arguments in a novel domain of historical texts. In particular, we introduce a new EE dataset for a corpus of nineteenth-century African American newspapers. Our goal is to study the discourse of slave and non-slave African diaspora rebellions published in the periodical press in this period. Our dataset features 5 entity types, 12 event types, and 6 argument roles that concern slavery and black movements between the eighteenth and nineteenth centuries. Historical newspapers present many challenges for existing EE systems, including the evolution of meanings of words and the extensive use of religious discourse in newspapers from this era. Our experiments with current state-of-the-art EE systems and BERT models demonstrate their poor performance over historical texts and call for more robust research efforts in this area.

1 Introduction

In the last two decades, the emergence of digital humanities has transformed scholarship in the humanities. Historical documents are now massively digitized into photos and texts that allow researchers to query across collections and languages (Piotrowski, 2012). Despite the convenience of these applications (Yang and Eisenstein, 2016), a gap still exists between datasets and research methods. As such, humanities scholars do not solely interpret historical facts from statistical figures derived from massive data. Rather, they prefer reading texts and interpreting words in historical and cultural context, or by associating texts with the circumstances surrounding their publication. This working methodology requires an emphasis on the quality of the data over the quantity of the data. Recent advances of natural language processing (NLP) aim to bridge the gap between qualitative and quantitative analyses by identifying, extracting, and counting contextual data (Won et al., 2018; Wadden et al., 2019; Lin et al., 2020). This new approach provides contextual information about real-life entities (e.g., individuals, locations, times, documents) which can be later integrated into knowledge bases (Won et al., 2018) to aid historical research and discourse analysis.

In this work, we explore Information Extraction (IE) in NLP for humanities research in support of the important and complicated process of **knowledge extraction** from historical texts. Particularly, we investigate the Event Extraction (EE) task which identifies event trigger words of pre-determined event types (the most important words/phrases to evoke events) (Li et al., 2013), together with its arguments (e.g., participants, locations). For example, in the following sentence an EE system should be able to detect the word "*proclaimed*" as a trigger word of the event type "*Law_Approve*" and associate it with the arguments, i.e., agent (*Capitol*), beneficiary (*the slave*), and datetime (*now*).

Freedom to the slave should now be ***proclaimed*** *from the Capitol, and should be seen above the smoke and fire of every battle field.*

To enable the development and evaluation of EE models for historical text, benchmark datasets play an important role. However, most of the current datasets in EE (i.e., ACE-2005 (Walker et al., 2005) and TAC KBP (Mitamura et al., 2015)) are not suitable for this domain for several reasons. First, these datasets are collected from various sources without a target topic (Walker et al., 2005; Mitamura et al., 2015). Therefore, tracking the evolution of some specific movements or progress, which is of great interest to literary scholars and historians, is not a feasible goal. Second, documents in these datasets

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2390–2400
August 1–6, 2021.

are derived from recent articles and documents in which the use of words in the text differ from their uses in the past. For example, some words obtain new semantics over time, and the dominance of religion in the past led to extensive use of religion-related words and figurative language in historical publications. Last but not least, existing EE datasets mostly concern events in common human life, such as giving birth, transportation, and crimes. These events might not relate to the subjects literary scholars and historians want to study.

To redress this problem, we introduce a novel EE dataset for historical texts, called BRAD, focusing on Black Rebellions in African Diaspora (i.e., African American population). BRAD's documents are selected by a humanities expert and are annotated by EE experts for 5 entity types, 12 event types, and 6 argument roles. Finally, we evaluate the state-of-the-art EE models on BRAD. Our experiments show that the performance for historical texts of current EE models is significantly poorer than those for modern texts, necessitating further research into this area. We will also release our dataset and code to facilitate future research.

2 Data Collection and Annotation

In this project we use documents from the African American newspaper corpus. These documents involve news articles derived from nineteenth-century African American periodicals[1] published from 1827 to 1909.

To create an EE dataset, we first designed a set of event types and annotation guidelines, consulting our humanities expert who specializes in nineteenth-century literature. In particular, we focus on the four most important events for Black rebellions presented in our corpus, including **Humanity**: a humanity event concerns a violation or facilitation of basic human rights (e.g. living, freedom, property); **Law**: a law event characterizes an introduction, approval or appeal of a law; **Conflict**: a conflict event represents an act of violence; it includes the initialization, development, and consequences of a violent act; and **Justice**: a justice event captures an act of punishment of the government to the people who violate a law. These four events are further expanded into 12 event sub-types. Tables 7 and 8 present event types along with their descriptions and examples in BRAD. To capture arguments for such events, we introduce five entity types (i.e., Person, Organization, Geographical-Political Entities, Time, and Document). The first four entity types follow the definition in the ACE 2005 guideline (Walker et al., 2005) while the Document type represents government documents (e.g., Slavery Act) used in events. Finally, we define six argument roles that such entity types can play in our events, including Time, Location, Agent, Patient, Object, and Beneficiary. Tables 9 and 10 provide more descriptions and examples of these argument roles for each event type.

The African American corpus is a large corpus of 177,582 articles. We thus select documents that are relevant to our focused topic of Black diaspora rebellions. First, automatic selection is done by keyword matching to identify documents related to slavery and insurrection. As such, our humanities expert defined a set of keywords for the topic of rebellion. In the nineteenth century this cluster of words were used interchangeably to describe African diaspora rebellion events (e.g., "*rebel*", "*revolt*", "*strike*", "*insurrection*"). We used the Stanford CoreNLP toolkit to split and tokenize documents into sentences and words. Next, for each document in the corpus, we counted the number of words in the document that appears in the designated keyword set (called matching rate). The top 1000 documents with the highest matching rates are selected for further consideration. In the second step, the humanities expert examined the 1000 documents to identify relevant documents for Black rebellions, leading to the selection of 151 documents used for the EE annotation.

In the next step we recruited two graduate students to annotate the selected documents for EE. Each student was independently trained on the annotation guideline and performed a group of exercises to better recognize events and entities. The students annotated the 151 documents for entity mentions and event triggers, achieving Cohen's Kappa scores of 0.81 and 0.82 respectively. Note that these scores are very close to the near-perfect agreement range of $[0.81, 0.99]$. To further improve the quality of the dataset, our humanities expert will resolve the annotation conflicts that arise between the two students, leading to the final annotation version of entity mentions and event triggers in the 151 documents. In the next step, given the reconciled entity mention and event trigger annotation, the two students continue to annotate event

---

[1] Douglass Monthly, The Frederick Douglass Paper, Freedom Journals, The Christian Recorder, The Colored American.

arguments for the event triggers. Our evaluation shows a Cohen's Kappa score of 0.75 that indicates a strong agreement between the two annotators. Also, the lower agreement score for event arguments suggests that event argument annotation is more ambiguous than those for entity mentions and event triggers. Finally, our domain expert was consulted to resolve any conflicts in event argument annotation, producing the final version of our BRAD dataset with the 151 documents. To facilitate the development of EE models, we then split BRAD into three portions for training, development, and test data with 101, 25, and 25 documents, respectively. Table 1 presents the statistics while Table 2 and 3 presents the frequencies of event and entity types in our BRAD dataset.

	Train	**Dev**	**Test**	**Total**
#document	101	25	25	151
#sentence	3,847	925	866	5638
#token	117,278	27,860	26,920	172,058

Justice_Execute	26
Justice_Sentence	14

Table 2: Distribution of event types in BRAD.

Annotation Challenges: During the EE annotation process of historical texts, we found several noteworthy challenges regarding the ability to achieve interpretive consensus of the texts.

First, for the domain expertise, we find that the use and meaning of words evolves over time and across geographical regions, potentially introducing new meanings or making one meaning more popular than the others. Language is always in perpetual flux. As such, understanding texts from the past requires analysis of the context in which texts were written. In order to be effective, the annotations must be attentive to these contexts. For example, in the following sentence, "*Congress*" and "*her*" are two mentions of the *USS Congress* battleship launched by the United State Navy in 1841. Without historical knowledge, our current perception might interpret "*Congress*" as the legislative branch of the United States. In fact, the second clause mentions the wooden hull that helps to clarify it as the battleship that sunk in 1862 during the US Civil War. Such misinterpretation might lead to incorrect annotations and analyses.

Entity Type	**#Entity**
PERSON (PER)	12,599
ORGANIZATION (ORG)	3,836
GEOPOLITICAL (GPE)	2,873
DOCUMENT (DOC)	1,121
DATETIME (TIME)	996

Table 3: Distribution of entity types in BRAD.

"*The* ***Congress*** *was visited and received the shots and shells in all part of* ***her*** *wooden hull*".

Second, we find that annotation disagreements are more likely to occur in the interpretation of event triggers. In BRAD, we allow event triggers to involve multiple words that cause span mismatches between annotations for some confusing cases (e.g., annotating the whole phrase "*make the black man equal*" as an event trigger or annotating "*make*" and "*equal*" as two separate triggers). Another form of popular disagreement involves mismatches on event types. Consider the following sentence as an example:

"*Believing his life to be in danger, Patmon stepped back, drew his revolver, and told the fellow to surrender, or he would* ***shoot*** *him* ."

Two annotators agree that the word "*shoot*" is an event trigger. However, one annotator considers this as an event of type *Conflict_Attack* as it is a part of the conflict between the overseer ("*Patmon*") and the slave ("*fellow*", "*him*"); the other annotator, on the other hand, treats "*shoot*" as a *Humanity_Deprive* event as the overseer is threatening to kill the slave (i.e., taking the right to life).

Data Analysis: To illustrate the ambiguity in BRAD, Table 4 shows five words with the highest frequency as event triggers (i.e., Event Count), along with the percentage of times these words are labeled as event triggers in the dataset (i.e., Event Rate) (Sims et al., 2019). This table demonstrates the likelihood that words with the highest event counts might not be annotated as event triggers in BRAD, thereby necessitating EE models to find a

Word	#Event	Event Rate
war	183	23.5%
rebellion	112	47.3%
insurrection	66	78.6%
revolt	77	60.2%
emancipation	58	82.9%
take	64	32.3%
put	35	47.3%
send	25	45.5%

Table 4: Event rates of the words with the highest event counts in BRAD.

	ACE 2005	BRAD
god	4.5%	17.5%
lord	0.3%	8.7%
heaven	0.7%	8.7%
mighty	0.2%	8.7%
sacred	0.2%	9.5%
curse	0.5%	5.6%
christian	1.7%	18.3%

Table 5: Percentages of documents containing religion-related words in BRAD and ACE 2005.

method of effectively capturing context in order to perform correct predictions.

Moreover, we find extensive use of religion-related words in BRAD compared to existing EE datasets. For example, considering the words "*lord*", "*heaven*", and "*christian*", the percentages of documents in ACE 2005 containing these words are only 0.3%, 0.7%, and 1.7% while those percentages for BRAD are 8.7%, 8.7%, and 18.3% respectively. Such language difference suggests the potential need to adapt existing language models to better capture the nature of historical texts which, in turn, will facilitate a more accurate performance of EE.

3 Experiment

There are three major EE tasks that BRAD supports for historical texts, including entity mention detection (EMD), event trigger detection (ED), and event argument extraction (EAE). This section aims to reveal the complexity of the EE tasks in BRAD by evaluating the performance of existing state-of-the-art models for EE on this dataset. In particular, we focus on the following state-of-the-art models for EE that leverage the pre-trained language model BERT (Devlin et al., 2019) for the text encoding and jointly perform predictions for all EE tasks in an end-to-end fashion (i.e., joint inference):

DyGIE++ (Wadden et al., 2019): This model utilizes dynamic span graphs to exploit long-range cross-sentence relationships for span representation propagation for joint IE.

OneIE (Lin et al., 2020): This model first identifies spans of entity mentions and event triggers. The detected spans are then paired to jointly predict entity types, event types, relations, and argument roles for IE. Global features are used to capture cross-task and cross-instance dependencies and are employed in the decoding phase with beam searches to improve extraction performance.

As such, we adapt the official implementations of such models from their original papers for our EE task in BRAD by ignoring the relation extraction task and re-tuning them on the BRAD development set. For both models, we employ the pre-trained BERT model (i.e., the bert-base-cased version) to encode input texts. Besides, motivated by the language difference between historical and modern texts, we further explore a variant of the BERT model by fine-tuning it on the African American corpus via the masked language modeling task (Devlin et al., 2019). Note that we exclude the 151 documents of BRAD in this fine-tuning process. This fine-tuned BERT model will also be fed into DyGIE++ and OneIE to perform EE in BRAD.

Result: Table 6 reports the performance of the models on the test set of BRAD over five sub-tasks: Entity Mention Detection (Entity), Event Trigger Identification, i.e., not concerning event types (Trig-I), Event Trigger Classification (Trig-C), Event Argument Identification, i.e., not concerning argument roles (Arg-I), and Event Argument Classification (Arg-C). For comparison, we also include the original performance of the models on the popular EE dataset ACE 2005. There are three major observations from the table. First, the performance of current EE models on BRAD is significantly and substantially worse than those on ACE across different tasks. It thus suggests that EE for historical texts in BRAD is a challenging task and more research effort is necessary to boost the EE performance for this domain. Second, comparing the performance of the models with different versions of BERT (i.e., original vs fine-tuned), it is clear that fine-tuning BERT on historical texts is beneficial for improving the performance of EE models on BRAD (especially for OneIE where the improvement is consistent across different EE sub-tasks with large margins). This observation suggests that pre-training BERT on modern texts is unable to capture the nuance of language use in

Task	Model	ACE	BRAD			BRAD$^{\#}$		
		F1	P	R	F1	P	R	F1
Entity	DyGIE++	90.7	85.6	75.9	80.5	84.3	78.6	81.4
	OneIE	90.3	85.4	77.0	81.0	85.0	79.4	82.1
Trig-I	DyGIE++	76.5	81.5	50.1	62.0	77.4	56.9	65.6
	OneIE	78.6	80.9	47.0	59.4	80.8	52.9	63.9

	OneIE	60.7	57.7	33.9	42.7	58.9	40.4	47.9
Arg-C	DyGIE++	52.5	48.8	24.6	32.7	42.5	25.4	31.8
	OneIE	58.6	49.6	29.1	36.7	52.1	31.6	39.4

Table 6: The performance of models on the test sets of BRAD and ACE 2005. The BRAD$^{\#}$ columns report the performance with BERT fine-tuned on the African American corpus.

history, thus impairing the models and requiring appropriate adaptation to boost the EE performance. Finally, we note that the human performance (F1 scores) for Entity, Trig-C, and Arg-C on BRAD are 95.43, 88.3, and 79.8 respectively. The large performance gaps between human and current EE systems thus presents many research opportunities for future work on BRAD.

4 Related work

Prior work in NLP for historical texts has mainly focused on spelling and text normalization (Pettersson et al., 2014; Bollmann et al., 2017; Flachs et al., 2019). Recently, some studies have undertaken research on historical texts with NLP tasks such as POS tagging (Yang and Eisenstein, 2016) and information extraction (Pettersson et al., 2016). However, none of this work has explored EE.

EE is an active research area due to the availability of EE datasets e.g., for general (Walker et al., 2005; Mitamura et al., 2015) and biomedical (Kim et al., 2011) domains. Most of prior studies focus on in-domain EE (Ahn, 2006; Li et al., 2013; Nguyen and Grishman, 2015; Chen et al., 2015; Nguyen et al., 2016; Yang et al., 2019; Wadden et al., 2019; Lai et al., 2020c; Nguyen et al., 2021). Some recent studies in EE have also addressed extensible learning settings for EE to new event types, e.g. zero-shot learning (Huang et al., 2018), few-shot learning (Lai et al., 2020a,b), or new domains (Naik and Rosé, 2020). The closet works to ours involve recent efforts to create new datasets for EE (Satyapanich et al., 2020; Ebner et al., 2020; Wang et al., 2020; Trong et al., 2020; Le and Nguyen, 2021). However, these works do not consider historical texts as we do.

6 Conclusion

We present BRAD, a new dataset for EE on historical texts that focuses on Black rebellions in the American Africa corpus. Our experiments demonstrate the poor performance of current models for EE on BRAD compared to those on modern texts, thus creating room for future research on EE for historical texts. We also illustrate one approach to improve current EE systems for historical texts via fine-tuning existing pre-trained language models. In the future, we plan to enlarge our datasets with more annotated documents and event types.

Type	Description	Examples
LAW Propose	A PROPOSE event occurs when an actor (Agent) introduces a bill, proposition, or treaty which benefits a group of people (Beneficial).	Below we give the salient points of the bill of an entertainment recently **given** in the interest of a certain church about to be organized in a certain town in New Jersey. The bill **introduced** in Congress last week by the congressman from North Carolina , to abolish the 15th amendment. It 's only effect will be to create support for the bill of congressman Crumpacker which **proposes** a reduction of representation in those States
LAW Approve	An APPROVE event occurs when a bill or order (Object) is passed by either the head of the government or a representative committee (Agent).	Be it **enacted** by the General Assembly of Maryland. Vermont has **passed** her Liberty Bill , New York has under discussion , and Massachusetts will soon report and **pass** her Act . But it is said that for the Government to **adopt** the abolition policy, would involve the loss of the support of the Union men of the Border Slave States.
LAW Repeal	A REPEAL event occurs when an active law (Object) is completely repealed by a state actor (Agent).	... that I determined to revoke the act of the Federal Constituent Assembly , whereby Slavery was **abolished**. Even the New York Tribune protests against making this war for the **destruction** of slavery, and insists that such a war would alienate a large body of the Northern people at present who adhere to the Government in the prosecution of the war. They want to se the Government march a powerful array into the traitorous States, proclaim liberty to every slave, and **wipe out** the last vestige of that barbarous system from the land ...
CONFLICT Protest	A PROTEST event occurs when people (Agent) come into a public area to demand some action. PROTEST events include, but are not limited to, protests, sit-ins, and riots as the result of a previous protest.	Almost simultaneously with the appearance of the minstrels there arose from every kennel in the neighborhood timely protest **barked** forth vigorously by a hundred curs, who, in common with their masters, cursed their common luck. It has attempted to supplant Government with anarchy, and the fury of a brutal **mob** for the beneficent operation of law, and the legally appointed law-makers. ...while the majority of the men were absent at a public **demonstration** at Myrtle-avenue Park, in another part of the city.
CONFLICT Attack	An ATTACK event occurs when a person or a organization (Agent) performs an violent act causing harm or damage to another person or organization (Patient).	Make the slave first, midst, and last Follow no longer the partial and side issues; **strike** for the abolition of slavery. . . . and hovering about Williamsport in an unaccountable manner - while the rebel troops are **burning , destroying** , pressing loyal men into service , or driving them from the houses they hoped to possess , and the wheat-fields they expected to reap , under the protecting folds of the Federal flag . The States which **rebelled** , after having been most thoroughly **whipped** in a great war , came back into the Union upon their promises to abide by the Constitution and Laws of the same .
CONFLICT Injure-Die	A Injure-Die event is defined as a death or wound of a person (Patient) which is the result of a violence event by another person (Agent).	The life of loyal men are being **sacrificed** by scores, and will, by and by, be **sacrificed** by thousands. Why should the nation **pour out its blood** and lavish its treasure by the million, consent to protect and preserve the guilty cause of all its troubles? Our loss is estimated at two hundred **killed** and **wounded**.

Table 7: Event types with their descriptions and examples in the BRAD dataset (to be continued in Table 8). Event trigger words are shown in bold.

Type	Description	Examples
CONFLICT Other	Conflict Other events are reserved for events that are related to conflicts, but not classified as one of the conflict event types above, including declaring war, threatening someone, forming an army, a movement, and a march.	Let the slaves and free colored people be **called into service**, and **formed** into a liberating army, to march into the South ... Their efforts in this direction have been crowned by entire **success**. He had **called** loud and earnestly upon the Government for reinforcements; but the Government was practically deaf to the **call**, and left him and his brave companions either to perform a miracle, or to be completely overwhelmed by superior numbers.
JUSTICE Arrest-Jail	An Arrest-Jail Event occurs when the movement of a person (Patient) is constrained by a state actor (Agent).	It appears that he obtained his information direct from German where a supposed agent of the company had been **arrested**, having in his possession incriminating documents. It is said to be possible to **imprison** a man for debt in Massachusetts. He **put her in jail** at Eastville and she stayed there for some time .
JUSTICE Sentence	A SENTENCE Event takes place when a punishment for a person or an organization (Patient) is issued by a state actor (Agent).	... and any person so offending shall be guilty of a felony, and shall, on conviction, be **sentenced to confinement** in the penitentiary of this State, for a period not less than ten nor more than twenty years from the time of **sentence** pronounced on such person. If any slave or servant be convicted or any crime the punishment whereof may be death or **confinement** in the penitentiary ..., but that it has been promptly put down and the guilty parties summarily **punished**.
JUSTICE Execute	An EXECUTE Event occurs when the life of a person (Patient) is taken by a state actor (Agent).	Hector Grant James Horney, and Esther Anderson, white servants, were **executed** at Chester, Kent county. All these , if the demand of the Administration and its friends is gratified , are to be **hanged** ; for the **punishment** of treason by our law is **death** , ... He made some confessions, and managed finally to escape, but was arrested, taken to El Dorado, tried, and **shot** - not, however, by regular process.
HUMANITY Deprive	An DEPRIVE Event occurs when someone's right (Patient) is taken away, disrespect, or discouraged in any form of expression including but not limited to law, action, and statement.	We thank Dr. CROFTS for the assurance of his sympathy, and hope often to receive his earnest words in behalf of our **enslaved** people. Before the **slaved** is freed, this and a hundred other plans will be critically canvassed , and the discussion of each will elicit some truth . ... shall the four millions slaves , now **robbed** of all their rights, and **degraded** to a level with brute beast...
HUMANITY Endow	An ENDOW Event occurs when someone's right is enriched or appreciated in any form of expression including but not limited to law, action, action and statement.	And as for lynching - let all the officers of the law, with all the powers of the law, **defend** the rights and life of every prisoner. Before the slaved is **freed** , this and a hundred other plans will be critically canvassed They are going into every community which **offers freedom** and **protection** to their citizens , where law is justly administered and where the rights of man are **respected** ; and there are many such sections in this country ; there will be the future homes of the Negroes .

Table 8: Event types with their descriptions and examples in the BRAD dataset. Event trigger words are shown in bold.

Event	Argument Role	Entity Type	Description	Examples
LAW Propose	Agent	PER ORG	The person or organization who proposes the law	The resolutions were **proposed** by the gentleman from Ohio. Slavery has been **brought** into the House.
	Beneficiary	PER ORG	The person or organization who benefits from the proposal	
	Object	DOC	The proposed law	
	Time	TIME	When the proposal takes place	
	Location	GPE	Where the proposal takes place	
LAW Approve	Agent	PER ORG	The person or organization who approves the law	Freedom to the slave should now be **proclaimed** from the Capitol. The act was duly **approved** by the Executive, published, and announced to the civilized words.
	Beneficiary	PER ORG	The person or organization who benefit from this approval	
	Object	DOC	The approved law	
	Time	TIME	When the approval takes place	
	Location	GPE	Where the approval takes place	
LAW Repeal	Agent	PER ORG	The person or organization who repeals the law	They shall **strike down** Slavery. ... we can not see why the institution of private property was to be **abolished**.
	Beneficiary	PER ORG	The person or organization who benefits from this repeal	
	Object	DOC	The repealed law	
	Time	TIME	When the repeal takes place	
	Location	GPE	Where the repeal takes place	
CONFLICT Protest	Agent	PER ORG	The person or organization who protests	The red cap was **paraded** through Cape Haytien. The men were present at a public **demonstration** in Brooklyn.
	Patient	ORG	The organization that the agent protest against	
	Time	TIME	When the protest takes place	
	Location	GPE	Where the protest takes place	
CONFLICT Attack	Agent	PER ORG	The attacking person or organization	Fremont is **scouring** the rebels beyond the borders of Missouri. On Wednesday morning the rebels prepared to **storm** our works in Plymouth.
	Patient	PER ORG	The target of the attack	
	Time	TIME	When the attack takes place	
	Location	GPE	Where the attack takes place	
CONFLICT Injure-Die	Agent	PER ORG	The person or organization who attempts to attack or kill	They **cut** men **in half**, and pieces from exploded shells, **killed** and **wounded** several. Most of the negroes, we regret to hear, are said to have been **massacred**.
	Patient	PER ORG	The person or organization who is injured or dead	
	Time	TIME	When the injury/death takes place	
	Location	GPE	Where the injury/death takes place	

Table 9: Descriptions and examples of argument roles for each event type in the BRAD dataset (to be continued in Table 10). Event triggers are bold and underlined. Arguments are highlighted using colors that match with their roles.

Event	**Argument Role**	**Entity Type**	**Description**	**Examples**
CONFLICT Other	Agent	PER ORG	The acting person or organization	The poor men of the South have been **pressed into the army** to fight the battle of slavery.
	Patient	PER ORG	The person or organization who is the object of the act	
	Time	TIME	When the action takes place	
	Location	GPE	Where the action takes place	
JUSTICE Arrest-Jail	Agent	PER ORG	The arresting agent or jailer	A few weeks ago, a man named Hancock was **arrested** in Union county, Arkansas. Several free colored men were **captured** with the rebels in Fort Fisher.
	Patient	PER	The person who is arrested	
	Time	TIME	When the arrest/jail takes place	
	Location	GPE	Where the arrest/jail takes place	
JUSTICE Sentence	Agent	PER ORG	The judge or court	It has been represented there are **confined** in the Government jail forty-five prisoners, who are not charged with crime, but are represented as being slaves
	Patient	PER ORG	The person who is sentenced	
	Time	TIME	When the sentencing takes place	
	Location	GPE	Where the sentencing takes place	
JUSTICE Execute	Agent	PER ORG	The person/organization who orders or carry out the execution	A man by the name of Martin. was tried in El Dorado on a similar charge and **hanged**. They seized him, and being then convinced of his guilt, **shot** him in the woods
	Patient	PER	The person who is executed	
	Time	TIME	When the execution takes place	
	Location	GPE	Where the execution takes place	
HUMANITY Endow	Agent	PER ORG	The person/organization who endows the patient	It is our right to **liberate** the slaves of an enemy. ... and **give freedom** to persons held to labor in the slave states.
	Patient	PER	The person who is endowed	
	Time	TIME	When the endowment takes place	
	Location	GPE	Where the endowment takes place	
HUMANITY Deprive	Agent	PER ORG	The person/organization who deprives the patient	They have **outraged**, and **robbed**, and **murdered** our peaceful citizens. ... by the atrocities of the rebels **delivering back into bondage** thousands of slaves .
	Patient	PER	The person who is deprived	
	Time	TIME	When the deprivation takes place	
	Location	GPE	Where the deprivation takes place

Abstract

Medical entity retrieval is an integral component for understanding and communicating information across various health systems. Current approaches tend to work well on specific medical domains but generalize poorly to unseen sub-specialties. This is of increasing concern under a public health crisis as new medical conditions and drug treatments come to light frequently. Zero-shot retrieval is challenging due to the high degree of ambiguity and variability in medical corpora, making it difficult to build an accurate similarity measure between mentions and concepts. Medical knowledge graphs (KG), however, contain rich semantics including large numbers of synonyms as well as its curated graphical structures. To take advantage of this valuable information, we propose a suite of learning tasks designed for training efficient zero-shot entity retrieval models. Without requiring any human annotation, our knowledge graph enriched architecture significantly outperforms common zero-shot benchmarks including BM25 and Clinical BERT with 7% to 30% higher recall across multiple major medical ontologies, such as UMLS, SNOMED and ICD-10.

1 Introduction

Entity retrieval is the task of linking mentions of named entities to concepts in a curated knowledge graph (KG). This allows medical researchers and clinicians to search medical literature easily using standardized codes and terms to improve patient care. Training an effective entity retrieval system often requires high quality annotations, which are expensive and slow to produce in the medical domain. It is therefore not feasible to annotate enough data to cover the millions of concepts in a medical KG, and difficult to adapt quickly enough to those newly appeared medical conditions and drug treatments under a public health crisis. Hence, a robust medical entity retrieval system is expected to have decent performance in a zero-shot scenario.

Zero-shot retrieval is challenging due to the complexity of medical corpora - large numbers of ambiguous terms, copious acronyms and synonymous terms. It is difficult to build an accurate similarity measure which can detect the true relatedness between a mention and a concept even when their surface forms differ greatly.

Early entity retrieval systems use string matching methods such as exact match, approximate match (Hanisch et al., 2005) and weighted keyword match e.g. BM25 (Wang et al., 2020). Although annotated training data is not required, such systems typically lack the ability to handle synonyms and paraphrases with large surface form differences. In recent years, large scale pretraining (Devlin et al., 2019) has been widely adopted in the medical domain such as Clinical BERT (Alsentzer et al., 2019) and BioBERT (Lee et al., 2019). Agarwal et al. (2019) also integrates graph structure information during pretraining. Most of them, however, require a finetuning step on annotated training data (Wu et al., 2020) before being applied to entity retrieval.

As an alternative to manually annotating a corpus, the rich semantics inside a KG itself can be utilized (Chang et al., 2020). One important entry is the **synonym**, whereby two medical terms may be used interchangeably. In addition, the **graphical structure** of a KG contains information on how concepts are related to each other and so can be used as another valuable resource for building an effective similarity measure. We therefore design *synonym-based tasks* and *graph-based tasks* to mine a medical KG. Trained with our proposed tasks, a simple Siamese architecture significantly outperforms common zero-shot benchmarks across multiple major medical ontologies including UMLS, SNOMED and ICD10.

Our contributions are as follows. (1) We pro-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2401–2405
August 1–6, 2021.

pose a framework which allows the information in medical KGs to be incorporated into entity retrieval models, thereby enabling robust zero-shot performance without the need of human annotations. (2) We apply the framework to major medical ontologies and conduct extensive experiments to establish the effectiveness of our framework. (3) When annotations are available, we show that the proposed framework can be easily plugged into an existing supervised approach and in so doing, deliver consistent improvements.

2 Formulation

Entity retrieval. Given a *mention* $\boldsymbol{m}$ and a *concept* $\boldsymbol{c} \in KG = \{c_1, c_2, ..., c_n\}$, the goal is to learn a similarity measurement $S(\boldsymbol{m}, \boldsymbol{c})$, so that the most relevant concept is assigned the highest score. A concept is also referred to as a *node* in a KG. We use them interchangeably below.

Zero-shot entity retrieval. We examine two zero-shot scenarios: 1) *zero-shot on mentions only*, which assumes unseen mentions but allows seen concepts at test time. 2) *zero-shot on mentions and concepts*, which assumes both to be unseen at test time.

3 Model Architecture

Siamese architecture. Mention $\boldsymbol{m}$ and concept $\boldsymbol{c}$ are firstly embedded into vectors, using a shared function T: $\vec{e_m} = T(\boldsymbol{m}), \vec{e_c} = T(\boldsymbol{c})$. T is also referred to as an encoder, for which we use the Transformer (Vaswani et al., 2017) encoder in this work. Similarity between a mention and a concept is then measured as the inner product: $S(\boldsymbol{m}, \boldsymbol{c}) = \langle \vec{e_m}, \vec{e_c} \rangle$.

Optimization. Assume model parameter is θ. We use in-batch negatives for optimization. Loss function for a batch of size B is defined as mean negative log likelihood:

$$L = -\frac{1}{B} \sum_{i=1}^{B} \log(P((\boldsymbol{m_i}, \boldsymbol{c_i})|\theta))$$

where the conditional probability of each mention-concept pair $(\boldsymbol{m_i}, \boldsymbol{c_i})$ in the batch is modeled as a softmax:

$$P((\boldsymbol{m_i}, \boldsymbol{c_i})|\theta) = \frac{\exp(S_\theta(\boldsymbol{m_i}, \boldsymbol{c_i}))}{\sum_{j=1}^{B} \exp(S_\theta(\boldsymbol{m_j}, \boldsymbol{c_j}))}$$

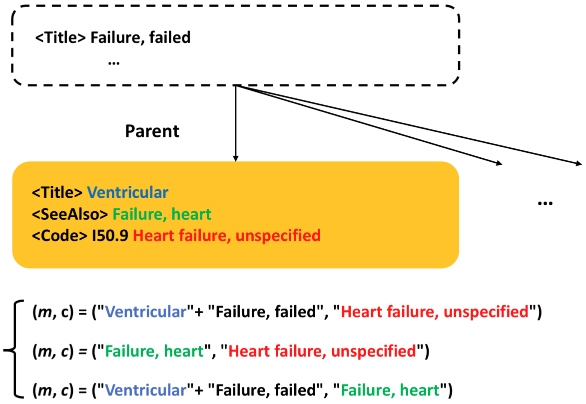

Figure 1: ICD-10 synonym-based task defined at an example node

4 Learning Task

We design our learning tasks by constructing mention-concept pairs $(\boldsymbol{m}, \boldsymbol{c})$. The goal is to capture multiple layers of semantics from a KG by leveraging its unique structure. Since each structure implies its own measure of similarity, we design learning tasks by finding very similar or closely related textual descriptions and use them to construct $(\boldsymbol{m}, \boldsymbol{c})$ pairs. We define two major types of tasks: *synonym-based* tasks and *graph-based* tasks. These are illustrated below for three major medical KG: ICD-10, SNOMED and UMLS.

4.1 ICD-10

The 10th version of the International Statistical Classification of Diseases, Clinical Modification (ICD-10) is one of the most widely used terminology systems for medical conditions. It contains over 69K concepts, organized in a tree structure of parent-child relationships.

Synonym-based task. In ICD-10, a child node is a more specific medical condition compared to its parent (e.g. `R07.9 Chest pain, unspecified` is a child of `R52 Pain, unspecified`). Each node N_i has three sections: The *Title* section contains a sub-specifier (e.g. `Chest`) of the title of the parent (e.g. `Pain`), therefore their concatenation gives the full concept description (e.g. `Chest Pain`). We denote it by $N_i^{TitleConcatenation}$. The *Code* section contains an ICD-10 code and its formal medical definition, denoted by $N_i^{CodeDescription}$. The *SeeAlso* section contains a similar concept, denoted by $N_i^{SeeAlso}$.

These three sections describe the same medical condition with different surface forms, therefore we define the ICD-10 synonym-based task as:

$$\boldsymbol{m} = N_i^L, \boldsymbol{c} = N_i^R$$

$$N_i^L, N_i^R \in \{N_i^{TitleConcatenation},$$

$$N_i^{CodeDescription}, N_i^{SeeAlso}\}, L \neq R$$

We illustrate it with an example in Figure 1.

Graph-based task. To incorporate the semantics of parent-child relationships into learning, we define ICD-10 graph-based task as:

$$\boldsymbol{m} = N_i^{CodeDescription}, \boldsymbol{c} = N_j^{CodeDescription}$$

$$N_i.is\_parent(N_j)$$

4.2 SNOMED

Systematized Nomenclature of Medicine – Clinical Terms (SNOMED) is a standardized clinical terminology used for the electronic exchange of clinical health information with over 360K active concepts.

Synonym-based task. Each node N_i in SNOMED has multiple synonymous descriptions $\{l_i^1, l_i^2, ..., l_i^d\}$, with l_i^1 as the main description. We therefore define SNOMED synonym-based task as:

$$\boldsymbol{m} = l_i^p, \boldsymbol{c} = l_i^q, p > q$$

$\frac{d*(d-1)}{2}$ unique $(\boldsymbol{m}, \boldsymbol{c})$ pairs are constructed at each node.

Graph-based task. SNOMED is a directed graph with 107 possible relationship types (e.g. `is_a`, `finding_site`, `relative_to`). A direct connection between two nodes is likely to imply a certain degree of similarity, thus we define the SNOMED graph-based task as:

$$\boldsymbol{m} = l_i^1, \boldsymbol{c} = l_j^1$$

$$N_i.is\_connected(N_j)$$

4.3 UMLS

The Unified Medical Language System (UMLS) is a compendium of a large number of curated biomedical vocabularies with over 1MM concepts. UMLS has almost the same structure as SNOMED, therefore we define the **synonym-based task** and **graph-based task** in a similar fashion to that of SNOMED.

For each task mentioned above, the $(\boldsymbol{m}, \boldsymbol{c})$ pairs generated at each node are combined and split into train and dev in a 80:20 ratio. We also define a **comb task**, where all the tasks are firstly down-sampled to equal sizes and then combined. A summary can be found in Table 1.

KG	Task Type	Train	Dev
ICD-10	syn	113K	28K
	graph	33K	8K
SNOMED	syn	1.4M	374K
	graph	955K	238K
UMLS	syn	27M	7M
	graph	7M	2M
Comb *(by down-sampling)*		198K	488K

Table 1: **Task Description**: Number of $(\boldsymbol{m}, \boldsymbol{c})$ pairs in train and dev for all tasks.

Dataset	Split	KG	Test size
MedM.	-	UMLS	66,572
COMETA	SG	SNOMED	4,350
	SS		4,369
	ZG		3,995
	ZS		4,283
3DNotes	ICD	ICD-10	5,742
	SN	SNOMED	7,521

Table 2: **Test Set Size.**

5 Datasets

We include three datasets in zero-shot evaluations. **MedMention** (Mohan and Li, 2019) is a publicly available corpus of 4,392 PubMed[1] abstracts with biomedical entities annotated with UMLS concepts. **COMETA** (Basaldella et al., 2020) is one of the largest public corpora of social media data with SNOMED annotations. It provides four train, dev, test splits: Stratified-General (SG), Stratified-Specific (SS), Zeroshot-General (ZG), Zeroshot-Specific (ZS). We also use a de-identified corpus of dictated doctor's notes named **3DNotes**(Zhu et al., 2020). It has two sets of annotations: one with ICD-10 (ICD split), another with SNOMED (SN split). The annotation follows the i2b2 challenge (Uzuner et al., 2011) guidelines.

Zero-shot performance is evaluated on the corresponding test sets. We report sizes of the test sets in Table 2.

6 Experiments

6.1 Experimental Settings

We train a model using each task and evaluate them across all test sets. Performance is compared against two common zero-shot entity retrieval benchmarks: BM25, and BERT encoder followed by inner-product similarity. For the latter, we tested multiple pre-trained versions including $\text{BERT}_{\text{base}}$, Clinical BERT and BioBERT.

Table 3: Retrieval performance R@1(25). Siamese architecture trained with our tasks are shown to significantly outperform benchmarks. Evaluation for *zero-shot on mentions only* is highlighted in **bold** the rest belongs to *zero-shot on mentions and concepts*. The former enjoys a bigger gain as expected.

Mention	Gold Concept	Syn	Graph
shortness of breath	dyspnea (finding)	✓	✗
GI hemorrhage	gastrointestinal hemorrhage (disorder)	✓	✗
coronary structure	coronary artery (body structure)	✗	✓
heart	heart structure (body structure)	✗	✓

Table 4: Prediction error of the model trained with SNOMED tasks evaluated on 3DNotes-SN.

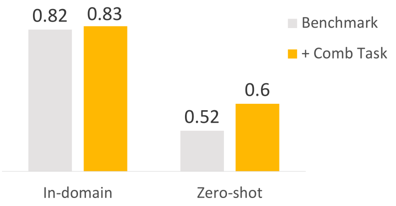

Figure 2: R@25. Using the *comb* task as an auxiliary to the primary supervised loss, the model gains 1% in-domain (3DNotes-SN) improvement , 8% zero-shot (COMETA-ZS) improvement.

Hyperparameters. For our Siamese architecture, the transformer encoder is initialized with $\text{BERT}_{\text{base}}$. We use the BertAdam optimizer with a batch size of 128, the initial learning rate of 3×10^{-5}, warm-up ratio of 0.02, max epochs of 50, followed by a linear learning rate decay.

Evaluation metrics. Top-k retrieval recalls (R@1, R@25) are used as metrics. We also assume that each mention has a valid gold concept in the KG.

6.2 Results

We report overall results in Table 3. Clinical BERT consistently outperforms the other pre-trained counterparts, which are therefore omitted. For evaluations of *zero-shot on mentions only* (e.g. UMLS tasks evaluated on MedMention which is UMLS annotated), we observe 12% to 45% gain for R@1 compared to benchmarks. For evaluations of *zero-shot on mentions and concepts* (e.g. UMLS tasks evaluated on COMETA which is SNOMED annotated), 7% to 30% higher R@1 is observed. *Comb* task has the most balanced performance gains across all datasets.

6.3 Analysis and Discussion

Task comparison. To further understand the difference between synonym-based tasks and graph-based tasks, we illustrate qualitative examples in Table 4. A model trained using the synonym task makes better predictions for scenarios involving medical synonyms and acronym (lines 1, 2). A model trained using the graph task performs better when mention and concept have an `is_a` relationship (lines 3, 4).

Auxiliary task. When annotations are available, our learning tasks can be used as an auxiliary to the primary loss. Using the 3DNotes-SN's annotated training set to train the primary supervised task, we set the *comb* task as its auxiliary counterpart by summing the losses. We evaluate zero-shot performance on COMETA-ZS. We observe an 8% increase in R@25, illustrated in Fig. 2. Since most annotations cover no more than a couple thousands concepts, which is a tiny portion of a typical medical KG's size, this demonstrates the generalizing capacity of our approach on the vast majority of unseen concepts.

Private KG. In practice, if the target medical ontology is a private KG (Wise et al., 2020; Bhatia et al., 2020), one can also consider customizing the learning tasks that follow the synonym and graph-based frameworks outlined in this work to bring greater gains.

7 Conclusion

We present a framework for allowing entity retrieval models to mine rich semantics from a medical KG. We show its effectiveness in zero-shot settings through extensive experiments. In addition, we demonstrate the ease with which the framework can be adapted to serve as an auxiliary task when annotations are available. Future research should explore more fine-grained approaches to combine tasks.

Abstract

Traditional toxicity detection models have focused on the single utterance level without deeper understanding of context. We introduce CONDA, a new dataset for in-game toxic language detection enabling joint intent classification and slot filling analysis, which is the core task of Natural Language Understanding (NLU). The dataset consists of 45K utterances from 12K conversations from the chat logs of 1.9K completed *Dota 2* matches. We propose a robust dual semantic-level toxicity framework, which handles utterance and token-level patterns, and rich contextual chatting history. Accompanying the dataset is a thorough in-game toxicity analysis, which provides comprehensive understanding of context at utterance, token, and dual levels. Inspired by NLU, we also apply its metrics to the toxicity detection tasks for assessing toxicity and game-specific aspects. We evaluate strong NLU models on CONDA, providing fine-grained results for different intent classes and slot classes. Furthermore, we examine the coverage of toxicity nature in our dataset by comparing it with other toxicity datasets.[1]

1 Introduction

As the popularity of multi-player online games has grown, the phenomenon of in-game toxic behavior has taken root within them. Toxic behavior is strongly present in recent online games and is problematic to the gaming industry (Adinolf and Turkay, 2018). For instance, 74% of US players of such games report harassment with 65% experiencing severe harassment. (ADL, 2019).

In the past few years, Natural Language Processing (NLP) researchers have proposed several online game/community toxicity analysis frameworks (Kwak et al., 2015; Murnion et al., 2018; Wang et al., 2020) and datasets (Märtens et al., 2015; Stoop et al., 2019). However, existing datasets (1) focus only on the single utterance level without deeper understanding of context in the whole conversation/chat, and (2) do not explicitly use semantic clues from the words within the utterance.

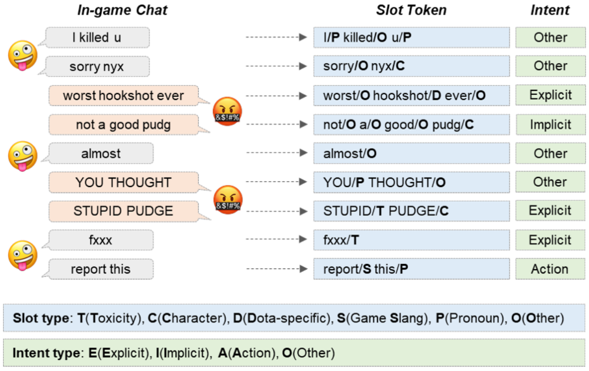

Figure 1: An example intent/slot annotation from the CONDA (CONtextual Dual-Annotated) dataset.

The chat in online games and communities is similar in nature to spoken language, an area studied by Natural Language Understanding (NLU). NLU research aims to best represent human communication by extracting semantic structure in the form of intent and slot analysis. Intent detection is the classification of the desired outcome of an utterance (or sentence), and slot filling is the labeling of each token (or word) in the utterance with the type of semantic information it carries. In recent literature, these two tasks are trained jointly to capture synergies between them, and these jointly trained models give better results (Zhang et al., 2019b). Furthermore, researchers have made available joint task datasets that contain the context of a multi-turn conversation (Budzianowski et al., 2018; Schuster et al., 2019)

Inspired by this NLU research progress, we

propose CONDA, an in-game toxicity detection dataset, with a robust dual-level annotation which enables intent detection and slot filling. Our dataset consists of 45k utterances from the chat logs of 1.9k *Dota 2* matches, labeled with 4 intent classes and 6 slot classes to address toxicity and the game-specific vocabulary. Figure 1 illustrates an example of CONDA including raw data (in-game chat) and processed data with slot and intent labels. In order to enable the dual semantic-level framework, we conduct lexicon-based automation for token-level data and human annotation for utterance-level data.

We investigate the CONDA dataset through an in-depth analysis. The large portion of game-specific classes in the dual levels enables the dataset to be more sophisticated in detecting toxicity in games. The combination of each intent with each slot class shows that dual annotation can help determine toxicity from gamer slang when used in both toxic and non-toxic situations. We also find more toxic utterances appear pre-game and post-game rather than during the games, especially peaking post-game due to the chat for post-victory celebration and recrimination.

We provide five strong baseline NLU models and compare the toxicity detection performance over our dataset. For evaluation, we apply four NLU metrics to assess performance in toxicity and game specific aspects. Results vary across models, indicating a challenge for improvement. Furthermore, we perform a transfer learning experiment with existing toxicity datasets. We find that the nature of toxicity in our dataset can generalize to other proposed taxonomies, including hatefulness, sexism and racism. Beyond this commonality, our experiment illustrates that CONDA is distinguished from other toxicity datasets due to game-specific characteristics. This paper then makes the following contributions:

- To the best of our knowledge, this is the first attempt to build a toxicity detection dataset with joint Natural Language Understanding aspects of intent classification and slot filling;
- We propose a robust dual semantic-level toxicity framework, which handles utterance and token-level patterns with rich in-game chatting history;
- We formalise NLU metrics for toxicity detection, evaluate strong NLU models on our dataset, and further conduct transfer learning experiments with other toxicity datasets.

2 Related Work

Toxicity Datasets in Online Games In multiplayer online games, prior research focused on analysis of anti-social or disruptive behavior, so-called toxic behavior (Blackburn and Kwak, 2014; de Mesquita Neto and Becker, 2018) including cyberbullying (Kwak et al., 2015) and griefing (Murnion et al., 2018). Although these terms contain similar elements, a single definition of toxic behavior is yet to emerge. Some studies have conducted data annotation using pre-defined lexicon categories (Märtens et al., 2015) or toxic player information (Stoop et al., 2019). These annotation methods are not robust enough to handle unlabelled toxicity words or unreported toxic players.

Toxicity Datasets in Online Community An extensive body of work has focused on datasets to detect toxicity including hate speech (Waseem and Hovy, 2016; Davidson et al., 2017; ElSherief et al., 2018) and abusive language (Nobata et al., 2016; Founta et al., 2018). However, the majority of toxicity datasets do not consider the context of a conversation, instead simply analysing a single utterance. Even if a model uses contextual information (Gao and Huang, 2017), it is limited to meta-information (e.g. news title or user name) which is not sufficient to understand a conversation. In our research, context is defined as linguistic contextual information, particularly previous single or multiple utterances. Along similar lines, recent studies have focused on conversation aiming to discover warning signals (Zhang et al., 2018), to generate intervention responses (Qian et al., 2019), or to measure the importance of context (Pavlopoulos et al., 2020). Existing toxicity datasets mainly focus on annotating at utterance-level, whereas ours conducts a dual-level annotation at utterance and token-level, while also providing a conversation history (see Table 1). These extra features are what distinguish CONDA.

NLU Datasets and Models In-game chat has similar characteristics to multi-turn dialogue in NLU. The approaches used in multi-turn dialogue analysis have not yet been observed in toxicity datasets. In NLU, generally, intent classification (IC) is treated as a semantic utterance classification task and slot filling (SF) is treated as a sequential token labelling task (Zhang and Wang, 2016). By conducting a joint model for the two tasks, a synergistic effect can be achieved (Zhang et al.,

Dataset	Approach	Domain	Labels	Conv.
(Märtens et al., 2015)	utterance-level	Game (Dota 2)	toxic, non-toxic	N
(Waseem and Hovy, 2016)	utterance-level	Twitter	racist, sexist, normal	N

2019b). To build multi-turn dialogue datasets, most studies have recruited workers via crowd-sourcing to collect task-oriented dialogues across different domains (e.g. in-car assistant (Eric et al., 2017), navigation and events (Gupta et al., 2018), multi-domains (Budzianowski et al., 2018), personal notifications (Schuster et al., 2019)). Recently, deep learning models have also been extensively studied in order to capture the contextual signals from multiple sequential inputs. (e.g. BiLSTM with attention (Wang et al., 2019), GRU with self-attention and context-fusion (Gupta et al., 2019). The models listed all show an increase in semantic detection performance when the context is included in the analysis.

3 CONDA

3.1 Data Collection

Our annotated dataset, CONDA, is based on the *Defense of the Ancients 2 (Dota 2)* data dump available at Kaggle[2]. *Dota 2* is a multiplayer online game where teams of five players attempt to destroy their opponents' ancient structure. The raw data is compiled from game matches including players, duration, match outcomes, and complete chat logs. In order to curate data, we select 50,000 utterances in complete chat logs from 1,921 matches.

3.2 Data Processing

Our data processing is designed to enable dual annotation, making utterance-level data suitable for human annotators and generating token-level data for lexicon-based automation. The main processes are creation of conversations, restructuring utterances while keeping original context, and generation of tokens.

We generate conversations to give human annotators a context of previous utterances when labelling the current utterance. We identify the beginning of a conversation as the first utterance in the match, or an utterance that occurs greater than 60 seconds after the previous utterance in the match. While the raw data is largely in English, other languages appear occasionally including Russian, Chinese, Spanish, etc. We exclude conversations with chat in non-English.

For the utterance-level data, we maintain the original form such as punctuation and case in order to keep context. In addition, we merge consecutive utterances by a single user within a conversation. These are combined into one utterance with a special token, [SEPA], added to denote the separation point (e.g. *'easiest [SEPA] game [SEPA] of my life'*). For the token-level data, we use contraction restoration (e.g. *'I'm' -> 'I am'*), whitespace tokenise each utterance, retain emoticons, but remove punctuation. This token-level processing is used for lexicon-based automated slot annotation.

Our final CONDA dataset (Table 2) consists of 44,869 utterances and 1,921 matches. We further create a subset, equivalent to about 10% of the full dataset, for a preliminary round of utterance-level annotation.

Dataset Feature	CONDA
Matches	1,921
Conversations	12,152
Utterances	44,869
Avg. utterances per match	23.3

Table 2: CONDA statistics.

---

3.3 Annotation

Dual Aspects Inspired by NLU, we provide a dual-level annotation approach to detect toxicity, which often relies on context. This allows one to find toxic intent even though an utterance does not contain any toxic words, or to determine non-toxic intent even if an utterance has toxic words. For example, Figure 1 shows an utterance *"not a good pudg"*, which does not contain any toxic words. However, considering the previous utterance of *"worst hookshot ever"*, we can identify hidden or implicit toxicity. As an example of the other way around, an utterance of *"happy fuck you day"* contains a toxic word but it is used for cheering after saying *"gg" (good game).*

Token-level Slot Annotation With the processed token-level data, an automated slot labelling is performed. Initially, we create six distinct slot labels: T (**T**oxicity), C (**C**haracter), D (**D**ota-specific), S (game **S**lang), P (**P**ronoun) and O (**O**ther). To construct the **T** lexicon, we combine several toxicity lexicons (see Section 8 Ethics) and remove overlaps. We also use the supplemental data sourced by Märtens et al. (2015) for the game-related lexicons (**C, D** and **S**) and carefully modify it. The **P** lexicon (e.g. *'u', 'ur'*) is constructed by this research because in-game chat is extremely abbreviated. Then, we perform lexicon-based automation by exact matching each lower-cased token against the lexicons. Anything not matching a lexicon is labelled **O**. We contrast this with typical NLU slot labelling where a semantic concept can stretch over a span of words. In comparison to other toxicity datasets, our lexicon-based slot labelling enables deeper understanding of game context.

Utterance-level Intent Annotation Given tokens with slot labelling and utterance-level data, we perform a test run on the subset of utterances using six annotators. Four annotators are game players and two are non-game players. This preliminary round is for fine-tuning annotation policy and analysing annotator agreement to inform final annotation for the full dataset. The annotators manually classified the utterances into four labels: E (**E**xplicit toxicity), I (**I**mplicit toxicity), A (**A**ction) and O (**O**ther). The label details are explained in the annotator instructions.

Annotator Instructions Each annotator was required to consider the earlier conversation, particularly, to detect implicit toxic behavior or to identify non-toxic behavior in the utterance having toxic-labelled tokens. The annotators worked independently of one another. The guidelines for human annotators were as follows:

Explicit toxicity: Typically contains toxic word(s). The intent is to insult or humiliate others, or to make others want to leave the conversation or quit the game. There is no need to consider the context (e.g. *'fuck off'*). May include one or more of the following aspects:

- Strong toxicity - blatant insulting or disrespecting others is obviously seen in the text, normally with severely toxic wording;
- Normal toxicity - impolite, rudely worded and unreasonable comment that insults or humiliates others;
- Cursing others with the intent to insult or humiliate them (e.g. *'noob'*[3]);
- Sexual wording or talk about sex-related behavior;
- Use of negative or hateful words to describe others (e.g. *'useless'*);
- Racist language that is targeted at insulting others (e.g. *'Peruvians', 'fucking russians'*);
- Inflammatory language, insulting others and trying to start a conversational fight.

Implicit toxicity: Hidden toxicity that normally cannot be seen from the text itself. The text might be factual or even positive (e.g. sarcasm). However, based on the utterance or conversation context, the intent of insulting or humiliating others can be inferred. Typically contains no toxic word (e.g. *'u are poor dude'*).

Action: Doesn't belong to I or E, but contains an action such as report, commend, pause, stop, or exit game.

Other: Doesn't belong to I or E or A. May or may not contain toxic words. Includes curses, self-deprecation or any other emotional expression that is NOT targeted at others (e.g. *'kill the fucking helicopter'*).

Findings in Annotation The preliminary round was useful for enabling discussion around annotation. For example, we decided that the token "ez"[4]

---

[3] "Noob" is a slang term for a newcomer, commonly used to insult someone inexperienced in games.

[4] "Ez" is an abbreviation for easy. It is often used to irritate other players in games, indicating "You are just way too easy".

or its variations are an implied slur against the opposition's quality and would generally be part of an **I** label utterance. Similarly, "g" is often a contraction for "go" and would be part of an **A** label utterance. Overall, we observed that the agreement measure for utterance classification was higher for gamer annotators only (Fleiss' kappa = 0.785) versus the whole group (Fleiss' kappa = 0.755). The lower inter-rater agreement in the whole group is because non-gamer annotators have low understanding of the game context and domain-specific language. Therefore, annotation of the whole dataset was performed by gamers only. Based on our annotation guidelines, they collectively manually annotated the utterances for the full dataset.

4 Dataset Analysis

The CONDA dataset consists of 9 columns - match ID, conversation ID, player ID, player slot, chat time, utterance, slot tokens (cleaned tokens with slot labelling), intent class, and slot classes. For example, the utterance *"gg wp"* for *"good game well played"* is shown in the slot tokens column as *"gg (S), wp (S)"*. Each column is further explained in AppendiX A.

Intent	%	Mean L.
E (**E**xplicit)	13.3	6.14
I (**I**mplicit)	6.4	4.16
A (**A**ction)	6.4	4.40
O (**O**ther)	73.9	3.18
Total	**100.0**	**3.71**

Slot	%
T (**T**oxicity)	4.9
C (**C**haracter)	5.4
D (**D**ota-specific)	1.4
S (Game **S**lang)	11.2
P (**P**ronoun)	13.5
O (**O**ther)	63.6
Total	**100.0**

Table 3: Intent labelling statistics (left) and slot labelling statistics (right). % is proportion of the dataset. Mean L. is mean number of tokens after cleaning.

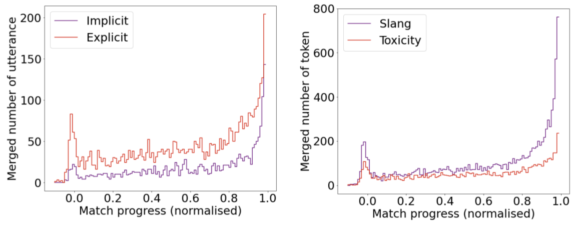
(d) Class "Other"

Table 4: Top 5 keywords in the S (game Slang) and T (Toxicity) slot classes, for each intent class. The number in brackets is the token count in that combination of classes.

Dual Annotation Proportion Table 3 gives the proportional breakdown of the CONDA dataset by intent and slot labels. Together the toxic utterance classes make up 19.7% of the data, emphasizing their prevalence in game chat. The proportion of the I (6.4%) and A (6.4%) intent classes, together 12.7% of all utterances, shows the more granular non-binary class structure captures an aspect of online games. Additionally, the average length of utterances of the E class (6.14) is greater than for each other class, indicating players strongly emphasize emotional frustration. In the proportion of slot labels, we can see the S (11.2%) class is more than double the C (5.4%) class and 8 times the D (1.4%) class, indicating general gamer slang is used for communication more than terms specific to the game being played. Overall, the large portion of these game-specific classes enables the dataset to be more sophisticated in detecting toxicity in games.

Dual Annotation Distribution To understand the effect of dual annotation on the toxicity context, we look at the distribution of the slot labels within each intent class. As seen in Figure 2b, the I intent class shows the highest proportion of the S slot class among non-O classes. Similarly, Figure 2c shows a relatively high proportion of the S slot class in the A intent class. This suggests that the combination of S slot and intent classes provides useful information because slang performs the function of carrying game-specific context. As a result, we focus more on T and S slot classes joined with other intent classes in order to investigate toxicity natures in games carried out from dual annotation.



(a) Class "Explicit, Implicit" (b) Class "Toxicity, Slang"

Figure 3: In-game chat histogram for intent (E,I) and slot (T,S) classes. Match progress is bucketed position within a match whose duration is normalised in [0,1], with <0 indicating pregame chat. Merged number of utterance/token is the count of all utterances/tokens from all matches in that match progress bin.

Keywords in Dual Annotation Table 4 shows the top 5 keywords by frequency from the T and S slot classes, for each intent class. In the combinations of S class, we observe the prominent position of "ez" in the E and I intent class. This indicates dual annotation captures toxicity from the slang largely used in games. In addition, "gg" appears in all combinations because it may have some toxicity attached via sarcasm. As dual annotation uses the conversational history, it is able to classify the same utterance in different intents.

Toxicity Analysis Over Time We further analyse in-game chat over time associated with the E, I intent classes and the T, S slot classes. As shown in Figure 3a, more toxic utterances appear pre-game and post-game rather than during the games. In pregame, sometimes players are upset due to the selected hero characters if their desired hero is taken by others, or are stressed by planning game strategies in a limited time. Toxic utterance frequency gradually rises towards the end, and peaks in post-game due to chat for post-victory celebration and recrimination. Interestingly, Figure 3b displays a similar pattern. Particularly, tokens for the S slot class increase sharply to the end, indicating significant amounts of slang are used to celebrate wins or humiliate defeated opponents.

Comparison with Other Datasets In Figure 4, we compare our dataset with other toxicity detection datasets using the metric of relative frequency of toxic utterances of each length. The datasets we compare with are **1) Waseem** (Waseem and Hovy, 2016) which consists of 16.2k tweets binary classified as racism/sexism or other, **2) FoxNews** (Gao and Huang, 2017) which is 1.5k sentences from Fox News discussion threads classified as hateful/non-hateful, and **3) StormfrontWS** (de Gibert et al., 2018) which is 10.7k conversation sentences from white supremacist website Stormfront classified as hate speech/non-hate speech. For this analysis, we merge classes into toxic/non-toxic as required. As an example of the CONDA dataset, we combine E and I intent classes into a toxic class, and A and O into a non-toxic class.

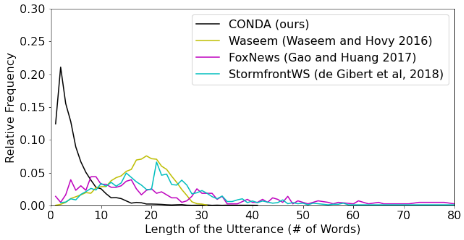


Figure 4: Distribution of toxic utterance length across similar datasets.

The distribution in CONDA is different to the other datasets in that the toxic utterances are shorter. This is due to the terseness of in-game chat during playing, with longer utterances occurring in pre-game and post-game discussion. Waseem has a particular distribution due to the character limit in Twitter (140 characters at the time). FoxNews and StormfrontWS are forums which foster the use of longer sentences.

5 Baseline Experiment

To explore the toxicity detection from an NLU perspective, we selected five baseline NLU models and compared their detection performance over our proposed dataset.

5.1 Data Preparation

We split the data into train/validation/test sets in the proportions of 0.6/0.2/0.2, or in samples 26,921/8,974/8,974. The data passed to the models is the tokenised utterances with punctuation removed, and for training the slot and intent labels.

5.2 Baseline NLU Models

The five NLU models are as follows:

- **RNN-NLU** (Liu and Lane, 2016) is an attention-based bi-directional recurrent neural network model that jointly predicts the current slot and the intent at each time step using shared hidden states and attention.
- **Slot-gated** (Goo et al., 2018) is an attention-based BiLSTM model which builds on sepa-

	Metrics												
Model	**UCA**	**U-F1(E)**	**U-F1(I)**	**U-F1(A)**	**U-F1(O)**	**T-F1**	**T-F1(T)**	**T-F1(S)**	**T-F1(C)**	**T-F1(D)**	**T-F1(P)**	**T-F1(O)**	**JSA**
RNN-NLU (Liu and Lane, 2016)	0.905	0.813	0.720	0.783	0.944	0.970	0.931	0.981	0.930	0.718	0.991	0.987	0.854

Inter-BiLSTM (Wang et al., 2018)	0.869	0.719	0.590	0.728	0.923	0.865	0.871	0.889	0.869	0.788	0.942	0.924	0.711
Capsule NN (Zhang et al., 2019a)	0.876	0.735	0.706	0.643	0.926	**0.991**	0.975	0.991	**0.982**	0.949	0.997	**0.994**	0.855
Joint BERT (Castellucci et al., 2019)	**0.921**	**0.872**	**0.768**	**0.800**	**0.954**	0.989	0.972	**0.992**	0.979	0.914	**0.998**	0.993	**0.895**

Table 5: Joint intent classification and slot labeling performance on CONDA for the five NLU baseline models. It is measured in the four multi-level metrics including: UCA (Utterance Classification Accuracy); the break-down U-F1 for each intent class - E (Explicit), I (Implicit), A (Action), O (Other); the overall T-F1 and breakdown for each slot class - T (Toxicity), S (game Slang), C (Character), D (Dota-specific), P (Pronoun), O (Other); and JSA (Joint Semantic Accuracy).

rate attended context for slot filling and intent classification while explicitly feeding the intent context into the process of slot filling via a gating mechanism.

- **Inter-BiLSTM** (Wang et al., 2018) combines two inter-connected BiLSTMs performing slot filling and intent classification respectively. The information flow between the two tasks occurs by passing the hidden states at each time step from each side to the other to support the decoding process.
- **Capsule NN** (Zhang et al., 2019a) is a capsule-based neural network that explicitly captures the semantic hierarchical relationship among words, slots and intents via a dynamic routing-by-agreement schema.
- **Joint BERT** directly utilizes the merit of pre-trained BERT (Devlin et al., 2019) and non-recursively conducts the joint prediction over the [CLS] token embedding for intent and the sequence of token embeddings for slots.

5.3 Evaluation Metrics

We propose to use the following four metrics for conducting a multi-aspect evaluation. The first two follow the existing traditional abusive language detection research for utterance level detection evaluation while the others are the metrics used for slot-level prediction evaluation and the joint task in NLU models.

(1) **UCA:** **U**tterance **C**lassification **A**ccuracy measures the sentence-level classification performance based on the ratio of the number of correctly predicted utterance to the total number of utterances.

(2) **U-F1:** **U**tterance **F1** score calculates the F1 score for each utterance class.

(3) **T-F1:** **T**oken **F1** score focuses on the prediction performance for slot tokens and calculates an F1 for each class and the token-based micro-averaged F1 score over all classes excluding label O.

(4) **JSA:** **J**oint **S**emantic **A**ccuracy measures the overall prediction performance over the semantic hierarchy. An utterance is deemed correctly analysed only if both utterance-level and all the token-level labels including Os are correctly predicted.

5.4 Implementation details

Links to the source code are given in Appendix C. For Joint BERT, Slot Gated SLU and Capsule NN, we set the number of epochs as 2, 8 and 60, respectively. For the RNN-NLU model, the global step is 1,200 and bidirectional RNN is used with the attention mechanism. For other hyper-parameters, the configuration for the best model in the official GitHub implementation of the baseline models is used. All the experiments are conducted on 16GB Tesla V100-SXM2 GPU with CUDA 10.1.

5.5 Baseline results

The experiment result is provided in Table 5. In columns 2 to 6, the metrics associated with utterance labels are shown. The UCA ranges between 0.87 (Inter-BiLSTM) and 0.92 (Joint BERT), and the U-F1 also illustrates a variance of results for each intent class. We observe that class O always achieves the highest F1 score due to its dominance in numbers throughout the dataset. Comparatively, class I presents relatively low F1 scores due to its subtle nature and reliance on understanding context. The variance in U-F1(I) implies potential improvement in implicit toxicity detection.

Columns 7 to 13 present the metrics related with token labels and show much higher overall performance than utterance labels. This indicates the lexicon-based slot automation gives underlying patterns the model can learn easily. Even so, slot class D always has a lower T-F1 score than other slot classes, indicating game-specific tokens in class D have flexible and variant forms, which increases the difficulty of detection. In the last column, the JSA which jointly handles utterance and token labels is shown. Due to the limitation on utterance level intent classification, it presents comparably low JSA scores, indicating a challenge for improvement.

Amongst the models, the non-recursive Joint BERT model performs the best due to the rich linguistic information learned in pre-training. Joint BERT has an implicit influence between the intent sub-task and the slot sub-task based on a joint loss, whereas the recursive models Slot-gated and Capsule NN have explicit influence flowing from intent to slot, leading to similar slot performance. These explicit lines of influence from one task to the other have shown to be successful in NLU and could be explored further in the toxicity detection task.

6 Transfer Experiment

We compared our dataset with the toxicity detection datasets introduced in Section 4 in terms of transfer performance over utterance-level binary prediction as toxic or non-toxic. That is, training on one dataset and testing on the others. For simplicity, we solely use the intent classification circuit of the Joint BERT as the prediction model.

6.1 Data Preparation

We combine classes into toxic/non-toxic as explained in Section 4. For each dataset, we split into train/test sets in the ratio of 0.9/0.1. The statistics for each dataset are shown in Table 6.

Dataset	**Train / Test**
Waseem	14,581 / 1,621
StormWS	9,849 / 1,621
FoxNews	1,373 / 1,095
CONDA (ours)	40,382 / 4,487

Table 6: Dataset sample counts for transfer experiment.

6.2 Transfer results

The transfer performance measured in UCA is given in Table 7. Firstly, we look at the test performance of each dataset trained on the other datasets, that is to compare results in each column. It can be seen from column 4 that CONDA's transferred performance is generally good when trained on each of the other three datasets, ranging from 0.81 to 0.83. This implies that CONDA covers the nature of toxicity that can be generalized from the other toxicity datasets which emphasize hatefulness, sexism and racism.

Changing the perspective to the rows, we compare the test performance for each dataset on a model on another dataset. StormfrontWS and CONDA perform well on Waseem, picking up the racism components there. However Waseem does not perform well when trained on either of those, suggesting their specific hate speech and game speech respectively is too focused. FoxNews training transfers the weakest results indicating its general news nature is too broad.

StormfrontWS performs well when trained on CONDA due to shared toxicity characteristics, but the performance of Waseem and FoxNews when tested on a model trained on CONDA is relatively low. We propose that this is due to two aspects of our dataset previously discussed: the specific game related nature of our language, and the shorter utterances in our set compared to the others.

		Testing			
		Waseem	StormWS	FoxNews	**CONDA**
Training	Waseem	-	0.8845	0.7287	0.8307
	StormWS	0.7118	-	0.7379	0.8329
	FoxNews	0.6931	0.8241	-	0.8056
	CONDA	0.6955	0.8748	0.6690	-

Table 7: Transfer Learning Result, UCA (Utterance Classification Accuracy).

7 Conclusion and Future Work

In this paper, we propose CONDA, a new dataset with dual-level (token and utterance) annotation for understanding in-game chat and to detect toxicity. Compared to previous studies, we draw on the NLU perspective and use the joint token-utterance aspect for detection of toxicity. Accordingly, we formalise a multi-level evaluation system. Through experiments with joint slot and intent NLU models, we show the promising potential of such models for toxicity detection utilizing the dual-level annotation. We also compare our dataset with other benchmark toxicity datasets in the literature through a transfer experiment. In future work, the automated token labelling can be manually adjusted and the size of the dataset can be expanded.

8 Ethics/Broader Impact Statement

The study follows the ethical policy set out in the ACL code of Ethics[5] and addresses the ethical impact of presenting a new dataset. In addition, it is approved by our Institutional Review Board (project number : 2019/741). As described in the data collection section, our annotated dataset, CONDA, is based on the *Dota 2* game chat where it can be accessed on Kaggle website (See Section 3.1).

For our automated slot labelling, we generated the game toxicity lexicon by taking the supplemental materials released by Märtens et al. (2015) and ElSherief et al. (2018) and the list of words banned by Google[6]. We then added variants or new toxic words found in the utterances extracted from Kaggle. For intent labelling, all volunteer annotators were recruited from academia and research students. They were informed about toxic behavior in online games before handling the data. Our instructions allowed them to feel free to leave if they were uncomfortable with the content. Due to privacy considerations, we group them by online game experiences and do not take into account annotators' demographic information.

The CONDA dataset is intended for toxicity detection in online games by providing both slot and intent labels. With respect to the potential risks, we note that the subjectivity of human annotation would impact on the quality of the dataset. In order to improve the quality of our dataset, we compared the inter-rater agreements between a gamers' group and a non-gamers' group, and then final annotation of the whole dataset was performed by gamers only.

Appendix

A The CONDA datasets

The CONDA dataset consists of 9 columns as follows:

- `matchId` (numeric): Each match has a unique ID from raw data.
- `conversationId` (numeric): Each conversation has a unique ID generated by this research to provide guidance for human annotation.
- `playerId` (alphanumeric): Individual players have a unique ID from raw data.
- `playerSlot` (numeric): Individual players have a unique number associated with their roles in each match.
- `chatTime` (numeric): Each utterance has time (in seconds) when it appears in each match. For example, an utterance occurring 10 minutes after starting the game has a chatTime of 600.
- `utterance` (alphanumeric): Original raw data before any data processing (e.g. ‘retard sf…’).
- `slotTokens` (alphanumeric): Tokenised, cleaned, and slot labelled data (e.g. retard (T), sf (C)).
- `intentClass` (alphabetic): Utterance-level annotated labels - E (Explicit), I (Implicit), A (Action), and O (Other).
- `slotClasses` (alphabetic): Token-level annotated labels - T (Toxicity), C (Character), D (Dota-specific), S (game Slang), P (Pronoun), and O (Other).

B Word clouds

(a) Class ’Explicit’ (b) Class ’Implicit’

(c) Class ’Action’ (d) Class ’Other’

Figure 5: Word clouds for each intent class

The word clouds visualizes the most frequent words associated with each intent class. The top keywords in each class are “noob” in E, “ez” in I, “report” in A, “gg” in O.

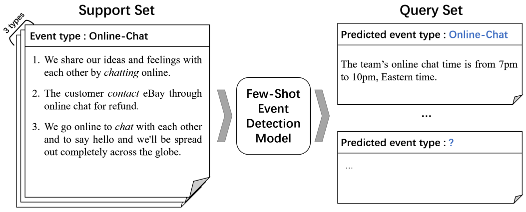
Abstract

Event detection (ED) aims at detecting event trigger words in sentences and classifying them into specific event types. In real-world applications, ED typically does not have sufficient labelled data, thus can be formulated as a few-shot learning problem. To tackle the issue of low sample diversity in few-shot ED, we propose a novel knowledge-based few-shot event detection method which uses a definition-based encoder to introduce external event knowledge as the knowledge prior of event types. Furthermore, as external knowledge typically provides limited and imperfect coverage of event types, we introduce an adaptive knowledge-enhanced Bayesian meta-learning method to dynamically adjust the knowledge prior of event types. Experiments show our method consistently and substantially outperforms a number of baselines by at least 15 absolute F_1 points under the same few-shot settings.



1. We share our ideas and feelings with each other by *chatting* online.
2. The customer *contact* eBay through online chat for refund.
3. We go online to *chat* with each other and to say hello and we'll be spread out completely across the globe.

The team's online chat time is from 7pm to 10pm, Eastern time.

Figure 1: A 3-way 3-shot event detection example, in which the model uses the support set to predict the event types of query samples.

1 Introduction

Event detection is an important task in information extraction, aiming at detecting event triggers from text and then classifying them into event types (Chen et al., 2015). For example, in "*The police* ***arrested*** *Harry on charges of manslaughter*", the trigger word is *arrested*, indicating an **"Arrest"** event. Event detection has been widely applied in Twitter analysis (Zhou et al., 2017), legal case extraction (de Araujo et al., 2017), and financial event extraction (Zheng et al., 2019), to name a few.

Typical approaches to event detection (Chen et al., 2015; McClosky et al., 2011; Liu et al., 2019) generally rely on large-scale annotated datasets for training. Yet in real-world applications, adequate labeled data is usually unavailable. Hence, methods that generalize effectively with small quantities of labeled samples and adapt quickly to new event types are highly desirable for event detection.

Various approaches have been proposed to enable learning from only a few samples, i.e., few-shot learning (Finn et al., 2017; Snell et al., 2017; Zhang et al., 2018a). Yet few-shot event detection (FSED) has been less studied until recently (Lai et al., 2020a; Deng et al., 2020). Although these methods achieve encouraging progress on typical N-way M-shot setting (Figure 1), the performance remains unsatisfactory as the *diversity* of examples in the support set is usually limited.

Intuitively, introducing high-quality semantic knowledge, such as FrameNet (Baker et al., 1998), is a potential solution to the insufficient diversity issue (Qu et al., 2020; Tong et al., 2020; Liu et al., 2016, 2020). However, as shown in Figure 2, such knowledge-enhanced methods also suffer from two major issues: (1) the incomplete coverage by the knowledge base and (2) the uncertainty caused by the inexact alignment between predefined knowledge and diverse applications.

To tackle the above issues, in this paper, we propose an Adaptive Knowledge-Enhanced Bayesian Meta-Learning (AKE-BML) framework. More specifically, (1) we align the event types between the support set and FrameNet via heuristic rules.[1] (2) We propose encoders for encoding the sam-

Chatting

Definition: A group of people (the Interlocutors or Interlocutor_1 and Interlocutor_2 together) have a conversation. No person is construed as only a speaker or only an addressee.

Arguments: Interlocutors, Interlocutor_1, Interlocutor_2.

LUs: badinage.n, banter.n, chat.n, chat.v, chit-chat.n, colloquy.n,…

Discussion

Definition: Two (or more) people (the Interlocutors, also encodable as Interlocutor_1 and Interlocutor_2) talk to one another. No person is construed as only a speaker or only an addressee. This frame differs from the Chatting frame in that the Interlocutors have a particular question that they are attempting to decide or understand.

Arguments: Interlocutors, Interlocutor_1, Interlocutor_2.

LUs: communicate.v, conference.n, consultation.n, debate.n, talk.n,…

Online-Chat

Miss in FrameNet.

Figure 2: An example of FrameNet. Left side: the relation between frame ‘Chatting’ and its sub-frame. Right side: the definitions and LUs (Lexical Units) of frame Chatting and Discussion. The blue words represent the mentions of arguments in definition. It can be seen that, in FrameNet, the definition of the sub-frame is similar to the definition of its super-frame. External knowledge base can provide rich semantic information, yet the knowledge base is typically incomplete, such as the missing of a desired frame “online-chat”.

ples and knowledge-base in the same semantic space. (3) We propose a learnable offset for revising the aligned knowledge representations to build the knowledge prior distribution for event types and generate the posterior distribution for event type prototype representations. (4) In the prediction phrase, we adopt the learned posterior distribution for prototype representations to classify query instances into event types.

We conduct comprehensive experiments on the aggregated benchmark dataset of few-shot event detection (Deng et al., 2020). The experimental results show that our method consistently and substantially outperforms state-of-the-art methods. In all six N-way-M-shot settings, our model achieves a large F_1 superiority of at least 15 absolute points.

2 Related Work

Event Detection. Recent event detection methods based on neural networks have achieved good performance (Chen et al., 2015; Sha et al., 2016; Nguyen et al., 2016; Lou et al., 2021). These methods use neural networks to construct the context features of candidate trigger words to classify events. Pre-trained language models such as BERT (Devlin et al., 2019) have also become an indispensable component of event detection models (Yang et al., 2019; Wadden et al., 2019; Shen et al., 2020). However, neural models rely on large-scale labeled event datasets and fail to predict the labels of new event types. A recent study utilized the basic metric-based few-shot learning method for event detection (Lai et al., 2020b). Deng et al. (2020) tackles few-shot learning for event classification with a dynamic memory network. To enhance background knowledge, ontology embedding is used in ED (Deng et al., 2021). These methods have achieved encouraging results in the few-shot learning setting. However, they do not address the problem of insufficient sample diversity in the support set. Our method leverages the knowledge in *FrameNet* to augment the support set for event detection.

Few-shot Learning and Meta-learning. Few-shot learning trains a model with only a few labeled samples in a support set and predicts the labels of unlabeled samples in the query set. Various approaches have been proposed to solve the few-shot learning problem, which mainly fall into three categories: (1) metric-based methods (Vinyals et al., 2016; Snell et al., 2017; Garcia and Bruna, 2012; Sung et al., 2018), (2) optimization-based methods (Finn et al., 2017; Nichol et al., 2018; Ravi and Larochelle, 2016), and (3) model-based methods (Yan et al., 2015; Zhang et al., 2018b; Sukhbaatar et al., 2015; Zhang et al., 2018a). However, these methods rely heavily on the support set and suffer from poor robustness caused by insufficient sample diversity of the support set.

Bayesian meta-learning (Ravi and Larochelle, 2016; Yoon et al., 2018) can construct the posterior distribution of the prototype vector through external information outside the support set. The effectiveness of this method has been shown in the few-shot relation extraction task (Qu et al., 2020). It inspires us to solve the problem of insufficient sample diversity in the task of few-shot event detection by introducing external knowledge. However, this method ignores the semantic deviation between knowledge and target types. Specifically, a knowledge base may provide incomplete coverage of target types in a given support set, which leads to inaccurate matching between a target type and knowledge.

3 Problem Definition

In this paper, the Few-Shot Event Detection (FSED) problem is defined as a typical *N-way-M-shot* problem. Specifically, a tiny labeled *support set* S is provided for model training. S contains N distinct event types and each event type has only M labeled samples, where M is typically small (e.g. $M = 5, 10, 15$). More precisely, in each FSED task we are given a small support set $S = \{(x_s, y_s)\}$.

Let $X_S = \{x_s\}_{s \in S}$ represent the samples in the support set S, i.e. $x_s = (I_s, tt_s)$, where I_s is the sentence of the sample x_s and tt_s is the candidate trigger word of x_s. We denote by Y_S an ordered list of event types, i.e. $Y_S = \{y_s\}_{s \in S}$, where each y_s is the ground-truth event type of sample x_s. For each support set S, we only consider a subset of event types T_s from the entire set of event types T. Hence, in the N-way-M-shot setting, $|T_S| = N$ and $|X_S| = |Y_S| = N * M$.

Moreover, we assume an external knowledge base $\mathscr{F}$ that contains a number of *frames*. Each frame $F_t \in \mathscr{F}$ consists of three parts: $F_t = (D_t, A_t, L_t)$, where D_t, A_t and L_t are the definition, arguments, and linguistic units (LUs) of the frame respectively. Please see Appendix A for details of FrameNet.

For each support set S, we are also given a query set Q composed of some unlabeled samples $X_Q = \{x_q\}_{q \in Q}$, where $x_q = (I_q, tt_q)$, I_q is the sentence of sample x_q, and tt_q is the candidate trigger word of x_q. Our goal is to learn a neural classifier for these event types by using the external knowledge and the support set. We will apply the classifier to predict the labels of the query samples in Q, i.e., $Y_Q = \{y_q\}_{q \in Q}$ with each $y_q \in T_S$. We do this by learning $p(Y_Q|X_Q, X_S, Y_S, \mathscr{F})$.

4 Adaptive Knowledge-Enhanced Bayesian Meta-Learning

We now present our adaptive knowledge-enhanced few-shot event detection approach. The overall structure of our method is shown in Figure 3. Our method represents each event type t with a prototype vector $\mathbf{v}_t$, which is then used to classify the query sentences. We use $\mathbf{V}_{T_S} = \{\mathbf{v}_t\}_{t \in T_S}$ to represent the collection of prototype vectors for all event types in T_S. Then the conditional distribution $p(Y_Q|X_Q, X_S, Y_S, \mathscr{F})$ can be represented as:

$$\int p(Y_Q|X_Q, V_{T_S}) p(V_{T_S}|X_S, Y_S, \mathscr{F})\, d\mathbf{V}_{T_S}. \quad (1)$$

To calculate Eq. 1, we first introduce the sample encoder and knowledge encoder to give the vector representations of samples and the knowledge of event types. Then we use the sample representations and knowledge representation to construct the adaptive knowledge-enhanced posterior distribution $p(V_{T_S}|X_S, Y_S, \mathscr{F})$ of $\mathbf{V}_{T_S}$ and give the likelihood $p(Y_Q|X_Q, V_{T_S})$ by $\mathbf{V}_{T_S}$ and sample representations. Finally we leverage Monte Carlo sampling to approximate the posterior distribution and draw each prototype sample by the stochastic gradient Langevin dynamics (Welling and Teh, 2011) to optimize model parameters in an end-to-end fashion. We now explain the framework in more details.

4.1 Sample and Knowledge Encoder

The purpose of encoding knowledge is to make up for the lack of diversity and coverage of the support set. Thus we align the knowledge and sample encoding and map them into the same semantic space. Intuitively, trigger and arguments are the main factors for entity detection. Hence, to align the trigger and arguments from samples and external knowledge, we design two encoders for the knowledge and samples, generating the final knowledge encoding $\mathbf{h}_t$ and the sample encoding $\boldsymbol{\mathcal{E}}(x)$ with the same dimensions.

Knowledge Encoder. Given a knowledge frame $F_t = \{D_t, A_t, L_t\}$ for the event type t, we encode it into a real-valued vector to represent the semantics of t. As shown in Figure 2, for a frame F_t, the linguistic units L_t can represent the features of the trigger words, the arguments A_t can represent the context of the trigger words in samples, and D_t describes the semantic relationship between A_t and t.

For each event type t, the proposed knowledge encoder uses BERT to generate the text encoding $\mathbf{E}_{D_t}$ and $\mathbf{E}_{L_t}$ from the description D_t and the LUs L_t respectively. Moreover, the arguments encoding $\mathbf{E}_{A_t}$ is a sequence of $\mathbf{e}_{A_t}^{(i)}$, i.e., the average token encoding in the i-th argument mention in D_t, which ensures that the encoding of A_t fully contains the semantics of the event type t. Then, as shown in Figure 3, the trigger word prior encoding and argument prior encoding are generated by follows:

- **Trigger word prior encoding.** We use attention to get the weighted sum of words in L_t as the trigger word prior encoding $\mathbf{e}_{L_t}^*$. The *query* of the attention is $\mathbf{E}_{D_t}$, *key* and *value* are both $\mathbf{E}_{L_t}$.
- **Argument prior encoding.** An attention mechanism is used to aggregate the arguments information into $\mathbf{e}_{A_t}^*$, where the *query* of the attention is $\mathbf{e}_{L_t}^*$, *key* and *value* are both $\mathbf{E}_{A_t}$.

Finally, we concatenate the trigger word prior encoding $\mathbf{e}_{L_t}^*$ and the argument prior encoding $\mathbf{e}_{A_t}^*$, and use a feed forward network f^h to generate the knowledge encoding vector $\mathbf{h}_t$ of event type t,

$$\mathbf{h}_t = f^h\left(\left[\mathbf{e}_{A_t}^*; \mathbf{e}_{L_t}^*\right]\right). \quad (2)$$

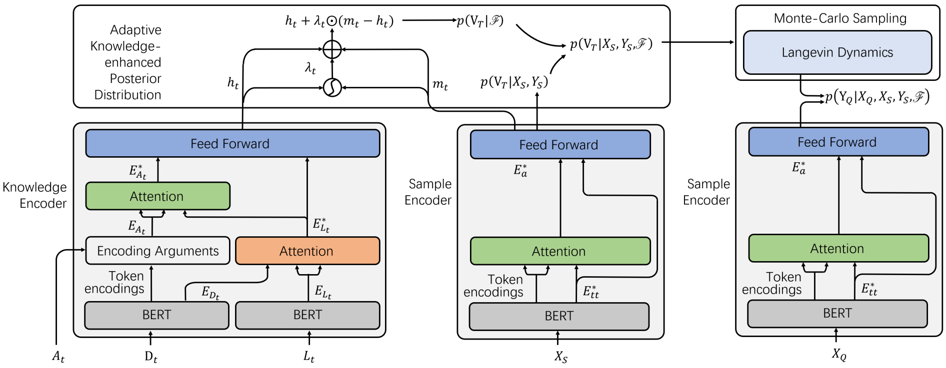

Figure 3: Framework overview. Our method combines both the external knowledge and the support set into a prior distribution of event prototype. We customize two encoders to generate sample representations and knowledge representations. Then we utilize the support set to generate a learnable offset for revising the aligned knowledge representations to generate the prior distribution for prototype representations. Finally, we use Monte-Carlo sampling and stochastic gradient Langevin dynamics to draw samples of prototypes for prediction.
