Recently, neural topic modeling approach has been attracting much research attention for understanding topic models of corpus due to its ability to leverage the advantages of both neural networks and probabilistic generative models. Compared to classical ones, this approach has three main advantages. First, its inference is amortized (Miao et al., 2016) and hence is much computationally simpler than that of the classical approach which requires to deal with a complicated optimization problem (Blei et al., 2003). Second, the gap between prototype and deployment processes become closer thanks to the power of some deep learning frameworks such as Pytorch (Paszke et al., 2019), Tensorflow (Abadi et al., 2016), and Flux.jl (Innes, 2018). Third, neural topic models are easy to be integrated with prior knowledge such as pre-trained word and text embeddings, which are prevalent and have shown the tremendous usefulness, e.g. GPT-3 (Brown et al., 2020), BERT (Devlin et al., 2019).

Several neural topic models are proposed recently to investigate the above advantages. Their reported experimental results are promising compared to the classical topic models. However, the reported results are not consistent or even contradict across these works. For example, for the same 20News dataset, (Miao et al., 2016) reports that their model i.e. NVDM obtains much better performance (measured by perplexity) than the classical LDA does, while the same experiments of (Srivastava and Sutton, 2017) show that LDA outperforms NVDM significantly. All these inconsistency and contradiction make it hard to assess the neural topic modeling approach comprehensively.

In this work, we would like to address this gap by conducting an extensive empirical study to accurately evaluate the typical existing neural topic models. Precisely, using a diverse set of large datasets, we examine the performance of the models in several tasks, including document modeling, topic discovery, and document representation for downstream classification. Our contributions are:

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4363–4368
August 1–6, 2021.

- To the best of our knowledge, our work is the first one which examines state-of-the-art neural topic models in a systematical mechanism.
- We also public our implementation [1] as an additional resource for better reproducibility and further improvement in topic modeling research.
- Based on the results of our extensive experiments, we provide some practical guidelines of using neural topic models for specific tasks.

2 Experiment Settings

In this section, we describe settings used in our experiments. We start by briefing the models chosen to examined. We then introduce the datasets and define the metrics used to examine the models.

2.1 Evaluated Models

Neural topic models. Existing neural topic models are generally based on encoder-decoder architectures. In those models, the encoders are some variants of variational auto-encoder (VAE) (Kingma and Welling, 2013) whose input is the bag-of-word vector of an input document. The decoders, on the other hand, are designed to recover the input document from the encoded vector. For a fair comparison with the classical topic models that work purely on bag-of-words representation of documents, we surveyed the state-of-the-art works on neural topic modeling and chose to examine the following models whose decoders also work with the same representation of the documents.

- **NVDM** (Miao et al., 2016): A pioneering work that applies the VAE architecture for topic modeling with the encoder is implemented by multilayer perceptron, the variational distribution is a Gaussian distribution, and the variational inference is based on minimizing the KL-divergence (Blei et al., 2017).
- **GSM** (Miao et al., 2017): A variant of **NVDM** whose variational distribution is softmax of a Gaussian distribution.
- **NVLDA** (Srivastava and Sutton, 2017): Another variant of **NVDM** in which the variational distribution is Dirichlet distribution and approximated by a Laplace approximation based on Gaussian distribution.
- **ProdLDA** (Srivastava and Sutton, 2017): A variant of **NVLDA** in which the decoder is designed by following the product of expert model and the topics are unnormalized.
- **Scholar** (Card et al., 2018): This model is designed to incorporate the metadata and labels associated with documents into the modeling of topics. If no metadata and no labels are available, this is similar to **ProdLDA** except that the encoder has only a single linear layer.
- **NSMDM** (Lin et al., 2019): The sparsity of documents' topics is modeled by Gaussian sparsemax distribution, and the variational inference is based on the Wasserstein distance.
- **NSMTM** (Lin et al., 2019): This model is a variant of **NSMDM** in which the Gaussian sparsemax distribution is also used for modeling the sparsity of the topics .
- **NVCTM** (Liu et al., 2019): Again, this model is much similar to **NVDM** except that the decoder make uses of a complicated transformation sequence for modeling the correlation of topics within documents.

The above list is certainly not exhaustive. There are several other notable models proposed recently. We however do not examine them in this work as they either do not model documents as bags but sequences of words (e.g., (Dieng et al., 2016)) or are not generative models (e.g., (Yang et al., 2020)).

In our experiments, for each of the aforementioned models, we make use of the implementations provided by the authors if these are any. We re-implement the provided implementation if it is not written in Pytorch, strictly follow the original one. If the implementation is not provided, we implement the models ourselves, strictly follow the description and settings in the published papers.

Classical topic models. We compare these methods above with two classical topic models, namely Non-negative Matrix Factorization (**NMF**) (Zhao et al., 2017) and Latent Dirichlet Allocation (**LDA**) (Blei et al., 2003). We examine both two widely used learning methods for LDA: online variational inference (**o_LDA**) and Gibbs sampling algorithm (**g_LDA**).

2.2 Datasets

We uses two types of corpus: long text corpus containing *W2E-content* and *20News* (Lang, 2008);

---

[1] https://github.com/smutahoang/ntm

Table 1: Dataset statistic

Dataset	#documents	#words	Avg. length	#labels
20News	15,465	4,159	73.52	20
W2E-content	84,017	11,123	256.62	30
W2E-title	105,522	4,051	6.90	30
Web Snippets	12,295	4,722	14.42	8

and short text corpus including *W2E-title* and *Web Snippets* (Ueda and Saito, 2003). Both W2E-content and W2E-title are derived from news articles in W2E dataset (Hoang et al., 2018) by using the whole content or title respectively of the articles in the top 30 topics (by the number of news articles). Documents in these datasets are labeled by their topics (*W2E-content* and *W2E-title*), category of the discussion they belong to (*20News*), or the category of the webpage they were collected from (*Web Snippets*).

For each dataset, we preprocess the datasets by: removing stopwords, then iteratively removing infrequent words and too short documents. These are conventional in prior works on topic modeling, and is to make sure that we have sufficient data for learning meaningful topics. The basic statistics of the preprocessed datasets are shown in Table 1. The diversity and the large sizes of these datasets allow us to evaluate the models accurately.

2.3 Evaluation Metrics

For a comprehensive evaluation, we examine the performance of the models in three aspects: (i) *document modeling* – measured by the perplexity of unseen documents or held-out words (Blei et al., 2003), (ii) *topic discovery* – evaluated by topic coherence, and (iii) *document representation* – quantified through the performance of the obtained documents' topic vectors in downstream tasks.

For measuring the perplexities, we train the model using 90% of documents (or 90% of words in each document, respectively) in the dataset, and compute the perplexity on the remaining 10% of documents (or words, respectively). The coherence of the learned topics are measured by *normalized point-wise mutual information (NPMI)* (Lau et al., 2014) of their top words. Lastly, we use classification task to examine the obtained documents' topic vectors. That is, we use these vectors to train a logistic regression model to classify the documents in each dataset by their labels. For this experiment, we perform 10-fold cross validation, and report the average micro F1 scores across the folds. To obtain robust findings, and also to examine the consistency of the models' performance, for each metric, each model, each number of topics, and each dataset, we run the experiments 10 times, and report the mean and variance of the performance across the runs. The number of topics is varied from half to three times the number of labels of documents in the corresponding dataset.

3 Experiment Results & Findings

Figure 1 shows the mean and variance of the models' unseen-document perplexity on different datasets and with different number of topics. Similarly, Figures 2, 3, and 4 show the means and variances of the models' held-out word perplexity, average F1 scores, and topic coherence respectively on the same datasets and with different number of topics. Note that the **o_LDA** model has no unseen-document perplexity as it does not has a straightforward method for computing the perplexity, while **NMF** has no perplexities as it is not a generative model. From the figures, we can observe that:

- **NVDM** and **NVCTM** are generally better than other models in modeling and representing documents as their perplexities are significantly lower and their average F1 scores are significantly higher. This is reasonable and expected as these two models learn the unnormalized topic vectors for documents while the others learn the normalized ones[2]. However, they underperform other models in discovery cohesive topics as their coherence scores are much lower than others' in most cases.
- None of the neural topic models in our study outperforms the classical **LDA** on all the datasets and in all the metrics.
- The classical models (i.e., **o_LDA**, **g_LDA**, and **NMF**) are generally more stable than the neural ones as their variances are generally much smaller than those the neural models.

From the above observations, we make the following implications, which can be served as some guidelines for evaluation and practical usage of neural topic models.

- **LDA**, especially **g_LDA**, is a strong baseline for topic modeling. It should be used to evaluate neural topic models comprehensively.
- The performance of neural models may not be stable and may vary significantly from run

---

[2] Here the normalized vectors are probability distribution vectors: their elements are non-negative and summing up to 1

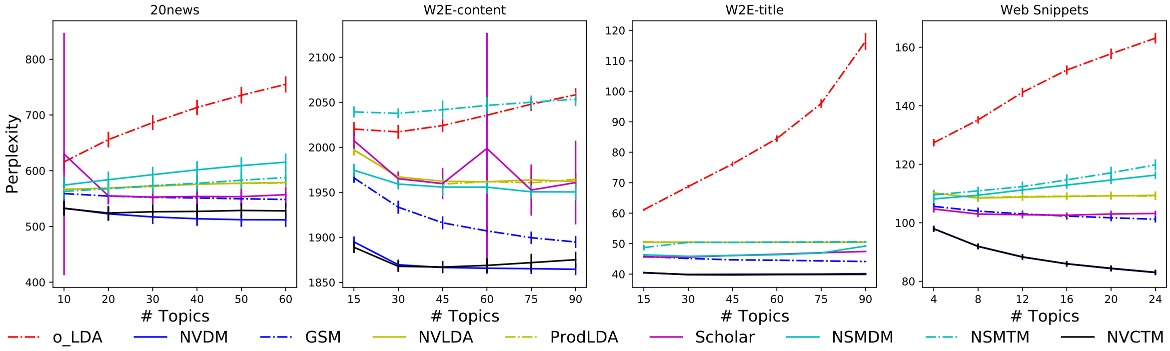

Figure 1: Unseen-document perplexity of the examined models: the lower is better

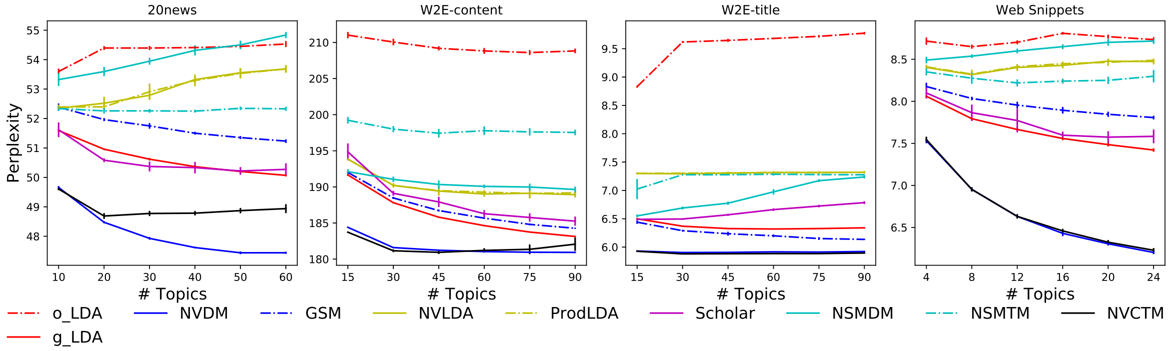

Figure 2: Held-out word perplexity of the examined models: the lower is better

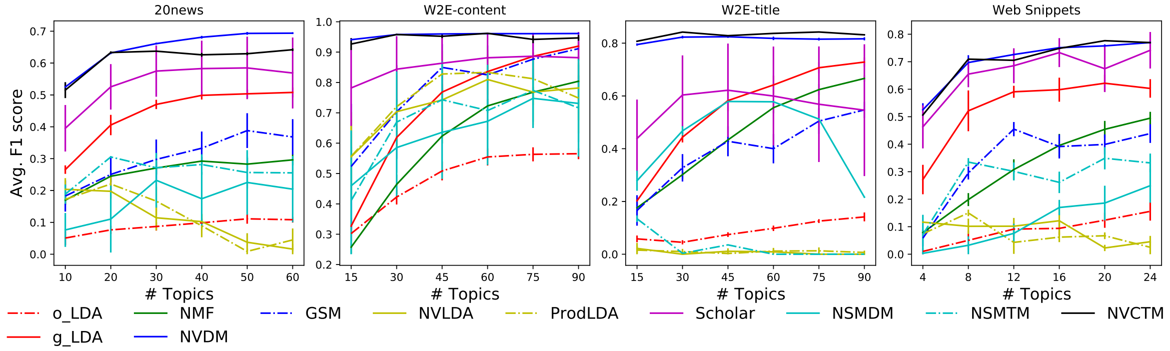

Figure 3: Average F1 scores of the examined models in downstream classification tasks: the higher is better

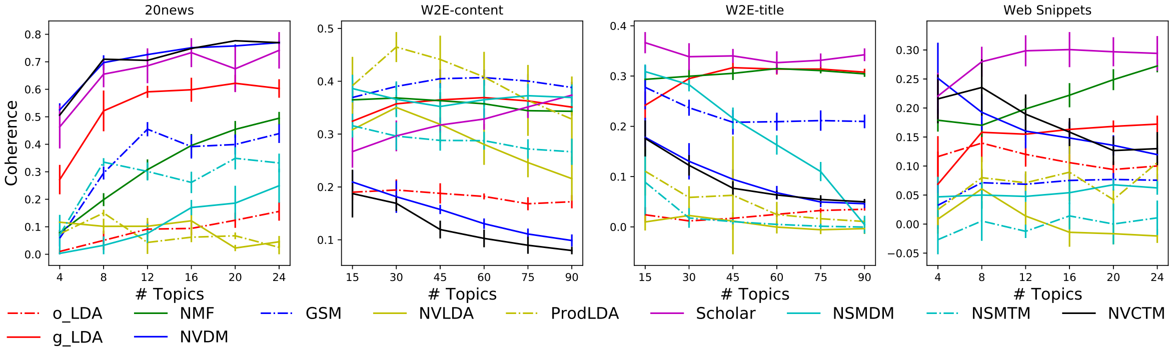

Figure 4: Coherence of topics learned by the examined models: the higher is better

to run. One should perform multiple runs on the same dataset to have accurate evaluation.

- Among the examined neural models, **Scholar** is more suitable for uncovering cohesive, meaningful topics from the corpus, while the unnormalized models (i.e., **NVDM** and **NVCTM**) are more suitable for modeling and representing documents in the corpus.

4 Conclusion

We have examined the performance state-of-the-art neural topic models in a systematic mechanism. From our extensive experiments, we found that classical methods, e.g. **LDA**, still have comparable expressive ability. We have also suggested some considerations for a comprehensive evaluation and practical usage of those models.

In the future, we would like to extend further by designing a fair comparison framework for neural methods that use other representation of documents, e.g. sequences of words, and from other approaches. We would also want to benchmark other issues in neural topic models, e.g., the posterior collapsing problem (He et al., 2019).

Abstract

Pre-trained language models (e.g., BERT) significantly alleviate two traditional challenging problems for Chinese word segmentation (CWS): segmentation ambiguity and out-of-vocabulary (OOV) words. However, such improvements are usually achieved on traditional benchmark datasets and not close to an important goal of CWS: practicability (i.e., low complexity as a standalone task and high beneficiality to downstream tasks). To make a trade-off between traditional evaluation and practicability for CWS, we propose a semi-supervised neural method via pseudo labels. The neural method consists of a teacher model and a student model, which distills knowledge from unlabeled data to the student model so as to improve both in-domain and out-of-domain CWS. Experiments show that our proposed method can not only keep the practicability of the lightweight student model but also improve the performance of segmentation effectively. We also evaluate a range of heterogeneous neural architectures of CWS on downstream Chinese NLP tasks. Results of further experiments demonstrate that our proposed segmenter is reliable and practical as a pre-processing step of the downstream NLP tasks at the minimum cost.[1]

1 Introduction

Natural language processing (NLP) tasks often leverage word-level features to exploit lexical knowledge. Segmenting a sentence into a sequence of words, especially for languages without explicit word boundaries (e.g., Chinese) not only extracts lexical features, but also shortens the length of the sentence to be processed. Thus, word segmentation, detecting word boundaries, is a crucial preprocessing task for many NLP tasks. In this aspect, Chinese word segmentation (CWS) is widely acknowledged as an essential task for Chinese NLP.

CWS has made substantial progress in recent studies on several benchmarks, which is reported by Huang and Zhao (2007) and Zhao et al. (2019). In particular, pretrained language models (PLMs), like BERT (Devlin et al., 2019), have established new state-of-the-art in sequence labeling (Meng et al., 2019). Various fine-tuning methods have been proposed to improve the performance of in-domain and cross-domain CWS based on PLMs (Huang et al., 2020; Tian et al., 2020). The two challenging problems in CWS, segmentation ambiguity and out-of-vocabulary (OOV) words, have been significantly mitigated by PLM-based methods that are fine-tuned on large-scale annotated CWS corpora. Such methods are even reaching human performance on benchmarks. Nevertheless, CWS is more valuable as a prelude for downstream NLP tasks than as a standalone task. Intrinsic evaluation of CWS on benchmark datasets only examines the effectiveness of current neural methods on word boundary detection. To better apply CWS in downstream NLP tasks, we should comprehensively re-think CWS from the perspective of practicability. In this paper, we define the practicability of CWS with two aspects: low complexity as a standalone task and high beneficiality to downstream tasks.

The complexity is twofold: 1) complexity of implementation and 2) time and space complexity of a CWS algorithm. Previous neural methods usually require additional resources (Zhou et al., 2017; Ma et al., 2018; Zhang et al., 2018b; Zhao et al., 2018; Yang et al., 2019; Qiu et al., 2020), such as external pre-trained embeddings. The complexity of implementation is reflected in the difficulty of acquiring external resources. External resources

vary in quality and the length of time for computation, For example, it is time-consuming to obtain effective pre-trained embeddings as they are trained on a huge amount of data. Generally, it is difficult to maintain high CWS performance for many previous neural methods in a low-resource environment. Neural methods with external resources achieve high CWS performance but at the cost of a high complexity of implementation. On the other hand, for training and inference, PLM-based CWS methods also consume large memory to store a huge number of parameters of their models. The speed of inference is usually slow. The huge memory consumption and slow inference prevent PLM-based CWS models from being deployed in small-scale smart devices. And, as CWS is often used with downstream models, this even weakens the applicability on smart devices as CWS is not supposed to take too much overhead in this situation.

The second is the beneficiality to downstream tasks. CWS is rarely used as a standalone task in industry. Existing CWS evaluations only rely on benchmarks and analyze the behavior of segmentation methods in a static scenario. Some well-known benchmarks are quite old (e.g., Bakeoff-2005) and not challenging for neural CWS anymore. Such evaluations are intrinsic, which are not associated with downstream NLP tasks. High CWS performance (e.g., Precision and F_1) does not mean that segmentation results are beneficial to downstream processing. Additionally, benchmark datasets have a plenty of segmentation noises that affect CWS training and evaluation. For instance, although the structure of “副” (vice) + “X” is segmented as two words: “副” (vice) and “X” in training data and never unified as a single word, “副校长” (vice-president) appears as one word in test data, note that: X presents any job titles, e.g., “总统” (president) and “经理” (manager). There are also many obvious errors due to annotation inconsistency in data. We have found, in one benchmark dataset, the word “操作系统” (operating system) is regarded as two words [“操作” (operate) + “系统” (system)] 6 times and appears as one word 14 times, respectively. Therefore, to measure and improve the beneficiality of CWS to downstream tasks, intrinsic evaluations on CWS benchmark datasets are not sufficient. We should perform extrinsic evaluations with downstream tasks.

To address the aforementioned practicability issue of CWS, we propose a semi-supervised neural method via pseudo labels. The method consists of two parts: a teacher model and a student model. First, we use a fine-tuned CWS model that is trained on the annotated CWS data as the teacher model, which can achieve competitive performance in traditional perspective for CWS. Then we collect massive unlabeled data and distill knowledge from the teacher model to the student model by generating pseudo labels. We filter out noisy pseudo labels to provide reliable knowledge for training the student model. The unlabeled data is easier to obtain than other external resources (e.g., lexicon and pre-trained embeddings) and can be updated anytime at a low cost. And we use the lightweight student model for inference, hence significantly reducing the memory consumption and inference time complexity. The practicability of our proposed method is competitive.

To sum up, the contributions of this work are as follows:

- Our proposed method distills knowledge from the teacher model via unlabeled data to coach the lightweight student model. The proposed method achieves a noticeable improvement over strong baselines for CWS by the traditional intrinsic evaluation.

- The lightweight student can be deployed on a small-scale device, even in a non-GPU environment. We abandon the PLM neural architectures (teacher model) during decoding. The speed of decoding is thus fast for practical application. Our method reduces the complexity of implementation, inference time, and memory consumption.

- We empirically investigate the effectiveness of the proposed method to downstream Chinese NLP tasks and analyze the impact of segmentation results on them via extrinsic evaluations.

2 Related Work

Since Xue (2003) formalizes CWS as a sequence labeling problem, many traditional statistical methods have achieved high performance for CWS on several benchmarks (Emerson, 2005). According to (Huang and Zhao, 2007) and (Zhao et al., 2019), CRF-based models (Tseng et al., 2005; Zhao and Kit, 2008; Zhao et al., 2010; Sun et al., 2012; Zhang et al., 2013) and neural methods (Zheng et al., 2013;

Pei et al., 2014; Chen et al., 2015; Cai and Zhao, 2016; Cai et al., 2017) have been reported to outperform traditional methods with high F_1 scores (0.95-0.97). In particular, Long Short-Term Memory Networks (LSTM) are the main backbone networks being used in these methods (Huang et al., 2015; Ma et al., 2018; Yang et al., 2019). Except for using LSTM, self-attention networks have been also employed for CWS (Duan and Zhao, 2020).

The OOV problem has been a long-standing challenge for CWS and it is particularly serious in the cross-domain scenario. To relieve this issue, many studies incorporate a variety of pre-trained word embeddings and external resources into CWS models (Zhou et al., 2017; Zhang et al., 2018b,a; Yang et al., 2019). Recently, with the development of PLMs (Devlin et al., 2018; Liu et al., 2019), fine-tuning methods benefit from a huge amount of the pre-trained knowledge for alleviating the OOV problem for CWS (Meng et al., 2019; Tian et al., 2020; Huang et al., 2020; Qiu et al., 2020). Such methods are nearly reaching human-level performance.

Nevertheless, external resources and PLMs result in additional costs in memory consumption and inference time. Knowledge distillation has been proposed to alleviate this additional cost issue (Ba and Caruana, 2014; Hinton et al., 2015). Kim and Rush (2016) propose to use knowledge distillation for neural machine translation while Mukherjee and Awadallah (2019) study several aspects of distillation to match the student model for sentiment classification. Jiao et al. (2020) adopt multiple distilling strategies to minimize the number of the parameters of the pre-trained language model. Different from these previous studies, our proposed method utilizes unified pseudo labels to improve the performance of the lightweight model. The model can provide positive influence as a preprocessing step to downstream tasks, compared with previous state-of-the-art methods.

3 Proposed Framework

Aiming at not only keeping competitive performance on benchmarks but also reducing the complexity of the CWS methods, our proposed framework consists of two essential modules: a student model and a teacher model, as shown in Figure 1. There is an obvious performance gap between the model based on PLMs (Huang et al., 2020) and the lightweight model (Duan and Zhao, 2020). The OOV issue is the main reason for the gap. Since the teacher model based on fine-tuned PLMs with high complexity can alleviate the OOV issue effectively, we use a combination of PLM-based teacher and lightweight student. First, the teacher model transfers pre-trained knowledge into a specific data distribution by annotating unlabeled data. Then we utilize a huge amount of such annotated data to distill knowledge from the teacher model to the lightweight student model. The pseudo labels provided by the teacher model can help the lightweight model to alleviate the OOV issue of CWS.

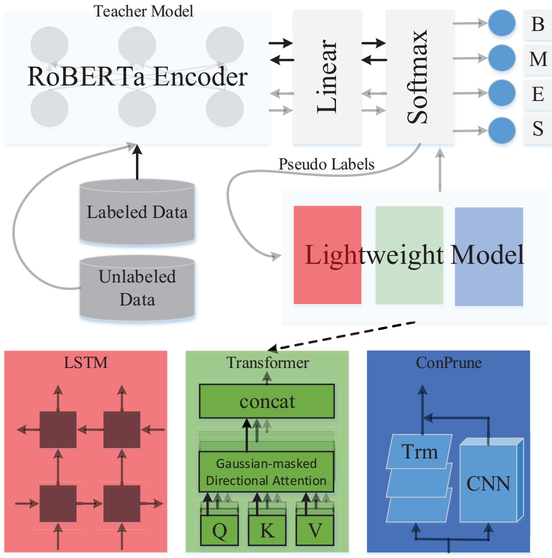

Figure 1: The illustration of our proposed framework. The red, green and blue blocks indicate the heterogeneous student models.

3.1 Teacher Model

Recently, there are several PLMs (e.g., BERT and RoBERTa) that have shown competitive performance for many NLP tasks. In particular, a modified RoBERTa model has been built for Chinese NLP tasks (Cui et al., 2019). Inspired by the previous success of PLM-based models on CWS (Huang et al., 2020), we use the RoBERTa-WWM PLM as the teacher model.

Normally, PLMs are trained for predicting words in general. To adapt PLMs and transfer their knowledge to CWS, we need to fine-tune PLMs on the annotated data of CWS. Let X denote the inputs, which are converted into a sequence of embeddings. For consistency, two tags (“[CLS]” and “[SEP]”) are added to the beginning and end of each sentence, respectively. A Linear transfer layer with

$W^{(t)} \in R^{d_{model}*N}$ replaces the original component, where d_{model} is the same as the size of dimensions of the pre-trained model and N presents number of tags in CWS annotated data ($N = 4$). We convert CWS annotations into annotations with a 4-tag set $T = \{B, M, E, S\}$ that indicates the **B**egin, **M**iddle, **E**nd of a word, or a **S**ingle character forming a word. After linear mapping, the teacher model adopts the function of Softmax and the greedy search for decoding.

$$p^{(t)}(x) = \text{Softmax}(h_t(x) \cdot W^{(t)} + b^{(t)}) \quad (1)$$

where $h_t(x)$ represents the hidden states of the teacher model. Complex algorithms (e.g., CRF or beam search) for decoding are abandoned in order to reduce the complexity. In addition, these complex algorithms only obtain a slight improvement for CWS. CRF increases the time complexity by n times and beam search requires more search time varying with the beam size, compared with the greedy search.

$$GreedySearch \rightarrow O(Mn)$$
$$BeamSearch \rightarrow O(Mnb^2)$$
$$CRF \rightarrow O(Mn^2)$$

where M is a constant representing other factors in the model complexity, n is the size of the sentence, and b is the width of beam.

The training of the teacher model is to minimize the errors by solving the following optimization function:

$$\min_{W^{(t)}} J_{seg}(y(x)|p^{(t)}(x, W^{(t)})) \quad (2)$$

where the loss function J_{seg} is computed by:

$$J_{seg}(y(x)|p^{(t)}(x)) = -\sum_{x} y(x)\text{log}p^{(t)}(x) \quad (3)$$

3.2 Student Model

To improve the practicability of CWS, our proposed framework rediscovers the potential of the lightweight models. The lightweight model suffers from the OOV problem compared with the teacher model. However, the lightweight model can help us to solve the practicability issue of CWS. We propose multiple lightweight models as the student model, as shown in Figure 1.

-ConPrune. This is a pruned PLM model, where three quarters of the PLM's layers are discarded. Particularly, we only use the first top 3 layers of the entire 12 layers. We also incorporate a Convolutional Neural Network (CNN) encoder to capture the local features of the sequence.

-LSTM. LSTM is the most popular architecture for sequence labeling tasks (Ma et al., 2018). As shown in Figure 1, for each input character c_i, the corresponding character uni-gram embedding and bi-gram embedding are represented as e_{c_i} and $e_{c_i c_{i+1}}$, respectively. The LSTM model is fed with the two types of character embeddings by concatenation operation, $w_i = e_{c_i} \oplus e_{c_i c_{i+1}}$. The loss function and the decoding are the same as the teacher model.

-Transformer. The Transformer is usually not working as well as LSTM for sequence labeling tasks despite its success on other tasks. We propose a new Transformer variant that is inspired by Duan and Zhao (2020). The modified Transformer utilizes the Gaussian directional mask to encode unigram features.

-CRF. Although CRF is not a dominant model for CWS, it still has great significance for practicability. We only utilize uni-gram and bi-gram features for CRF, keeping the same as neural methods for a fair comparison. It does not rely on any auxiliary features, e.g., accessor variety (AV) (Feng et al., 2004) or pointwise mutual information (PMI) (Sun et al., 1998).

All formulations and details of the student models are shown in Appendix A.

3.3 Pseudo Labels

Neural networks typically predict the probability of each class by Softmax. In the form of distillation, knowledge is transferred to the distilled model by using a distribution that is produced by the teacher model with a temperature in its Softmax. However, the architectures of the student models are completely different from the teacher model, as shown in the last section. Unlike previous studies on distilling knowledge, the process of knowledge distillation in our framework is essentially the same as the original CWS task. Particularly, our proposed method distills the knowledge from the teacher model to the student model by using a huge amount of unlabeled data as the knowledge container. It is easy to obtain unlabeled data from the Internet. The pseudo labels are generated together with noisy labels and we reduce the impact of noisy labels. Due to the high correlation between training data and unlabeled data, we directly distill knowl-

Table 1: Statistics of our datasets. The upper part of the table shows the details of the CWS benchmarks and the bottom for the downstream NLP tasks. All datasets come from the official websites.

edge from the teacher model to the student model, and the final loss is shown as follow:

$$J_u(y(u)|p^{(s)}(u)) = -\sum_{x_u} y_u \text{log} y^*(x_u) \tag{4}$$

$$\begin{aligned} J(\Theta_s, \Theta_u) &= J_{seg}(\Theta_s) + \alpha J_u(\Theta_u), \\ \Theta_s : y(x)|p^{(s)}(x)&, \Theta_u : y(u)|p^{(s)}(u) \end{aligned} \tag{5}$$

where s denotes the student model, α is a weight to balance the losses on the labeled data and unlabeled data ($\alpha = 0.5$ in our experiments). The loss function is calculated with two parts. One is from the labeled data, the other is from the unlabeled data x_u. Hard prediction of the teacher model on the unlabeled data produces noisy labels y_u. And the prediction of the student model on unlabeled data is y^*. To reduce the redundant computation, pseudo labels are mix-sampled according to a regular interval. The sampling strategy chooses the different n-gram features with the annotated data, which makes the distribution of unlabeled sentences different from the annotated data. Instead of optimizing the loss function jointly, we adopt a two-stage optimizing method. The first stage trains student models on the large-scale annotated data. In the second stage, the student model is continued to be trained on the data with labels predicted from the teacher model. Since the teacher model is also fine-tuned on the annotated data, the two-stage training does not suffer from the catastrophic forgetting issue.

4 Experiments

4.1 Datasets and Settings

To examine the advantage of distilling knowledge and the complexity of our proposed framework via pseudo labels, we conducted experiments on five benchmarks (Bakeoff-2005[2] and CTB6). The statistics of the benchmarks are shown in Table 1. We randomly picked 10% sentences from the training data as the development data for tuning. The unlabeled data were collected from the People's Daily website. We crawled 5,000 articles. For consistency, we pre-processed unsegmented sentences, which is similar to previous work (Cai et al., 2017). In addition, to empirically validate the beneficiality of the proposed CWS method to downstream tasks, we carried out comprehensive experiments on named entity recognition (NER) and machine translation (MT). The details of datasets for these two tasks are shown in Table 1. We used F_1 as the evaluation metric for NER and BLEU (Papineni et al., 2002) for MT.

Parameters	Teacher	Student		
		Prune	LSTM	Trans
Hidden states	768	768	256	256
uni-gram embeds	768	768	50	256
bi-gram embeds	-	-	50	-
learning rate	2e-5	1e-5	1e-3	0.1
batch size	64	256	64	4096
dropout	0.1	0.1	0.2	0.1
hidden layers	12	3	3	6
epochs	10	20	30	200

Table 2: The hyper-parameters. "Prune" represents the ConPrune and "Trans" represents the modified Transformer.

To fine-tune the teacher model (i.e., RoBERTa-WWM), we adjusted a few crucial hyper-parameters for it, as shown in Table 2. The hyper-parameters of the student model were tuned with the development sets. We evaluated inference speed for all models on the same hardware configuration (Non-GPU environment: Intel(R) Core(TM) i9-10900KF CPU @ 3.70GHz //GPU environment: Nvidia GeForce RTX 3090). All other hyper-parameters and search ranges are shown in Appendix B.

Table 4: Experiment results on the Bakeoff-2005 datasets. The best results obtained by non-PLM models. Our results are significantly better ($p < 0.05$ bootstrap resampling) than all previous state-of-the-art results.

4.2 Results of Intrinsic Evaluation

As shown in Table 3, we investigated the effect of the proposed method on the benchmark Bakeoff-2005, which is the most widely-used dataset for CWS. "Teacher" denotes the teacher model as introduced in section 3.1. It achieves competitive performance as it is based on a state-of-the-art pretrained model. Other models are the student models.

Experimental results in Table 4 show that our proposed semi-supervised method significantly improves the performance on all 5 benchmark datasets, compared with the pure student model. Surprisingly, results of the proposed semi-supervised method are even close to those of the teacher model. We also compared our proposed method against previous SOTA models, as shown in Table 4. In particular, Tian et al. (2020) and Huang et al. (2020) utilize PLMs which are slower in inference than non-PLM CWS models. This paper focuses on the methods with low complexity. These results demonstrate that our proposed method achieves state-of-the-art performance compared with non-PLM methods. Although there is a small performance gap between our proposed method and fine-tuned PLM methods, the advantage of our method over PLMs is that our method is much faster in both CPU and GPU environments, as displayed in Table 3, which is the key interest of our work. From this perspective, our method is more readily to be used in downstream tasks than previous state-of-the-art PLM methods. In addition, our proposed method not only maintains the advantages of the basic neural methods but also has a low complexity for practicability. Meanwhile, the method leverages easily available unlabeled data to make up for the insufficiency of the student model.

4.3 Results of Extrinsic Evaluation

The performance of models on various CWS benchmarks only demonstrates the merits of models themselves. However, CWS results of different methods that achieve good performance on benchmarks are not necessarily beneficial for specific downstream tasks. We therefore investigated the effect of using different CWS results on the two popular downstream Chinese NLP tasks (NER and MT) to analyze the beneficiality of CWS methods to other tasks. The benchmarks of these two tasks that we adopted are both widely acknowledged in the literature of NER and MT. Particularly, we used

	MT (BLEU)		CWS (F_1)		NER (F_1)		
	ZH→EN		Seg. Train	Seg. Test	NR	NP	NT
Char	21.16	Gold	1.000	1.000	.895	.880	.864
Teacher	23.51 +2.35		.991 -.009	.993 -.007	.897 +.001	.875 -.005	.862 -.002
CRF	23.37 +2.21		.990 -.010	.992 -.008	.907 +.012	.880 -.000	**.877 +.013**

ConPrune	23.71 +2.55		.990 -.010	.992 -.008	.903 +.008	.879 -.001	.863 -.001
ConPrune†	**23.73 +2.57**		.988 -.012	.991 -.009	**.915 +.020**	**.884 +.004**	**.877 +.013**

Table 5: Results on NER and MT. "NR, NP and NT" represent entities of person, place and organization. "Gold" denotes gold-standard word segmentations for NER and "Char" indicates the character-level neural model based on Transformer for baseline comparison. † indicates that the corresponding model utilizes the proposed semi-supervised method.

the "PKU" open resources for NER evaluation and a Chinese-to-English machine translation task from WMT-18[3] for MT evaluation. The model for NER employs word-based LSTM to extract context information and applies a CRF layer stacked over LSTM for decoding. It utilizes random word-level embeddings which can be further fine-tuned later. The evaluation of this task is the same as CWS (F_1). The MT model is based on the Transformer (Vaswani et al., 2017) neural network. We used Byte Pair Encoding (BPE) for alleviating the issue of rare words. We kept all other hyper-parameters of the NER and MT models as those widely used. We then fed CWS results produced by different models into the NER and MT models. Results are shown in Table 5.

Clearly, our proposed method can provide word segmentations that are beneficial for the two downstream tasks. The performance of NER using segmentation results yielded by our proposed method is better than others, even ground-truth word segmentations. All segmentation systems achieve good performance with no evidence of OOV. However, there are still some distinctions between two CWS methods, which will be analyzed in the case study section. Except for the quality of word segmentations, the speed of our proposed method is fast enough to support specific downstream tasks. Surprisingly, we find that word segmentations with high F_1 scores on CWS benchmarks do not necessarily indicate high performance on downstream tasks. Especially, the optimal performance of segmentation results ("Seg. train" and "Seg. test") does not suggest the highest performance on NER ("NR", "NP" and "NT"), as shown in Table 5. This might be due to two reasons. First, gold results in NER have noises, which is similar to CWS. Our proposed method has a strong robustness to deal with noisy labels. Second, word segmentation errors do not necessarily cause error propagation.

4.4 Case Study

To make further progress on CWS, it is important to understand errors that CWS methods are making. Hence we randomly selected typical errors from the PKU test set and manually analyzed them.

The segmentation errors can be roughly divided into two categories. One is the type of errors with OOV words. The proposed semi-supervised method can alleviate the issue of OOV words effectively. For instance, "威尔第" (Verdi) is segmented into two words incorrectly by the pure student model. This split frequently occurs in the unlabeled data, and such knowledge is distilled from the teacher model. The semi-supervised method can revise these OOV words.

Except for the type of errors of OOV words, the rest of errors are mainly caused by segmentation inconsistency. For example, the word "人" (person) should be regarded as a suffix word behind some words, e.g., "中国+人" (Chinese) and "代理+人" (agent). "人" (person) also exists as part of other words, e.g., "关系人" and "继承人". Simply training neural model on such inconsistent segmentation data may be insufficient to solve these segmentation errors without further efforts in data processing. This situation naturally raises a question: do the errors caused by segmentation inconsistency really influence the performance of downstream NLP tasks?

To answer this question, we conducted additional experiments on the two downstream NLP tasks. In NER, segmentation results of non-entity

---

[3] `http://data.statmt.org/wmt18/translation-task/`

words hardly affect the performance of NER. For instance, the word “不懈奋斗” (untiringly struggle) is regarded as a word according to the criterion of “PKU”. Previous state-of-the-art methods that achieve high F_1 scores for CWS can segment it correctly. While our proposed method splits this unit into two independent words “不懈” (untiringly) and “奋斗” (unremitting). However, these two words do not belong to any entities. In other words, the better performance for segmenting non-entity words does not necessarily indicate better performance of NER. In addition, segmentation results of entity words directly affect the veracity of NER. There is a phrase “西方七国集团” (the Group of Seven, abbreviations: G7) in a sentence. This segment is an organizational entity. In word segmentation, it is regarded as two words “西方” (western) and “七国集团” (the group of seven countries) according to ground-truth segmentation results. Previous state-of-the-art methods are usually able to segment it correctly. By contrast, our proposed method segments it into three words “西方” (western), “七国” (seven countries) and “集团” (group). Surprisingly, the final result of NER is out of expectation. The entity with incorrectly segmented words by our method is correctly recognized. Gold segmentation does not achieve a better result on this entity. The vague boundary of a word may increase the uncertainty and difficulty of downstream Chinese NLP tasks. There are many prefix and suffix words in Chinese. Sometimes, it is hard to determine whether these words are a single word or not. For this reason, high performance of CWS is not equal to high performance of Chinese NER.

In MT, due to the technique of BPE, rare words are segmented into sub-words. The issue of unknown words can thus be alleviated effectively. Even if a word as simple as “日本” (Japan) is segmented into two words incorrectly, NMT models are able to prevent the error propagation of segmentation in the training step. Thus, a faster segmentation system, rather than a high-performance segmentation system, is more practical for NMT. To analyze NMT translation differences between two sentences with different segmentation results, we also supply the additional analysis in Appendix C. We find that segmentation results with slight differences make translation results varying. The boundary of words may lead to these differences. But we also conjecture that this is more due to the robustness of NMT models.

5 Conclusion

To bring a positive impact of CWS to downstream NLP tasks, this paper makes a trade-off between the traditional evaluation and the complexity (e.g., implementation and decoding speed), which makes the segmenter more practical. We propose a semi-supervised method that distills knowledge via pseudo labels into the lightweight student model. The method is low coupling, which significantly improves the performance of multiple heterogeneous tiny neural architectures. The proposed framework can achieve competitive performance on CWS benchmarks and the speed of the student model also satisfies the practical requirement. In summary, the advantages of our model are twofold. First, the inference speed of the method is much faster than PLM methods. It can run under low resource conditions, even on CPUs. Second, the model provides efficient segmentation results for downstream NLP tasks.

A Model Architecture

This paper introduces multiple heterogeneous tiny neural architectures as the student model. To better describe each model, all formulations of the student models are shown as follows.

-ConPrune. ConPrune prunes three quarters of 12 layers of the used PLM. To extract local features, we incorporate a Convolutional Neural Network (CNN) encoder into the pruned model. The kernel size determines the distance of scanning. The input sequence is converted into two vector matrices $\mathbf{E}_t$ and $\mathbf{E}_c$. Word positions are also mapped into a feature matrix $\mathbf{E}_p$. The input to the encoder consists of four parts that are token embedding $\mathbf{E}_t$, position embedding $\mathbf{E}_p$, segment embedding $\mathbf{E}_s$ and CNN embedding $\mathbf{E}_c$. Because of the specificity for CWS, all segment embeddings of sequences are regarded as the same mapping matrix $\mathbf{E}_s$. The input of the two components are:

$$\mathbf{E}_{trm} = \mathbf{E}_t + \mathbf{E}_p + \mathbf{E}_s, \mathbf{E}_{cnn} = \mathbf{E}_c \tag{6}$$

The convolutional encoder involves a filter $W \in \mathbb{R}^{hk}$, which is applied to a window of h characters to produce a new feature.

$$W_{cnn} = \operatorname{Relu}\left(W \cdot x_{i:i+h-1} + b\right) \tag{7}$$

where $Relu$ is a type of activation function. $x_{i:i+h-1}$ indicates the matrix of $\mathbf{E}_c$.

The pruned encoder consists of 3 base Transformer encoded layers with multiple multi-head self-attention layers to extract contextual features for each character. The multi-head self-attention layer adopts "Scaled Dot-Product Attention" which is formulated as:

$$\operatorname{Attn}(Q, K, V) = \operatorname{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right) V \tag{8}$$

where Q, K, V represents a query and a set of key-value pairs through a linear transformation respectively, and d_k is the dimension of K.

$$\operatorname{MultiAttn}\left(E_{trm}\right) = \left[head_1, ..., head_k\right] W^O \tag{9}$$

$$head_i = \operatorname{Attn}\left(E_{trm} W_i^Q, E_{trm} W_i^K, E_{trm} W_i^V\right) \tag{10}$$

where W^O, W_i^Q, W_i^K, W_i^V are trainable parameters.

-LSTM. LSTM can be used as a lightweight architecture for sequence labeling tasks. Rigorous tuning can obtain competitive performance for CWS. The model handles sequence features very well. For each input character c_i, the corresponding character uni-gram embedding and bi-gram embedding are represented as e_{c_i} and $e_{c_i c_{i+1}}$, respectively. The LSTM model is fed with the two types of character embeddings by concatenation operation, $w_i = e_{c_i} \oplus e_{c_i c_{i+1}}$. We get the outputs of the student representations from the LSTM model as follow:

$$\overrightarrow{h_s} = \overrightarrow{LSTM}\left(w_1, w_2, \ldots, w_i\right) \tag{11}$$

$$\overleftarrow{h_s} = \overleftarrow{LSTM}\left(w_1, w_2, \ldots, w_i\right) \tag{12}$$

$$h_s = \overrightarrow{h_s} \oplus \overleftarrow{h_s} \tag{13}$$

-Transformer. This paper adopts a modified Transformer which follows the previous study by Duan and Zhao (2020). The modified Transformer changes the multi-head self-attention to the multi-head Gaussian directional attention. Given an input sequence, the attention function can be described as mapping a query and a set of key-value pairs. The Gaussian directional attention incorporates the Gaussian directional attention into traditional self-attention module to pay attention to the neighboring characters of each position and capture features between characters as a fix Gaussian weight for attention. The Gaussian weight function and the multi-head Gaussian directional attention are computed as:

$$G_{i,j} = \sqrt{\frac{2}{\sigma\pi}} \int_{-\infty}^{-d_{i,j}} exp(-\frac{x^2}{2\sigma^2}) dx \tag{14}$$

where i and j are two adjacent positions, $d_{i,j}$ is the distance between the two characters, σ represents the standard deviation of the function. We set this hyper-parameter as 2.

$$\operatorname{GDA}(Q, K, V) = \operatorname{softmax}(\frac{QK^T G}{\sqrt{d_k}}) V \tag{15}$$

where GDA represents the Gaussian directional attention, d_k is the dimension of the matrix K. Q, k and V are vectors which are similar to the base Transformer. The multi-head attention are computed as:

$$\begin{aligned} MultiGDA &= [head_1, head_2, ..., head_k] W^o \\ head_i &= GDA(QW_i^q, KW_i^k, VW_i^v) \end{aligned} \tag{16}$$

B Hyper-parameter Setting

To improve the reproducibility, we list all important hyper-parameters of the teacher model (Table 6), the student models (Table 7 and 8), the word-based NER models (Table 9) and the NMT model. We randomly pick 10% sentences from the training data as the development data for the tuning. In addition, we use the original development set of WMT-18 for MT. We utilize the uniform-sample to choose the hyper-parameters. In particular, we use the hyper-parameters of the modified Transformer model and the NMT model following previous studies (Vaswani et al., 2017; Duan and Zhao, 2020).

C Case Study

For NMT, it is difficult to analyze translation results as the interpretability of NMT is poor. We start with examples and focus on the differences between two translations with different segmentation results in addition to sentence-level BLEU scores. The Pinyin sequences for the two Chinese sentences are shown in Figure 2 and translations are shown in Table 10. We find that segmentation results with slight differences make translation results varying. The boundary of words may lead to these differences. There is a considerable discrepancy when the neural machine translation system stops training at different steps. That shows the neural machine translation system is unstable. It is full of uncertainty, and it still brings great challenges for the MT model itself and other crucial techniques.

Analysis of Tree-Structured Architectures for Code Generation

Samip Dahal **Adyasha Maharana** **Mohit Bansal**

`{sdpmas, adyasha, mbansal}@cs.unc.edu`

Abstract

Code generation is the task of generating code snippets from input user specifications in natural language. Leveraging the linguistically-motivated hierarchical structure of the input can benefit code generation, especially since the specifications are complex sentences containing multiple variables and operations over various data structures. Moreover, recent advances in Transformer architectures have led to improved performance with tree-to-tree style generation for other seq2seq tasks e.g., machine translation. Hence, we present an empirical analysis of the significance of input parse trees for code generation. We run text-to-tree, linearized tree-to-tree, and structured tree-to-tree models, using constituency-based parse trees as input, where the target is Abstract Syntax Tree (AST) of the code. We evaluate our models on the Python-based code generation dataset CoNaLa and a semantic parsing dataset ATIS. We find that constituency trees encoded using a structure-aware model improve performance for both datasets. We also provide an analysis of those aspects of the input parse trees which are most impactful. For instance, we find that structure-aware encodings are better at modelling inputs with multiple variables and capturing long-range dependencies for code generation.[1]

1 Introduction

Code generation is the task of converting input user specifications written in natural language (NL) to code snippets in a target programming language. It is a task-driven variant of semantic parsing, which translates natural language input to formal machine-executable representation. Recent works have utilized the Abstract Syntax Tree (AST) - which is the syntactic tree representation of target source code - to generate better code snippets (Yin and Neubig, 2017, 2018; Sun et al., 2020; Rabinovich et al., 2017). The use of ASTs has achieved strong results but there has been relatively less work on utilizing the parse trees of the NL input. Constituency or dependency trees representing the syntactic structure of input can be leveraged to perform sub-tree alignment with corresponding AST of target code and benefit the downstream task. Hence, in this paper, we present several tree-to-tree models for the code generation task that convert the parse tree representation of NL input to AST representation of target source code. First, we base our model on the Transformer architecture (Vaswani et al., 2017). However, the standard Transformer is not designed to preserve the tree structure of the input parse trees. Hence, to better encode the trees, we modify a structure-aware Tree Transformer model (Nguyen et al., 2020) for the tree-to-tree code generation task. We focus on constituency-based parse trees in this paper because of space constraints as this is a short paper. Moreover, as pointed out by Nguyen et al. (2020), there is little evidence of constituency structures being learned implicitly in language models, whereas dependency structures have been shown to be implicitly embedded in models like BERT (Devlin et al., 2019; Hewitt and Manning, 2019). We evaluate our models on the CoNaLa dataset (Yin et al., 2018) and find that incorporating constituency parse trees in input using structure-aware encoders improves the quality of generated code. We further evaluate our models on the ATIS dataset (Hemphill et al., 1990), which translates natural language sentences into their lambda calculus logical forms and show that a structure-aware Transformer significantly improves performance over a standard Transformer.

We also focus on analyzing the input parse trees to find the aspects that benefit code generation. Our analysis comprises ablation experiments on our pro-

posed structure-aware model and pattern analysis of the output from different models with respect to the characteristics of input natural language specification. Specifically, we analyze the variation in performance with the presence of user-defined identifiers and variable entities in input sentence, and the complexity of input trees. We find that the structure-aware model improves performance when such identifiers and variables are present towards the end of the input sentences and when the input sentences are short in length.

2 Related Work

Code Generation. Code generation for general-purpose programming languages is a recent phenomenon, earlier works being focused on domain-specific languages (Gulwani and Marron, 2014; Raza et al., 2015). Recent works have mainly applied sequence-to-tree models for code generation, with the tree being the AST of target source code (Dong and Lapata, 2016; Yin and Neubig, 2017; Rabinovich et al., 2017; Yin and Neubig, 2018, 2019; Shin et al., 2019; Xu et al., 2020; Sun et al., 2020). While the use of ASTs for code generation has been substantially studied, to the best of our knowledge, the use of input parse tree for code generation is largely unexplored.

Semantic Parsing. Several methods have been proposed to parse natural language sentences to formal meaning representations like lambda calculus (Wong and Mooney, 2007), Alexa Meaning Representation Language (Kumar et al., 2017), Abstract Meaning Representations (AMR) (Banarescu et al., 2013), structured queries (Iyer et al., 2017; Yin and Neubig, 2018), etc. Many of the recent works for semantic parsing have focused on sequence-to-tree models leveraging tree structures like AST as the intermediate representation for target meaning representation (Yin and Neubig, 2018; Sun et al., 2020). Code generation can also be regarded as a form of semantic parsing where the target meaning representation is programming language snippet.

Source Trees and Structure-Aware Models. Several structure-aware tree-encoders have also been proposed to process the source trees (Chen et al., 2017a,b; Yang et al., 2017; Nguyen et al., 2020). While many of the tree-encoders are dependent on recurrent mechanism and hence are unparallelizable, Nguyen et al. (2020) propose a Transformer-based structure-aware model that is parallelizable. Concurrently, several tree-to-seq models have been proposed that leverage source syntactic trees for NLP tasks like machine translation (Eriguchi et al., 2016; Yang et al., 2017; Eriguchi et al., 2017; Chen et al., 2017b) and sentence modeling (Shi et al., 2018). There has been some work on leveraging hybrid tree - a joint tree-like representation of the NL sentence and corresponding meaning representation - for semantic parsing (Lu et al., 2008; Jie and Lu, 2018), while Harer et al. (2019) made use of source tree structures for code correction. However, the same is unexplored in the context of code generation. We study the use of tree-to-tree models for code generation and provide analysis of its various modules.

3 Our Models

3.1 Baseline (Sequence-to-Tree Model)

We use a standard Transformer model (Vaswani et al., 2017) as our natural language-to-code baseline. We build a sequence-to-tree model with a regular Transformer encoder and decoder. The encoder maps the source sequence $\mathbf{x} = x_1, x_2, ..., x_n$ to its vector representation $\hat{\mathbf{x}} = \hat{\mathbf{x_1}}, \hat{\mathbf{x_2}}, ..., \hat{\mathbf{x_n}}$, which is passed into the decoder. At each time step t, we linearize the AST generated till time step $t-1$ i.e. AST $y_{<t}$ and concatenate its embedding with the embedding of the corresponding parent actions, following Yin and Neubig (2017). Decoder takes this partial AST vector representation and source vector representation $\hat{\mathbf{x}}$ from encoder as input and expands the frontier non-terminal node of the partial AST. Here, ASTs are linearized by the pre-order depth-first traversal and the expansion of the AST, at each time step, is constrained by the grammar rules of the underlying programming language. We adopt the ASDL grammar and transition system (Yin and Neubig, 2018) that decomposes the production of an AST into a sequence of actions. At each time step t, the action a_t can be of 3 types (see Appendix for details). Given the input specification $\mathbf{x}$, the probability of generating an AST $\mathbf{y}$ can be expressed in terms of probabilities of generating corresponding actions: $p(\mathbf{y} \mid \mathbf{x}) = \prod_t p(a_t \mid \mathbf{x}, y_{<t})$. Here, a_t is the action at time step t and $y_{<t}$ is the partial AST generated upto time step t. We also use a pointer network (Vinyals et al., 2015) to allow the model to copy relevant entities from input sequence while generating a terminal AST node.

3.2 Linearized Tree-to-Tree Model

Here, we use the identical model architecture as our baseline (see Sec. 3.1) but we replace the input NL sequence with its linearized constituency-based parse tree. Constituency trees aim to describe syntactic structure of the sentence by dividing it into sub-phrases. As discussed in Sec. 1, this structural information can promote alignment between source and target sub-trees (AST), thereby improving downstream generation task. In our model, constituency trees are linearized by the pre-order depth-first traversal (see Fig. 5 in Appendix). Our output is the AST representation of code.

3.3 Structured Tree-to-Tree Model with Hierarchical Accumulation

A standard Transformer encoder (see Sec. 3.1) is not designed to process the structural information of input parse trees. On the other hand, many tree-based models have been proposed in the past to process the structural information (Chen et al., 2018; Eriguchi et al., 2016; Rao et al., 2019) but most of them are based on recurrent mechanism and hence, not parallelizable like Transformer-based models. This observation motivated us to build a Transformer-based structure-aware tree-to-tree model. In this paper, we adapt Tree Transformer, an attention-based tree-to-tree model with hierarchical accumulation proposed by Nguyen et al. (2020), for code generation. Hierarchical accumulation aims to encode the tree by performing a series of operations including upward cumulative-average and weighted aggregation on the interpolated tree matrix. Furthermore, the model includes hierarchical embeddings to induce biases that reflect hierarchy within each branch of the tree and among the siblings within a subtree. Finally, subtree masking is used to filter out irrelevant information during upward cumulative-average and weighted aggregation operations. In this model, our target is identical to that of our baseline i.e., the AST representation of the source code, which is later converted to source code with the help of the transition system. We linearize the AST in the same fashion as our baseline, concatenate it with the corresponding parent actions vector in the hidden dimension and pass it into the decoder along with the leaves and nodes vector representations from the encoder. We also add a pointer network (Vinyals et al., 2015) to allow the model to copy from leaves of input parse tree while generating a terminal AST node. Without pointer network, our model architecture is identical to the Tree Transformer, so we refer the reader to Nguyen et al. (2020) for a complete description of the model architecture.

Method	**BLEU**
Xu et al. (2020)	27.2
Baseline: Text-to-Tree	28.13

Model 2: Structured Constituency Tree-to-Tree	**30.30**

Table 1: Results on the test set of CoNaLa dataset.

4 Experimental Setup

Dataset. We evaluate each of the models described in Sec. 3 on the CoNaLa (Yin et al., 2018) and ATIS (Hemphill et al., 1990) datasets. The CoNaLa dataset contains 2379 manually curated intent-snippet pairs for training (200 of which we use for validation) and 500 pairs for test. Although the CoNaLa dataset consists of 600k additional mined intent-snippet pairs, we train our models only on the manually-curated training dataset and compare them with Xu et al. (2020) model trained on the same dataset and without the use of reranker. The ATIS dataset consists of 4434, 491 and 448 pairs for training, validation, and test respectively. Following previous works, we use corpus-level BLEU-4 and exact-match accuracy metrics for evaluation on CoNaLa and ATIS datasets respectively. See Appendix for details on training and inference.

5 Results

Table 1 shows BLEU scores from our experiments on the CoNaLa dataset. Our baseline Transformer model outperforms previous state-of-the-art LSTM-based model (Xu et al., 2020) by 0.93 BLEU points. The linearized constituency tree-to-tree model hinders the BLEU score compared to our baseline. However, the structured constituency tree-to-tree model significantly outperforms baseline by 2.17 ($p<0.01$)[2] BLEU points and linearized constituency tree-to-tree model by 2.59 ($p<0.01$) BLEU points. It also outperforms the baseline model by 8% in terms of **human-evaluated** code quality (see Appendix). This suggests that the structured inputs can provide important cues for generating high quality code snippets through structure-aware encodings. This information is lost when trees are converted to linearized inputs, thereby

leading to a drop in performance over the text-to-tree baseline. It is important to note that our models have significantly higher number of parameters compared to (Xu et al., 2020) (roughly 44-49M for our models vs 2M for their model) as their model consists of only one layer of LSTM. However, we ran the LSTM model with higher number of parameters by increasing the embedding dimensions and the number of hidden layers in encoder LSTM and we did not see significant improvement in BLEU score. This indicates that the superior performance of our models is primarily due to the rather than the increased count of learnable parameters.

Table 2 shows accuracy scores from our experiments on the ATIS dataset. Our baseline model performs significantly worse than the LSTM-based TRANX (Yin and Neubig, 2018) and the accuracy further drops with the linearized constituency tree-to-tree model. Our structured model, however, performs significantly better than the aforementioned models ($p<0.01$), a trend we observed in results on the CoNaLa dataset as well. The accuracy of the structured model is still slightly worse than the TreeGen model (Sun et al., 2020). This might be because the TreeGen model consists of an AST reader which encodes the partial code tree generated in previous timesteps using structure-aware tree convolutions, during generation at each timestep. Our model lacks such a module for the target AST. Nonetheless, the overall trend among our three models suggests that parse trees benefit semantic parsing as long as their structure is incorporated in the model. However, if this extra hierarchical information is encoded in a linear fashion, it results in negative contribution to semantic parsing (row 4 in Table 2). Overall, our results also provide motivation for joint modelling of both, input and output parse trees, for semantic parsing.

6 Analysis

6.1 Ablation Tests

We ablate our best model to understand the effect of the various modules in Tree Transformer on target task and present results in Table 3. First, we remove subtree masking which allows each node of the tree to attend over nodes that are not in the subtree rooted at that node in hierarchical accumulation. Second, we remove the use of hierarchical embeddings in our model. On the CoNaLa dataset, both experiments result in negative impact on the model's performance. This suggests that subtree masking is a crucial mechanism for structure-aware encoding i.e, for each node in the parse tree, only the relevant information within the subtree rooted at the node is useful. Comparatively, the results show that subtree masking is more important than hierarchical embeddings.

6.2 Pattern Analysis

Following Yin and Neubig (2017) and Xu et al. (2020), we next analyze the input intents and the corresponding code generated by the baseline model and the structured model (on a subset of test samples of CoNaLa datset) to find recurring patterns. First, we observe that input specifications in CoNaLa dataset contain quoted strings, which often occur as user-defined identifiers or strings in generated code as well. We find that when these quoted strings appear towards the end of the input sentence, the difference in quality of output code by the two models in terms of average BLEU score is higher than usual i.e., more than 5 BLEU points (row 2 of Table 4). Moreover, when the input sentence contains two or more quoted strings,

I: Create list var_0 containing 100 instances of object var_1

Figure 2: Sample predictions of our models when multiple quoted strings appear in the input sentence. (I=Input, BM=Baseline Model, SM=Structured Model)

Pattern	Baseline	Structured
All Intents	20.23	**23.74**
Ending with quoted string	20.79	**26.42**
Multiple quoted strings	23.55	**29.20**
No quoted strings	10.04	**12.42**

Table 4: Comparison of average BLEU scores of baseline model and structured model in relation to different characteristics of input intents of CoNaLa dataset. Results are shown on the test set.

the baseline model often fails to capture the semantic relationship between those strings in the output code resulting in lower BLEU scores (row 3 of Table 4). However, in the absence of any quoted strings, the structure-aware model does better than the baseline by only 2 BLEU points (row 4 of Table 4). This shows that the structured input, when paired with a structure-aware encoder, helps capture dependencies between semantic units. Fig. 1 and Fig. 2 provide examples of both these scenarios and Table 4 compares the average BLEU scores.

Similarly, we notice that there are variable entities like city, airline, airport, time, etc. in the input specifications, which also appear in the corresponding outputs in the ATIS dataset. We find that our structure-aware model outperforms the baseline model by 12.57 points when such variables occur at the end of the input sentence (see row 3 in Table 6), suggesting that the model is able to capture long-term dependencies (see Fig. 8).

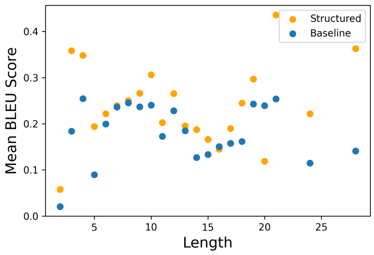

Figure 3: Plot of input intent length vs. mean BLEU score for our baseline and structured model on the test set of CoNaLa dataset.

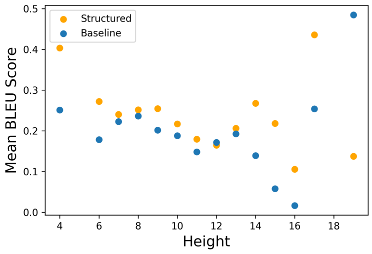

Figure 4: Plot of height of input parse tree vs. mean BLEU score for our baseline and structured model on the test set of CoNaLa dataset.

6.3 Comparison Based on Input Complexity

We compare the performance of the baseline text-to-tree and structured tree-to-tree models w.r.t. input complexity i.e. the length of input sentences and height of the input parse trees in the test set of CoNaLa dataset. The variation of mean BLEU scores w.r.t. length of input sentence and height of input trees is shown in Figures 3 and 4 respectively. In both figures, we observe that the structure-aware model outperforms baseline by wider margins for inputs of shorter length and height. Similarly, there are smaller but consistent improvements for inputs of medium complexity. The margins are largest for samples of high complexity, but this observation is supported by relatively few data points (see scatter plots in Appendix). From these results, we infer that the structured model is particularly helpful for short input sentences or parse trees in code generation. Similarly, the structured model significantly outperforms the baseline for shorter intent lengths in the ATIS dataset. However, we did not find any clear linkage between the height of input tree and the performance of our models on the ATIS dataset (see Figures 9 and 10 in Appendix).

7 Conclusion

We experimented with models to utilize input constituency parse trees for code generation and semantic parsing. Our tree-to-tree model significantly outperforms other approaches for code generation and is competitive for semantic parsing. We find that the hierarchical structure of parse trees helps the structure-aware model capture semantic relationships between user-defined identifiers and variable entities in the input intent.

Appendices

A Our Models

A.1 Baseline (Sequence-to-Tree Model)

We use a standard Transformer model (Vaswani et al., 2017) as our natural language-to-code baseline. We build a sequence-to-tree model with a regular Transformer encoder and decoder. The encoder maps the source sequence $\mathbf{x} = x_1, x_2, ..., x_n$ to its vector representation $\hat{\mathbf{x}} = \hat{\mathbf{x_1}}, \hat{\mathbf{x_2}}, ..., \hat{\mathbf{x_n}}$, which is passed into the decoder. At each time step t, we linearize the AST generated till time step $t-1$ i.e. AST $y_{<t}$ and concatenate its embedding with the embedding of the corresponding parent actions, following Yin and Neubig (2017). The decoder takes this partial AST vector representation and the source vector representation $\hat{\mathbf{x}}$ from encoder as input and expands the frontier non-terminal node of the partial AST. Here, the ASTs are linearized by the pre-order depth-first traversal and the expansion of the AST, at each time step, is constrained by the grammar rules of the underlying programming language. We adopt the ASDL grammar for Python and transition system (Yin and Neubig, 2018) that decomposes the production of an AST into a sequence of actions. At each time step t, the action a_t can be of 3 types:

- *ApplyRule Action*: Applies production rule R to the partial AST.
- *Reduce Action*: Denotes the completion of a field with optional or multiple cardinalities.
- *GenToken Action*: Expands a terminal node by generating a leaf token.

Given the input specification $\mathbf{x}$, the probability of generating an AST $\mathbf{y}$ can be expressed in terms of the probabilities of generating the corresponding actions:

$$p(\mathbf{y} \mid \mathbf{x}) = \prod_t p(a_t \mid \mathbf{x}, y_{<t}) \qquad (1)$$

Here, a_t is the action at time step t and $y_{<t}$ is the partial AST generated upto time step t. We also use a pointer network (Vinyals et al., 2015) to allow the model to copy relevant entities from input sequence while generating a terminal AST node with GenToken Action.

B Experimental Setup

Training and Inference. All of our models have 6 encoder layers and 6 decoder layers. Our models are trained on GPUs using Google Colab and each model takes 2-3 hours for a single run. We perform manual hyperparameter tuning, using 4-5 runs for each model. We tried learning rates within the range [1e-4, 5e-5]. After manual tuning, for CoNaLa dataset, we trained all the models using learning rate of 1e-4. For ATIS dataset, we use learning rate of 2e-4 for our baseline model, 5e-5 for our Linearized Tree-to-Tree model and 4e-5 for our structured model. We use batch size of 64.

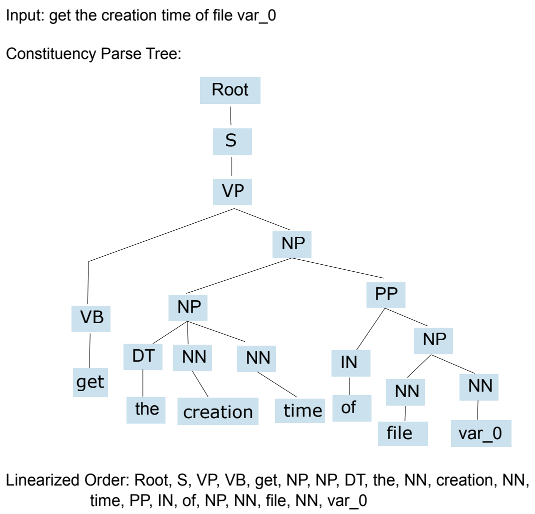

Figure 5: Constituency parse tree of natural language specification *get the creation time of file var_0* and its linearized form. Words from the input specification are leaves of the tree.

Models	**Wins**	**Loses**	**Tie**
Structured T2T vs. Baseline	35%	27%	38%

Table 5: Results from human evaluation of generated code. Wins and Loses refer to the %times code generated from structured tree-to-tree model was chosen over those from baseline model.

We parse source text into constituency trees using Stanford CoreNLP parser (Manning et al., 2014). During inference, we use beam search with beam size of 30 for CoNaLa dataset and beam size of 1 for ATIS dataset to predict the output AST for a given natural language intent. We begin the beam search with one AST initialized with the root node and run until maximum time-step T or until we find K complete ASTs, where K is the beam-size. The maximum time-step is set to 200.

C Results

C.1 Human Evaluation

We also perform human evaluation of 100 samples from the CoNaLa dataset (see Table 5). The annotator (non-coauthor graduate student, proficient in Python) was instructed to pick the better code output for a given input specification. The samples contained shuffled outputs from our baseline and structure-aware models. Outputs from structure-aware model were preferred 35% of the times while those from the baseline were preferred 27% of the times and rest of the instances ended in a tie over code quality.

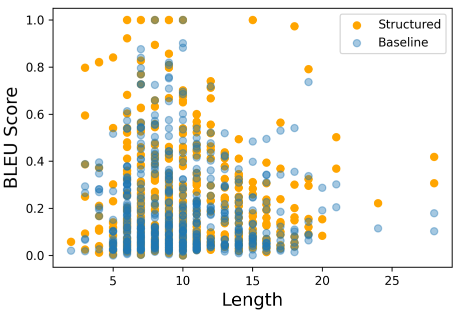

Figure 6: Scatter plot of input length vs. BLEU score for samples from the test set of CoNaLa dataset.

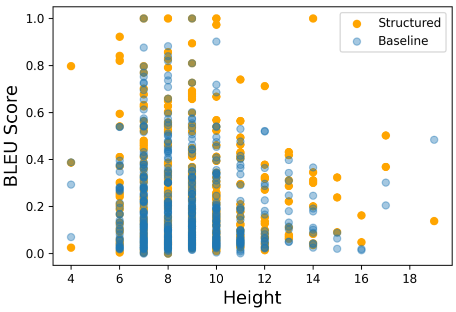

Figure 7: Scatter plot of height of input parse tree vs. BLEU score for samples from the test set of CoNaLa dataset.

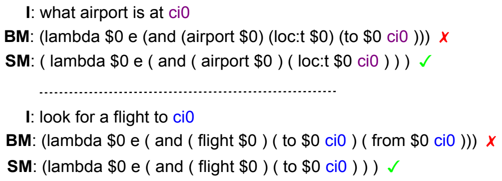
C.2 Scatter Plots

We present two scatter plots for demonstrating the effect of input complexity on model performance for the CoNaLa dataset. Fig. 6 compares sentence-level BLEU score of predictions from our baseline and structured models against the length of input sentences. Similarly, Fig. 7 compares sentence-level BLEU score of predictions from our baseline and structured models against the height of input parse trees. Both of these comparisons are performed on the test set of CoNaLa dataset.



```
I: what airport is at ci0
BM: (lambda $0 e (and (airport $0) (loc:t $0) (to $0 ci0 ))) ✗
SM: ( lambda $0 e ( and ( airport $0 ) ( loc:t $0 ci0 ) ) ) ✓
.........................................................................
I: look for a flight to ci0
BM: (lambda $0 e ( and ( flight $0 ) ( to $0 ci0 ) ( from $0 ci0 ))) ✗
SM: (lambda $0 e ( and ( flight $0 ) ( to $0 ci0 ) ) ) ✓
```

Figure 8: Outputs of our baseline and structured model for the ATIS dataset when variable entities appear at the end of input sentences.

Pattern	Baseline	Structured
All Intents	75.89	**86.83**
Not ending with a variable	74.52	**80.18**
Ending with a variable	76.31	**88.88**

Table 6: Comparison of accuracies of baseline model and structured model in relation to different characteristics of input intents of ATIS dataset. Results are shown on test set.

C.3 Pattern Analysis

Following Yin and Neubig (2017) and Xu et al. (2020), we next analyze the input intents and the corresponding code generated by the baseline model and our best model (on a small test sample), i.e., Structured Constituency Tree-to-Tree to find recurring patterns. We observe that the code generated by the structured model is significantly better for input intents containing certain characteristics. First, we observe that input specifications in CoNaLa dataset contain quoted strings (see placeholder `str_0` in Fig. 1 of the main text). These strings often occur as user-defined identifiers in the input sentence and as strings in generated code as well. We find that when these quoted strings appear towards the end of the input sentence, the difference in quality of output code by the two models in terms of average BLEU score is higher than usual i.e., more than 5 BLEU points (see row 2 in Table 4). We also find that when the input sentence contains two or more quoted strings, the baseline model often fails to capture the semantic relationship between those strings in the output code, resulting in lower BLEU scores. However, the structure-aware model succeeds at the task, resulting in higher BLEU scores (see row 3 in Table 4). In the absence of any quoted strings, the structure-aware model does better than the baseline by only 2 BLEU points (see row 4 in Table 4). This shows that when the structured input is paired with a structure-aware encoder, it helps capture the semantic relationships between multiple units. Fig. 1 and Fig. 2 provide examples of both these scenarios and Table 4 compares the average BLEU score of all the examples in the test set with 1) quoted string at the end of input sentence, 2) two or more quoted strings and 3) zero quoted strings,

Similarly, we notice that there are variable entities like city (`ci0` in Fig. 8), airline, airport, time, etc in the input specifications, which also appear in the corresponding outputs in the ATIS dataset. Such variables are anonymized with identifiers of same type following (Dong and Lapata, 2016). We find that when such variables occur at the end of the input sentence, our structured model does signifi-

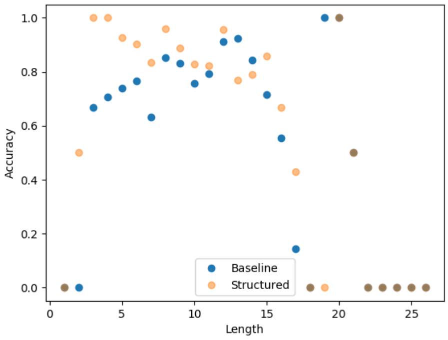


Figure 9: Plot of length of inputs vs accuracy on the test set of ATIS dataset.

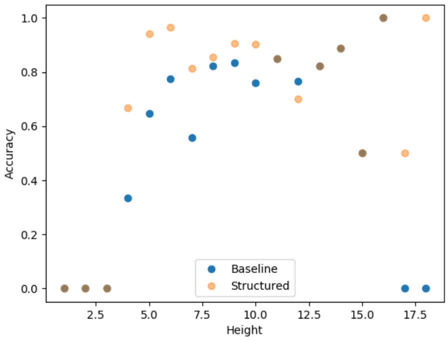

Figure 10: Plot of height of input parse trees vs accuracy on the test set of ATIS dataset.

cantly better than our baseline (see row 3 in Table 6) but the difference decreases in cases where the variables don't occur at the end of the input sentence (see row 2 in Table 6). Fig. 8 provides examples of the cases where variable entities occur at the end of the input sentences.

C.4 Comparison Based on Input Complexity

We compare the performance of our two models with respect to the complexity of input sentences. We rank the complexity of an input sentence by its length and the height of the corresponding parse tree i.e., the longest length of the path from the root node of the tree to its leaves. Firstly, we do this analysis on CoNaLa dataset. Fig. 3 presents a plot of length of input sentences and mean BLEU scores of generated code snippets. Fig. 4 presents a plot of height of input trees and mean BLEU scores of generated code snippets. Similarly, Figures 6 and 7 are scatter plots of sentence-level BLEU scores for generated code snipppets vs. length of input sentences and height of input parse trees respectively. We can see in both Fig. 3 and 4 that there is a wider gap between mean BLEU score of our structured model and baseline in the beginning, with the structured model performing significantly better. The gap narrows in the middle and widens towards the end. However, as we can see from the Figures 6 and 7, there are very few data points towards the end to draw any conclusion. From these observations, we infer that for code generation, structured model is particularly helpful for short input sentences or for short input parse trees. Similarly, the structured model significantly outperforms the baseline for shorter intent lengths in the ATIS dataset. However, we did not find any clear linkage between the height of input sentences and performance of our models for semantic parsing with the ATIS dataset. Fig 9 plots length of input sentences against accuracy and Fig 10 plots height of input parse trees against accuracy of outputs for samples in the test set of ATIS dataset.

How Does Distilled Data Complexity Impact the Quality and Confidence of Non-Autoregressive Machine Translation?

Abstract

While non-autoregressive (NAR) models are showing great promise for machine translation (MT), their use is limited by their dependence on knowledge distillation from autoregressive models. To address this issue, we seek to understand why distillation is so effective. Prior work suggests that distilled training data is less complex than manual translations. Based on experiments with the Levenshtein Transformer and the Mask-Predict NAR models on the WMT14 German-English task, this paper shows that different types of complexity have different impacts: while reducing lexical diversity and decreasing reordering complexity both help NAR learn better alignment between source and target, and thus improve translation quality, lexical diversity is the main reason why distillation increases model confidence, which affects the calibration of different NAR models differently.

1 Introduction and Background

When training NAR models for neural machine translation (NMT), sequence-level knowledge distillation (Kim and Rush, 2016) is key to match the translation quality of autoregressive (AR) models (Gu et al., 2018; Lee et al., 2018; Ghazvininejad et al., 2019; Gu et al., 2019). Knowledge distillation was first proposed to obtain small *student* models that match the quality of a higher-capacity *teacher* models (Liang et al., 2008; Hinton et al., 2015). Sequence-level knowledge distillation (SLKD) trains the student model $p(\boldsymbol{y} \mid \boldsymbol{x})$ to approximate the teacher distribution $q(\boldsymbol{y} \mid \boldsymbol{x})$ by maximizing the following objective: $\mathcal{L}_{\text{SEQ-KD}} = -\sum_{\boldsymbol{y} \in \mathcal{Y}} q(\boldsymbol{y} \mid \boldsymbol{x}) \log p(\boldsymbol{y} \mid \boldsymbol{x}) \approx -\sum_{\boldsymbol{y} \in \mathcal{Y}} \mathbb{1}\left[\boldsymbol{y} = \hat{\boldsymbol{y}}\right] \log p(\boldsymbol{y} \mid \boldsymbol{x})$, where $\mathcal{Y}$ represents the space of all possible target sequences, and $\hat{\boldsymbol{y}}$ is the output from running beam search with the teacher model q.

However, we do not yet have a clear picture for how SLKD impacts NAR training. Ren et al. (2020) show that SLKD reduces the degree of dependency between target tokens. Gu et al. (2018) hypothesize that SLKD reduces the number of modes in the output distribution (alternative translations for a source). This hypothesis was supported by experiments that use multiway parallel data to simulate the modes (Zhou et al., 2019). Zhou et al. (2019) also investigate the impact of data complexity on NAR translation quality – they generate distilled data of varying complexity with AR models of different capacity and show that higher-capacity NAR models require more complex distilled data to achieve better translation quality. They further show that generating distilled references with mixture of experts (Shen et al., 2019) improves NAR translation quality. However, training samples can be complex in different ways, and it remains unclear how different types of data complexity alter the internal working of NAR models and their translation quality. We also anticipate that data complexity may impact the uncertainty and calibration of NAR models – an understudied question, unlike for AR models (Ott et al., 2018; Wang et al., 2020).

This paper focuses on two types of data complexity – lexical diversity and degree of word reordering. We expose two state-of-the-art NAR models (Mask-Predict (Ghazvininejad et al., 2019) and Levenshtein Transformer (Gu et al., 2019)) to distilled references of varying complexity on the WMT14 German-English task. Experiments show that decreasing reordering complexity and reducing lexical diversity via distillation both help NAR models learn better alignment between source and target and thus improve translation quality. Further analysis shows that knowledge distillation lowers model uncertainty by reducing lexical diversity, which affects the calibration of Mask-Predict and Levenshtein Transformer models in opposite directions.

2 Generating Diverse Distilled References

We measure **distilled corpus complexity** with:

- **Word Reordering Degree** computed by the average fuzzy reordering score (FRS) (Talbot et al., 2011) over all sentence pairs. FRS is an MT evaluation metric introduced to distinguish significant changes in reordering rules of MT systems on syntactically distant language pairs. A higher FRS indicates that the hypothesis is more monotonically aligned to the source. Zhou et al. (2019) show that distilled data has a higher FRS than the real data which may benefit NAR models.
- **Lexical Diversity** which captures the diversity of target word choices given a source word. We compute the lexical diversity $LD(d)$ of the distilled corpus d by averaging the entropy of target words y conditioned on a source word x (Zhou et al., 2019): $LD(d) = \frac{1}{|\mathcal{V}_x|} \sum_{x \in \mathcal{V}_x} \mathbb{H}\left[y \,|\, x\right]$, where $\mathcal{V}_x$ denotes the source vocabulary.

To isolate the impact of complexity factors, we seek to control the **faithfulness** $F(d)$ of the distilled data d to the real parallel data r. We compute it as the KL-divergence of the alignment distribution between the real data r and the distilled data d (Zhou et al., 2019): $F(d) = \frac{1}{|\mathcal{V}_x|} \sum_{x \in \mathcal{V}_x} D_{\mathrm{KL}}\left[\, p_r(y \,|\, x) || \, p_d(y \,|\, x)\right]$.

Distilled Sample Generation To encourage diversity according to the corpus-level metrics above, we select distilled references for each source from the k-best list of AR hypotheses,[1] using instantiations of the following score:

$$\text{score}(\hat{\boldsymbol{y}}|\boldsymbol{x}, \boldsymbol{y}) = \lambda \, \text{sim}(\hat{\boldsymbol{y}}, \boldsymbol{y}) + (1 - \lambda) \, \text{cxty}(\hat{\boldsymbol{y}}, \boldsymbol{x})$$

where the similarity $\text{sim}(\hat{\boldsymbol{y}}, \boldsymbol{y})$ measures how faithful the hypothesis $\hat{\boldsymbol{y}}$ is to the original reference $\boldsymbol{y}$ and the complexity $\text{cxty}(\hat{\boldsymbol{y}}, \boldsymbol{x})$ captures the relationship between the target sequence $\hat{\boldsymbol{y}}$ and source sequence $\boldsymbol{x}$. The similarity function is the smoothed sentence-level BLEU (Chen and Cherry, 2014) w.r.t the original reference. We use three different complexity functions: 1) **FRS**, 2) **word-alignment score**[2] that measures complexity on a word level, and 3) **NMT score**[3] that measures complexity on a sentence level.

	Real	Distill	Δ
Original	24.2	26.6	+2.4
Reordered	30.0	29.4	−0.6

Table 1: BLEU scores on the original WMT14 En-De and the synthetic reordered version. For each task, we compare LevT models trained on real vs. distilled data.

3 Experimental Settings

Set-Up We use En-De and De-En datasets from WMT14 (Bojar et al., 2014) with the same preprocessing steps as Gu et al. (2019). We evaluate translation quality with case-sensitive tokenized BLEU,[4] using the Moses tokenizer.

Models We use two state-of-the-art NAR models:

- **Mask-Predict (MaskT)** (Ghazvininejad et al., 2019) uses a masked language model (Devlin et al., 2019) to generate the target sequence by iteratively masking out and regenerating the subset of tokens that the model is least confident about.
- **Levenshtein Transformer (LevT)** (Gu et al., 2019) generates the target sequence through iterative insertion and deletion steps.

All AR and NAR models adopt the *base* Transformer architecture (Vaswani et al., 2017). We train all models using a batch size of $64,800$ tokens for maximum $300,000$ steps and select the best checkpoint based on validation perplexity (see Appendix for details). During inference, we set the maximum number of iterations to 10. All word alignments in this paper are generated automatically using *fast-align* (Dyer et al., 2013).[5]

4 Preliminary: SLKD Helps NAR Learn Word Alignment

Our work is motivated by the hypothesis that SLKD helps NAR models learn (implicit) alignment between source and target words. We first test

---

[1] This is inspired by sequence-level interpolation (Kim and Rush, 2016), but they select hypothesis using BLEU while we use more diverse criteria. We use beam search with $k = 32$.

[2] Sum of the log probabilities of each target word conditioned on its aligned source words given by *fast-align*.

[3] Log probability of the target sentence conditioned on the source given by an AR model.

[4] `https://github.com/pytorch/fairseq/blob/master/fairseq/clib/libbleu/libbleu.cpp`

[5] This might introduce alignment errors leading to lower absolute FRS scores than with if we had access to gold manual alignments. However, this measurement noise is unlikely to impact our findings because 1) it is likely to be small on distilled data generated by autoregressive NMT models, which should be easier to align than original translations, and 2) distilled data versions are expected to be impacted uniformly.

	Data Property			BLEU ↑	
Data Version	FRS	LexDiv	Faith	MaskT	LevT
Real	0.46	0.36	0.0	28.0	27.6
Distilled	0.55	0.18	7.9	29.6	30.6
selection via BLEU					
+0.5 NMT	0.55	0.17	7.6	29.5	30.6
+0.5 w-align	0.57	0.18	7.6	29.2	30.1 ↓
+0.5 FRS	0.61	0.19	7.6	28.8 ↓	29.6 ↓
selection via BLEU					
+0.2 NMT	0.55	0.17	7.8	29.2	30.4
+0.2 w-align	0.58	0.18	7.9	28.7 ↓	30.0 ↓
+0.2 FRS	0.64	0.19	7.8	28.5 ↓	29.7 ↓

Table 2: Translation quality on WMT14 De-En. In the bottom two groups, models are trained on distilled data with similar faithfulness (*Faith*) but varying degree of reordering (FRS) and lexical diversity (*LexDiv*). ↓ marks significant drops compared to the first row in each group based on the paired bootstrap test at $p < 0.05$ (Clark et al., 2011).

this hypothesis by evaluating the effect of SLKD on two datasets: a) En-De train/dev/test sets from WMT14, and b) a synthetic version of the same task, where word alignment information is embedded by pre-reordering the source words so that they are monotonically aligned with target words (in train/dev/test sets).

While SLKD improves BLEU by +2.4 on the original En-De task, it has no benefit on the synthetic task (Table 1). This supports our hypothesis and is consistent with other findings on real data: Ghazvininejad et al. (2019) and Gu et al. (2019) showed that SLKD improves the quality of NAR models more on syntactically distant language pairs such as German-English than on Romanian-English. Furthermore, Ran et al. (2019) showed that automatically pre-reordering the source words improves the translation quality of NAR models. However, unlike in our experiment, SLKD is still needed in real translation scenarios, as exactly pre-ordering the source is not feasible at test time. Thus, we turn to understanding how distilled data helps NAR models on real translation tasks.

5 Reduced Lexical Diversity in SLKD Improves Translation Quality

We have shown that, similar to the effect of pre-reordering, SLKD benefits NAR training by reducing the difficulty of learning the source-target alignment. However, apart from the word reordering degree, reducing the lexical diversity on the target side can also reduce the difficulty of learning the alignment. In this section, we investigate how the two types of data complexity affect how well NAR models capture the source-target alignment, and therefore translation quality.

	Acc	Conf	ECE ↓
AR Transformer	63.9	72.3	10.34
MaskT w/o SLKD	63.7	74.2	10.49
MaskT w/ SLKD	65.1	86.5	21.41
LevT w/o SLKD	66.8	53.3	20.26
LevT w/ SLKD	65.9	71.3	15.17

Table 3: Average token-level accuracy (*Acc*), confidence (*Conf*), and inference ECE (ECE) of AR and the two NAR models trained with and without SLKD.

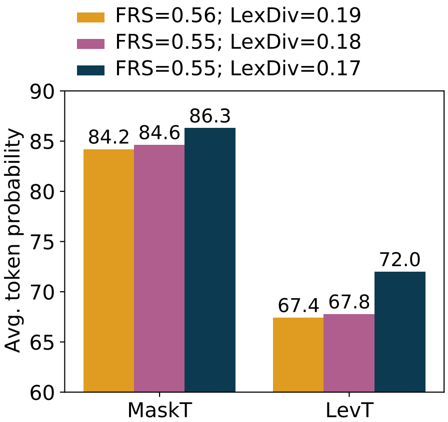
SLKD impacts both complexity types: the first two rows of Table 2 show that SLKD increases FRS by +0.09, reduces lexical diversity by −0.18, and boosts the BLEU of MaskT and LevT by 1.6–3.0 over their counterparts trained on real data.

We then compare NAR models trained on distilled data with varying degree of reordering and lexical diversity while controlling for faithfulness (2nd and 3rd group of rows in Table 2). While the absolute BLEU deltas are small, BLEU decreases significantly as the lexical diversity increases despite reduced degree of reordering. This indicates that increased lexical diversity prevails over the effect of lower degree of reordering in decreasing BLEU scores.

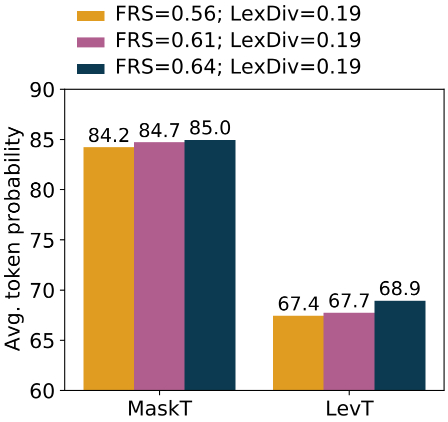
6 SLKD Increases Confidence of Source-Target Attention

To better understand how SLKD helps NAR learn the alignment between source and target, we measure how the *confidence* of the source-target attention changes over decoding iterations. Following Voita et al. (2019), we define the *confidence* of attention heads as the average of the maximum attention weights over source tokens, where the average is taken over target tokens. Higher confidence scores indicate that the model is more certain about which parts of the source sequence to attend to when predicting the target tokens.

As seen in Figure 2, SLKD increases the confidence of source-target attention on both MaskT and LevT. The increase is larger for MaskT than for LevT. For LevT, SLKD increases the attention confidence the most at early decoding iterations. At later iterations, as the model becomes more confident about which source tokens to attend to given the target tokens generated at previous iterations,



(a) Impact of lexical diversity



(b) Impact of word reordering

Figure 1: Average token-level uncertainty of MaskT and LevT trained on distilled data with decreasing degree of lexical diversity (a) and word reordering (b) from yellow to blue.

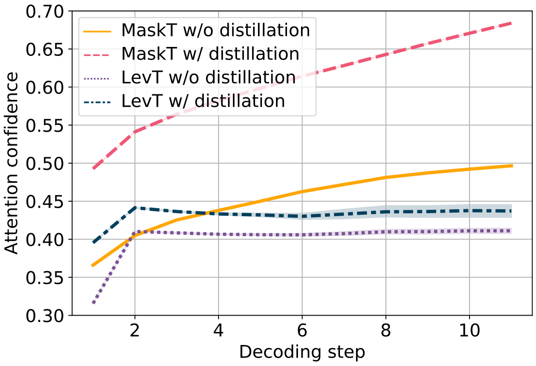


Figure 2: Source-target attention confidence of LevT and MaskT as a function of decoding step.

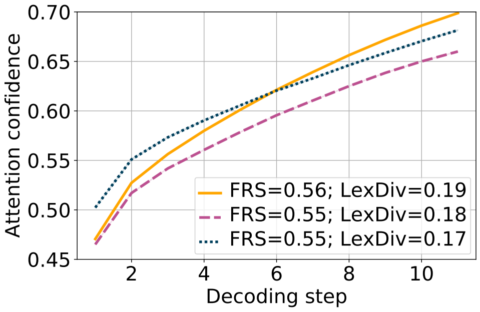
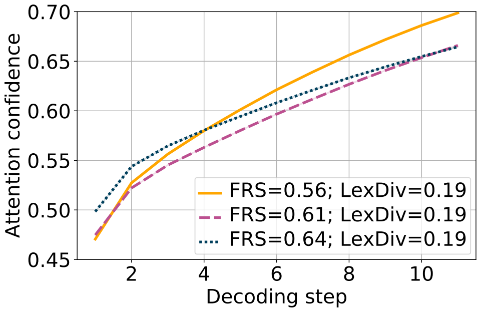
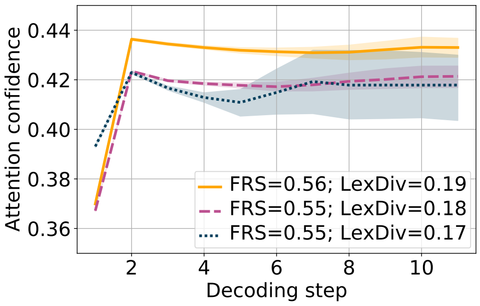


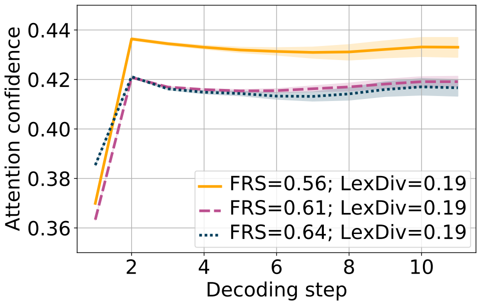
(a) LexDiv on MaskT



(b) FRS on MaskT



(c) LexDiv on LevT



(d) FRS on LevT

Figure 3: Source-target attention confidence as a function of decoding step comparing MaskT and LevT trained on distilled data with varying degree of lexical diversity (a, c) and word reordering (b, d).

the impact of SLKD becomes smaller.

Next, we separate the impact of lexical diversity and word reordering (Figure 3). Reducing both types of complexity leads to more concentrated source-target attention at early iterations. By contrast, models trained on more lexically and syntactically diverse data have more distributed source-target attention at iterations, and the attention becomes more concentrated at later iterations as more target tokens have been generated.

Overall, these results suggest that reducing lexical diversity and degree of word reordering both help NAR find the source-target alignment and thus reduce the error rate at the early decoding stage.

7 Reduced Lexical Diversity in SLKD Improves Model Confidence

Ott et al. (2018) show that the intrinsic uncertainty of translation – due to the existence of multiple semantically equivalent translations for the same source – is a source of uncertainty in the AR models' output distribution. We hypothesize that these effects might be amplified with NAR models, yet little is known about the confidence and calibration of NAR models. We measure the impact of SLKD on model uncertainty using the average token probability of the models' translation outputs, and the inference Expected Calibration Error (ECE) (Wang et al., 2020) that measures how the model's confidence on a prediction matches to the correctness of the prediction. As shown in Table 3, both MaskT and LevT become more confident when trained with SLKD. However, SLKD causes MaskT to be overconfident and hurts its calibration by $+11\%$ ECE.[6] By contrast, SLKD changes LevT from underconfident to slightly overconfident, improving its calibration by -5% lower ECE.

Next, we isolate the impact of lexical diversity and degree of word reordering on model uncertainty.[7] We measure the average token probability of MaskT and LevT trained on data with varying lexical diversity but close FRS scores (Figure 1a), and vice versa (Figure 1b). Decreasing lexical diversity by -0.02 significantly reduces model uncertainty by 2.1–4.6%, whereas the impact of word reordering degree is small: increasing FRS by $+0.08$ only increases the average uncertainty by 0.8–1.5%. By contrast, SLKD boosts FRS by $+0.09$ over the real data. This suggests that reduced lexical diversity is the main reason why SLKD increases model confidence in lexical choice, which raises concerns since Ding et al. (2021) showed that lexical choice errors are also propagated from AR to NAR models through SLKD.

8 Conclusion

We investigated the effect of knowledge distillation in NAR models trained on distilled data that differs along two types of complexity – lexical diversity and degree of word reordering. Reducing lexical diversity and decreasing word reordering degree both boost the confidence of source-target attention, suggesting that they help NAR models learn the alignment between source and target. Furthermore, distillation increases model confidence by reducing lexical diversity, which improves calibration for LevT but leads to much worse calibration for MaskT. These findings reveal a connection between distillation and existing techniques to improve NAR via pre-reordering (Ran et al., 2019) or integrating external alignment information in the source-target attention (Li et al., 2019).[8]

Our findings are based on experiments on the WMT14 English-German corpus, which is widely used in the literature of NAR translation and has interesting typological properties. While we expect these findings to hold for other tasks that exhibit similar degrees of reordering and lexical diversity, it remains to be seen to what degree they generalize to other language pairs and data settings.

We hope that this work will inspire future research on understanding of the positive and negative impact of knowledge distillation on NAR models, as well as of the more advanced approaches to improving NAR by integrating lexical choice and word reordering knowledge. In addition, our work also calls for future work on improving the calibration of NAR models.

---

[6] This might be due to decoding where MaskT repeatedly masks out and re-predicts its least confident predictions.

[7] We only measure their isolated impact on model uncertainty, not ECE, because we could not isolate lexical diversity from degree of word reordering while controlling faithfulness, which impacts ECE through accuracy.

[8] These techniques still rely on knowledge distillation for training, while this paper contributes a systematic study of factors that impact the effectiveness of distillation.

A Data Preprocessing Details

Following Gu et al. (2019), we preprocess the WMT14 En-De and De-En datasets (Bojar et al., 2014) via normalization, tokenization, true-casing, and joint BPE (Sennrich et al., 2016) with $37K$ operations.[9] The training data contain 3.9M sentence pairs, and the validation and test sets contain $3,000$ and $3,003$ sentence pairs, respectively.

B Model and Training Details

All AR and NAR models adopt the *base* Transformer architecture (Vaswani et al., 2017) with $d_{\text{model}} = 512$, $d_{\text{hidden}} = 2048$, $n_{\text{heads}} = 8$, $n_{\text{layers}} = 6$, and $p_{\text{dropout}} = 0.3$. We tie the source and target embeddings with the output layer weights (Press and Wolf, 2017; Nguyen and Chiang, 2018). We use label smoothing of 0.1. We train the models using Adam (Kingma and Ba, 2015) with initial learning rate of 0.0005 and a batch size of $64,800$ tokens for maximum $300,000$ steps. We select the best checkpoint based on validation perplexity. The total number of parameters is 65M for the AR model, 66M for MaskT, and 91M for LevT. Training takes around 230 hours for each NAR model and 110 hours for each AR model on 4 Tesla P40 GPUs.

C Detailed Experimental Results

Table 4 shows the scores of corpus-level metrics, test BLEU and validation perplexity of MaskT and LevT trained on various distilled versions of WMT14 De-En training data generated through diverse reference generation (Section 2).

D Reference Generation Examples

We show that the k-best list generated by the AR model using beam search is both lexically and syntactically diverse through a random example selected from the training set (Table 5).

Abstract

Argumentation exposes individuals to conflicting viewpoints and can help them make more informed decisions based on the pros and cons of a particular issue. While recent studies of argumentation in Natural Language Processing have mainly focused on understanding the effect of various factors of persuasion (i.e. the source, audience, and language style), the impact of exploiting the relationships among controversial topics when predicting argument persuasiveness remains under-explored. In this paper, we model the relatedness among controversial topics utilizing an embedding-based method based on individuals' stances on the topics. We then leverage these *topic embedding* features and incorporate *topic semantics* features extracted from the arguments along with the previously studied factors of persuasion. We show that incorporating both types of topic relatedness features explicitly leads to significant improvement in predicting persuasiveness and also helps enhance generalization to rare topics, in a few-shot setting.

1 Introduction

Emergence of social media and online argumentative forums provide users with a platform to gain information, express, and form opinions on a diverse set of controversial topics (i.e. issues). The increasing importance of these online platforms has motivated NLP researchers to use these platforms as one of the main domains to study the important factors of persuasion. In particular, prior work has shown that characteristics of the speaker (i.e. source), prior beliefs of the audience (Lukin et al., 2017; Durmus and Cardie, 2018), and language style (Feng and Hirst, 2011; Tan et al., 2016) are important factors in determining persuasiveness of the arguments in online argumentation platforms. Although there has been evidence in previous studies of Social Sciences that people's perceptions on a particular controversial topic may be related to their perceptions on other controversial topics (Judd and Krosnick, 1989; Sapra, 2012), the impact of exploiting this relationship among controversial topics are under-explored in NLP studies of persuasion. In this paper, we explicitly study the effect of incorporating topic relatedness among controversial topics in predicting argument persuasiveness.

To study the impact of involving topic relatedness in argument persuasion, we define two types of features: (1) *topic embedding features* and (2) *topic semantics features*. Prior work has shown that topic is an important factor (Das et al., 2016) to determine whether an emotional vs. a logical argument will be received positively by the audience. We hypothesize that encoding underlying relationship among topics with topic embedding features will be helpful in predicting persuasion since similar strategies may be effective for related topics. We further define topic semantics features to encode how focused vs. divergent each of the arguments made by the debaters is given the discussion topic, similar to Zhang et al. (2016).

We first develop an embedding-based technique inspired by (Barkan and Koenigstein, 2016) to determine the relationship among controversial topics. This methodology leverages users' stances on the topics to determine the relationship among them. We then incorporate the *topic embedding features* and *topic semantics features*, along with the previously studied factors of persuasion. We find that incorporating the topic relatedness features help improve state-of-the-art results in persuasion prediction. Moreover, we conduct experiments in a few-shot setting and show that these features help models achieve significantly better generalization performance for the rare topics.

2 Dataset

We use DDO (Durmus and Cardie, 2019) for our study. DDO includes 67,315 debates from 23 different categories, 36,294 users with their background information (e.g. political ideology, and religious ideology), and 198,759 votes from the users when they are as readers of these debates. For each debate, two debaters with different viewpoints express their opinions on a controversial topic in rounds. After the debate, voters evaluate the debaters with respect to various criteria and they share whether any of the debaters changed their stance on the topic. Users also have an opportunity to share their demographic and ideological information such as gender, ethnicity, income level, education level, political ideology, and religious ideology. They also share their stance on a pre-defined list of controversial topics (i.e. BIG ISSUES, such as *Abortion*, *Gay Marriage*, and *Global Warming* etc.)[1] that we use to determine semantic relatedness among these controversial topics.

3 Methodology

3.1 Topic Related Embeddings

Topic Embeddings. To capture the underlying relatedness between the debate topics, we learn the embedding for each controversial topics with a method inspired by Barkan and Koenigstein (2016). We hypothesize that the users' opinions (i.e. whether they are SUPPORTING or OPPOSING) on similar topics are related. We treat a set of controversial issues with the same stance from a user as a set of words appearing in the same context and use adapted Skip-gram algorithm proposed by (Mikolov et al., 2013). The embedding vectors are optimized by predicting the topic similarity that is defined as the probability that a pair of topics appearing in the same group with respect to users' opinions. We then can use these vectors to compare the similarity of each pair of the big issues.

Issue	Top similar issues: Similarity
Torture	Iran-Iraq War: 0.90 Electoral College: 0.85 Border Fence: 0.85 Military Intervention: 0.74 Racial Profiling: 0.71
Welfare	Minimum Wage: 0.97 Occupy Movement: 0.86 Medicaid & Medicare: 0.85 Labor Union: 0.84 National Health Care: 0.84
Capitalism	Flat Tax: 0.80 Social Programs: 0.73 Electoral College: 0.69 Affirmative Action: 0.69 Stimulus Spending: 0.66
Environment Protection	Medical Marijuana: 0.93 Abortion: 0.85 Global Warming Exists: 0.85 Drug Legalization: 0.82 United Nations: 0.82

Table 1: Most similar issues for *Torture*, *Welfare*, *Capitalism*, and *Environment Protection* issues.

Table 1 shows the most similar controversial issues for each of the given issues, where the similarity is calculated by the cosine similarity between the embedding vectors. We observe that some of these associations can be more related to relatively intuitive topic similarity between these issues (i.e., *Capitalism* and *Flax Tax*, and *Environmental Protection* and *Global Warming Exists*). However, in some cases, the similarity between controversial issues may have more complicated motivations such as users' underlying ideologies (i.e., as in the case of *Environmental Protection* and *Abortion* which can be justified by the study conducted by Sapra (2012)). Therefore, this method may help identify relationships among controversial issues that are not as intuitive to come up with.

Topic-Centric Attribute Embeddings. There is evidence showing there is a strong association between the users' demographics and their stances towards controversial topics (Sapra, 2012; Tedin et al., 1977). Although prior studies of persuasion has studied the effect of users' attributes on persuasiveness (Lukin et al., 2017; Durmus and Cardie, 2018, 2019), they did not explicitly model the relationship between the users' attributes and their stance towards the controversial topics. To explicitly model this relationship, we create embeddings for users' attributes in a similar way as the issue embeddings introduced in Section 3.1. We optimize the embeddings with the probability of a certain attribute appearing with a given issue-stance pair for each particular user.

Table 2 shows top similar issue-stance combinations for users with given political and religious ideology categories. Similarly, we calculate similarity by the cosine similarity between the embedding vectors. This approach reveals certain associations between users attributes (e.g. Political Ideology) and their stances (e.g. PRO vs. CON) towards certain controversial issues (e.g. *Gay Marriage*). For

---

[1] See https://www.debate.org/big-issues/ for the full list of the Big Issues.

Ideology	Issue-stance: Similarity
Conservative	Gay Marriage-CON: 0.94
	Abortion-CON: 0.93
	Global Warming Exists-CON: 0.92
	Euthanasia-CON: 0.92
	Border Fence-PRO: 0.92
	Death Penalty-PRO: 0.89
Liberal	Gun Rights-CON: 0.87
	Environmental Protection-PRO: 0.83
	Medicaid & Medicare-PRO: 0.83
	Affirmative Action-PRO: 0.83
	Global Warming Exists-PRO: 0.82
	Barack Obama-PRO: 0.81

Table 2: Most similar issue-stance combinations for the given categories of *Political Ideology*.

example, we find that users with *Conservative* vs. *Liberal* political ideologies has different views on *Global Warming* (i.e. CON vs. PRO respectively) issue looking at the similarity of corresponding embeddings.

3.2 Predicting Persuasiveness

We aim to predict which debater, either the PRO or CON side, expresses more persuasive arguments in the debate (i.e., received more votes for the *"Made more convincing arguments"* criterion.).

Debate Topic Representation. We collect debates related to list of issues in BIG ISSUES by using the words of these issues as keywords (e.g. debate topic *"Abortion should be illegal if it pregnancy does not endanger the mother's life and she is adult."* is related to BIG ISSUE "ABORTION"). The dataset includes 2,893 debates and 10,441 votes. We represent the debate topic with the **topic embedding** of the corresponding BIG ISSUE as introduced in Section 3.1. We further encode the text of the debate topic with a fine-tuned BERT (Devlin et al., 2019) taking average embedding of all the tokens to get the representation of the **topic semantics**. We concatenate these two types of embeddings to get the final representation of the debate topic.

Representing User Information. Previous work shows that both characteristics of the debaters and the audience and the linguistic features of the debate arguments are important factors in persuasion studies (Lukin et al., 2017; Durmus and Cardie, 2018, 2019; Longpre et al., 2019). Similar to prior work, to encode the background information, we first represent the user background with one-hot representation (**ONE-HOT**) to capture the users' selections on the categories (e.g., gender, political ideology, religious ideology, and etc.) or the opinion similarity with the voters. However, this representation can be very sparse and not relevant to the topic information. Therefore, we also experiment with the topic-centric embedding-based method (**ATT-EMB**) proposed in Section 3.1. We compute the background similarity as the cosine similarity of the representation vectors for the users (i.e., debaters and voters).

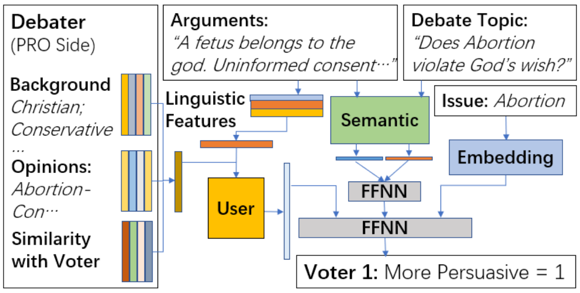

Figure 1: Overall model structure. *User, Semantic, Embedding* blocks denote the encoders for user information, argument semantics, and topic embedding. *FFNN* is a multi-layer feed-forward neural network.

Linguistic Features. Consistent with the prior work (Durmus and Cardie, 2018), to encode the arguments in the debates, we extract linguistic features including the information about the style (i.e., length, links), sentiment polarity, subjectivity (Wilson et al., 2005), and argument lexicon features (Somasundaran and Wiebe, 2010)) etc. Similar to the topic semantics introduced in Section 3.2, we also represent the semantics of the arguments with the same fine-tuned BERT.

Proposed Model. We employ a model that contains separate encoders to represent the debater characteristics, arguments, and topic-related features, as shown in Figure 1. The model encodes the debater's background information and opinions towards the BIG ISSUES, and combines the linguistic features extracted from arguments to represent the users. For the text in the debate, the model consists a siamese network structure (*Semantic* Block + *FFNN* block) (Reimers and Gurevych, 2019) to encode the relation between arguments and debate topics. Then, the model extracts the issue representation from the pretrained issue embedding introduced in Section 3.1. Finally, the user representation, together with the representation for the argument semantics and topic embedding, is passed through a multi-layer feed-forward neural network to predict the voter's perception on the persuasiveness.

Model	F1 (%)
Majority	33.25
Bi-LSTM+Glove	33.41
SBERT	50.05
ONE-HOT+Linguistic+Topic SVM	41.38
ATT-EMB+Linguistic SVM	53.51
ATT-EMB+Linguistic+Topic SVM	59.04
Ours with ONE-HOT	57.03
Ours W/O ARGUMENT	63.81
Ours W/O ATT-EMB	51.33
Ours W/O TOPIC	64.21
Ours	**65.62**

Table 3: Macro F1 scores. **Ours** denotes the model explained in Figure 1. We split the collected debates to train (70%), validation (15%), and test (15%) sets.

4 Baselines

(1) Majority Baseline: We assign the label that appears the most in training set to be the prediction for all test instances. **(2) SVM**: We concatenate debate topic representation, user and linguistic features and classify with SVM with RBF kernel. **(3) Bi-LSTM** (Hochreiter and Schmidhuber, 1997): Following (Durmus et al., 2019; Li et al., 2020), We encode the arguments and topic representation with bidirectional LSTM encoders and use a *FFNN* as classification head[2]. **(4) SBERT** (Reimers and Gurevych, 2019): Sentence-BERT (SBERT) has demonstrated that fine-tuning BERT in a Siamese/Triplet network architecture achieves the state-of-the-art results over various sentence-level classification benchmarks. We use a Siamese network to encode the sentence representation from arguments and debate topics.

5 Results

Model Ablations. The full proposed model contains three parts: user-based features (which can be represented by one-hot vectors or topic-centric user embeddings), argument-based features, and topic-based features. To understand the contribution of each component to prediction performance, we conduct ablation studies for the settings where (1) Using ATT-EMB (i.e. topic-centric user embeddings proposed in this work) vs. ONE-HOT representation to encode the user background, (2) Removing the representation for user background (W/O USER), (3) Removing the argument features and (W/O ARGUMENT) (4) Removing the topic-related features (W/O TOPIC)[3].

Model	Frequent	Rare	Δ
Ours with ATT-EMB	63.31	60.12	**-3.19**
Ours w/o ATT-EMB	56.25	52.65	-3.60
Ours w/o TOPIC-EMB	64.20	58.37	-5.83

Table 4: Results (%macro F1) for the few-shot setting experiment. Δ denotes the performance difference when testing the Rare debates.

Table 3 demonstrates the macro F1 scores for the baselines and the ablations for our model. We observe that our model outperforms the feature-based baselines significantly. For both the SVM model and the deep models, we observe a large performance drop when we use one-hot embedding representation features instead of topic-centric user embeddings. This shows that encoding the relationship between the user background and their opinions on the topics explicitly improves the prediction performance significantly. The experiments on Bi-LSTM and SBERT show that although large-scale pretrained language representation model helps achieve better performance than the baseline, encoding the semantics with deep neural network encoders alone is not as effective as our proposed method. Comparing to the baselines, our proposed method that utilizes the information from different components (i.e. users, language and topic) is more effective. Ablation study shows that components that encode the topic semantics (i.e. ATT-EMB and TOPIC) play an important role to achieve the best performance.

Few-shot Setting. We study whether the topic embeddings also enhance the generalizability across different issues. We split the debates in the test set into frequent and rare categories looking at how often debates with the same topic appear in the training set (more than 200 vs. less than 20). Table 4 shows the results comparing to the baselines for corresponding 324 frequent and 131 rare debates. We see that the gap between the prediction performance is significantly more when we remove the attribute embedding and the topic embeddings, which indicates that the topic-related embeddings benefit the knowledge transferring among debates with different topics.

portant area of study in the Sociology, Psychology (Kelman, 1961; Burgoon et al., 1975; Chaiken, 1987; Tykocinskl et al., 1994; Chambliss and Garner, 1996) and NLP communities (Hasan and Ng, 2014; Habernal and Gurevych, 2016a,b; Fang et al., 2016; Al-Khatib et al., 2017; Wang et al., 2019). The emergence of social media and argumentative forums has further attracted researchers to study the dynamics of persuasion on these platforms, including Twitter (Tan et al., 2014), ChangeMyView community on Reddit (Tan et al., 2016; Hidey et al., 2017) and DDO (Durmus and Cardie, 2019). In this work, we use DDO since it includes a wide-range of user information including users' opinions on various controversial topics as well as well-structured debates with audience votes.

Topic Aware Argument Mining. Farra et al. (2015) studied the effect of topic relevancy or consistency on essay scoring. Bosc et al. (2016) proposes a dataset of Social Media data with coarse topic labels extracted from the hashtags (e.g., #AppleWatch). Zeng et al. (2020) designed a model to encode the latent topics of argumentative conversations. Unlike the previous work, our work studies the effect of argument topic for structured debates explicitly for predicting persuasion.

7 Conclusion

In this paper, we study the impact of topic-relatedness in debate persuasion and find that involving the semantics and features of the debate topics will achieve the best performing model. Moreover, we find that using pretrained embeddings that jointly encode the issues related to the topics and people's characteristics will largely benefit the training process and generalizability. Finally, we find that focusing on the debate topic in making arguments can be an effective strategy in online debates.

A Appendix

A.1 Implementation Details

We initialize the semantic encoder for arguments and debate topics with the BERT-base model with 110M parameters. We pad the input sentences with BERT start and end symbols (i.e., [CLS] and [SEP]). For each round of the debate, we take at most three sentences (as (Li et al., 2020)) to take average and represent the arguments. The hidden size for the Bi-LSTM layers is 300. The size for the hidden states for *FFNN* blocks are 256. During training, we use cross entropy as the loss function and stochastic gradient decent (SGD) as the optimizer. We initialize all parameters randomly and train all the model with 10 epochs. The best performing models on the validation set are evaluated on the test set.

One Teacher is Enough?
Pre-trained Language Model Distillation from Multiple Teachers

Abstract

Pre-trained language models (PLMs) achieve great success in NLP. However, their huge model sizes hinder their applications in many practical systems. Knowledge distillation is a popular technique to compress PLMs, which learns a small student model from a large teacher PLM. However, the knowledge learned from a single teacher may be limited and even biased, resulting in low-quality student model. In this paper, we propose a multi-teacher knowledge distillation framework named MT-BERT for pre-trained language model compression, which can train high-quality student model from multiple teacher PLMs. In MT-BERT we design a multi-teacher co-finetuning method to jointly finetune multiple teacher PLMs in downstream tasks with shared pooling and prediction layers to align their output space for better collaborative teaching. In addition, we propose a multi-teacher hidden loss and a multi-teacher distillation loss to transfer the useful knowledge in both hidden states and soft labels from multiple teacher PLMs to the student model. Experiments on three benchmark datasets validate the effectiveness of MT-BERT in compressing PLMs.

1 Introduction

Pre-trained language models (PLMs) such as BERT and RoBERTa have achieved notable success in various NLP tasks (Devlin et al., 2019; Yang et al., 2019; Liu et al., 2019). However, many PLMs have a huge model size and computational complexity, making it difficult to deploy them to low-latency and high-concurrence online systems or devices with limited computational resources (Jiao et al., 2020; Wu et al., 2021).

Knowledge distillation is a widely used technique for compressing large-scale pre-trained language models (Sun et al., 2019; Wang et al., 2020). For example, Sanh et al. (2019) proposed DistilBERT to compress BERT by transferring knowledge from the soft labels predicted by the teacher model to student model with a distillation loss. Jiao et al. (2020) proposed TinyBERT, which aligns the hidden states and the attention heatmaps between student and teacher models. These methods usually learn the student model from a single teacher model (Gou et al., 2020). However, the knowledge and supervision provided by a single teacher model may be insufficient to learn an accurate student model, and the student model may also inherit the bias in the teacher model (Bhardwaj et al., 2020). Fortunately, many different large PLMs such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) and UniLM (Dong et al., 2019) are off-the-shelf. These PLMs may encode complementary knowledge because they usually have different configurations and are trained on different corpus with different self-supervision tasks (Qiu et al., 2020). Thus, incorporating multiple pre-trained language models into knowledge distillation has the potential to learn better student models.

In this paper, we present a multi-teacher knowledge distillation method named MT-BERT for pre-trained language model compression.[1] In MT-BERT, we propose a multi-teacher co-finetuning framework to jointly finetune multiple teacher models with a shared pooling and prediction module to align their output hidden states for better collaborative student teaching. In addition, we propose a multi-teacher hidden loss and a multi-teacher distillation loss to transfer the useful knowledge in both hidden states and soft labels from multiple teacher models to student model. Experiments on three benchmark datasets show MT-BERT can effectively improve the quality of student models for PLM compression and outperform many single-teacher knowledge distillation methods.

---

[1] We focus on task-specific knowledge distillation.

August 1–6, 2021.

2 MT-BERT

Next, we introduce the details of our multi-teacher knowledge distillation method MT-BERT for pre-trained language model compression.[2] We first introduce the multi-teacher co-finetuning framework to jointly finetune multiple teacher models in downstream tasks, and then introduce the multi-teacher distillation framework to collaboratively teach the student with multiple teachers.

2.1 Multi-Teacher Co-Finetuning

Researchers have found that distilling the knowledge in the hidden states of a teacher model is important for effective student teaching (Sun et al., 2019; Jiao et al., 2020). However, since different teacher PLMs are separately pre-trained with different settings, finetuning them independently may lead to some inconsistency in their feature space, which is not optimal for transferring knowledge in the hidden states of multiple teachers. Thus, we design a multi-teacher co-finetuning framework to obtain some uniformity among the hidden states output by the last layer of different teacher models for better collaborative student teaching, as shown in Fig. 1. Assume there are N teacher models, and denote the hidden states output by the top layer of the i-th teacher as $\mathbf{H}^i$. We use a shared pooling[3] layer to summarize each hidden matrix $\mathbf{H}^i$ into a unified text embedding, and then use a shared dense layer to convert it into a soft probability vector $\mathbf{y}_i$. Finally, we jointly optimize the summation of the task-specific losses of all teacher models, i.e., $\sum_{i=1}^{N} \mathrm{CE}(\mathbf{y}, \mathbf{y}_\mathrm{i})$, where $\mathrm{CE}(\cdot,\cdot)$ stands for the cross-entropy loss and $\mathbf{y}$ is the ground-truth label. Since the pooling and prediction layers are shared among different teachers, the feature space of the output hidden states from different teacher PLMs can be aligned, which can help them collaborate better for student teaching.

2.2 Multi-Teacher Knowledge Distillation

Next, we introduce our proposed multi-teacher knowledge distillation framework, which is shown in Fig. 2. Two loss functions are used for knowledge distillation, i.e., a multi-teacher hidden loss and a multi-teacher distillation loss.

The multi-teacher hidden loss aims to transfer knowledge in the hidden states of multiple teachers.

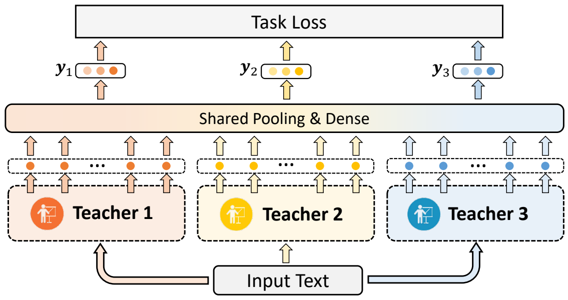

Figure 1: The multi-teacher co-finetuning framework.

Assume there are N teacher PLMs, and each of them has $T \times K$ Transformer layers. They collaboratively teach a student model with K layers, and each layer in the student model corresponds to T layers in teacher PLMs.[4] Denote the hidden states output by the j-th layer of the student model as $\mathbf{H}_j^s$, and the corresponding hidden states output by the $(T \times j)$-th layer of the i-th teacher model as $\mathbf{H}_{Tj}^i$. Following (Sun et al., 2019), we apply the mean squared error (MSE) to the hidden states of corresponding layers in the student and teacher models to encourage the student model to have similar functions with teacher models. The multi-teacher hidden loss $\mathcal{L}_{MT-Hid}$ is formulated as follows:

$$\mathcal{L}_{MT-Hid} = \sum_{i=1}^{N} \sum_{j=1}^{T} \mathrm{MSE}(\mathbf{H}_\mathrm{j}^\mathrm{s}, \mathbf{W}_\mathrm{ij} \mathbf{H}_\mathrm{Tj}^\mathrm{i}), \quad (1)$$

where $\mathbf{W}_{ij}$ is a learnable transformation matrix.

The multi-teacher distillation loss aims to transfer the knowledge in the soft labels output by multiple teachers to student. The predictions of different teachers on the same sample may have different correctness and confidence. Thus, it may be suboptimal to simply ensemble (Fukuda et al., 2017; Liu et al., 2020) or choose (Yuan et al., 2020) soft labels without the help of task labels. Since in task-specific knowledge distillation the labels of training samples are available, we propose a distillation loss weighting method to assign different weights to different samples. The weights are based on the loss inferred from the predictions of corresponding teacher against the gold labels. More specifically, the multi-teacher distillation loss $\mathcal{L}_{MT-Dis}$ is formulated as follows:

$$\mathcal{L}_{MT-Dis} = \sum_{i=1}^{N} \frac{\mathrm{CE}(\mathbf{y}_\mathrm{i}/\mathrm{t}, \mathbf{y}_\mathrm{s}/\mathrm{t})}{1 + \mathrm{CE}(\mathbf{y}, \mathbf{y}_\mathrm{i})}, \quad (2)$$

---

[2] Codes available at https://github.com/wuch15/MT-BERT

[3] In MT-BERT we use attentive pooling because it performs better than average pooling and "[CLS]" token embedding.

[4] Here we assume that all teacher models have the same number of layers. We will explore to generalize MT-BERT to scenarios where teacher models have different architectures in our future work.

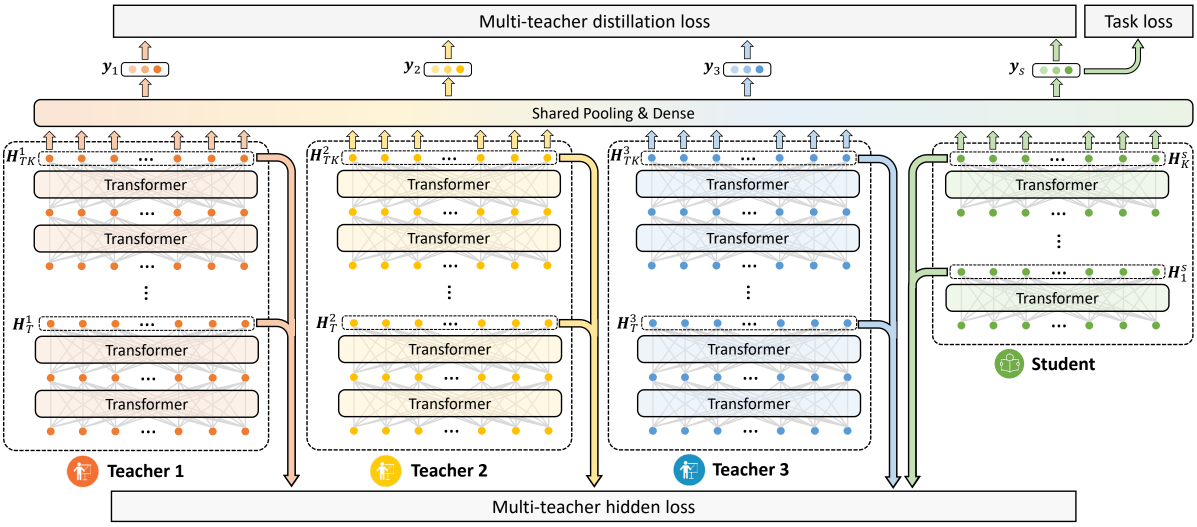

Figure 2: The multi-teacher knowledge distillation framework in MT-BERT.

where t is the temperature coefficient. In this way, if a teacher's prediction on a certain sample is more close to the ground-truth label, its corresponding distillation loss will gain higher weight.

Following (Tang et al., 2019; Lu et al., 2020), we also incorporate gold labels to compute the task-specific loss $\mathcal{L}_{Task}$ based on the predictions of the student model, i.e., $\mathcal{L}_{Task} = \text{CE}(\mathbf{y}, \mathbf{y}_s)$. The final loss function $\mathcal{L}$ for learning the student model is a summation of the multi-teacher hidden loss, multi-teacher distillation loss and the task-specific loss, which is formulated as follows:

$$\mathcal{L} = \mathcal{L}_{MT-Hid} + \mathcal{L}_{MT-Dis} + \mathcal{L}_{Task}. \quad (3)$$

3 Experiments

3.1 Datasets and Experimental Settings

We conduct experiments on three benchmark datasets with different sizes. The first one is SST-2 (Socher et al., 2013), which is a benchmark for text sentiment classification. The second one is RTE (Bentivogli et al., 2009), which is a widely used dataset for natural language inference. The third one is the MIND dataset (Wu et al., 2020c), which is a large-scale public English news dataset.[5] We perform the news topic classification task on this dataset. The detailed statistics of the three datasets are shown in Table 1.

In our experiments, we use the pre-trained 12-layer BERT, RoBERTa and UniLM (Bao et al., 2020)[6] models as the teachers to distill a 6-layer and a 4-layer student models respectively. We use the token embeddings and the first 4 or 6 Transformer layers of UniLM to initialize the parameters of the student model. The pooling layer is implemented by an attention network (Yang et al., 2016; Wu et al., 2020a). The temperature coefficient t is set to 1. The attention query dimension in the attentive pooling layer is 200. The optimizer we use is Adam (Bengio and LeCun, 2015). The teacher model learning rate is 2e-6 while the student model learning rate is 5e-6. The batch size is 64. Following (Jiao et al., 2020), we report the accuracy score on the SST-2 and RTE datasets. In addition, since the news topics in the MIND dataset are highly imbalanced, following (Wu et al., 2020b) we report both accuracy and macro-F1 scores. Each experiment is independently repeated 5 times and the average scores are reported.

Dataset	#Train	#Dev	#Test	#Class
SST-2	67k	872	1.8k	2
RTE	2.5k	276	3.0k	2
MIND	102k	2.6k	26k	18

Table 1: The statistics of the three datasets.

3.2 Performance Evaluation

We compare the performance of MT-BERT with two groups of baselines. The first group includes the 12-layer version of the teacher models, i.e., BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) and UniLM (Bao et al., 2020). The second group includes the 6-layer and 4-layer student

models distilled by DistilBERT (Sanh et al., 2019), BERT-PKD (Sun et al., 2019) and TinyBERT (Jiao et al., 2020), respectively. The results of different methods are summarized in Table 2.[7] Referring to this table, we find MT-BERT can consistently outperform all the single-teacher knowledge distillation methods compared here. This is because the knowledge provided by a single teacher model may be insufficient, and incorporating the complementary knowledge encoded in multiple teacher models can help learn better student model. In addition, compared with the teacher models, MT-BERT has much fewer parameters and its performance is comparable or even better than these teacher models. It shows that MT-BERT can effectively inherit the knowledge of multiple teacher models even if the model size is significantly compressed.

Teachers	**SST-2**	**RTE**	**MIND**	
	(Acc.)	(Acc.)	(Acc./Macro-F)	
BERT	92.1	65.8	72.8	50.6
RoBERTa	92.9	68.9	73.0	50.7
UniLM	93.3	70.6	73.4	50.9
BERT+RoBERTa	93.6	71.2	73.3	50.9
BERT+UniLM	93.9	73.7	73.6	51.1
RoBERTa+UniLM	94.3	74.9	73.7	51.3
All	94.6	75.7	74.0	51.5

Table 3: Different combinations of teacher models.

We also compare MT-BERT with several multi-teacher knowledge distillation methods proposed in the computer vision field that ensemble the outputs of different teachers for student teaching (You et al., 2017; Liu et al., 2020). The results are shown in Fig. 3. We find our MT-BERT performs better than these ensemble-based multi-teacher knowledge distillation methods. This is because these methods do not consider the correctness of the teacher model predictions on a specific sample and cannot transfer useful knowledge encoded in the intermediate layers, which may not be optimal for collaborative knowledge distillation from multiple teachers.

3.3 Effectiveness of Multiple Teachers

Next, we study the effectiveness of using multiple teacher PLMs for knowledge distillation. We compare the performance of the 6-layer student model distilled from different combinations of teacher models. The results are summarized in Table 3. It shows that using multiple teacher PLMs can achieve better performance than using a single one. This is because different teacher models can encode complementary knowledge and combining them together can provide better supervision for student model. In addition, combining all three teacher PLMs can further improve the performance of student model, which validates the effectiveness of MT-BERT in distilling knowledge from multiple teacher models.

3.4 Ablation Study

We study the effectiveness of the two important techniques in MT-BERT, i.e., the multi-teacher co-finetuning framework and the distillation loss

---

[7] We take the original reported results of baseline methods on the SST-2 and RTE datasets, and we run their codes to obtain their results on the *MIND* dataset.

Figure 5: Effectiveness of different loss functions.

weighting method. We compare MT-BERT and its variants with one of these modules removed, as shown in Fig. 4. The student model has 6 layers. We find the multi-teacher co-finetuning framework is very important. This is because the hidden states of different teacher models can be in very different spaces, and jointly finetuning multiple teachers with shared pooling and prediction layers can align their output hidden spaces for better collaborative student teaching. In addition, the distillation loss weighting method is also useful. This is because the predictions of different teachers on the same sample may have different correctness, and focusing on the more reliable predictions is helpful for distilling accurate student models.

We also verify the effectiveness of different loss functions in MT-BERT, which is shown in Fig. 5. We find the task loss is very important. It is because in our experiments the corpus for task-specific distillation are not large and the direct supervision from task labels is useful. In addition, the distillation loss is also important. It indicates that transferring the knowledge in soft labels plays a critical role in knowledge distillation. Moreover, the hidden loss is also helpful. It shows that hidden states of different teacher models can provide useful knowledge for student model learning.

4 Conclusion

In this paper, we propose a multi-teacher knowledge distillation method named MT-BERT for pre-trained language model compression, which can learn small but strong student model from multiple teacher PLMs in a collaborative way. We propose a multi-teacher co-finetuning framework to align the output hidden states of multiple teacher models for better collaborative student teaching. In addition, we design a multi-teacher hidden loss and a multi-teacher distillation loss to transfer the useful knowledge in both hidden states and prediction of multiple teacher models to student model. The extensive experiments on three benchmark datasets show that MT-BERT can effectively improve the performance of pre-trained language model compression, and can outperform many single-teacher knowledge distillation methods.

Abstract

Text generation from semantic parses is to generate textual descriptions for formal representation inputs such as logic forms and SQL queries. This is challenging due to two reasons: (1) the complex and intensive inner logic with the data scarcity constraint, (2) the lack of automatic evaluation metrics for logic consistency. To address these two challenges, this paper first proposes SNOWBALL, a framework for logic consistent text generation from semantic parses that employs an iterative training procedure by recursively augmenting the training set with quality control. Second, we propose a novel automatic metric, BLEC, for evaluating the logical consistency between the semantic parses and generated texts. The experimental results on two benchmark datasets, *Logic2Text* and *Spider*, demonstrate the SNOWBALL framework enhances the logic consistency on both BLEC and human evaluation. Furthermore, our statistical analysis reveals that BLEC is more logically consistent with human evaluation than general-purpose automatic metrics including BLEU, ROUGE and, BLEURT. Our data and code are available at `https://github.com/Ciaranshu/relogic`.

1 Introduction

Natural language generation (NLG) from semantic parses is to generate the text description for the formal representation input such as logical forms, AMR, and SQL queries. It has drawn widespread attention because of its substantial contributions to the interpretability and usability of the latest natural language interfaces (Gatt and Krahmer, 2018; Chen et al., 2020b; Hu et al., 2020; Mishra et al., 2019; Yu et al., 2019; Ngomo et al., 2013; Wang et al., 2018; Gardent et al., 2017; Wang et al., 2020a; Wang, 2019; Koutrika et al., 2010a). Recently, pretrained large-scale language models like BERT (Devlin et al., 2018), T5 (Raffel et al., 2020), and GPT-3 (Brown et al., 2020) have raised the ability to generate natural language from formal texts to a promising level of fluency and coherence.

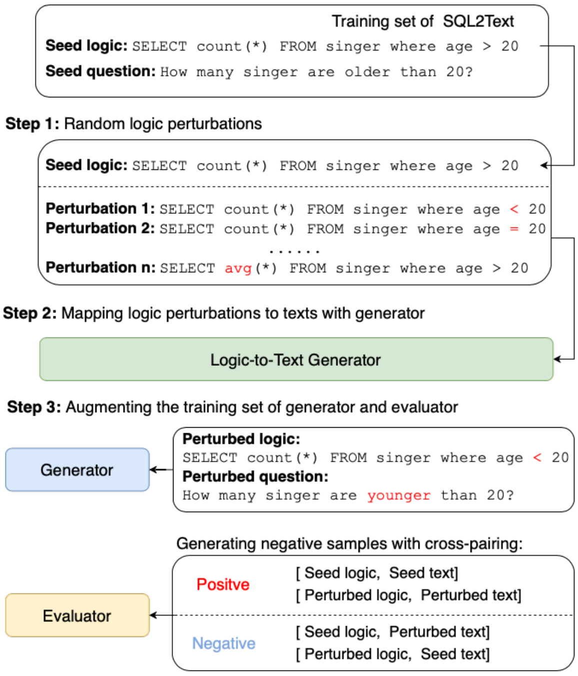

Figure 1: Our data augmentation procedure for the generator and evaluator in the SNOWBALL framework.

However, NLG from semantic parses still has suffered from two crucial challenges: (1) the data scarcity constraint due to the bias on certain types of logic forms or expensive labeling work (Iyer et al., 2017; Yaghmazadeh et al., 2017), which potentially leads to the unsatisfied fidelity of remaining the complex and intensive inner logic in the generated text based on our empirical research; (2) The general-purpose automatic metrics (Novikova et al., 2017a) such as BLEU (Papineni et al., 2002), ROUGE (Lin, 2004) and BLEURT (Sellam et al.,

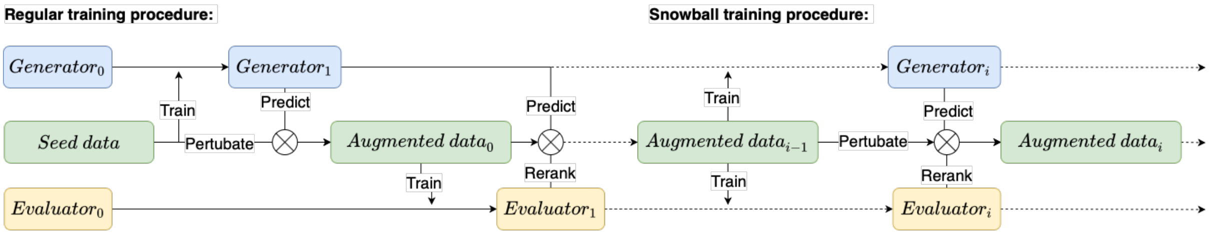

Figure 2: Our SNOWBALL framework employs an iterative training procedure over a generator and evaluator through data augmentation.

2020) are not ideal for explicitly measuring the logic consistency (Wang et al., 2020b; Harkous et al., 2020), because they tend to evenly weight each word in the generated text without fully attending on the fatal logical keywords.

To address these two critical problems, we propose the SNOWBALL framework for high-fidelity text generation from semantic parses and the BLEC automatic evaluation metric for logic consistency:

Snowball Framework. Our SNOWBALL framework, as illustrated in Figure 2, trains two modules to ensure high-fidelity text generation: (1) a generator that maps the logical form to its textual description, and (2) an evaluator that indicates the logic consistent score of each pair of logical form and textual sentence. Rather than training the generator and evaluator independently, SNOWBALL performs iterative training on the generator and the evaluator. To deal with the data scarcity issue, we propose a data augmentation procedure to cover valid logic variations with diverse natural language expressions to improve generalizability. To this end, during each iteration, various unseen logic pairs could be automatically generated with rule-based enumerated logic forms and their corresponding text predicted by the generator. The evaluator is then used to filter out the high reliable augmented logic pairs for the next training iteration.

BLEC Metric. To evaluate the logic consistency of the text generated by the model, we propose a rule-based automatic evaluation metric called Bidirectional Logic Evaluation of Consistency, or BLEC. It takes the logical form and the generated corresponding natural language text as input, then outputs a label indicating if they represent consistent logic. Compared with the neural network evaluator, BLEC can be easily deployed to different datasets, as long as the parser (i.e., the grammar of the logical form) is given.

In our experiments, we exam the effectiveness of our proposed approaches on the benchmark datasets of NLG from semantic parses derived from existed Text-to-SQL dataset *Spider* (Yu et al., 2018) and Table-to-Text dataset *Logic2Text* Chen et al. (2020b). Our analysis shows that our BLEC metric has a substantially positive Pearson score with human annotations, demonstrating better logic consistency than other automatic metrics. The BLEC result shows that the SNOWBALL framework leads to accordant enhancement in logic consistency on two datasets compared to the single-pass training method based on BART (Lewis et al., 2020).

Our key contributions are summarized into three-folds: (1) We propose a simple but effective training framework SNOWBALL that strengthens the logic faithfulness of generated text by covering diverse logic variations. (2) We propose a new logic evaluation metric BLEC that accurately measures the logical consistency with a refined keyword matching mechanism. (3) Our experiment results demonstrate that SNOWBALL at most increases the BLEC from 10.1% on SQL-to-Text and 1.2% on Logic-to-Text tasks compared to the baseline. Moreover, our statistical analysis reveals that BLEC achieves a +0.66 Pearson correlation coefficient compared with human labels, serving as a much better automatic evaluation metric than not only the traditional BLEU and ROUGE metrics, but the latest BLEURT metrics.

2 Related Work

2.1 Parses-to-Text

The source of data-to-text (D2T) datasets is mostly a flat ontology structure, like E2E(Novikova et al., 2017b), LogicNLP(Chen et al., 2020a), RotoWire(Wiseman et al., 2017), and ToTTo(Parikh et al., 2020), which is not powerful enough to encode rich semantic relationships in the ontology. Second, some datasets, such as WebNLG(Gardent et al., 2017), E2E, and RotoWire, have a limited number of domains. E2E is on the restaurant domain, and RotoWire is on the basketball domain.

Moreover, some of them only have loose alignments between input and sentence, e.g., RotoWire.

Generating the natural language descriptions for the logic forms or parses as a sub-task of D2T, has been studied in various datasets and tasks, such as GCC grammar to text (White, 2006), and UCC grammar to text (Gardent and Plainfossé, 1990). There are a lot of works that leverage the neural networks to conduct the generation on various tasks, for example, generating natural language from AMR (Song et al., 2018; Ribeiro et al., 2019; Damonte and Cohen, 2019), logic forms (Chen et al., 2020b), as well as SQL parses (Xu et al., 2018; Ngonga Ngomo et al., 2013; Koutrika et al., 2010b). However, different from these works, our work focuses on the logic consistency generation from parses. So we will mainly discuss and evaluate the model based on the logic between parses and questions.

2.2 High-fidelity Text Generation

As for the end-to-end neural-based text generation models, collaborating the auxiliary task during model training is an intuitive method that introduces the logic regulation to the models. For instance, the fidelity classification task proposed by Harkous et al. (2020), the auxiliary span extraction tasks by Kryscinski et al. (2020),the table-text optimal-transport matching and embedding similarity losses by Wang et al. (2020b) and the content matching task presented by Parikh et al. (2020) are proved to be effective. Nevertheless, to the best of our knowledge, we are the first to bridge the training procedure of evaluator and generator together with the iterative training framework snowball. Furthermore, we attempt to construct a new automatic metric and a new dataset dedicated to evaluating the logic consistency of text generation. The concentration of our work differs from the related high-fidelity text generation work (Chen et al., 2020b; Chan et al., 2019; Nie et al., 2018; Tian et al., 2019; Wang et al., 2020a), by attempting to present the panorama of the challenges of logic-consistent text generation instead of focusing on the model-wised modifications.

3 Snowball Framework

The SNOWBALL framework addresses the challenge of the complex and intensive inner logic with data sparsity constraint for the high-fidelity text-generation from semantic parses. As illustrated in Figure 2, SNOWBALL assures the logic consistency with three bases: (1) Iterative training procedure synergistically enhances the generator and evaluator in the adversarial fashion; (2) Data augmentation based on rule-based logic perturbations and neural-based text generation covering diverse unseen logic variations for iterative training; (3) Structure-aware encoding boost the sensibility of the encoder on mild logic shift.

3.1 Iterative Training

Rather than training the generator and evaluator independently, SNOWBALL performs training on the generator and the evaluator iteratively. As demonstrated in Figure 2, the prerequisite of the snowball training procedure is the regular training procedure: (1) the $Generator_0$ is trained on the benchmark NLG datasets with the normal end-to-end approach into trained $Generator_1$; (2) meanwhile, the logic forms in the seed data are converted into variations with given rules, then the $Generator_1$ predicts the text for each mutated logic forms to be a completed logic pair; (3) The initial $Evaluator_0$ is then trained on those augmented logic pairs.

Then, during the SNOWBALL procedure, the generator and evaluator are collaboratively improved through several training iterations, and during each iteration, a three-step adversarial interaction would be conducted between the generator and evaluator: **Step 1:** The trained $Evaluator_{i-1}$ could be used to rerank the beam search results given by the decoder of the generator, consequently leading to increased quality of the augmented logic pairs, $Augmented\ data_{i-1}$; **Step 2:** The $Generator_i$ is capable to better retain the logic consistency by training on the $Augmented\ data_{i-1}$ which contains more unseen logic variations uncovered in the seed data; **Step 3:** The enhanced $Generator_i$ predicts the increasingly realistic-like perturbed sentences from the perturbed logical forms, which brings more challenging negative samples to the training set of the $Evaluator_i$. The data augmentation in the first step would be further described in Section 3.2.

To be specific, our generator and evaluator in SNOWBALL are described as follows.

Generator The generator maps the logical form to the corresponding natural language sentences. We choose the pre-trained BART model (Lewis et al., 2020) following the standard transformer architecture (Vaswani et al., 2017), which contains the encoder and decoder architecture as the denoising autoencoder pre-trained on the task of corrupted text reconstruction. The input of the encoder is the structure-aware representation of the logic forms (Section 3.2), while the target output of the decoder is the aligned textual description for the input parses.

Evaluator An evaluator indicates the logic consistent score of pairs of logical forms and textual sentences, which is vital for assessing the performance of the logic-focused text generator. In contrast to other text generation tasks, generating sentences from logical forms especially requires the evaluator to be reasonably sensitive to the subtle logic shifts of the model predictions. For instance, deleting negation words such as 'not' is fatal for our task by significantly compromising the logic consistency. Therefore, we exploit a binary classification architecture similar to the BART-based natural language inference model (Lewis et al., 2020) as our evaluator to compute the consistency between the pairs of logical form and text $[L, Q]$. The input of the encoder is the concatenation of the L and Q appended an $[EOS]$ token, and the logic scores γ are computed as:

$$\gamma = \sigma(\omega([h_{d_1}, h_{d_2}, h_{d_3}...])) \tag{1}$$

where h_{d_n} denotes the last hidden states of the decoder, ω denotes the max-pooling layer, and σ is the sigmoid activation function.

3.2 Data Augmentation

As the labeled training data for both the generator and evaluator is extremely limited, we propose a data augmentation procedure to enlarge the training set by covering variations of logic forms paired with diverse natural language expressions to improve the generalizability. To be specific, our data augmentation consists of three steps as depicted in Figure 1 from a seed dataset with human annotation:

Step 1: Logic perturbation Instead of modifying the natural language sentences, we choose to corrupt the logic consistency by perturbing logical forms mainly because of two reasons: (1) The regular structures of logical forms guarantee the procedure of the logical corruption to be comparatively controllable; (2) The perturbed logical forms could be easily validated with the corresponding parser and grammar checker. The perturbations of each given logical form could be enumerated exhaustively according to hand-tuned rules to cover the following logic inconsistencies:

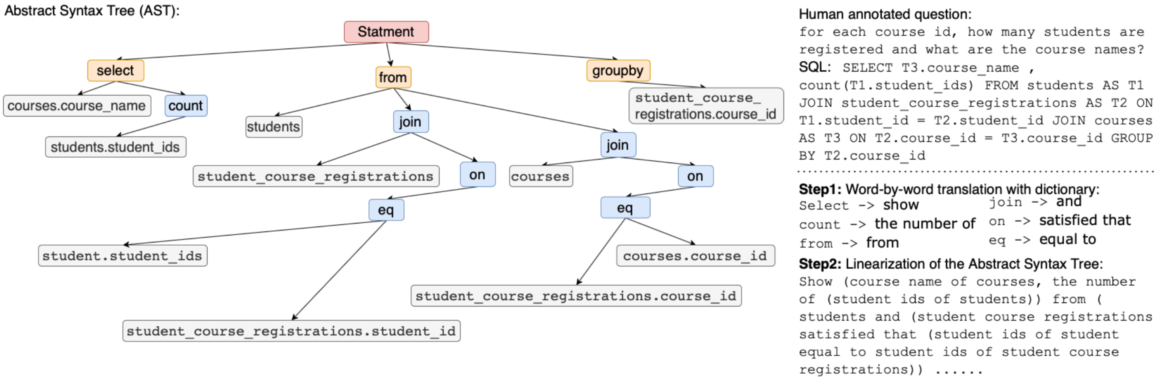
- **Logic shift:** The logic shift indicates that the generated text logically distinct from the input logical forms, such as turning the assertive sentences into negative sentences. This could be attributed to the perturbations of aggregators, operators, logic conjunction, etc.

- **Phrase and number changes:** The phrase changes mean that the generated sentence modifies the appointed phrase from the logical forms, while the number changes are that the numerical values in the logical forms are perturbed.

- **Entity insertion, deletion and swapping:** Perturbations of entities is a common drawback that most natural language generation models suffer. This includes the phenomenon that the predicted sentences neglect the entities mentioned in the logical forms, insert unrelated entities to the logical form, or mislay them.

Step 2: Inference from perturbed logic After logic perturbation, the generator could be exploited as the artificial annotator to generate the corresponding sentence for each logical form in a semi-supervised manner. Compared to the rule-based or template-based method, the recent pre-trained seq-to-seq models empirically generate the natural language sentences with better fluency and coherency. Though this method could easily create a considerable amount of labeled data meanwhile avoid the expensive human annotation, what can not be ignored is that the model-based generator naturally would introduce unexpected noise during augmentation. Therefore, the quality control for the data augmentation is one of the most crucial cornerstones for a satisfactory result.

Step 3: Dataset composition As shown in Figure 1, the example in the seed dataset is denoted as [Seed logic, Seed text], and the augmented examples are denoted as [Perturbed logic, Perturbed text]. Intuitively, we may take the augmented [Perturbed logic, Perturbed text] to be not only the training example for the generator but also the positive sample for the evaluator, while crossover pairs [Seed logic, Perturbed text] and [Perturbed logic,



Human annotated question:
`for each course id, how many students are registered and what are the course names?`

SQL: `SELECT T3.course_name , count(T1.student_ids) FROM students AS T1 JOIN student_course_registrations AS T2 ON T1.student_id = T2.student_id JOIN courses AS T3 ON T2.course_id = T3.course_id GROUP BY T2.course_id`

Step1: Word-by-word translation with dictionary:
`Select` -> show
`count` -> the number of
`from` -> from
`join` -> and
`on` -> satisfied that
`eq` -> equal to

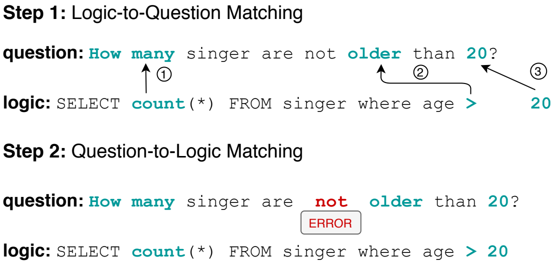
Step2: Linearization of the Abstract Syntax Tree:
`Show (course name of courses, the number of (student ids of students)) from ( students and (student course registrations satisfied that (student ids of student equal to student ids of student course registrations)) ......`

Figure 3: The example of word-by-word translation and linearization of structure-aware encoding.

Seed text] would be suitable negative samples for the evaluator.

3.3 Structure-aware Encoding

The logical forms normally have equivalent structured representations to precisely express the complex relations between a set of objects. For instance, the executable codes written in Python or SQL could be parsed into abstract syntax tree(AST) (Noonan, 1985) denoting the mutual relations among occurred constructs in the source code, while the knowledge bases may be converted into knowledge graphs that depict the relations between entities with directed edges. Compared to the plain text inputs, the structure-aware encoding capturing not only the sequential information from texts but also the internal logic from structural representations recently has been proved to be more effective in several Graph-to-Text tasks (Song et al., 2018; Ribeiro et al., 2020). To make full use of the intrinsic knowledge of the pre-trained BART model, we follow the similar approach proposed by Ribeiro et al. (2020) to linearize the structural representations of the SQL queries and logical forms respectively (Figure 3). Furthermore, the logical forms from different domains or datasets may vary in keywords, so normalizing them into a unified form would bridge the gaps between different logic NLG datasets and then increase the generalization ability of our framework. Hence, the logical forms would be firstly word-by-word translated into the unified intermediate semi-textual forms according to a manually annotated dictionary. Then the parenthesis is inserted into the semi-textual forms to denote the hierarchy of the correlated structured representations such as ASTs.



Step 1: Logic-to-Question Matching

question: `How many singer are not older than 20?`

logic: `SELECT count(*) FROM singer where age > 20`

Step 2: Question-to-Logic Matching

question: `How many singer are not older than 20?`

logic: `SELECT count(*) FROM singer where age > 20`

Figure 4: A sample of BLEC. The words marked in green are the matched tokens while the words marked in red are the tokens with no match.

4 BLEC for Logic Consistency Evaluation

Because the general-purpose automatic metrics such as BLEU, ROUGE, and BLEURT are not ideal for explicitly measuring the logic consistency, we propose BLEC, a new rule-based automatic evaluation metric called Bidirectional Logic Evaluation of Consistency. We apply a bidirectional evaluation to determine the logical consistency of pairs of logical forms and questions. The intuition behind this metric is that some key tokens such as number, operator, and keywords in the logical form should always be matched with some tokens that represent similar meanings in the question, and vice versa. An example is shown in Figure 4, BLEC first traverses the key tokens in the question, trying to find the tokens with the same meaning in the logic form to match them. Then, in step two, the sample is marked as inconsistent because there is one token with no match from the question to the logical form.

Formally, given a logical form $L = l_1, l_2, ..., l_n$ containing n word tokens and a questions $Q = q1, q2, ..., q_m$ containing m word tokens, the proposed evaluation metric performs token level

Dataset		Train	Dev	Test
SQL2Text	Generator	5600	1400	1034
	Evaluator	-	1142	1142
Logic2Text	Generator	8566	1095	1092
	Evaluator	-	1041	1041

Table 1: The statistics of the SQL2Text and Logic2Text dataset.

matching on l_i and q_j to test the consistency. To be specific, the matching procedure contains two steps, i.e. matching from L to Q as well as matching from Q to L. In step one, each key token l_i^{key} in L tries to match with the tokens in Q. In step two, each key token q_j^{key} in Q tries to match with the tokens in L. If no tokens are found that could be matched with any key tokens in either step one or step two, the sample will be marked as negative, vice versa. The final score is the accuracy of all the samples:

$$\textsc{Blec} = \frac{\sum_{s \in S} match(s)}{|S|} \tag{2}$$

Where S denotes the dataset while $match(*)$ is the matching function with binary output, i.e. 1 for positive and 0 for negative.

Compared with the neural network evaluator requiring data-specific training, BLEC can be easily deployed to different datasets. In our experiments, we demonstrate that BLEC can be applied to two different datasets of text generation from two types of semantic parse input, and it shows a substantial agreement with human evaluation for evaluating logic consistency between the semantic parse input and the text output (Table 2).

5 Experiment Settings

5.1 Datasets

Text generation from semantic parses has different forms depending on the input formal representation. To demonstrate that our SNOWBALL and BLEC can be applied to different types of inputs, we study two tasks: (1) SQL2Text with the SQL query as the input and (2) Logic2Text with the logic forms as the input.

To this end, we make use of two existing publicly available datasets: For SQL2Text, we use the Spider dataset (Yu et al., 2018), a complex cross-domain semantic parsing and text-to-SQL dataset. Generating natural language from formal languages with abundant logic representations could be regarded as the inverse semantics parsing process. Therefore, we reverse the input and output as a dataset for the text generation from SQL queries with complicated logic. As the test set of the Spider dataset remains undisclosed, 20% of the original Spider training set is converted into a development set, and 80% of the training set remains to be the training set, and the original development set is exploited as the test set for our SQL2Text task. For Logic2Text, we use an existing Logic2Text dataset from Chen et al. (2020b). We pick the SENT and LOGIC_STR fields from the original Logic2Text to compose our own train data. We then change SENT to TEXTand change LOGIC_SET to LOGIC as our one keyword of each sample in the dictionary of our dataset.

In contrast, evaluating the logical consistency between logical form and text is closely related to the sequence classification tasks such as fact verification and natural language inference (NLI). According to the best of our knowledge, there is no existing dataset for evaluating the logical consistency between logical form and generated text. Therefore, we simplified the logic evaluation as a two-sequence binary classification problem and then construct the dataset with the development set and test set dedicated for our proposed evaluator. The dataset is constituted from the development and test set of Spider and Logic2text by three methods: (i) The [logical form, Text] pairs in the two datasets are regarded as positive samples; (ii) The human-labeled negative samples by intentionally introducing the logical inconsistency to the known [logical form, Text] pairs in the two datasets; (iii) The manually scored [logical form, Text] prediction given by the trained generator on the two datasets which contain both positive and negative samples. As for the human-labeled negative samples, we attempt to cover the possible logic perturbations mentioned in section 3.2 with minimum modification to the original [logical form, Text] pairs. For example, a coincident pair [`SELECT avg(age) FROM dogs`, What is the **average** age of dogs?] would be corrupted into [`SELECT avg(age) FROM dogs`, What is the **oldest** age of dogs?]. Table 1 summarizes the statistics of each dataset for both generator and evaluator, respectively.

5.2 Baselines and Implementation Details

The baselines for assessing the performance of SNOWBALL framework are the attention-based LSTM machine translation model (Tao et al., 2019), and the single-pass trained models which are the models trained before performing SNOWBALL iteration. For instance, the `BART-large` generator trained in the second SNOWBALL iteration would be compared to the identical `BART-large` generator in the zero SNOWBALL iteration. The hype-parameter settings of the models trained on *SQL2Text* and *Logic2Text*, mostly follow the default setting of BART model from Huggingface (Lewis et al., 2020; Wolf et al., 2020). However, the learning rate of evaluator and tokenizer are slightly different, namely the learning rate of evaluator on *SQL2Text* is 2e-5 for `BART-base` and is 5e-6 for `BART-large`, while the learning rate of evaluator on *Logic2Text* is 1e-5 for both `BART-base` and `BART-large`.

5.3 Multitask Learning

Due to the lack of data of logic NLG, intuitively collaborative training on *SQL2Text* and *Logic2Text* dataset may prevent the models from bias fitting to their confined training data. Aside from the standard special separators used by BART tokenizer, we further introduce *[SQL]* and *[logic]* tokens to be the control codes to indicate if one sample is from *SQL2Text* or *Logic2Text* dataset, similar as (Keskar et al., 2019). For each sample fed into the BART model, a corresponding control token is contacted in the front of the input logical form according to that sample source. Therefore, the distribution $p(Q_{SQL}|L_{SQL}, [SQL])$ of the *SQL2Text* models and $p(Q_{Logic}|L_{Logic}, [logic])$ of the *Logic2Text* models could be learned respectively during the backpropagation that takes the control tokens into account, while training the generator and evaluator in the MTL fashion.

5.4 Human Evaluation

To evaluate if the sentence generated by the model is logically consistent, we randomly sample 90 questions from the test set of Spider and a test set of logic2text separately to form a human evaluation set. The samples of each setting will be divided into two parts and assigned to two different annotators. Each part contains 10 overlap and 40 non-overlap examples, which means one person has to label 50 samples for a setting. As for the human evaluation, the annotators label the [logical form, text] as True or False based on two criteria: (1) the logic consistency between logical form and text; (2) The grammaticality of the text. After labeling, we estimate the accuracy of the model predictions by computing the expectation of the true labels from 80 non-overlap data. To prove the consistency of the annotators, we use the 10 overlap data to calculate the cohen kappa score. Only if the kappa score is over 0.4 which implies that this estimated accuracy is valid, the results would be reported. In Table 4, we only human annotated the results given by the models trained without snowball iteration and trained with 4 snowball iterations. It demonstrates the correlation between human evaluation and BLEC metrics in these two time steps instead of directly evaluating the improvement of model performance.

6 Results and Analysis

6.1 Correlation Analysis on BLEC

To show that BLEC is consistent with human judgment, we test the Pearson correlation between the BLEC score and the human evaluation result. We also include ROUGE and BLEU for comparisons. Therefore, we apply these four automatic metrics (BLEU, ROUGE, BLEURT, BLEC) to a human-labeled dataset and compare the evaluation results. This dataset is constructed by extracting 50 samples from each of the different Snowball iterations, 15 iterations in total. As shown in Table 2, the logic consistency between BLEC and human evaluation is 0.66 while BLEU, ROUGE, and BLEURT obtain scores below or around zero. This shows that the BLEC score is capable of testing the logical consistency between logic forms and questions.

Metrics	Pearson	p-value
ROUGE (Lin, 2004)	-0.30	0.28
BLEU (Papineni et al., 2002)	-0.24	0.40
BLEURT (Sellam et al., 2020)	+0.02	0.94
BLEC	**+0.66**	**0.007**

Table 2: The correlation with human annotation of BLEU, ROUGE, BLEURT, and our proposed BLEC.

6.2 Effectiveness of Snowball Framework

Generator The experimental results of the generator in our SNOWBALL framework are shown in Table 4. We found that the SNOWBALL training framework empirically leads to the improvement of

Input SQL:	`SELECT count(*), max(Percentage) FROM country_language` `WHERE LANGUAGE = "Spanish" GROUP BY CountryCode`
Pre-processed SQL:	(the number of (all items)) , (the maximum of (percentage)) that belongs to (countrylanguage) , that have ((language) equal to (spanish)) , grouped by (countrycode)
Label:	What is the total number of countries where **Spanish** is spoken by the **largest** percentage of people?
BART-base	the number and percentage of languages that are **Spanish** for each country code.
+snowball (iteration = 4)	the number of languages and **maximum** percentage of languages in each country code?
+multi-tasking	How many languages does **Spanish** have in each country code?
+snowball (iteration = 4)	Show the number and **maximum** percentage for each country code.
BART-large	How many languages are there in each country and what is the percentage of the language spoken in that country?
+snowball (iteration = 4)	Find the number of languages and **maximum** percentage of **Spanish** for each country code.
+multi-tasking	Find the number and percentage of speakers of **Spanish** in each country code.
+snowball (iteration = 4)	Find the number and **highest** percentage of speakers of **Spanish** for each country code

Table 3: Example outputs from different models with or w/o performing the MTL and SNOWBALL iteration.

	SQL2Text Test Set								
Metrics	BLEC						Human		
Snowball	-	1	2	3	4	5	-	4	κ
LSTM Seq2Seq	22.6								
BART-base	76.4	78.6	78.5	**84.1**	79.7	78.1	22	45	0.69
+MTL	89.1	**89.5**	89.2	88.9	88.6	88.1	66	68	0.5
BART-large	91.8	91.3	**93.7**	91.8	93.2	93.0	75	74	0.7
	Logic2Text Test Set								
Metrics	BLEC						Human		
Snowball	-	1	2	3	4	5	-	4	κ
LSTM Seq2Seq	41.1								
BART-base	87.9	86.1	**88.6**	87.4	87.7	87.8	83	85	0.48
BART-large	86.7	**87.8**	85.2	87.1	86.0	88.5	86	78	0.48

Table 4: The results of SNOWBALL generator using BLEC and human evaluation over different iterations.

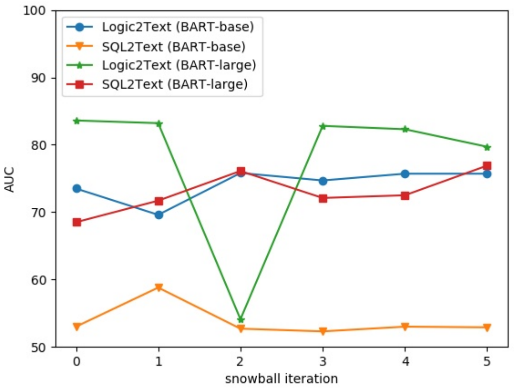


Figure 5: The result of SNOWBALL evaluator based on the AUC scores on the test set. The iteration = 0 means the model is under the regular training procedure as described in Figure 2.

the logic consistency. Evaluated by our proposed BLEC metric, the performance of `BART-base` generator improves the logic consistency by 10.1% on SQL2Text and by 0.7% on Logic2Text. Similarly, the performance of `BART-large` generator acquires the improvement by 2.1% on SQL2Text and by 1.2% on Logic2Text. Under the MTL setting on SQL2Text, the logic faithfulness of the`BART-base` generator is further enhanced by 16.6% compared to single-pass training, and is even boosted by 17.1% by combing with SNOWBALL training.

Evaluator The results of the evaluator in our SNOWBALL framework are illustrated in Figure 5. Empirically the snowball framework is more effective to the evaluators base on `BART-base` than `BART-large`, this is likely because that the `BART-large` models have already obtained enough intrinsic knowledge to accurately judge the validness of the [Logical form, Text] pairs. The data augmentation procedure of the SNOWBALL framework may introduce unexpected noise to the evaluators, which may cause a catastrophic reduction in terms of AUC and other metrics. On the other hand, the snowball framework indeed enhances the performance of the evaluator based on relative inferior `BART-base` by improving the performance on the *SQL2Text* by 10.9% as well as the *Logic2Text* by 3.1%. These results indicate that our proposed SNOWBALL framework is most suitable for tasks suffering from both domain data scarcity and the lack of external knowledge.

6.3 Case Study

Table 3 shows example outputs from our model with different settings. Apparently, in this case, the entity **Spanish** and the aggregator **maximum** are the touchstones for evaluating the logic consistency of each model. The prediction from the BART-large based generator trained under both snowball and multi-tasking frameworks simultaneously is the only one that acquires the seamless sentences from the input SQL. Furthermore, we also notice that multi-tasking learning significantly alleviates the artifacts within the generated text. Based on the fact that, compared to the vanilla generators, the generator solely trained with snowball framework would enhance the logic consistency but also increase an unnatural sense to the generated sentences at the same time, we may argue that there is a trade-off between fluency and logic consistency of our purposed snowball framework. The model-level modification may collaboratively enhance the fluency and logic consistency of the NLG, which we would remain for future studies.

7 Conclusion

In this paper, we propose SNOWBALL, a neural network-based framework to augment the data alternatively by a generator, and an evaluator. In addition, we propose BLEC, an automatic evaluation metric that could evaluate the logic consistency between question and logic forms by directional matching. We also formulate two datasets and the experimental results show the effectiveness of the proposed framework. This method is applicable to other Data-to-Text tasks, because domain-specific rules for perturbations can be derived for most structural data with pre-defined structures or grammar.

8 Ethics Statement

The datasets we use are built by selecting and processing from two datasets that are open to the public, separately. The data sources we utilize to construct our datasets are Spider and Logic2Text, two complex and cross-domain text-to-SQL datasets. Besides, we use three experts to annotate about 500 data beyond the original dataset. We admit that some biases may still exist in our datasets, even though we have double-checked the data they annotated and the data from the original datasets.

Authors with SQL expertise annotate and verify our datasets through 1) selecting about 500 representative samples from the original dataset, 2) changing the entities of the samples, 3) using three different labels to mark which type of change has been done to the sentences, and 4) double-checking the quality of the data we annotate.

We conduct several experiments of different settings on our AWS server, with 8 Tesla V100 GPUs, to test the efficiency of our models. To be more specific, our experiments contain two different types. The first type of them is that we train both generator and evaluator using SQL2Text or Logic2Text. The second type of them is that we utilize SQL2Text and Logic2Text to train generators, use one of them to train evaluators in the first epoch, and train the next several epochs with both of them.

A BLEC Details

BLEC uses bidirectional keyword matching to detect the logic consistency. Table 5 shows several sample cases for constructing BLEC metrics. As shown in the table, the first column shows the type of matching rules. “Special” means that these rules are only contained in one of the datasets. Then, the following 3 columns display the tokens in different languages. Using the tokens, the algorithm can detect if the question matches the parse. For instance, given a pair of question and SQL parse, the algorithm could check if “MAX” is in SQL parse. If so, it will try to match one of the possible tokens corresponding to “MAX”, i.e. largest/ greatest, etc., in the question, and vice versa. It is worth noting that, this table only shows a small part of the algorithm, however, all the rules can be classified as one of the three types.

Type	Spider	Logic2text	Natural Language
Negation	NOT	not_eq	not/ none...
Operator	>	filter_greater	larger/ more/ greater...
	<	filter_smaller	smaller/ less/ fewer...
	MAX	max	largest/ greatest...
	COUNT	count	total/ how many...
Special	ASC	-	ascending/ fewest...
	DESC	-	descending/ highest...
	-	most_str_eq	majority/ most...

Table 5: Sample rules for BLEC.

Inducing Semantic Roles Without Syntax

Julian Michael[1] **and Luke Zettlemoyer**[1,2]

`{julianjm,lsz}@cs.washington.edu`

Abstract

Semantic roles are a key component of linguistic predicate-argument structure, but developing ontologies of these roles requires significant expertise and manual effort. Methods exist for automatically inducing semantic roles using syntactic representations, but syntax can also be difficult to define, annotate, and predict. We show it is possible to automatically induce semantic roles from QA-SRL, a scalable and ontology-free semantic annotation scheme that uses question-answer pairs to represent predicate-argument structure. By associating arguments with distributions over QA-SRL questions and clustering them in a mixture model, our method outperforms all previous models as well as a new state-of-the-art baseline over gold syntax. We show that our method works because QA-SRL acts as *surrogate syntax*, capturing non-overt arguments and syntactic alternations, which are central motivators for the use of semantic role labeling systems.[1]

1 Introduction

Semantic role labeling (SRL) requires extracting propositional predicate-argument structure from language, i.e., *who* is doing *what* to *whom*. Applications of SRL include information extraction (Christensen et al., 2011), machine reading (Wang et al., 2015), and model analysis (Tenney et al., 2019; Kuznetsov and Gurevych, 2020), and semantic roles form the backbone of many more general meaning representations (Banarescu et al., 2013; Abend and Rappoport, 2013).

The primary challenge, and promise, for SRL systems is to distill syntactically variable surface structures into semantic predicate-argument structures from an ontology (Palmer et al., 2005; Baker et al., 1998). However, ontologies and their associated training data require time and expertise to annotate and do not readily generalize to new domains, limiting their broad-coverage applicability. Prior work towards mitigating this problem includes unsupervised induction of semantic roles from syntactic representations (Lang and Lapata, 2010). However, the need for formal syntactic supervision retains some of the annotation and generalization difficulties of supervised SRL, and it has proven difficult to do much better than a simple syntactic baseline (Lang and Lapata, 2011). An alternative is to use an ontology-free annotation scheme like QA-SRL (He et al., 2015), which represents roles with natural language questions. While QA-SRL can be annotated at large scale (FitzGerald et al., 2018), many different QA-SRL questions may correspond to the same role, making it more

Table 2: Example QA-SRL question-answer pairs from the development set of the QA-SRL Bank 2.0 (FitzGerald et al., 2018). Questions may be represented in a verb-agnostic way by recording the form of the verb in the **verb** slot (e.g., *stem*, *past participle*). Note that the syntax used in questions may differ from the syntax in the source sentence, for example in the above questions using *diverted* in its passive form.

difficult to use in downstream tasks.

We show how to overcome this difficulty, by automatically inducing an ontology of semantic roles corresponding to clusters of QA-SRL questions (see Table 1 for an example clustering). We use a model to predict a distribution over QA-SRL questions associated with each argument in a corpus, and cluster them to maximize likelihood under a simple model we call a *Hard Unigram Mixture*. Our model can be effectively optimized both by EM and greedy methods, which affords the benefits of tunable hierarchical clustering without sacrificing scalability (Section 3).

Experiments in semantic role induction (Section 4) show that our method outperforms all previous methods in the literature, as well as a new state-of-the-art baseline over gold syntax. This is despite requiring no formal syntactic supervision or theory, where the formalism used by previous work is highly informative of gold standard semantic roles (Section 5). We also present a detailed analysis (Section 6) showing why our method works: QA-SRL acts as *surrogate syntax*, removing (role-irrelevant) syntactic variation in the source text such as that from *non-overt* arguments (e.g., phrases extracted from relative clauses), while itself exhibiting (role-relevant) syntactic alternations which capture the behavior of verbal predicates (Table 1). Taken together, these results paint a path towards on-the-fly, data-driven construction of useful, interpretable ontologies of semantic structure.

2 Task Setting

The input to our task is a set of natural language sentences, where a subset of the tokens are marked as *predicates*. Each predicate has a set of *arguments*, and each argument x corresponds to a set of spans $x = \{s_1, \dots, s_m\}$ in the predicate's sentence.[2]

An ontology of semantic roles is a set of *frames* (corresponding to semantic predicates), and each frame has a set of associated *roles* (corresponding to participants in the event or state denoted by its frame). There may also be a set of *modifier roles* (e.g., location or time) which can appear with any frame. In supervised semantic role labeling, each predicate in the input data must be assigned to one of the frames in a given ontology, and each of a predicate's arguments must be assigned roles from its frame (or modifier roles). In semantic role induction, our task is to produce both the ontology and these assignments.

We follow prior work (Lang and Lapata, 2010) in treating semantic role induction as a clustering problem and assuming a single frame per predicate lemma.[3] Given input data marked with predicates and their arguments, we cluster the arguments for each predicate into sets corresponding to semantic roles. We may then compare these clusters to gold labels using clustering metrics (Section 4.3).

---

[2] Previous work (Lang and Lapata, 2010) assumes a syntactic dependency tree and marks each argument by its syntactic head, which allows for features based on argument lemmas and dependency paths. We instead assume sets of argument spans, but no syntax tree; this allows for features based on spans (such as QA-SRL questions). Both approaches are ways of featurizing the same gold arguments.

[3] Some ontologies, like FrameNet (Baker et al., 1998), define frames that span multiple lemmas (e.g., *buy* and *sell* share a *Commercial Transaction* frame), whereas others like PropBank (Palmer et al., 2005) use frames which are specific to each lemma, denoting something closer to word sense. In our case, assuming a single frame per lemma simplifies modeling and allows us to compare to previous work. However, modeling predicate sense is an important problem for future work, as we will suggest in Section 6.3.

3 Modeling

Our model treats each argument x as a set of counts of QA-SRL questions,[4] denoted $\phi(x)$. We produce these counts from a trained QA-SRL question generator (Section 3.1) and cluster them by maximizing their likelihood under a mixture model (Section 3.2) using a hybrid of flat and hierachical clustering (Section 3.3).

3.1 Generating QA-SRL Features

For each argument x of a predicate, we leverage a trained QA-SRL parser to generate pseudocounts $\phi(x)$ of simplified QA-SRL questions, which will form the input features for the clustering step.

Simplified QA-SRL Example QA-SRL questions are shown in Table 2. These questions contain information which is not directly relevant to semantic roles, such as tense, aspect, modality, and negation. Since this creates sparsity for our model, we remove it as a preprocessing step. In particular, we replace the **aux** and **verb** slot values with either *is* and *past participle* (for passive voice), _ and *present* (for active voice when **subj** is blank), or *does* and *stem* (for active voice when **subj** is present). We also replace all occurrences of *who* and *someone* with *what* or *something*.

Generating Question Counts Let p denote a predicate, s denote a span, and q denote a simplified QA-SRL question. To generate our question count vectors ϕ, we reproduce the QA-SRL question generator of FitzGerald et al. (2018), which generates a distribution $\mathrm{P}(q \mid p, s)$ over QA-SRL questions conditioned on a predicate p and answer span s in a sentence. This model uses a BiLSTM encoder, concatenating the output representations of span endpoints and feeding them into a custom LSTM decoder which models the QA-SRL slot values in sequence. We modify the model to use BERT (Devlin et al., 2019) features as input embeddings for the BiLSTM (details in Appendix A).

Recall from Section 2 that an argument x consists of a set of spans from its sentence. We generate question counts $\phi(x) \in \mathbb{R}_{\geq 0}^{|q|}$ by taking the mean

$$\phi(x) = \frac{1}{|x|} \sum_{s \in x} \mathrm{P}(q \mid p, s),$$

where $\mathbb{R}_{\geq 0}$ denotes the nonnegative real numbers and $|q|$ is the number of possible simplified QA-SRL questions. Since $|q|$ is large, to make this tractable we approximate $\mathrm{P}(q \mid p, s)$ with beam search, using a sparse representation and assigning counts of 0 to questions outside the beam.

3.2 Objective

Let $\mathbf{X} = \{x_1, \ldots, x_n\}$ be the set of input arguments for clustering. Our goal is a clustering $\mathbf{C} = \{C_1, \ldots, C_k\}$ which is a partition of $\mathbf{X}$. We model each argument's questions $\phi(x)$ as being drawn from a mixture model over latent roles, each corresponding to a cluster $C \in \mathbf{C}$. We maximize likelihood under this model, which we call a Hard Unigram Mixture, with the addition of a connectivity penalty which encourages roles not to appear twice for the same predicate instance.

The Hard Unigram Mixture (HUM) Recall that $\phi : \mathbf{X} \to \mathbb{R}^d_{\geq 0}$ assigns question pseudocounts to each $x \in \mathbf{X}$. Let π denote a probability distribution over $\{1, \ldots, k\}$ and θ a distribution over $\{1, \ldots, d\}$. We propose the *Hard Unigram Mixture* loss

$$\mathcal{L}^{\mathrm{HUM}}_{\lambda}(\mathbf{C}) = -\log \mathrm{P}(\mathbf{X} \mid \mathbf{C}) - \lambda \log \mathrm{P}(\mathbf{C}),$$

where

$$\mathrm{P}(\mathbf{X} \mid \mathbf{C}) = \prod_{i}^{k} \max_{\theta} \prod_{x \in C_i} \mathrm{P}(\phi(x) \mid \theta)$$

is the *data likelihood* and

$$\mathrm{P}(\mathbf{C}) = \max_{\pi} \prod_{i}^{k} \pi_i^{||C_i||}$$

is the *clustering likelihood*, writing $||C||$ for the sum of the ϕ counts in a cluster C. The data likelihood prefers more, smaller clusters, the clustering likelihood prefers fewer clusters, and λ is a hyperparameter that trades off between them.[5]

Connectivity Penalty Let $p(x)$ denote the predicate instance corresponding to an argument x. We propose a *connectivity penalty*

$$\mathcal{L}^{\mathrm{cp}}(\mathbf{C}) = \frac{1}{2} \sum_{i}^{k} \sum_{x_1, x_2 \in C_i} \delta(p(x_1) = p(x_2)),$$

---

[4] As of now, this model only works for English, as QA-SRL is only defined and annotated in English.

[5] Here, $\mathcal{L}^{\mathrm{HUM}}_{1}$ is equivalent to the negative log likelihood under the maximum likelihood estimate of a mixture of unigrams model (Nigam et al., 2000) constrained to hard assignments $\mathbf{C}$; hence the name *Hard Unigram Mixture*. Further theoretical and empirical comparison to prior work is provided in Appendix G.

where δ is the indicator function, which discourages clusterings where multiple arguments of the same predicate instance are assigned the same role. This assumption has also been leveraged by prior models (Lang and Lapata, 2011; Titov and Klementiev, 2012).

Loss Function Our full loss is then

$$\mathcal{L}_{\lambda}(\mathbf{C}) = \mathcal{L}_{\lambda}^{\text{HUM}}(\mathbf{C}) + \mathcal{L}^{\text{cp}}(\mathbf{C})$$

with the single hyperparameter λ.

3.3 Hybrid Clustering

We optimize $\mathcal{L}_{\lambda}$ in three steps: flat pre-clustering, greedy merging, and tuned splitting. This approach provides us with both the efficiency benefits of flat clustering and the relative determinism, interpretability and tunability of hierarchical clustering.

Flat Pre-Clustering For pre-clustering, we minimize $\mathcal{L}_0$ via hard EM. To avoid likelihoods of 0 in $\mathcal{L}_0^{\text{HUM}}$, we smooth our estimates of θ using a Dirichlet prior. To optimize $\mathcal{L}^{\text{cp}}$ via EM, we draw x_1 from the previous iteration's clustering in order to compute the contribution of each x_2 to the loss. With sufficiently large k, this can produce a high-precision clustering in $O(nk)$ time to serve as input to the merging step.

Greedy Merging After pre-clustering, we produce a binary cluster tree by iteratively merging pairs of clusters which greedily minimize $\mathcal{L}_0$. Since $\lambda = 0$, the loss grows monotonically when merging clusters. The loss at each merge can be efficiently updated by maintaining maximum likelihood estimates θ for each cluster.

Tuned Splitting Finally, we iteratively split the cluster tree produced by the merging stage. At each step, we split the cluster C_i with the lowest log data likelihood per item $\frac{\log \text{P}(C_i|\mathbf{C})}{|C_i|}$. We then choose the clustering which minimizes $\mathcal{L}_{\lambda}$, with $\lambda > 0$ tuned during model development.[6]

4 Experimental Setup

Data We run experiments on the distribution of PropBank (Palmer et al., 2005) provided for the CoNLL 2008 Shared Task (Surdeanu et al., 2008). We use the same setup as previous work, removing arguments annotated with reference (R-) and continuation (C-) roles, keeping only verbal predicates,[7] and using the development set for model development and the training set for testing.

Our one preprocessing difference from previous work is that instead of using the dependency-based SRL annotations provided in the CoNLL 2008 dataset, we use full answer spans, which we reconstruct by aligning the CoNLL 2008 data back to the original annotations in the Penn Treebank (Marcus et al., 1993) and PropBank.[8]

4.1 Models

***HUM of QA-SRL Questions* (HUM-QQ)** We train a QA-SRL parser on the expanded set of the QA-SRL Bank 2.0 (FitzGerald et al., 2018) using the architecture described in Section 3.1. In the pre-clustering step, we estimate $k = 100$ clusters. For tuned splitting, we choose λ to maximize performance on the development set. Hyperparameters are detailed in Appendix B.

SYNTF This model assigns each argument to a cluster corresponding to the label of its syntactic dependency to its parent, using the syntactic formalism provided in CoNLL 2008 Shared Task data. Past work has found SYNTF to be a strong baseline (Lang and Lapata, 2011).

Prior Work We compare to Bayesian generative modeling (Titov and Klementiev, 2012, BAYES), which is state-of-the-art on gold syntax, and an embedding-based method (Luan et al., 2016, SYMDEP/ASYMDEP) which is state-of-the-art using automatic syntax. These as well as all other prior approaches (e.g., Lang and Lapata, 2011; Titov and Khoddam, 2015; Woodsend and Lapata, 2015) crucially rely on syntactic features.

4.2 Auxiliary Clustering Rules

For SYNTF and HUM-QQ, we experiment with several auxiliary clustering rules.

Lexical Rules We employ three lexical rules, each producing a separate cluster for all arguments whose spans exactly match a phrase contained in the rule's lexicon. Our rules are for negation (5

---

[6] A comparison of this method against a constant-k baseline and oracle upper bound is given in Appendix E.

[7] While we ignore nominal predicates, our method naturally generalizes to nominalizations, which are provided with QA-SRL annotations in QANom (Klein et al., 2020).

[8] Using gold spans is necessary in order to compare to previous work and use the CoNLL 2008 dataset for evaluation of role induction. In a more realistic setting where gold argument spans are not available, we could use the span detector of FitzGerald et al. (2018) to construct argument spans.

phrases), modals (23 phrases), and discourse modifiers (55 phrases). These lexica were written to correspond to the `AM-NEG`, `AM-MOD`, and `AM-DIS` roles on the basis of the PropBank annotation guidelines (Babko-Malaya, 2005) and development set.[9]

Passive to Active Conversion We also propose a syntactic rule that applies only to SyntF, where we the transform the dependencies as follows:

- The `LGS` label, meaning "logical subject," is a dependency label given for *by*-phrases modifying a passive verb whose object denotes what is normally the subject of the verb's active form (Surdeanu et al., 2008). We change this to `SBJ`.
- Passive voice can be detected when the predicate verb is in past participle form (part-of-speech tag `VBN`) and its syntactic parent is a *be*-verb (part of speech `VC`, lemma "be"). In these cases, we change the syntactic label of any `SBJ` dependents into `OBJ`.

4.3 Metrics

Purity/Collocation To compare with previous work, we follow Lang and Lapata (2010) in using purity and collocation based F1 score for our main evaluation. Purity measures cluster homogeneity: it assigns to each cluster the gold label for which it has the most points, and then measures the proportion of points which have their cluster's assigned label. Collocation measures cluster concentration: it assigns each gold label to the cluster which contains the most of its points, and then measures the proportion of points which are in their gold label's assigned cluster. These are calculated independently for each verb and averaged, weighing each verb by its number of argument instances. The harmonic mean of the final results is reported as an F1 score.

B^3 For deeper analysis, we use the B^3 (*B-cubed*) family of clustering metrics (Bagga and Baldwin, 1998). B^3 precision and recall are the precision and recall of each point's predicted cluster against its gold cluster, averaging over points. In comparison to purity and collocation, these metrics are tougher and more discriminative between clusterings, respecting important constraints like the cluster completeness constraint of Rosenberg and Hirschberg (2007), among others (Amigó et al., 2009). B^3 also allows us to reliably report scores along slices of the data for analysis purposes, as well as account for each slice's contribution to the total error. We report full B^3 results for our models in Appendix F and encourage future work to use these as the primary metrics.

Model	**PU**	**CO**	**F1**	**ΔF1**
		Gold Syntax

+ lex	**85.4**	**88.8**	**87.1**	**+7.5**

Table 3: Main results. The addition of a few simple rules to the SyntF baseline puts it significantly above existing approaches, and incorporating these rules into our QA-SRL-based model pushes performance even further, despite not using gold syntax at all. Evaluation numbers for baselines besides SyntF are drawn directly from prior work.

5 Results

Main results are shown in Table 3. Our auxiliary rules put SyntF significantly above the state of the art for gold syntax (with 85.2 F1 versus 83.0). HUM-QQ surpasses it with 87.1 F1 in the best case, despite not using gold syntax at all.

5.1 A Stronger Syntactic Baseline

For SyntF, the addition of either lexical (negation, modal, and discourse) rules or the passive-to-active conversion produce competitive models, covering over 75% of the gap from baseline to Bayes. Used together, our rules bring the score to 85.2 F1, surpassing Bayes by 2.2 points. Table 5 breaks down these improvements by measuring B^3 performance on relevant roles.

For the lexical rules, we find that the negation and modal rules nearly completely capture their

---

[9] Full lexica for these rules are provided in Appendix C.

Table 5: Breakdown of B^3 F1 scores on the training set for the labels most relevant to our auxiliary rules. The lexical rules capture `AM-NEG`, `AM-MOD`, and `AM-DIS` very well, and the active/passive rule significantly improves performance on `A0` and `A1`, which are by far the most frequent role labels in the data. A rule-by-rule performance breakdown is provided in Appendix D.

roles, with the discourse rule providing significant improvements as well. In contrast, previous models have struggled with these roles, as reported by Lang and Lapata (2011, Table 4, `NEG` and `DIS` roles). However, this is better seen as a shortcoming of the evaluation than the models: these roles are relatively uninteresting from the perspective of semantic role induction, as they are closed-class, not specific to particular predicates, and don't correspond to a semantic argument or modifier of the event denoted by the predicate. It might have been reasonable to exclude these arguments from the task at the outset, but instead, using our rules can mostly account for them while maintaining some comparability to prior work.

The passive-to-active conversion also produces a sizable gain, particularly on the core roles `A0` and `A1` (Table 5). Titov and Klementiev (2012) informally note that the Bayes model learns some syntactic alternations; of these, the passive alternation is perhaps the most impactful as it can apply to any transitive verb. What we've found is that a simple rule accounting for the passive construction in the syntax provided to the Bayes model can account for a large majority of its gains.

These results provide extra context in which to interpret the existing literature on semantic role induction. The fact that our simple auxiliary rules bring the syntactic baseline beyond the existing state of the art raises questions about whether the performance differences between previously published models are due to their relative abilities in capturing their intended phenomena — such as selectional restrictions and distributions over argument heads (Lang and Lapata, 2014) — or capturing these rules. It is not clear how much of the 5.2 F1 gain over SyntF from our auxiliary rules is redundant with previous models. It seems likely that applying our rules to them would produce a result competitive with HUM-QQ, but it would still rely on gold syntax. Our focus is the utility of QA-SRL as features; indeed, it is also conceivable that applying a hierarchical model like Bayes to QA-SRL features would bring further improvements as well.

5.2 Superiority Without Syntax

HUM-QQ benefits disproportionately from the lexical rules, with a 5 F1 gain as opposed to the 2.8 F1 gain for SyntF. This is because PropBank's `NEG`, `MOD`, and `DIS` arguments almost never occur in QA-SRL, so they get nonsense questions from the model (see Appendix J, Table 12).[10] However, even the baseline model with no lexical rules or connectivity penalty surpasses the performance of the baselines using automatic syntax, all of which fall short of SyntF on gold.[11] With these additions, HUM-QQ sets a new state of the art beyond our enhanced SyntF baseline, with 87.1 F1.

Table 4 compares our model to SyntF + lex on the most common roles using B^3. HUM-QQ greatly improves over SyntF on core arguments

---

[10] In practice, when using arguments predicted by a QA-SRL span detector (FitzGerald et al., 2018), we can remove the lexical rules entirely since the corresponding arguments will not be present.

[11] To be fair, these models use the automatic parses provided with the CoNLL 2008 data, which were produced by MaltParser (Nivre et al., 2006) at the time. Using state-of-the-art methods to predict the parses today would almost certainly improve the semantic role induction results, but probably not past gold parses.

(73→85 F1), but performs worse on modifiers (74→61). Since core arguments make up 74% of arguments in the corpus, HUM-QQ brings a large improvement overall (74→82) and core arguments still account for a majority of its error (at 61%).

SYNTF's high performance on modifiers can be traced back to representational choices in the CoNLL 2008 Shared Task syntax (Surdeanu et al., 2008), which uses several dependency types that are semantic in nature, such as `TMP`, `LOC`, `MNR`, and `DIR`, among others. These often correlate well with gold modifier role labels, especially `TMP` (87 F1) and `LOC` (81 F1).[12] This fact has led some prior work, e.g., Titov and Klementiev (2012), to use these dependency labels as clusters directly, so as to avoid the need to model modifier roles and instead focus on core arguments. Since we eschew syntactic features, we are forced to recover PropBank modifier roles from the ground up, making the task more difficult (explored more in Section 6.2).

6 What does QA-SRL Encode About Semantic Roles?

Semantic roles are traditionally characterized as abstractions over syntactic arguments and modifiers (Gruber, 1965; Fillmore, 1968). Despite their deep entanglement with syntax, we have found that significant improvements in semantic role induction are possible without explicit syntactic analysis of the sentence, instead leveraging distributions of QA-SRL questions for each argument. In this section, we show that this is because QA-SRL questions provide *surrogate syntax*, recapitulating the aspects of syntax that are important for semantic roles (Section 6.1). Where QA-SRL questions fail to capture aspects of PropBank semantic roles, this arises in part from ontological differences with PropBank on modifiers (Section 6.2) and limitations of our experimental setup ignoring predicate sense (Section 6.3).

6.1 Surrogate Syntax

HUM-QQ brings the largest improvement over SYNTF on core arguments `A0` and `A1`. To investigate this, we identify the verbs which saw the greatest increase in B^3 F1 score on each role individually. What we find is that QA-SRL works by acting as *surrogate syntax*: it removes much of the (role-irrelevant) syntactic variation in the source text, while still exhibiting (role-relevant) syntactic alternations which capture the syntactic behavior of the predicate verb.

Reducing Syntactic Variation For `A0`, the three verbs with the greatest improvement from SYNTF to HUM-QQ are *compete*, *conduct*, and *connect*, all with gaps of over 40 F1.[13] For each of these, their `A0` arguments have a wide range of syntactic functions assigned by SYNTF, with `SBJ` less than 50% of the time — despite the fact that where the `A0` role is present, it is designed to correspond to the grammatical subject (Babko-Malaya, 2005). We found that this is because these verbs frequently have *non-overt* subjects, which are not direct syntactic dependents of the predicate in CoNLL 2008 syntax (74% of a random sample of 30 sentences with `A0` arguments of these three verbs, 10 from each; see Appendix H.1). They appear in phrases like 'two competing *objectives*' (with adjectival clauses), 'urging *directors* to conduct a fair auction' (with control verbs), or '*a maze of halls* that connects film rooms' (with relative clauses). In these cases, the SYNTF baseline does poorly, as the correspondence between the `SBJ` dependency and `A0` role only holds consistently for overt subjects.

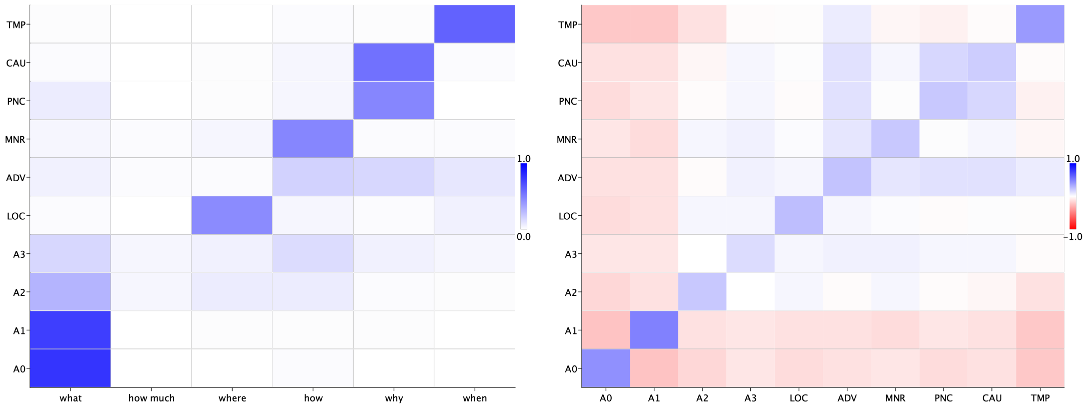
In contrast, HUM-QQ assigns the vast majority of `A0` arguments in these cases with questions that put the *wh*-word in subject position, e.g., *What competes with something?* or *What conducts?* Here, QA-SRL removes much of the syntactic variation from the source text and recovers something close to the underlying grammatical relation between the argument and the verb, while also providing information about the verb's subcategorization frames (e.g., the presence of an object in *What connects something?*), aiding in recovery of the semantic role.

Capturing Syntactic Alternations For `A1`, The verbs with the greatest improvement are *propose*, *prefer*, *price*, and *relate*, with a gap of >50 F1 between models. Of the top 50 such verbs, 48 are transitive with `A1` as the transitive object (see Appendix H.2). In these cases, the passive alternation allows the argument to be asked about in either the subject (*What is proposed?*) or object (*What does something propose?*) position. We find that QA-SRL does this, frequently combining questions

---

[12] See Lang and Lapata (2014, Table 2) for a detailed contingency table.

[13] To reduce variance from low-frequency verbs, we measure this gap after smoothing their precision and recall with 10 counts of the weighted aggregate for the model.



(a) Distribution of *wh*-words for each role.

(b) Normalized PMIs between gold roles.

Figure 1: Cooccurrence between gold role labels and *wh*-words in QA-SRL (left) or each other in HUM-QQ's predicted clusters (right). The distributions of *wh*-words are normalized per role, and NPMI between gold labels is chance-corrected, where negative values (red) are clustered apart more often than by chance, and positive values (blue) are preferentially grouped together.

about passive subject and active object into one role: for 62% of the top 50 verbs, the cluster corresponding to `A1` gives greater than 20% probability *each* to passive subject and active object questions. This happens because the Hard Unigram Mixture objective clusters together distributions whose uncertainty is spread over the same set of elements, which here correspond to syntactic alternations. As an example, Table 1 shows the induced clusters for *give*, which exhibit both passive and dative alternations; *give* gained 31 F1 on `A1` in HUM-QQ.

6.2 Mismatched Modifiers

HUM-QQ struggles to identify PropBank modifier roles, and it has room for improvement on trailing arguments like `A2` and `A3`. In QA-SRL, the semantics of these roles are primarily expressed by the initial *wh*-word, such as *when*, *where*, *why*, *how*, etc. Figure 1a shows the distribution of *wh*-words appearing for each role in the training set. To a large extent, each role is concentrated on a corresponding *wh*-word, but there are exceptions. `A2`, `A3`, and `AM-ADV` are widely spread between *wh*-words, and *how* and *why* account for a significant portion of questions for several roles each. See Appendix J, Table 11 for full questions.

To visualize how this affects clustering results, Figure 1b shows the normalized pointwise mutual information (NPMI; Bouma, 2009) between gold labels in HUM-QQ's predicted clusters (see Appendix I for how this is calculated). While `A0` and `A1` are distinguished well from all other roles, the trailing arguments `A2` and `A3` are not well distinguished from modifiers, reflecting the difficulty of the argument–adjunct distinction for these arguments, which often have similar meanings to modifiers and form a significant error case for supervised labelers (He et al., 2017). `AM-ADV` tends to be confused with other modifier roles, which reflects its definition in the PropBank guidelines as a sort of "catch-all" role for meanings not captured in the other modifiers (Babko-Malaya, 2005). Finally, `AM-CAU` (*cause*) and `AM-PNC` (*purpose, not cause*) tend to be confused with each other, since they both elicit *why* questions.

Argument–Adjunct Distinction Scores are significantly lower for trailing core arguments `A2-4` than for `A0` and `A1`. Since part of the problem seems to be confusion with modifier roles (Figure 1b), we conduct an oracle experiment to enforce the argument–adjunct distinction by doubling the size of the feature space to $\phi(x) \in \mathbb{R}^{2|q|}_{\geq 0}$ and projecting gold core arguments and modifiers into orthogonal subspaces.

Results are shown in Table 6 (+ gold arg/adj). The oracle boosts performance by 3 points, with particular focus on trailing arguments `A2` (69→78) and `A4` (65→78), as well as modifiers `AM-ADV` (39→47), `AM-MNR` (50→57), and `AM-LOC` (55→61). However, overall performance on modifiers is still far below the syntactic baseline. Given the coarse semantics of English *wh*-words in comparison to PropBank modifier roles (Figure 1a), it may be that finer-grained features are necessary to significantly increase performance on modifiers.

B^3 F1	`A0`	`A1`	`A2`	`A3`	`A4`	Args	`TMP`	`ADV`	`MNR`	`LOC`	`PNC`	`CAU`	Mods	All
SyntF + lex	78	71	63	55	67	73	**87**	**51**	60	**81**	65	**67**	**74**	74
HUM-QQ + lex	90	87	69	54	65	85	78	39	50	55	56	36	61	82
+ gold arg/adj	91	89	78	65	78	88	77	47	57	61	58	35	64	85
+ gold sense	91	90	74	58	75	87	80	43	55	64	63	47	65	84
+ both	**92**	**92**	**83**	**70**	**81**	**90**	81	**51**	**64**	69	**66**	46	69	**87**

Table 6: Breakdown of B^3 F1 scores on the training set for the most common labels in our ablation studies. The first two rows are repeated from Table 4.

6.3 Scrambled Senses

Despite core arguments significantly improving under HUM-QQ, they remain the largest source of error. To investigate this, we examine the verbs with the worst F1 on core arguments. The top verbs are *go*, *settle*, *confuse*, *turn*, and *follow*, with <60 F1. Half of the top 20 have 4 or more predicate senses annotated in PropBank, where different senses often manifest their roles differently: for example, the subject is `A0` when *settling with the IRS* (sense 2), but `A1` when *settling into a new job* (sense 3). To quantify this, we run an oracle experiment where we induce roles for each verb sense separately instead of each verb lemma. Results are shown in Table 6 (+ gold sense). Performance improves particularly on trailing arguments `A2`, `A3` and `A4`, which tend to differ greatly in meaning and realization for different predicate senses. A combined oracle (+ both) shows that the gains are mostly complementary with those from the argument/adjunct distinction oracle. These results suggest that future work on semantic role induction should prioritize modeling predicate senses.

7 Conclusion

We have shown that QA-SRL provides a way to do state-of-the-art semantic role induction without the need for formal syntax. It works by providing *surrogate* syntax: it captures long-distance dependencies to non-overt arguments and exhibits syntactic alternations which allow us to detect varied ways of expressing the same role. These results suggest that QA-SRL can provide some of the practical benefits of sophisticated syntactic formalisms that have separate layers of functional structure, like Combinatory Categorial Grammar (Steedman, 1996, 2000), Head-Driven Phrase Structure Grammar (Pollard and Sag, 1994), or Lexical Functional Grammar (Bresnan et al., 2015) — but without grammar engineering or expert data annotation.

One challenge is that QA-SRL is currently only defined for English. Future work may benefit from our lessons about the utility of surrogate syntax when designing similar annotation methodologies for other languages; combining this with insights from existing work on grammar development for diverse languages (Bender et al., 2002) may be key.

While formal ontologies of semantic roles and syntax are difficult to formulate and scale, our results show how it may be comparatively feasible to formulate, scale, and build robust models for the *phenomena* that such ontologies are meant to explain. QA-SRL exhibits enough of these phenomena that a relatively simple model over it (the Hard Unigram Mixture in Section 3) yields state-of-the-art induced semantic roles which are interpretable and linguistically meaningful. This suggests that identifying and gathering supervision for more phenomena (e.g., those related to word sense or modifier semantics) in a relatively theory-agnostic way, then building models grounded in linguistic theory, may be a promising avenue for future work. This general approach has recently been applied to syntax as well, for example leveraging constituency tests (Cao et al., 2020) and naturally-occurring bracketings (Shi et al., 2021).

The fact that discrete structures can be reliably derived from ontology-free annotation schemes like QA-SRL can potentially inform future efforts to construct large-scale ontologies of semantic structure. QA-SRL has the further benefit over traditional SRL of including a broader scope of *implicit* arguments than those addressed by supervised systems, as shown by Roit et al. (2020). Taken together, our results suggest that with the right kind of annotation scheme, it should be possible to construct rich semantic ontologies in new domains, without expert curation and in a data-driven, linguistically motivated way.

A QA-SRL Question Generator

We reproduce FitzGerald et al. (2018)'s architecture, encoding sentences with a stacked alternating LSTM (Zhou and Xu, 2015) with highway connections (Srivastava et al., 2015) and recurrent dropout (Gal and Ghahramani, 2016), and representing spans by concatenating the output embeddings of their endpoints (Lee et al., 2016). The question generator is a specialized LSTM decoder which only outputs the tokens allowed in each QA-SRL slot. The current predicate is indicated by an embedded binary feature input to BiLSTM encoder, and answer span representations are input at each step of the LSTM decoder. We make two changes from FitzGerald et al. (2018): 1) As opposed to GloVe (Pennington et al., 2014) or ELMo (Peters et al., 2018), We embed the inputs with BERT-base (Devlin et al., 2019) in the 'feature' style with a learned scalar mix over layers, and 2) we additionally concatenate the output embedding of the predicate to the input of the LSTM decoder.

B Hyperparameters

QA-SRL Question Generator The BiLSTM encoder uses a hidden size of 300, 4 layers, 0.1 recurrent dropout probability, and a 100-dimensional predicate indicator embedding. The LSTM decoder has a 100-dimensional hidden state and predicts QA-SRL slots with 200-dimensional embeddings via an MLP with a 100-dimensional hidden layer. We train on all QA pairs in the QA-SRL Bank 2.0 expanded training set using BERT's variant of Adam (Kingma and Ba, 2015) with a learning rate of $5\mathrm{e}{-5}$ and batch size of 32, selecting the model with minimal perplexity on the expanded development set. To produce our feature vectors ϕ, we decode questions with a beam size of 20 and a minimum probability cutoff of 0.01.

Flat Pre-Clustering We perform flat clustering with 100 clusters, skipping this step for verbs with 100 arguments or less. We use a concentration parameter of $\alpha = 0.01$ (i.e., uniform base measure with a sum of 0.01) and do 5 random restarts, each running until the loss decreases by less than $1\mathrm{e}{-5}$ per iteration, and choose the run that yields the lowest loss.

Model	PU	CO	F1	ΔF1
SYNTF	81.6	77.8	79.6	0.0
+ negation	82.8	77.8	80.2	+0.6
+ modals	83.0	79.8	81.3	+1.7
+ discourse	82.6	77.8	80.1	+0.5
+ pass→act	83.6	80.8	82.2	+2.6
+ all rules	87.3	83.1	85.2	+5.6

Table 7: Detailed results for auxiliary rules on SYNTF.

Tuned Splitting Our final model (HUM-QQ + lex) uses $\lambda = 0.35$.

C Rule Lexica

Here we list the full lexica for the auxiliary clustering rules described in Section 4.2.

Negation 5 items: *n't*, *never*, *no*, *no longer*, *not*.

These are drawn directly from the PropBank guidelines (Babko-Malaya, 2005, p. 32).

Modals 23 items: *'d*, *'ll*, *'ve*, *able*, *ca*, *can*, *can't*, *could*, *going*, *gon*, *gonna*, *have*, *may*, *might*, *must*, *ought*, *shall*, *should*, *used*, *will*, *wo*, *won't*, *would*.

Note the inclusion of *have*, *used*, *able*, and *going*, which are parts of phrasal modals (e.g., *have to*), which are included in `AM-MOD` according to the PropBank guidelines (Babko-Malaya, 2005, p. 32).

Discourse 55 items: *after all*, *ah*, *also*, *and*, *and so*, *as a result*, *as we've seen before*, *as well*, *but*, *certainly*, *damn*, *either*, *for example*, *for instance*, *for one*, *for one thing*, *frankly*, *furthermore*, *gosh*, *hence*, *however*, *in addition*, *in any case*, *in any event*, *in contrast*, *in fact*, *in other words*, *in particular*, *in that case*, *in this case*, *in turn*, *indeed*, *instead*, *ironically*, *moreover*, *nonetheless*, *of course*, *oh gosh*, *oh my god*, *oh my gosh*, *on the other hand*, *or*, *particularly*, *rather*, *regardless*, *similarly*, *so*, *specifically*, *thereby*, *therefore*, *though*, *thus*, *too*, *uh*, *um*.

Note the inclusion of some interjections, (*ah*, *oh my gosh*, etc.), which are included in `AM-DIS` according to the PropBank guidelines (Babko-Malaya, 2005, p. 31).

D Auxiliary Rule Performance Breakdown

In Table 7, we provide a more detailed accounting of the improvements that arise from our auxiliary rules described in Section 4.2 and Table 5.

Tuning Method	PU	CO	F1
Constant $k = 6$	83.9	86.7	85.3
$\lambda = 0.35$	85.4	88.8	87.1
F1 Oracle	**87.6**	**89.6**	**88.6**

Table 8: Comparison of methods to determine the number of clusters for each verb. All reported numbers are for HUM-QQ+ lex.

Setting	Objective
$\lambda = 1$	Mixture of Unigrams Likelihood
$\lambda = 0$	Jensen-Shannon Divergence
$\lambda = -1$	Mutual Information

Table 9: Objectives reproduced by the HUM loss for different settings of λ, described in Appendix G.

The negation and discourse rules bring precision improvements, likely because they mostly have `ADV` dependencies outgoing. The modal rule improves both precision and recall because modals have many different kinds of outgoing dependencies, due to their status as heads of clauses (which can serve in many syntactic capacities). Finally, the passive alternation rule aids precision by splitting `SBJ` between active and passive uses, and aids recall by grouping `LGS` with the active `SBJ` and passive `SBJ` with active `OBJ`. This mainly affects the core argument labels `A0` and `A1`, as shown in Table 5 — especially `A1`, as we also find for QA-SRL questions in Section 6.1.

E Tuned Splitting Evaluation

Our model has a single parameter λ which determines the number of clusters for each verb via the tradeoff between the data likelihood and clustering likelihood. We compare this to a constant baseline (the same number of clusters for all verbs) and an oracle upper bound which chooses the split that maximizes the purity/collocation F1 score for each verb independently. As shown in Table 8, we improve on the constant baseline by 1.8 points (85.3→87.1), but fall short of the oracle by 1.5 points (87.1→88.6). There is room for improvement, but errors in the tuning step may not be the most significant factor to concern future work.

F B^3 Results

Results using B^3 metrics on models we tested are shown in Table 10.

Model	B^3P	B^3R	F1	ΔF1
Gold Syntax				
SyntF	74.7	68.3	71.3	0.0
+ lex	79.1	70.4	74.5	+3.2
+ pass→act	77.4	72.1	74.7	+3.4
+ all rules	**82.2**	**74.7**	**78.3**	**+7.0**
Automatic QA-SRL				
HUM-QQ	71.1	79.0	74.8	+3.5
− conn. pen.	71.6	75.7	73.6	+2.3
+ lex	**79.8**	**83.4**	**81.6**	**+10.3**
+ lex + MI	77.7	82.1	79.9	+8.6

Table 10: B^3 Results on models we tested. The gap between HUM-QQ and SyntF is larger than for purity and collocation, as B^3 is a tougher metric which is more discriminative between clusterings. The last model variant (+MI) is described in Appendix G.

G Related Clustering Algorithms

Recall the Hard Unigram Mixture loss

$$\mathcal{L}^{\text{HUM}}_{\lambda}(\mathbf{C}) = -\log \mathrm{P}(\mathbf{X} \mid \mathbf{C}) - \lambda \log \mathrm{P}(\mathbf{C}).$$

Different settings of λ reproduce several objectives present in the literature, summarized in Table 9. As written in Section 3, when $\lambda = 1$, minimizing $\mathcal{L}^{\text{HUM}}_{1}$ maximizes likelihood of the data $\mathbf{X}$ under a mixture of unigrams model (Nigam et al., 2000).

When the number of clusters k is fixed, setting $\lambda = 0$ as in our greedy merging step (Section 3.3) is equivalent to enforcing a uniform prior π over mixture components. In this case, the gain in loss on each merge is the Jensen-Shannon Divergence (JSD) between the merged clusters, scaled by their total size and using each cluster's size to determine its mixing weights in the divergence, as in the mixture-based definition of JSD by Lin (1991). JSD is used in the same way by Chrupała (2012), without the scaling and weighting, as a similarity measure for agglomerative clustering.

Finally, setting $\lambda = -1$ reduces the HUM loss to the mutual information between the QA-SRL questions under ϕ and the cluster assignment C, which has been used in prior work to encourage informative clusterings (Michael et al., 2020). This is related to the *distributional clustering* paradigm of Pereira et al. (1993), which aims to identify common factors that explain distributional data, and which Slonim and Tishby (1999) frame in terms of an information bottleneck that maximizes mutual information between the data and a jointly distributed 'relevance' variable (though in our case, the reference variable is the cluster assignment itself). Setting $\lambda = -1$ in the greedy merging step, we find (in Table 10) that using a mutual information criterion in this way hurts performance. We guess this is because the objective incentivizes clusters of uniform size, which does not match the highly skewed distributions of gold semantic roles.

H Manual Analysis Results

H.1 Improved Verbs on `A0`

The top 50 verbs by F1 gain on `A0` from SyntF to HUM-QQ are: *compete*, *conduct*, *connect*, *combine*, *dominate*, *restore*, *require*, *yield*, *limit*, *ban*, *direct*, *tie*, *oversee*, *contain*, *identify*, *increase*, *evaluate*, *specialize*, *allow*, *assist*, *restrict*, *found*, *grant*, *feature*, *propose*, *detail*, *force*, *convert*, *veto*, *rate*, *bolster*, *appoint*, *enact*, *design*, *list*, *lead*, *resolve*, *retire*, *schedule*, *reach*, *analyze*, *remove*, *speed*, *manage*, *deliver*, *underlie*, *revise*, *emerge*, *enable*, *block*.

We examined 30 sentences containing the top 3 verbs (*compete*, *conduct*, and *connect*). There were 31 `A0` arguments of these verbs in these sentences. Of these, 8 (26%) were overt, 11 (35%) were extracted subjects of relative clauses, 5 (16%) were modified by the predicate appearing in an adjectival clause, 5 (16%) were subjects of open complements of control verbs, and 2 (6%) were otherwise implicit (subject of an adverbial clause or open complement not under a control verb).

H.2 Improved Verbs on `A1`

We examined the top 50 verbs by their difference in B^3 performance on `A1` between SyntF and HUM-QQ. 48 of them are transitive; the other two are bolded. In decreasing order of F1 gain, they are: *propose*, *prefer*, *price*, *relate*, *involve*, *help*, *choose*, *consider*, *design*, *mention*, *identify*, *release*, *include*, ***exist***, ***range***, *value*, *revise*, *lead*, *associate*, *need*, *increase*, *import*, *prove*, *feel*, *place*, *determine*, *limit*, *found*, *enact*, *control*, *cancel*, *dilute*, *disclose*, *select*, *exclude*, *force*, *insure*, *accrue*, *damage*, *calculate*, *hurt*, *secure*, *delay*, *regard*, *record*, *open*, *use*, *concern*, *weaken*, *adjust*.

I Calculating Normalized PMI

Here we describe some special concerns for our use of normalized PMI in Section 6.2.

Pointwise mutual information (PMI) is a measure of how likely two items (such as tokens in a corpus) are to occur together relative to chance (Church and Hanks, 1989). One feature of PMI is that it tends to be larger for rare events: if two items x and y always occur together, then their PMI is $-\log \mathrm{P}(x, y)$. This can make it difficult to assess association patterns among items with greatly varying probabilities (e.g., the `AM-CAU` role appears for 1% of arguments, while `A1` appears for 27%). So we use *normalized* PMI (NPMI; Bouma, 2009), which factors out the effect of item frequency on PMI. Formally, the NPMI of x and y is

$$\left(\log \frac{\mathrm{P}(x, y)}{\mathrm{P}(x)\,\mathrm{P}(y)}\right) \Big/ -\log(\mathrm{P}(x, y)) \;, \qquad (1)$$

taking the limit value of -1 when they never occur together, 1 when they only occur together, and 0 when they occur independently. We use NPMI to analyze the co-occurrence of *gold labels* in *predicted clusters*: A pair of gold labels with high NPMI are preferentially grouped together by the induced roleset, whereas two labels with low NPMI are preferentially distinguished. The joint distribution between gold labels is generated by drawing one point (x) uniformly at random from the data, drawing another (y) uniformly at random from x's predicted cluster, and reading the gold labels of both. NPMI has been used to analyze clusters in this way by Michael et al. (2020).

Calculating NPMI naïvely on our full clustering has a caveat. The denominator of the PMI term in Equation 1, $\mathrm{P}(x)\,\mathrm{P}(y)$, uses marginal probabilities of x and y over the corpus to calculate chance co-occurrence. But our clusters are constrained not to overlap between verbs, so this does not correctly estimate chance cooccurrence in our setting. Instead, we use the expectation over verbs of within-verb chance cooccurrence:

$$\sum_{v} \mathrm{P}(x \mid v)\,\mathrm{P}(y \mid v)\,\mathrm{P}(v),$$

where $\mathrm{P}(v)$ is proportional to the number of arguments for the verb v.

J Question Distributions by Role

We list the top questions and their probabilities for modifier roles in Table 11. Questions for core roles and the ones covered by our lexical rules are in Table 12. We use *verb* (or *verbs*, or *verbed*) as a placeholder for the verb, which in practice is replaced with the predicate for a given instance.

Role	**Top Questions**	**Prob**
`TMP`	When does something verb something?	0.34
	When does something verb?	0.21
	When is something verbed?	0.18
	When does something verb somewhere?	0.03
	When does sth. verb to do something?	0.02
	How does something verb?	0.01
	How is something verbed?	0.01
`ADV`	Why does something verb something?	0.13
	How does something verb something?	0.12
	When does something verb something?	0.09
	How is something verbed?	0.08
	How does something verb?	0.08
	Why does something verb?	0.05
	Why is something verbed?	0.04
	When does something verb?	0.04
	What does something verb?	0.03
	When is something verbed?	0.03
`MNR`	How is something verbed?	0.25
	How does something verb?	0.22
	How does something verb something?	0.19
	What does something verb?	0.02
	Where does something verb?	0.02
	Why does something verb something?	0.02
	How does something verb somewhere?	0.02
`LOC`	Where does something verb something?	0.24
	Where is something verbed?	0.22
	Where does something verb?	0.21
	When does something verb something?	0.04
	How does something verb something?	0.03
	How does something verb?	0.02
	How is something verbed?	0.02
`PNC`	Why does something verb something?	0.29
	Why is something verbed?	0.21
	Why does something verb?	0.08
	Why does something verb somewhere?	0.05
	What is something verbed to do?	0.03
	How is something verbed?	0.03
	What is something verbed for?	0.02
`CAU`	Why does something verb something?	0.32
	Why does something verb?	0.16
	Why is something verbed?	0.16
	Why does something verb somewhere?	0.04
	How does something verb?	0.04
	Why does sth. verb to do something?	0.03
	How does something verb something?	0.02
`DIR`	Where does something verb?	0.40
	How does something verb?	0.17
	Where is something verbed?	0.10
	Where does something verb something?	0.07
	How is something verbed?	0.06
	How does something verb something?	0.03

Table 11: Top questions in the QA-SRL features on the training set for modifier roles. Most of the roles align with a particular *wh*-word especially well, especially for *when*, *where*, and *why*. But `AM-ADV` takes a variety of *wh*-words, and *how* appears often for nearly all modifier roles. In longer questions, 'something' is abbreviated for space.

Role	Top Questions	Prob
`A0`	What verbs something?	.65
	What verbs?	.14
	How is something verbed?	.02
`A1`	What does something verb?	.42
	What is verbed?	.25
	What verbs?	.09
	What verbs something?	.03
	What does something verb to do?	.02
`A2`	What does something verb?	.12
	How is something verbed?	.07
	What verbs something?	.07
	Where is something verbed?	.06
	What is verbed?	.06
	How does something verb?	.06
	How much does something verb?	.04
`A3`	How does something verb?	.15
	What does something verb?	.09
	How is something verbed?	.07
	Why does something verb something?	.06
	How does something verb something?	.05
	When does something verb?	.05
	Where does something verb?	.04
`A4`	What does something verb to?	.17
	Where does something verb?	.17
	How does something verb?	.16
	How much does something verb?	.14
	What does something verb something to?	.04
	How is something verbed?	.03
`NEG`	What verbs something?	.40
	What verbs?	.15
	What is verbed?	.12
	How is something verbed?	.05
	How does something verb?	.03
	How does something verb something?	.03
`MOD`	What verbs something?	.22
	How does something verb something?	.11
	What verbs?	.09
	Why does something verb something?	.07
	What is verbed?	.06
	How does something verb?	.06
	How is something verbed?	.06
`DIS`	When does something verb something?	.15
	How does something verb something?	.15
	What verbs something?	.08
	How is something verbed?	.07
	How does something verb?	.07
	Why does something verb something?	.06
	When does something verb?	.05

Table 12: Top questions in the QA-SRL features on the training set for core roles and the ones covered by our lexical rules. The questions for `AM-NEG`, `AM-MOD`, and `AM-DIS` often don't make sense, e.g., asking for the subject of the verb. No QA-SRL questions are appropriate or were annotated for many arguments of these types. On the other hand, the core roles behave essentially as expected: `A0` is dominated by the subject, `A1` has a mix of subjects and objects, with some complements, and `A2` and on have a wider spread of different expressions. Since the core argument roles have predicate-specific meanings, the distributions here can only be interpreted as aggregates across many such meanings.

Plot and Rework: Modeling Storylines for Visual Storytelling

Abstract

Writing a coherent and engaging story is not easy. Creative writers use their knowledge and worldview to put disjointed elements together to form a coherent storyline, and work and rework iteratively toward perfection. Automated visual storytelling (VIST) models, however, make poor use of external knowledge and iterative generation when attempting to create stories. This paper introduces ***PR-VIST***, a framework that represents the input image sequence as a story graph in which it finds the best path to form a storyline. PR-VIST then takes this path and learns to generate the final story via a re-evaluating training process. This framework produces stories that are superior in terms of diversity, coherence, and humanness, per both automatic and human evaluations. An ablation study shows that both plotting and reworking contribute to the model's superiority.

1 Introduction

Writing a story is a complicated task. Human writers use their knowledge to tie all the disjointed elements, such as people, items, actions, or locations, together to form a coherent storyline. Writers also re-evaluate their work constantly during the writing process, and sometimes even alter their writing goals in the middle of a draft. Flower and Hayes (1981) characterize a solo writer's cognitive process as a series of components in which the writer's own knowledge is described as the long-term memory, and the planning, translating, and reviewing steps can occur in a recursive, interconnected manner. These creative steps are essential to human writing. However, automated visual storytelling (VIST) models that compose stories given five images (Huang et al., 2016) do not make extensive use of human knowledge to tie the elements together, nor do they use human insight to evaluate the outputs and guide the generation process.

As for linking elements, most works generate visual stories in an end-to-end fashion (Huang et al., 2016; Kim et al., 2018), treating the task as a straightforward extension of image captioning. Recent works have begun to use relations between entities to improve visual storytelling, but often narrow in a particular subset of relations, such as relations between elements within the same image (Yang et al., 2019), relations between two adjacent images (Hsu et al., 2020), or relations between scenes (Wang et al., 2020). The full potential of rich real-world knowledge and intra-image relations have yet to be fully utilized. As for re-evaluation, recent work uses reward systems (Wang et al., 2018b; Hu et al., 2019) or estimated topic coherence (Wang et al., 2019) to automatically assess the output story and guide the generation process. However, these approaches are often optimized towards predefined aspects such as image relevancy or topic coherence, which do not necessarily lead to engaging stories from a human perspective. In the cognitive process of human writing, the writer's judgment is critical, and visual storytelling models could benefit by considering human ratings.

This paper introduces ***PR-VIST***, a novel visual storytelling framework that constructs a graph and captures the relations between all the elements in the input image sequence, finds the optimal path in the graph that forms the best storyline, and uses this path to generate the story. An overview of PR-VIST is shown in Figure 1.

- **Stage 1 (Story Plotting):** PR-VIST first constructs a story graph for the image sequence by extracting various elements (i.e., term nodes, object nodes) from all the images and linking these elements using external knowledge (i.e., VIST graph, VG graph). PR-VIST then finds

August 1–6, 2021.

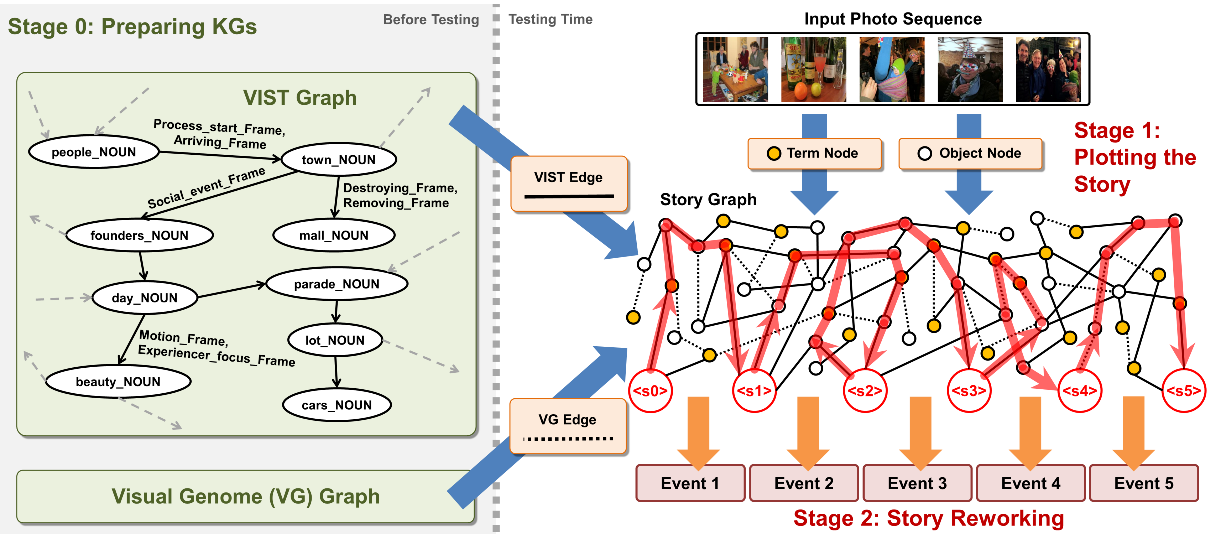

Figure 1: Overview of PR-VIST. In **Stage 1 (Story Plotting)**, PR-VIST first constructs a graph that captures the relations between all the elements in the input image sequence and finds the optimal path in the graph that forms the best storyline. In **Stage 2 (Story Reworking)**, PR-VIST uses the found path to generate the story. PR-VIST uses a story generator and a story evaluator to realize the "rework" process. In **Stage 0 (Preparation)**, a set of knowledge graphs that encode relations between elements should be prepared for the uses in Stage 1.

the best path in the story graph as the storyline and passes it to Stage 2.

- **Stage 2 (Story Reworking):** PR-VIST uses a story generator and a story evaluator to realize the reworking process: the generator takes the storyline produced in Stage 1 as the input to generate the story and backpropagates with an evaluator-augmented loss function. The evaluator, a discriminator model trained on human rating score data to classify good and bad stories, outputs a story quality score and modifies the loss. After a few optimization epochs, the generator eventually learns to generate stories that reflect human preferences.

In **Stage 0 (Preparation)**, a set of knowledge graphs that encode relations between elements are prepared for use in Stage 1. In this work, we prepare two knowledge graphs: a VIST graph and a visual genome (VG) graph. We construct the VIST graph based on the VIST dataset, representing in-domain knowledge; the VG graph is an existing resource (Krishna et al., 2017), representing generic knowledge. Note that as the PR-VIST framework is generic, it can use any knowledge graphs as needed.

Automatic and human evaluations show that PR-VIST produces visual stories that are more diverse, coherent, and human-like. We also conduct an ablation study to show that both story plotting (Stage 1) and reworking (Stage 2) contribute positively to the model's superiority. We believe this work also shows the potential of drawing inspiration from human cognitive processes and behavior to improve text generation technology.

2 Related Work

Visual Storytelling Researchers have been trying to advance the visual storytelling task since it was introduced by Huang et al. (2016). Some work modifies end-to-end recurrent models for better story generation (Hsu et al., 2018; Gonzalez-Rico and Fuentes-Pineda, 2018; Kim et al., 2018; Huang et al., 2019; Jung et al., 2020), and some use adversarial training to generate more diverse stories (Chen et al., 2017; Wang et al., 2018a,b; Hu et al., 2019). These methods produce legitimate stories and easier to implement because they relies only on one dataset. However, the generated stories can sometimes be monotonous and repetitive.

Leveraging External Resources for VIST Another set of work leverages external resources and knowledge to enrich the generated visual stories. For example, Yang et al. (2019) apply ConceptNet (Liu and Singh, 2004) and self-attention for create commonsense-augmented image features; Wang et al. (2020) use graph convolution networks on scene graphs (Johnson et al., 2018) to associate objects across images; and KG-Story (Hsu et al., 2020) is a three-stage VIST framework that uses

Visual Genome (Krishna et al., 2017) to produce knowledge-enriched visual stories.

Editing or Optimizing Visual Stories A few prior work tries to post-edit visual stories or optimize the story content toward specific goals. VIST-Edit is an automatic post-editing model that learns from an pre- and post-edited parallel corpus to edit machine-generated visual stories (Hsu et al., 2019). While VIST-Edit is useful, it requires parallel training data, which is often unavailable. Hu et al. (2019) use a reward function to optimize the generated stories toward three aspects; Li et al. (2019) customize the emotions of visual stories. These methods use automatic metrics to optimize visual stories toward specific goals; our work, on the other hand, leverages the human evaluation data to guide the generation process.

Story Plotting in Story Generation Research in automatic story generation has demonstrated the effectiveness of story plotting (Yao et al., 2018; Fan et al., 2019), which typically involves organizing the "ingredients" into a well-organized sequence of events. Nevertheless, none of the studies applied story plotting for visual stories.

3 Stage 0: Preparation

To prepare for story plotting, we collect information from the images and knowledge from the knowledge graphs.

3.1 Story Element Extraction

To extract information from the images, two extraction methods are used to extract image-oriented and story-oriented story elements: *objects* and *terms*, respectively representing image and story intuition.

Objects These can be detected by current object detection models, for which we use a pre-trained object detection model—Faster-RCNN (Ren et al., 2015). To ensure the detected objects' reliability, only those objects with the top five confidence scores are used in each image.

Terms These are story-like nouns such as events, time, and locations, which current object detection models are unable to extract. Therefore, we further use a Transformer-GRU (Hsu et al., 2020) to predict story-like terms. For each image and story pair, we use image objects as the input and the nouns in the corresponding human-written story as the ground truth. The Transformer-GRU learns to convert objects to nouns commonly used in stories.

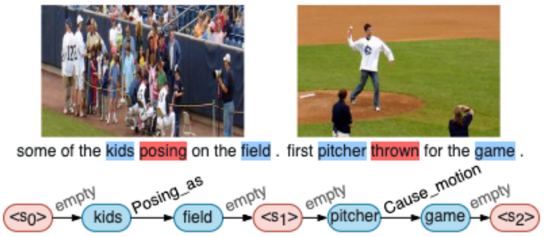

Figure 2: From the stories in VIST training data, a story is transformed into a golden storyline following the human reading direction, as part of the VIST graph.

3.2 Knowledge Graph Preparation

To collect interactive relations between nouns, we prepare Visual Genome graph $\mathcal{G}_{vg}$ and VIST graph $\mathcal{G}_{vist}$. These graphs contain interlinked real-world objects and terms, displaying visual and storytelling interaction. Table 1 summarizes the statistic of each graph.

Visual Genome Graph $\mathcal{G}_{vg}$ describes pairwise relationships between objects in an image, describing visual interactions. No prepositional relations are included; only verb relations are preserved. All relations are converted into semantic verb frames using Open-SESAME (Swayamdipta et al., 2017), in which the semantic frames were pre-defined in FrameNet (Baker et al., 1998).

VIST Graph we propose $\mathcal{G}_{vist}$ to collect the storytelling interactions. We develop this novel story knowledge graph by converting references in the VIST training and validation datasets (Huang et al., 2016) to graphical data. Following the reading direction, in each reference, we extract nouns and semantic verb frames using SpaCy[1] and Open-SESAME to obtain noun–verb–noun (NVN) tuples. Using nouns and semantic verb frames as nodes and edges, these are collectively assembled into a golden storyline. For example, for "first pitcher thrown for the game" in Figure 2, we extract *pitcher*, *game*, and *Cause_motion*, which is a semantic verb frame for *thrown*, as a NVN tuple. Additionally, we include a noun token $<$`s`$_i>$ as the transition point to the next sentence or termination point of a story, and a verb frame token `empty_frame` to interlink two nouns when a semantic frame is absent. To conclude, all of the golden storylines are assembled into $\mathcal{G}_{vist}$.

---

[1] SpaCy: https://spacy.io/

	Nodes	Relations	Links
$\mathcal{G}_{vg}$	3,323	564	22.31
$\mathcal{G}_{vist}$	2,048	531	11.75
$\mathcal{G}_{vg+vist}$	4,158	880	22.78

Table 1: The statistics of knowledge graphs. The table shows the number of distinct nodes and relations in each graph. It also shows the average link per node. Note that the nodes and relations from $\mathcal{G}_{vg}$ and $\mathcal{G}_{vist}$ have overlaps.

4 Stage 1: Story Plotting

4.1 Storyline Predictor

In Stage 1, PR-VIST uses a storyline predictor to find what it deems the best path in the story graph as the storyline and then pass this to Stage 2. For the storyline predictor, we use UHop (Chen et al., 2019), a non-exhaustive relation extraction framework. A single hop is defined as searching from one entity to another entity by a single relation. UHop performs multiple single-hop classifications consecutively in the graph to find the path representing the storyline, that is, a path that consists of a sequence of nouns and verb frames.

Single-hop classification can described as Equation 1 and Figure 3. In step i, at the current head entity h_i, the model is given a list of candidate relations $r_i \in R_i$ and tail entities $t_i \in T_i$. Each r_i is in [verb.t_i] or [verb.noun] format, containing information for both the verb frame and the tail noun entity. The scoring model F is given *objects* and predicted relations $r_1, ..., r_{i-1}$ as input. The model predicts a score for each r_i and selects the highest verb-noun pair r_i from Q:

$$r_i = \arg\max_{q \in Q} F(objects, r_1, ..., r_{i-1}). \quad (1)$$

Training UHop learns to find a path for the storyline from the golden storyline. The training procedure starts with an initial noun token entity <`s0`> in the golden storyline for single-hop classification, where $h_1 =$ <`s0`>. It learns to select the correct relation r_i from a list of candidate relations R_i in $\mathcal{G}_{vg}$ and $\mathcal{G}_{vist}$. Then, it calculates the error to the noun and verb frame in the golden storyline for backpropagation. In the next hop, the framework proceeds to the next noun in the golden storyline and repeats the single-hop classification.

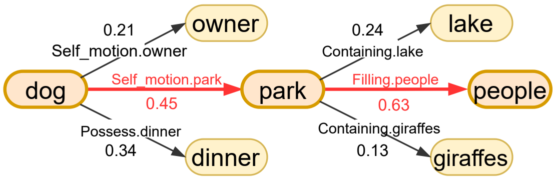

Figure 3: Storyline pathfinding process. All entities are from *object* or *term* list, and all relations are in [verb.noun] format, which the verbs are verb frames from knowledge graphs and the nouns are the tail entities. The single-hop classification begins with `dog`. The storyline predictor is given three candidate relations. The framework selects the highest score relation and move on to the next entity `park`. Then, the single-hop classification repeats.

Testing In PR-VIST's testing step, for each story, five images are transformed into a story graph $\mathcal{G}_{story}$. As demonstrated in Figure 1, we first extract the *object* and *term* story elements for each story, and then link these together using the verb frames in $\mathcal{G}_{vist}$ and $\mathcal{G}_{vg}$ as edges. This yields a well-defined graph presenting a comprehensive view of five images for each story—$\mathcal{G}_{story}$. Next, a trained UHop finds a storyline in $\mathcal{G}_{story}$, where all entities are only the *objects* and *terms* from the given five images. The framework starts with <`s0`> to perform single-hop classification, where $h_1 =$ <`s0`>. Unlike training, it only selects r_i from R_i listed in $\mathcal{G}_{story}$. In the next hop, the previous predicted entities are used as the start entity: $h_0 = t_{i-1}$. It then continues to hop from entity to entity until it reaches the next token <`s1`>. The path from <`si-1`> to <`si`> is called an event e_i. The path search from <`si`> to the next token <`si+1`> continues until the search is terminated by the termination decision described in UHop. Eventually, the model finds a storyline of arbitrary length L, that is, a storyline that contains any number of events: $e_1, ..., e_L$.

4.2 Implementation Details

HR-BiLSTM (Yu et al., 2018) is adopted as the scoring model F, in which *objects* are converted to word embeddings via GloVe (Pennington et al., 2014) as $E(object)$. All relation embeddings $E(r)$ are decomposed into graphical embedding E_{graph} and textual embedding E_{text}. E_{graph} transforms a verb frame v and a tail entity's image position p^t into a one-hot vector, denoting the graphical and image positional information. E_{text} is composed of the verb frame and tail entity word embedding. Then, E_{graph} and E_{text} are concatenated into a unified representation $E(r)$. We formulate the representation of relation r as

$$\begin{aligned} E_{graph}(r) &= [\mathbb{1}(v); \mathbb{1}(p^t)], \\ E_{text}(r) &= [E_w(f); E_w(t)], \\ E(r) &= [E_{graph}(r); E_{text}(r)], \end{aligned} \tag{2}$$

where $\mathbb{1}(\cdot)$ returns the one-hot representation, $E_w(\cdot)$ returns the word embeddings via GloVE, and [;] denotes concatenation.

A verb frame and tail entity are combined into r_i due to relational ambiguity issues among candidate relations. Using Figure 3 as an example, given a head entity *dog*, candidates *self_motion.park* and *self_motion.owner* represent different semantic meanings when tail entities *park* and *owner* are included. However, excluding tail entities results in identical relation candidates *self_motion* and thus ambiguity between two different candidates.

5 Stage 2: Story Reworking

In story reworking, the framework consists of two components: the story generator and the story evaluator. The story generator generates a story according to the storyline, and the story evaluator—a discriminator trained on the MTurk human ranking data to classify good and bad stories—outputs a story quality score and modifies the loss functions.

5.1 Story Generator

A storyline consists of a set of events $e_1 ... e_L$ that are input to the story generator, which is based on the Transformer (Vaswani et al., 2017). Unlike most VIST models, the story generator is dynamic: the number of output sentences depends on the number of events. To manage a diverse number of events, the Transformer is designed as a sentence generator that iteratively generates one sentence per event until it generates L sentences. For each step i, event e_i and the previous predicted sentence y_{i-1} are used to predict the next sentence y_i. After L steps, the story generator outputs a story $s = y_1, ... y_L$.

5.2 Story Evaluator

Most VIST works use human evaluations to examine their work's quality via crowdsourcing, comparing their generated stories with the baseline stories. In this paper, we use the first- and last-place stories in the MTurk human ranking data as positive and negative samples. The story evaluator, a discriminator trained on the MTurk human ranking data, learns to distinguish positive and negative samples. It outputs a score for each story, and the scores are converted into rewards, as shown below:

$$p_{LM}(u|s) = \text{softmax}(\tanh(\mathbf{W}LM(s)) + \mathbf{b}), \tag{3}$$

$$\mathcal{R}(s) = -p_{LM}(u|s) + c, \tag{4}$$

where $LM(\cdot)$ is a GRU language model (Cho et al., 2014), $u = 1$ indicates story s is a positive sample, and $u = 0$ indicates s is a negative sample. Language model $p_{LM}(\cdot)$ returns a score from 0 to 1 to reflect story quality. The story evaluator $\mathcal{R}(\cdot)$ returns a reward, an inverse of $p_{LM}(\cdot)$ with coefficient $c = 1.5$. The reward later manipulates the loss, optimizing toward human preference. Note that the story evaluator is pre-trained.

5.3 Optimization with Story Evaluator

For optimization, the story generator uses sentence-level and story-level loss functions. Given reference $y_1^*, ..., y_L^*$ and predicted story $y_1, ..., y_L$, in the maximum likelihood estimation (MLE) optimization process, in each step from 1 to L, the model predicts a sentence y_i to calculate the loss between y_i and y_i^* and then backpropagates, as shown in Figure 4. After predicting L sentences, in story-level optimization, the model predicts $y_1, ..., y_L$ to calculate the negative log-likelihood to the reference $y_1^*, ..., y_L^*$ and then backpropagates. The sentence-level and story-level optimization by MLE on dataset $\mathcal{D}$ are formulated as

$$J_{sen}^{MLE}(\theta, \mathcal{D}) = \sum_{Y \in \mathcal{D}} -\log p_\theta(y_i | e_i, y_{i-1}), \tag{5}$$

$$J_{story}^{MLE}(\theta, \mathcal{D}) = \sum_{Y \in \mathcal{D}} \frac{1}{L} \sum_{i=1}^{L} -\log p_\theta(y_i' | e_i, y_{i-1}'), \tag{6}$$

where e_i and y_i denote the i-th event and the sentence respectively, y_i' represents the updated sentence after sentence-level optimization, and θ represents the story generation model parameters, which are updated using Adam (Kingma and Ba, 2015).

After training for 30 epochs [2], the story evaluater begins to manipulate the story-level loss. Inspired by reinforcement learning (Williams, 1992), which utilizes rewards to guide the training process, we use the story evaluator $\mathcal{R}(\cdot)$ [3] to encourage the

---

[2] The generation model converges at around 20 epochs in our experiment, and we give it extra 10 epochs for precautions.

[3] The pre-trained LM's weights are frozen to stabilize the training.

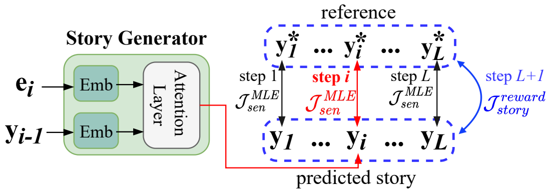

Figure 4: Optimization flowchart for story generator. For steps 1 to L, the model is optimized using sentence-level loss. In step $L+1$, all sentences are generated, and the model is optimized using story-level loss.

generation model to focus on stories preferred by humans. The reward directly multiplies the story-level loss as

$$J^{reward}_{story}(\theta, \mathcal{D}) = \begin{cases} J^{MLE}_{story} & \text{if epoch} \le 30 \\ \mathcal{R}(s) J^{MLE}_{story} & \text{if } 30 < \text{epoch} \le 60 \end{cases}. \quad (7)$$

6 Experimental Results

6.1 Data Setups

We used four datasets in this paper: the VIST dataset, Visual Genome, ROCStories, and MTurk human ranking data. The VIST dataset and Visual Genome are used to construct the knowledge graphs, and ROCStories (Mostafazadeh et al., 2016) is a large quantity of pure textual stories used for pre-training the story generator. The VIST dataset is also used in story plotting to train the storyline predictor and in story reworking to fine-tune the story generator. Notably, we also collected MTurk human ranking data to train the story evaluator. We used the ranking results from KG-Story[4] (Hsu et al., 2020). This data contains two experiments, each of which ontains 500 distinct photo sequences. A photo sequence contains a set of machine-generated stories ranked by 5 MTurk workers. Thus we have 5000 rankings from MTurk workers. Specifically, MTurk workers were asked to rank AREL (Wang et al., 2018a), KG-Story, two KG-Story ablation models, and reference stories, using three different model settings in each experiment. We selected the rank-1 and rank-5 stories as positive and negative samples.

6.2 Baselines

We used several competitive baseline models. **AREL** (Wang et al., 2018a) and **GLAC** (Kim et al., 2018) are end-to-end models with reinforcement learning and global-location attention mechanisms that achieved top ranks in the VIST Challenge (Mitchell et al., 2018). **KG-Story** (Hsu et al., 2020), the current state-of-the-art framework, utilizes a knowledge graph to enrich story contents and generates stories using Transformer.

6.3 Evaluation Methods

Per the literature (Wang et al., 2018a), human evaluation is the most reliable way to evaluate the quality of visual stories; automatic metrics often do not align faithfully to human judgment (Hsu et al., 2019). Therefore, in this paper, we prioritize human evaluation over automatic evaluations.

Human Evaluation: Ranking Stories and Filling a Questionnaire We recruited crowd workers from Amazon Mechanical Turk (MTurk) to assess the quality of the generated stories. For each experiment, we randomly selected 250 stories, each of which was evaluated by five different workers in the US. The experiment includes a comparison study with three baseline models and three ablation studies, and each annotator was compensated \$0.10 for each experiment. Workers were asked to rank the stories (*e.g.*, ours and those of the baseline/ablation models) based on their overall quality.

In addition, the user interface also provides a questionnaire to collect in-depth feedback from MTurk workers. The questions include "What do you like about the best stories" and "What do you dislike about the worst stories" for workers to select aspects that affect overall story quality. These aspects are provided by Huang et al. (2016): they include focus, coherence, shareability, humanness, grounding, and detail. We calculated the average rank and the majority rank among five workers for each story, as well as total votes for each model's best and worst aspects.

Non-Classic Automatic Evaluation: BLEURT, voc-d, and MLTD Many VIST studies have shown that classic automatic evaluation scores like BLEU and METEOR correlate poorly with human judgment (Hsu et al., 2020; Hu et al., 2019; Wang et al., 2020; Li et al., 2020; Yang et al., 2019; Hsu et al., 2019; Wang et al., 2018a; Modi and Parde, 2019). These n-gram matching metrics fail to account for the semantic similarity to the reference stories and lexical richness in the generated stories.

Therefore, we adopted BLEURT (Sellam et al., 2020), a state-of-the-art BERT-based evaluation

---

[4] Data obtained from the authors of KG-Story.

AREL : avg rank #3.6
the parade started with a lot of people in the parade. there were a lot of people there. there was a lot of people there. there were a lot of people there. there were a lot of cars in the parade.

GLAC : avg rank #2.4
the marathon was about to begin. there were many people there. it was a great day. everyone was very excited. they were all very fast.

KG-Story : avg rank #2.2
the parade started with a beautiful day. many people showed up. there were runners. everyone was watching the parade. one woman stood in a car to get everyone involved. it was a nice car.

PR-VIST : avg rank #1.8
we went to see the parade. there was a band guard. many people showed up to watch the parade runners. the runners started to gather in line. there were many cars at the show. the family decided to walk around town.

Figure 5: Generated stories for PR-VIST and baseline models. MTurk workers were asked to rank the stories.

metric, to further correlate generated stories and reference stories based on their semantic meaning. We also adopted lexical diversity metrics voc-d and MLTD (McCarthy and Jarvis, 2010) to quantify story lexical richness. Several works have shown that lexical diversity is positive correlated to story quality (Liu et al., 2019; Dai et al., 2017).

6.4 Results

In our experiments, the stories generated by PR-VIST have an average of 5.96 sentences. 57.3% of these stories contain at least one event (sentence) that uses story elements extracted from two (or more) images, showing PR-VIST's ability to utilize intra-image entities.

Human Evaluation We asked MTurk workers to rank four stories: those of PR-VIST, the three baseline models, and the state-of-the-art KG-story. Table 2 shows the results. PR-VIST outperforms other models in average ranking: it outranks AREL by 0.24 and KG-Story by 0.16. As for the percentage of 1st-rank stories, PR-VIST produces 12.0% more than AREL and 7.5% more than KG-Story. Figure 5 shows a representative example. Compared with end-to-end models (*i.e.*, AREL and GLAC), graph-based methods (*i.e.*, KG-Story and PR-VIST) generate more diverse stories. Compared with KG-Story, whose sentences are relatively simple and plain, generating sentences such as "Many people showed up", our model reuses entities such as "parade" in the first sentence and associates relations with other entities, *e.g.*, "people" and "runners", to compose "many people showed up to watch the parade runners".

Moreover, Figure 6 shows the questionnaire (see Section 6.3) result for the best-ranked stories. For PR-VIST and KG-Story's best-ranked stories, the PR-VIST story count is significantly higher in all aspects; specifically, coherence, shareability, and humanness are higher than other categories.

Method	1st	2nd	3rd	4th	Avg	Major
AREL	20.6% (258)	26.8%	27.2%	25.4%	2.57	2.56
GLAC	21.7% (271)	24.2%	25.5%	28.6%	2.61	2.73
KG-Story	25.1% (314)	25.2%	25.7%	24.0%	2.49	2.53
PR-VIST	**32.6% (407)**	23.7%	21.7%	**22.0%**	**2.33**	**2.28**

Table 2: Human rankings between PR-VIST and three methods. The first four columns indicate the percentage of worker rankings for each method, and the fifth and the last column denote the average and majority ranks (1 to 4, lower is better). PR-VIST outperforms other models in average ranks ($p<0.05$, $N=250$), majority ranks, and also the percentage of 1st-rank stories.

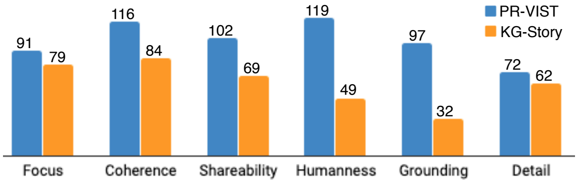

Figure 6: Aspect-wise votes for PR-VIST and KG-Story's first-place stories collected via the questionnaire (see Section 6.3). PR-VIST outperforms drastically in coherence, humanness, and grounding.

Automatic Evaluations Table 3 shows that the proposed method outperforms all the baselines in BLEURT,voc-d, and MLTD. Although n-gram-based automatic metrics are known to correlate poorly with human judgment in VIST (see Section 6.3), it is still noteworthy that PR-VIST results in significantly lower BLEU-4 scores. This might be cause by the fact that PR-VIST uses knowledge to enrich the story content and increase lexical diversity, but could lower the performance in n-gram matching.

Method	BLEU-4	METEOR	BLEURT	MLTD	voc-d
AREL	**14.4**	**35.4**	0.52	22.45	0.53
GLAC	10.7	33.7	0.71	32.87	0.67
KG-Story	9.93	32.2	0.72	40.52	0.71
PR-VIST	7.65	31.6	**1.37**	**45.79**	**0.73**

Table 3: The first two columns show the results of classic n-gram based metrics. The third column shows BLEURT, a BERT-based metric. The last two columns show the lexical diversity evaluation results (MLTD and voc-d). High lexical diversity corresponds to low scores for n-gram metrics.

7 Ablation Study

Three factors contribute to PR-VIST's superior performance: story elements, knowledge graphs, and plot reworking. To evaluate the effectiveness of each factor in our framework, we conducted three ablation studies using human evaluations. The evaluation results are shown in Table 4. All three experiments use the same qualitative analysis, and each experiment ranks PR-VIST and two settings with certain components removed.

Story Elements PR-VIST is compared to two models, each of which uses only *objects* or *terms* for the storyline predictor to plot storylines.

Knowledge Graphs PR-VIST is compared to two models, each of which uses only $\mathcal{G}_{vist}$ or $\mathcal{G}_{vg}$ for the storyline predictor to plot storylines.

Plot and Rework PR-VIST is compared to two models: one without reworking and one without plotting or reworking. Without-reworking means the discriminator is removed, that is, the story generator uses Equation 6 for all epochs. Without-plotting-reworking means that the storyline predictor is additionally removed, so no frames are included; *terms* are used directly as the story generator's input.

Table 4 shows that PR-VIST outperforms all the ablation models. Furthermore, the first and second experiments show that MTurkers prefer story-like storylines to image-like storylines. That is, *terms* and $\mathcal{G}_{vist}$ are better than *objects* and $\mathcal{G}_{vg}$. For the third experiment, we note a steady improvement from without-plotting-reworking to PR-VIST, showing the effectiveness of the proposed method. An example is shown in Figure 7. The model cannot manage the abundant story elements without the guidance of story plotting. Comparing PR-VIST with PR-VIST w/o R, we see that reworking revises and enlivens (e.g., "[organization] in [location]") the stories.

	objects	*terms*	$\mathcal{G}_{vg}$	$\mathcal{G}_{vist}$	Plot	Rework	Avg	Major
1	✓	✓	✓	✓	✓	✓	1.89	1.87
		✓	✓	✓	✓	✓	1.98	2.00
	✓		✓	✓	✓	✓	2.12	2.13
2	✓	✓	✓	✓	✓	✓	1.97	1.94
	✓	✓		✓	✓	✓	1.98	1.99
	✓	✓	✓		✓	✓	2.00	2.06
3	✓	✓	✓	✓	✓	✓	1.95	1.93
	✓	✓	✓	✓	✓		2.00	2.02
	✓	✓	✓	✓			2.03	2.08

Table 4: Human evaluation results for ablation studies: 1. Story elements 2. Knowledge graph 3. Plot and Rework. PR-VIST outperforms in all ablation settings, indicating the importance of using all components.

PR-VIST: we visited the [organization] in [location]. everyone gathered in the [organization] room to celebrate.

PR-VIST w/o R: i visited [organization] [location]. everyone gathered in the [organization] room.

PR-VIST w/o PR: today was the first place i saw a man sign for our trip to [location] [organization]. everyone was in his room at [organization] house.

Figure 7: Snippet of stories generated by the proposed method and two configurations: without reworking (R) and without plotting or reworking (PR). Nouns and verb frames are denoted in blue and red. Reworked parts are marked with wavy underlines.

8 Discussion

To understand areas for improvement, in the human ranking evaluation, we asked crowd workers to select the aspect (out of six) they disliked about the worst story (see Section 6.3.) Of the negative votes, 24.6% were for "grounding." Namely, lower-ranked stories are often not visually grounded. We examined the outputs and found that Faster-RCNN in Stage 1 sometimes predicts objects that are inaccurate but semantically related to the context. Figure 8 shows a typical example, where the soccer ball is identified as a frisbee, which is incorrect but still fits the "sports" theme. When the storyline predictor is unable to distinguish such mistaken objects from appropriate objects, grounding errors occur. A better object detector would mitigate this problem, or we could jointly optimize plotting and generation, for instance by including reworking within storyline plotting.

9 Conclusion

We propose a novel story plotting and reworking framework to mimic the human story-writing process. To the best of our knowledge, no study has integrated knowledge graph and story plotting to utilize visual elements in VIST. Also novel is our approximation of human-preferred stories by reusing and aggregating story generation using the results of human-annotated story ranking evaluations, e.g., human evaluation results from MTurk. We also propose a novel questionnaire embedded in the comparative study to collect detailed, meaningful human-annotated data from MTurk. Experiments attest PR-VIST's strong performance in diversity, coherence, and humanness.

10 Ethical Considerations

Although our research aims to produce short stories that are vivid, engaging, and innocent, we are aware of the possibilities of utilizing a similar approach to generate inappropriate text (e.g., violent, racial, or gender-insensitive stories). The proposed visual storytelling technology enables people to generate stories rapidly based on photo sequences at scale, which could also be used with malicious intent, for example, to concoct fake stories using real images. Finally, as the proposed methods use external knowledge graphs, they reflect the issues, risks, and biases of such information sources. Mitigating these potential risks will require continued research.

Abstract

Developing effective distributed representations of source code is fundamental yet challenging for many software engineering tasks such as code clone detection, code search, code translation and transformation. However, current code embedding approaches that represent the semantic and syntax of code in a mixed way are less interpretable and the resulting embedding can not be easily generalized across programming languages. In this paper, we propose a disentangled code representation learning approach to separate the semantic from the syntax of source code under a multi-programming-language setting, obtaining better interpretability and generalizability. Specially, we design three losses dedicated to the characteristics of source code to enforce the disentanglement effectively. We conduct comprehensive experiments on a real-world dataset composed of programming exercises implemented by multiple solutions that are semantically identical but grammatically distinguished. The experimental results validate the superiority of our proposed disentangled code representation, compared to several baselines, across three types of downstream tasks, i.e., code clone detection, code translation, and code-to-code search.

1 Introduction

Code representation learning has become an essential technique to support various software engineering tasks. Most of previous code representation learning approaches (Chen and Zhou, 2018; Jain et al., 2020; Nie et al., 2020) focus on a particular programming language, while learning code representations for multiple programming languages, though challenging, is an important step towards more generalizable and interpretable code embeddings. In principle, code snippets can be seen as code token sequences where their structural information often manifests as tree or graph data structures like AST (Abstract Syntax Tree). The downstream tasks often take full advantage of different code modalities (DQ et al., 2019) (e.g., structural information and textual tokens in the form of natural languages) to achieve better performance.

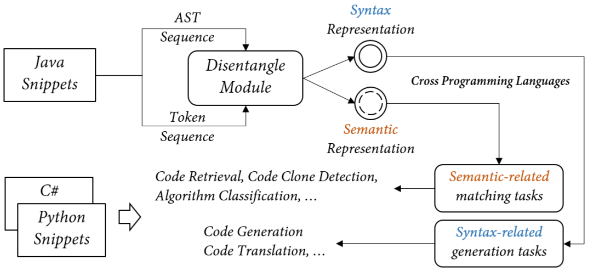

Figure 1: We disentangle the code representation into semantic and syntactic parts. The semantic part, which is relevant to code functionality but is often independent of a specific language, can be reused for semantic-related tasks across programming languages. The syntax part, which is related to a particular language but does not represent the code functionality, can be reused to control syntactic transformations for cross-programming language generation tasks.

It is noteworthy that syntax-level noise is an important issue in cross-language semantic-related tasks. Simply mixing textual token information and structural information of code (e.g., ASTs) often can not boost the performance on the cross-language code tasks. In this paper, we investigate a new approach that disassociates the latent semantic and syntactic representations of multi-lingual code snippets. The semantic representation excluding syntax information is more suitable for cross-language semantic-related code tasks as shown in Figure 1. We therefore study a new multi-lingual AST-guided code disentanglement technique called CODEDISEN, in order to provide a disentangled representation of code snippets that separates the la-

tent syntax representations for masked ASTs from its latent semantic counterpart for solving a particular programming exercise. Our new multi-lingual code representation disentanglement approach effectively utilises available linguistic resources, i.e., ASTs and textual code tokens. Overall, the main contributions of this paper are as follows:

- To the best of our knowledge, it is the first time that we formulate the code representation learning problem from the perspective of disentangling code semantics and syntax information across multiple programming languages.
- We propose an AST-guided disentangled code representation learning approach for multiple programming languages. We employ masked AST information to guide the disentanglement of code semantics and syntax, and design a cross-language reconstruction loss and a posterior distribution loss for modeling the fact that programs written in different languages for the same problem can share the similar program semantic. Furthermore, attentive code position loss can effectively fuse AST information into an effective code representation.
- To validate the effectiveness of our approach, we have conducted extensive experiments on three downstream tasks (i.e., code-to-code search, code translation and clone detection). Experimental results show that the latent semantic and syntax representation learned by our approach are nearly orthogonal, and the learnt disentangled semantic representation can significantly boost the performance of the downstream cross-language tasks.

2 Preliminaries

2.1 Code Syntax and Semantics

The Abstract Syntax Tree (AST) is an abstract representation of the syntax structure of source code. As shown in Figure 2, compilation nodes, e.g. `augment_list`, represent syntactic information, and leaf variable nodes, e.g. `range`, represent semantic information. In this paper, we parse the source codes into ASTs by using tree-sitter[1], an open source syntax parser, which supports multiple programming languages. We traverse the nodes of an AST based on the depth first algorithm, and consider the traversed paths as syntax representation of the code snippets. Using AST paths can significantly reduce the learning effort to extract grammatical information of code. *To restrict the AST paths to syntax information only, we masked leaf nodes during the traversal because the semantic information of the code snippets often comes from the leaf variable nodes.* Introducing masked AST paths to CodeDisen ensures that our approach can take some semantic meanings from the textual tokens in code snippets rather than ASTs, which can be used to learn the general syntax representation adhering to a specific language.

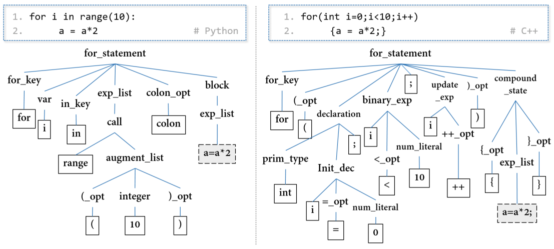

Figure 2: Python and C++ code snippets with their ASTs for the same problem. The solid boxes represent the leaf nodes. Note that the compilation nodes for a=a$\star$2 are almost identical.

2.2 Problem Statement

We denote code snippets for solving the same programming problem j as $\{\langle x_1, \ldots, x_n \rangle | x_i \in P_j\}$, where x_i is the solution of programming language i. In our experiments, we tested Java, Python, C++ and C#, thus the number of languages is $n = 4$. For each code snippet x_i, we construct a raw representation vector $\langle x_i, x_i^{ast} \rangle$, where x_i denotes a sequence of tokens, and x_i^{ast} represents syntax information derived from the abstract syntax tree of code snippet x_i.

For the same problem j, the code snippets $x_1, \ldots, x_n$ of multiple languages share the same semantic, although they have different programming language syntax z_i. Variants of Variational AutoEncoders (VAE) have been proposed to encode the raw vector $\langle x_i, x_i^{ast} \rangle$ into the latent representation. We aim to disentangle latent representation into two untangled parts: semantic y and syntax z latent representation of code. Formally, the objective of encoding is $\langle x_i, x_i^{ast} \rangle \rightarrow \langle y_i, z_i \rangle$ for each code snippet. For that purpose, we have to add multiple additional losses to the VAE architecture to enforce the effective disentanglement of code semantic and syntax. Next, we will introduce the design of multiple additional losses to effectively enforce disentanglement for code representation learning under the multi-lingual setting.

---

[1] `https://tree-sitter.github.io`

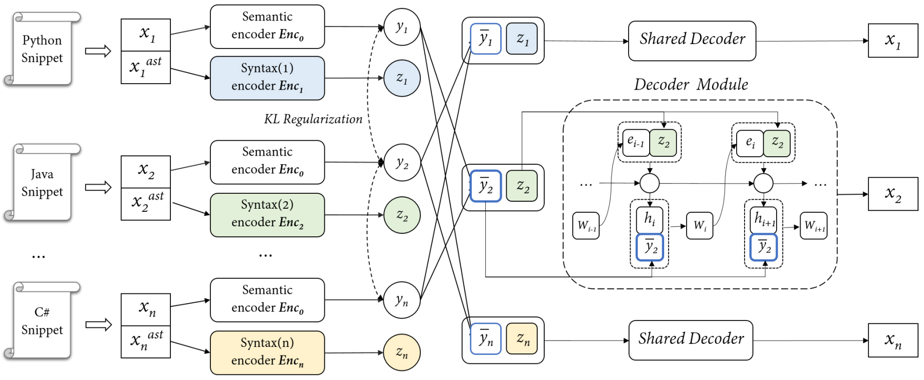

Figure 3: The reconstruction of code snippets written in multiple programming languages for the same problem. Enc_0 corresponds to the Semantic (Y) Encoder shared parameters among all programming languages. Enc_i corresponds to the Syntax (Z) Encoder dedicated to programming language i with independent parameters (*IZ*). The *KL divergence term* is imposed to the semantic latent variable *y* to enforce the alignment of different code snippets in the semantic space. The *decoder* also shares the parameters among all programming languages.

3 CODEDISEN Approach

Our approach is a variant of notable VAE architecture. In this paper, we start from the vMF-Gaussian Variational Autoencoder (VGVAE) model (Chen et al., 2019b), which is proposed to disentangle textual semantics from language syntax within the same human language. Our problem setting differs from disentanglement setting of human language in that: (1) We focus on dealing with multiple programming languages, instead of a single language. (2) Unlike human languages, programming language is a formal symbol system and has much stricter syntax rules than human languages, so we can make use of the AST information derived from a code snippet. To handle multiple programming languages, we propose CODEDISEN which adds more inputs and multiple losses to the VGVAE to effectively enforce the disentanglement of code semantics and syntax.

Figure 3 shows the overall architecture of our CODEDISEN approach. Unlike the unsupervised VGVAE, our approach introduces the masked AST x_i^{ast} that just retains the syntax information and removes almost all semantic information by masking leaf nodes. x_i^{ast} provides a strong supervision signal for disentangling code semantics y_i from code syntax z_i. For brevity, we will describe the factorization process from perspective of single code snippet. Following the conditional independence assumption in the graphical model, the joint probability $p_\theta(x, x^{ast}, y, z)$ can be factorized as:

$$\begin{aligned} &p_\theta(x, x^{ast}, y, z) \\ &= p_\theta(y)p_\theta(z)\prod_{t=1}^{T} p_\theta(w_t|w_{1:t-1}, y, z)p(x^{ast}|x), \end{aligned} \tag{1}$$

where w_t is the t-th word of x and $p_\theta(w_t|w_{1:t-1}, y, z)$ is given by a softmax over a vocabulary $\mathcal{V}$, $p(x^{ast}|x)$ is a deterministic transformation process. Different from the VGVAE variants (Chen et al., 2019b), we propose the following factorization $q_\varphi(y, z|x, x^{ast}) = q_\varphi(y|x)q_\varphi(z|x^{ast})$ to approximate the posterior when applying neural variational inference, since x^{ast} just retains the syntax information, and x contains more semantic information that is missing in compilation nodes. The objective of VAE is to maximize a lower bound of marginal log-likelihood, thus the basic loss $\mathcal{L}_0$ is written as:

$$\begin{aligned} \mathcal{L}_0 = &-\mathop{\mathbb{E}}_{y,z\sim\, q_\theta(y|x), q_\theta(z|x^{ast})} \log p_\theta(x|y, z) \\ &+ \mathrm{KL}\left(q_\theta(y|x) \parallel p_\theta(y)\right) + \mathrm{KL}\left(q_\theta(z|x^{ast}) \parallel p_\theta(z)\right). \end{aligned} \tag{2}$$

3.1 Encoders and Decoder

In this paper, we assume that $q_\theta(y|x)$ follows a vMF distribution (Chen et al., 2019b) and $p_\theta(y)$ follows the uniform distribution $vMF(\cdot; 0)$. Similarly, we assume that $q_\theta(z|x^{ast})$ follows a Gaussian distribution $\mathcal{N}(\mu_\beta(x^{ast}), diag(\sigma_\beta(x^{ast})))$ and that the prior $p_\theta(z)$ is $\mathcal{N}(0; I_d)$, where I_d is a $d \times d$ identity matrix. Concretely, we implement the *semantic encoder* Enc_0 (i.e., $q_\varphi(y|x)$) *shared among all languages* as a bidirectional long short-term memory network (BiLSTM) followed by a 3-layer feedforward neural network. Similarly, we adopt an independent BiLSTM model followed by a 3-layer feedforward network for each syntax encoder Enc_i adhering to programming language i (i.e., $q_{\varphi_i}(z_i|x_i^{ast})$). We also select LSTM model as the shared decoder of our generative model. As shown in Figure 3, at the decoding stage, we concatenate the syntactic variable z with the previous word's embedding as the input to calculate hidden state h' since grammatical information is more influenced by code token positions. Furthermore, we concatenate the semantic variable y with hidden state h' to predict the code token at each step, which could make full use of semantic information.

3.2 Losses for Disentanglement

In order to effectively enforce the disentanglement of code semantics and syntax, we design three additional loss terms, in addition to the loss $\mathcal{L}_0$.

Cross-Language Reconstruction Loss Since the code snippets $\{\langle x_0, x_1, \ldots, x_n\rangle \,|x_i \in P_j\}$ solve the same problem of P_j, they should share the same program semantics, inducing the cross-language reconstruction loss. Concretely, we hope that code snippet x_i can be reconstructed from its own syntax representation z_i and semantic representation $\overline{y}_i$. $\overline{y}_i$ is derived from latent semantic representations $\{y_k|k \neq i\}$ of code snippets $\{x_k|k \neq i\}$ that do not use language i. Formally, $\langle \overline{y}_i, z_i\rangle \to \langle x_i\rangle$. If we can regenerate x_i successfully, it means that $\{y_i\}$ share the almost same program semantic for problem P_j, and z_i encodes language-specific syntax information of programming language i.

As shown in Figure 3, at each step, we input $X = \{x_1, x_2, \ldots, x_n\}$, which is a set of code snippets that have the same program semantics p_j for problem j and are written in distinct programming languages. Formally, the cross-language reconstruction loss can be formulated as:

$$\mathcal{L}_{rec} = -\sum_{i=1}^{n} \mathbb{E}\left[\log p_\theta(x_i|\overline{y}_i, z_i)\right], \tag{3}$$

where $\overline{y}_i$ is calculated as:

$$\overline{y}_i = F_{Linear}(f_{cat}(\overline{Y}_i)), \tag{4}$$

where $\overline{Y}_i$ represents all the latent semantic variables except y_i, i.e., $\overline{Y}_i = \{y_k|k \neq i\}$, $f_{cat}(\cdot)$ is the function of concatenation, and F_{Linear} aims to fuse the concatenated vector to the same dimension as y_i, through a linear layer.

Posterior Distribution Loss Since all the code snippets of n programming languages for the same problem j share the same program semantics p_j, we expect that the posterior distribution $q_{\varphi_i}(y_i|x_i)$ of code snippets of programming language i should be close to the mean posterior distribution $q_m(y_m|x_m)$ of code snippets of all programming languages.

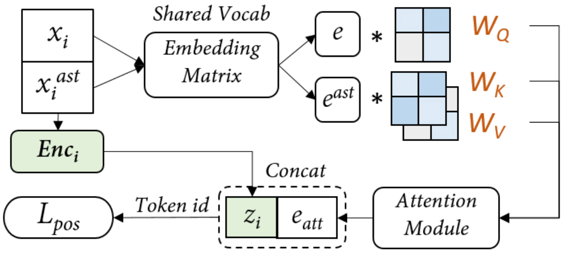

Figure 4: An illustration for the attentive position loss of language i at encoding stage.

Concretely, we employ KL terms (Chen and Zhou, 2018) to constrain the distribution discrepancy between $q_{\varphi_i}(y_i|x_i)$ and $q_m(y_m|x_m)$ in the latent space. Formally, The posterior distribution constraint loss for programming language i is defined as:

$$\begin{aligned}\mathcal{L}_{dist(i)} &= \mathrm{KL}(q_{\varphi_i}(y_i|x_i) \,\|\, q_m(y_m|x_m)),\\ q_m(y_m||x_m) &= vMF(\frac{\sum_{i=0}^{n}\mu(x_i)}{n}, \frac{\sum_{i=0}^{n}\kappa(x_i)}{n^2}),\end{aligned} \tag{5}$$

where vMF is the same definition as in (Chen et al., 2019b). The whole posterior distribution loss function is defined as:

$$\mathcal{L}_{dist} = \sum_{i=1}^{n} \mathcal{L}_{dist(i)}. \tag{6}$$

Attentive Code Position Loss As observed in (Chen et al., 2019b), the position information of code token x_i has a significant impact on its syntax, such as `import` is always at position `0` in Python. To better utilise ASTs to represent syntactic information, we introduce an *Token2AST* attention-based code position loss ($\mathcal{L}_{pos}$) to predict positions of code tokens based on the embedding e_i of x_i and the embedding e_i^{ast} of x_i^{ast}. We map the e_i^{ast} to the token side e_i via attention mechanism as shown in Figure 4. Firstly, there is a correlation between the AST nodes and the tokens, e.g., variable `a` is expected to have a higher weight with *identifier* in Figure 2. Secondly, the length of AST sequences is often much longer than that of the tokens in the code snippet. Therefore the attentive code position loss can fuse AST and token information to better extract syntactic features.

We implement $\mathcal{L}_{pos}$ for both encoder and decoder to predict code tokens position i, which consists of a 3-layer feedforward neural network $f(\cdot)$

with the input from the concatenation of the samples of the syntactic variable z and the attention embedding vector e_{att} at input position i. The $\mathcal{L}_{pos}$ and e_{att} are defined as:

$$e_{att} = \text{softmax}(\frac{(e_i \cdot W_q) \cdot (e_i^{ast} \cdot W_k^T)}{\sqrt{d}}) \cdot (e_i^{ast} \cdot W_v)$$

$$\mathcal{L}_{pos} = - \mathop{\mathbb{E}}_{z \sim q_{\varphi}(z|x)} \left[\sum_i \log \text{softmax}(f([e_{att}; z]))_t \right], \tag{7}$$

where d is the dimension of the embedding, to increase the training stability, $\text{softmax}(\cdot)_t$ indicates the probability of a code token at position t, and W_q, W_k, and W_v respectively denotes the query, key and value matrix in the attention mechanism.

Overall Objective We subsequently define the overall objective as the combination of the aforementioned basic loss and three additional losses for disentanglement. The total loss function is formulated as follows:

$$\mathcal{L} = \mathcal{L}_0 + \alpha \cdot \mathcal{L}_{rec} + \beta \cdot \mathcal{L}_{dist} + \gamma \cdot \mathcal{L}_{pos}. \tag{8}$$

4 Experiment and Analysis

In this section, we aim to address the following research questions: (1) *Can the program semantics and syntax be successfully disentangled by our proposed* CODEDISEN? (2) *Will disentangled semantics indeed improve the performance of downstream tasks*? and (3) *What is the generalizability of disentangled code representation across different programming languages*? We also perform ablation analysis to investigate the effect of each module of the model, as well as a qualitative analysis of detailed examples.

To answer the above questions, our experiments will validate the following two principles: ***(1) Equivalence of Semantics.*** Given a sequence of semantically identical code snippets $x_1, \ldots, x_n$ and their corresponding masked ASTs $x_1^{ast}, \ldots, x_n^{ast}$, CODEDISEN will yield y_i and $\overline{y}_i$ (see Eq. (4)), if $x_i = Decode(y_i, z_i) = Decode(\overline{y_i}, z_i)$, then we have $y_i = \overline{y_i}$, which means the shared semantic encoder Enc_0 extracts the same features for those code snippets. Further, given $x_i \neq x_j$ and $y_i = \overline{y}_i = y_j$, we have $z_i \neq z_j$, which means $Enc_{1 \ldots n}$ yields the respective syntax representations adhering to programming language $1 \ldots n$. ***(2) Orthogonality of Semantic and Syntax Vector.*** If the semantic vector y is completely disentangled from the syntax vector z, just applying y to downstream tasks will improve the performance, compared to applying x to downstream tasks. However, just applying z will perform poorly.

Implementation Details As for building vocabulary, we observe that more than 95% of the vocabulary of multi-lingual code snippets are user-defined variable names, with a tiny percentage of keywords and compilation nodes with respect to each programming language. Additionally, variable names in different code snippets for the same problem are likely to share semantics, which can facilitate implicit alignment of the semantics of code snippets of different languages. Hence, we resort to constructing a *shared vocabulary* for all code snippets and ASTs of all programming languages. More implementation details are referred to the Appendix A.1.

4.1 Dataset and Downstream Tasks

For multi-lingual cross-training, we use the CLCDSA dataset (Nafi et al., 2019), which is composed of 26,000 code snippets across four programming languages (i.e., Java, Python, C# and C++). This dataset is collected from three open source programming contest sites (i.e., AtCoder[2], Google CodeJam[3] and CoderByte[4]). All solutions in this dataset are functionally similar but written in different programming languages. In our experiments, we choose Java, Python, C# and C++ as the target languages, and limit the maximum code tokens length to 128. Consequently, we obtain a training dataset containing $2,500$ samples per language, and 500 samples for both validation and testing.

Code Clone Detection Code cloning across languages, which reuses a fragment of source code via copy-paste-modify, is a common way for code reuse and software prototyping. We treat the solutions belonging to different languages for the same problem as positive samples and the other random solution combinations in each batch as negative samples. We control the number of positive/negatives samples are balanced. We set the threshold as 0.8, which means that the cross-language input code pairs are semantic identical if the cosine similarity between them is greater than 0.8. For evaluation, we select LSTM (Sundermeyer et al., 2012), Tree-LSTM (Shido et al., 2019), TBCNN (Mou et al., 2016) and GraphCodeBERT (Guo et al., 2020) models as baselines.

	2.5k	*Java/Python/C#/C++*	**44.765**	**116.90**	**59.159**

Code-to-Code Search During software development process, developers often look for code snippets that offer similar functionality (Kim et al., 2018). Our goal is to search the code snippet of other programming languages with the same functionality based on the current code snippet. To be more challenging, there is only one code snippet matching the query in the queried collection. We compare the code snippet in the source language with all code snippets in the target language to calculate their cosine similarity. For evaluation, we select BiLSTM (Linhares Pontes et al., 2018), Tree-LSTM (Shido et al., 2019), TBCNN (Mou et al., 2016) and GraphCodeBERT (Guo et al., 2020) models as baselines, and we adopt Accuracy, MRR and NDCG as evaluation metrics.

Code Translation In cross-language reconstruction, we know that x_i and x_j are source and target code fragments, which are semantically identical and belong to the same problem P_j. However, in cross-language code translation, we do not know x_j and have to sample a random code snippet $x_j^{'}$ in language j to obtain syntactic features $z_j^{'}$. We use this task to demonstrate that our model extracts non-zero and identical syntactic features for the same programming language. In addition, we use Tree-LSTM and VGVAE as baselines, to demonstrate the superior performance of our model on cross-programming language tasks.

4.2 Disentangled or Not? (RQ1)

To check the equivalence of semantics, we conduct experiment of reconstruction on Python code snippets. For a given Python code snippet x_i in the test set, our CODEDISEN yields the *aggregated semantic vector* $\overline{y}_i$ from semantically identical code snippets of other programming languages, i.e. Java or Java/C#/C++, as well as the *syntax vector* z_i from the Python code snippet x_i. Then $\overline{y}_i$ and z_i are jointly used to reconstruct the Python code snippet $\overline{x}_i$. We adopt the BLEU (Papineni et al., 2002), CIDER (Vedantam et al., 2015) and ROUGE (Lin, 2004) to measure the quality of reconstructed text $\overline{x}_i$ from x_i.

Table 1 shows the reconstruction performance of our CODEDISEN under various multi-lingual settings with different sizes of dataset. From this table, we observe that our model which is trained using AST information of 1,000 ($1k$) Java and 1,000 ($1k$) Python programs significantly outperforms vanilla VGVAE. It is also interesting to find that our model achieves a significant performance improvement when (1) we increase the training data from $1k$ to $2.5k$ samples for each language and (2) expand the bi-lingual model to a multi-lingual architecture (Java/Python/C#/C++). Furthermore, when comparing with VGVAE, CODEDISEN achieves 15.7%, 80.6% and 9.2% performance gains in terms of BLEU-1, CIDER and ROUGE-L, respectively. It is worth noting that CODEDISEN when trained using $1k$ samples still outperforms the bi-lingual model trained using $2.5k$ samples. The total dataset sizes used for training CODEDISEN are $1k \times 4 = 4k$ and $2.5k \times 2 = 5k$. This indicates that the multi-lingual architecture is good at dealing with more languages in training, since variable names may share similar semantics across different programming languages.

To further check the orthogonality of semantic and syntax vectors, we conduct experiments using the shared semantic vector and language-specific syntax vectors on downstream tasks. As shown in Table 2, CODEDISEN (Y) denotes only using the output y of the shared semantic encoder Enc_0 in code-to-code search. The performance has a significant improvement compared to BiLSTM without Enc_0. CODEDISEN (Z) means only using the output z of the syntax encoder, whose performance even has a dramatic drop. This indicates that the hidden vector y contains rich semantic information, while the hidden vector z rarely contains semantic information. As shown in Table 3, CODEDISEN (R) means randomly sampling a code snippet $x_j^{'}$ in the training set to extract syntactic feature $z_j^{'}$ for reconstruction. We can observe that little degradation in model performance indicates that the syntax vector of randomly sampled $x_j^{'}$ is almost the same as that of the original code snippet x_j of the same language j. When we set the variable z to zero tensor, we find that the model performance drops significantly. It confirms that the syntax vector z is critical in the reconstruction process and z is almost identical within the same programming language.

4.3 Downstream Task Performance (RQ2)

To better verify whether the disentangled multi-lingual code semantic representation can boost the performance of downstream tasks, we fine-tune the model on the downstream tasks of code translation, code-to-code search and code clone detection under the cross-language setting.

As shown in Table 4, CodeDisen (Y) that only considers the semantics of code achieves the best performance, significantly outperforming the performance of counterpart CodeDisen (Z) that only considers the syntax of code. We set the threshold value to 0.8 according to the testing performance on code clone detection task. When we set the threshold to 0.5, the performances of Tree-LSTM and CodeDisen are 0.576/0.954/0.718, and 0.724/0.992/0.837, in terms of Precision, Recall and F1, respectively. This is because that if we set the threshold to a lower value, more code snippets may be classified as duplicates, thus the recall increases while the precision decreases. Therefore, we choose a threshold of 0.8 to better compare the differences in performance between models.

It is noteworthy that the models such as Tree-LSTM and TBCNN, which accept ASTs of a program as their inputs can obtain high recall but low precision. This indicates that if the ASTs are same, to a large extent, the two programs can be considered as semantically identical, so the recall is high. However, the ASTs of different programming languages vary greatly and generate many temporal variables during compilation, thus introducing noise nodes, so the precision can be low. Our approach combines the advantages of token and AST features while obtaining high precision and recall on cross-programming language tasks. GraphCodeBERT, a pre-trained model on the code corpora of multi-programming language, is suitable for fine-tuning on specific task of a programming language. For the task of code clone detection, we simply fine-tune the model based on the released checkpoint of GraphCodeBERT, under the setting of our scenario. For the task of code-to-code search, we extract the last layer of GraphCodeBERT output and take the average value as the feature of the code segment, and calculate the cosine similarity to select the target from candidates, as described in the Appendix A.3. As shown in Table 2 and Table 4 , we can find that GraphCodeBERT does not adapt well to cross-programming language semantic matching related tasks.

Table 3 shows that although Tree-LSTM is more suitable for encoding the structure information of code than our LSTM-based model, our CodeDisen (R) still outperforms Tree-LSTM in BLEU-1, ROUGE-L, CIDER by 3.7%, 11.1%, 2.0%, respectively. By introducing AST information, our CodeDisen (R) also has a significant improvement when compared to VGVAE. Table 2 shows that Tree-LSTM and TBCNN perform poorly for cross-language code search tasks. The main reason is that both Tree-LSTM and TBCNN are based only on the input representation of an AST. However, the ASTs of two semantically equivalent programs written in two different languages (e.g., Java and Python) can be generated quite differently by the compilers of these two languages, hence introducing syntax-level noise.

4.4 Generalizability of CodeDisen (RQ3)

To investigate the generalizability of our semantic module across languages, we evaluate our model on unseen datasets in different languages. In addition, we compare the performance when combining different languages in the code-to-code search task to demonstrate the superiority of multi-lingual structures. From Table 5, we observe that when

-L_{pos}	41.19	55.05	110.1
L_{pos}-att	41.93	56.90	102.6

we use the shared semantic encoder trained on the Java/Python dataset, our model still achieves good results on C++-C# and Java-C# code-to-code search tasks after fine-tuning. Note that C++-C# data are not there when training CODEDISEN , and our model keeps most of its performance on Java-Python dataset in Table 2. This is a good evidence that the semantic representations extracted by our model are generalizable across languages.

For Java-Python code search, the code semantic encoder trained on four languages (Java/Python/C#/C++) performs better than the one trained on two language (Java/Python). For C++-Python code search, we ensure the training dataset free of C++ code snippets. We find that the code semantic encoder trained on Java/Python/C# performs better than the one trained on Java/Python. These indicate that our multi-lingual architecture can further utilise the samples of more programming languages to train a better semantic encoder, and is extensible to train more language-specific syntax encoders.

4.5 Ablation Study

We conduct ablation analysis to understand the performance contribution from different component in our model. As shown in Table 6, we choose the model trained on four languages as the baseline (CODEDISEN). In fact, we find that the independent *Syntax* encoders (IZ) and KL term (KL) have a significant impact on the multi-lingual model. When we remove these components, the BLEU-1 scores of our model drop by 12.65% and 8.06%. This suggests that the design of implicit semantic alignment and syntactic independence between multiple programming languages is effective.

We also explore the role of attention in the code position loss, while AST sequences are usually much longer and more complicated than code tokens. The results show that when we use the code position loss without *Token2AST* attention (L_{pos}-att), performance of (L_{pos}-att) is close to that of (-L_{pos}) removing code position loss. It means our *Token2AST* attention mechanism could merge the syntactic AST features and the semantic features of tokens to handle the long sequence dependence.

4.6 Qualitative Analysis

We conduct case study to further investigate results of the semantic extraction in code refactoring and abstract syntax representation, as shown in Table 7. From *Case 1*, it is clear to see that the variable names in the generated snippets are consistent with the semantic input Java snippets. Then we compare the semantic information between the generated and the input semantic code pairs. As shown in *Case 2*, the syntax input does not have "`Yes`" or "`No`" at all, but our generated snippet extracts this from the semantic input very well. In addition, we have rewritten the complex multivariate input form of Java into the simple map input of Python, which demonstrates that our model can extract semantics well. On the other hand, we find that the generated snippets are compliant with Python syntax. In conjunction with the random syntax sampling discussed earlier, we can further show that the syntax variables we extracted abstractly represent the syntax of specific programming language.

5 Related Work

Deep Code Representation The existing code representation works represent code snippets in three ways, i.e., token-based representation, AST-based representation, and graph-based representation. As for token-based representation (Hindle et al., 2012; Bhoopchand et al., 2016), code snippets are tokenized into token sequences and each code token is represented as a real-valued vector. As for AST-based representation, one line of work is to directly represent the tree structure via Tree-CNN (Mou et al., 2016) or Tree-LSTM (Chen et al., 2018) . Another line of work is to indirectly represent the AST by linearizing the AST into a sequence of nodes (Hu et al., 2018; Alon et al., 2019; Liu et al., 2020) via traversing. Wan et al. (Wan

Table 7: Example of generated results by code translation (*Java/Python*).

	Case 1
Semantic	Scanner sc = new Scanner(System.in); int a = sc.nextInt(); int b = sc.nextInt(); if(a < b) System.out.println (b); else System.out.println (a);
Syntax	h1 = int (input ()) h2 = int (input ()) print (h1 - h2)
Reference	a , b = map (int ,input ().split ()) print (max(a , b))
Generated	a , b = map (int ,input ().split ()) print (a + b)
	Case 2
Semantic	Scanner sc = new Scanner (System.in); int A = sc.nextInt(); int B = sc.nextInt(); int C = sc.nextInt(); if(C <= A + B) System.out.println (“ Yes ”); else System.out.println (“ No ”);
Syntax	n = int (input ()) if n == 12 : print (1) else : print (n + 1)
Reference	A , B , C = map (int ,input ().split ()) if A + B < C : print (“ No ”) else : print (“ Yes ”)
Generated	A , B = map (int ,input ().split ()) if A == B : print (“ YES ”) else : print (“ NO ”)

et al., 2018; Wang et al., 2020b; Wan et al., 2019; Hua et al., 2021) propose to integrate the semantics of code from different views (e.g., the tokens, AST and control-flow graph) into a hybrid feature space, and put forward a hybrid representation approach, for the task of code summarization, code search and code clone detection. As for graph-based representations several works resort to parse the program into a graph (e.g., augmented AST, control-flow graph, and data-flow graph) (Li et al., 2015; LeClair et al., 2020; Wan et al., 2019; Sui et al., 2020; Guo et al., 2020). Benefiting from the strong power of pre-training technique in natural language processing, recently, several works (Kanade et al., 2020; Feng et al., 2020; Guo et al., 2020) propose to pre-train a masked language model on the large-scale of code corpora, like BERT (Devlin et al., 2019). CodeBERT (Feng et al., 2020) pre-trains a language model on the source codes and natural language descriptions, and significantly boosts performance on code search. GraphCodeBERT (Guo et al., 2020) advances the CodeBERT by incorporating the data-flow information among variables into pre-training.

Multilingual Knowledge Transfer For multilingual tasks, if we treat word embedding spaces isomorphic between different languages, which has been shown not to hold in practice (Søgaard et al., 2018), and fundamentally limits their performance. Sabet et al. (2019) train a bilingual model on bilingual corpora by introducing a cross-lingual loss in addition to the monolingual loss. The model learns to translate on each other by inputting parallel data sets at one step simultaneously. This ensures that the word and n-gram embeddings of both languages lie in the same space. Our approach is primarily referenced to text-controlled generation, which transfers the knowledge by dissociating tangled representations. Cross-training disentangling methods (Chen et al., 2019a,b; Wang et al., 2020a) on the controlled text generation task, which are implemented in a VGVAE framework and guided by paraphrase reconstruction loss have inspired us a lot. In particular, the syntax input of the code can be conveyed via AST. Code syntax regularity can be well exploited in multilingual architectures to achieve semantic alignment in dissociated latent spaces to improve the quality of representations with desirable generalizability.

6 Conclusion

In this paper, we propose a novel disentangled code representation learning approach under multilingual setting. We introduce three dedicated losses to enforce the disentanglement of code semantics and syntax. Comprehensive experiments on the three downstream tasks validate the effectiveness of our disentangled semantic and syntax representation. In the future, we will devise more effective disentanglement models for code representation learning. Another line is to extend the proposed approach to cross-lingual customer service robots, where answers of different languages for the same question share the same semantic information.

A Appendices

A.1 Training Details

All the experiments are conducted on 2 Geforce GTX 1080Ti GPUs. It tasks about 4 hours to train CODEDISEN . For encoder and decoder networks of CODEDISEN, we use the same BiLSTM model structure. The embedding size is 100 and the hidden size is 100. The dimensionality of *Semantic* latent variable vector is 50. The dimensionality of *Syntax* latent variable vector is 50. Specially, the hidden size in feed-forward network and attention mechanism is also 100. The coefficient α of the cross-language reconstruction loss $\mathcal{L}_{rec}$ is 1.0. When calculating the KL divergence term, the coefficient β of the Posterior distribution loss $\mathcal{L}_{dist}$ is 0.1, the coefficient of the $vMF(\cdot)$ KL divergence is $1e$-4 and the coefficient of the $Gaussian(\cdot)$ KL divergence is $1e$-3. The coefficient γ of the attentive code position loss $\mathcal{L}_{pos}$ is 1.0. We train each model for 60 epochs and the batch size is 10 for each programming language.

A.2 Case Study

As shown in Table 8, the semantic inputs and reference code snippets are semantically identical yet grammatically different. Based on the semantic information extracted from a Java code snippet and the syntax information extracted from a random selected Python code snippet, our approach can generate a Python snippet similar to the reference Python snippet which is semantically similar to Java input. We find that the semantics of the snippet we generated and the reference snippet are very similar, especially the content of printed string, such as “`YES`” or “`NO`”, “`Even`” or “`Odd`”, even the rare words (“`Christmas Eve...`”). At the same time, the generated code snippets are completely unaffected by randomly sampled syntax input. This means that our semantic and syntactic disentanglement modules perform well in extracting shared semantic information from code snippets for the same programming exercise and general syntactic features belonging to specific programming language.

Note that our generative model will be deficient in reconstructing mathematical expressions. For example, the reference snippet is “`a%2==0`” or “`b%2==0`” and the generated is “`a%b`”. The main reason is that the specific content of mathematical expressions is less weighty in the semantic expression of a code snippet, and our model tends to focus more on generating an expression rather than on the content of expressions. Another drawback is that our model can not generate long code snippets well, e.g., `'')` is missing after the “`print(``Christmas Eve ... Eve`” in the third example. In the future, we will replace the original mathematical expressions with word descriptions of longer token length to increase the weight in reconstruction loss function. In addition, we will use tree-structured decoders to guarantee the executability of the generated code so as to increase long dependencies.

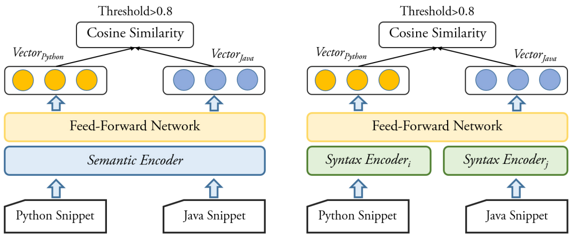

Figure 5: The framework of code clone detection. The left shows training on the semantic module and the right shows training on the specific syntax modules.

A.3 Architecture of Downstream Tasks

In this section, we detail the model architecture of cross-language code clone detection and code-to-code search tasks. The model for the code translation is identical to the cross-language reconstruction model used for the disentanglement training, except that the code snippets from which the syntactic latent variables are extracted are randomly sampled.

The key component of the proposed downstream tasks flow is the Bi-NN. It is modeled as two underlying subnetworks followed by a classification layer. In our work, the underlying subnetworks are semantic and syntax modules and other baseline networks such as BiLSTM. The classifier we defined as a 2-layer shared feed-forward network and calculate the cosine similarity of the input cross-language samples.

A.3.1 Code Clone Detection

Code cloning across languages, which reuses a fragment of source code via copy-paste-modify, is a common way for code reuse and software prototyping. We train and test the code clone detection task on *Java/Python*, *Python/C++*, *C++/C#* and *C#/Java* language pairs. In particular, we calculate the metric scores on average, as shown in Figure 5. We treat the solutions belong to different

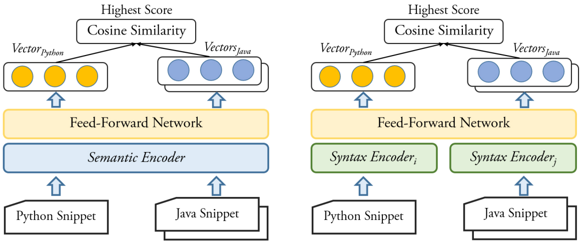

Figure 6: The framework of code-to-code search. Given a query code snippet written in Python as well as a series of candidate code snippets written in Java, the goal of code-to-code search is to retrieve the most relevant Java snippets based on cosine similarity.

languages for the same problem as positive samples and the other random solution combinations in each batch as negative samples. To be more challenging, we extracted 350 programming problems from CLCDSA dataset such that each problem has only one solution per language for evaluation. We control the number of positive/negatives samples are balanced. We set the threshold as 0.8(@80). It means that if the cosine similarity of cross-language input code pairs is greater than 80%, we consider them as semantic clone pairs. In addition, we use the semantic module and the syntax modules compared to baselines in Table 4 to validate that extracted semantics features could improve the performance and our syntax modules may perform poorly because of missing semantic information.

A.3.2 Code-to-Code Search

The training language pair combinations and dataset construction are the same as the code clone detection task. We control that each programming language has only one unique solution for each programming problem. When evaluating our model, we compare the code snippet in source query language to the all code snippets in target language, calculating their cosine similarity. Then we predict the type of algorithm by greedy choosing the highest score sample as shown in Figure 6. In contrast to the usual algorithm classification of one-hot tags, we chose to compare the similarity with all samples of the target domain to do code-to-code search. This makes the more difficult and convincing task to validate the quality of the semantic representation of the code.

Exploring Self-Identified Counseling Expertise in Online Support Forums

Abstract

A growing number of people engage in online health forums, making it important to understand the quality of the advice they receive. In this paper, we explore the role of expertise in responses provided to help-seeking posts regarding mental health. We study the differences between (1) interactions with peers; and (2) interactions with self-identified mental health professionals. First, we show that a classifier can distinguish between these two groups, indicating that their language use does in fact differ. To understand this difference, we perform several analyses addressing engagement aspects, including whether their comments engage the support-seeker further as well as linguistic aspects, such as dominant language and linguistic style matching. Our work contributes toward the developing efforts of understanding how health experts engage with health information- and support-seekers in social networks. More broadly, it is a step toward a deeper understanding of the styles of interactions that cultivate supportive engagement in online communities.

1 Introduction

Online social media forums play a critical role in health-related information sharing (Record et al., 2018). Health experts have noted that they can help reduce healthcare inequalities and improve access to health care, for instance by empowering coalitions of people living with chronic illness or specific disabilities (Griffiths et al., 2012), or by providing an anonymous forum for people seeking emotional support (De Choudhury and De, 2014). On the other hand, these forums elevate concerns about spreading medically inaccurate, misleading, or unsound information (Domínguez and Sapiña, 2015; Gage-Bouchard et al., 2018), which has had harmful public health impacts (Poland et al., 2011; Nobles et al., 2019). One study concluded that health information seekers in forums such as Reddit are likely to enact suggested behaviors regardless of perceived credibility (Record et al., 2018). However, the researchers also noted that this openness to information could be an opportunity for experts to encourage healthy behaviors through information sharing.

In this landscape, it is critical to understand the dynamics that cultivate safe communities that benefit the health and well-being of their participants and the broader implications for health communication (Chou et al., 2009). Health experts are thus considering social media's role in their interactions with patients and broader public health issues, and their role in engaging with the platforms (Domínguez and Sapiña, 2015; Nobles et al., 2019, 2020). This motivates an important research direction: understanding how experts engage with users in online platforms. This can inform platform design, moderation decisions, and health promotion efforts by experts.

This work focuses on understanding the engagement with professionals in the domain of mental health with two main research questions: (RQ1) Do experts have distinct influences as compared to non-experts in their interactions with support-seekers in online mental health?; and (RQ2) Do the experts' behaviors reflect established counseling principles and findings regarding behaviors associated with positive counseling outcomes? To answer these questions, we analyze responses from self-identified mental health professionals (MHP) to support-seekers in mental health and support communities on Reddit, and compare them to responses from other users who we refer to as *peers*. This is an important comparison, as many peers share similar health experiences, which prior work has found is associated with higher empathic concern (Hodges et al., 2010).

First, we test whether a text classifier can distin-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4467–4480
August 1–6, 2021.

guish between responses to support seekers from MHPs and peers. We find that it can, with 70% accuracy (well above random chance of 50%). Second, we analyze comments leading to further engagement with the support-seeking posters, as existing counseling principles emphasize the importance of eliciting client engagement in expert counseling sessions (Miller and Rollnick, 2012; Pérez-Rosas et al., 2018). Third, we analyze the users' linguistic tendencies, drawing inspiration from analyses of counseling conversations, which have offered insight into counselor behaviors associated with high quality sessions grounded in existing theories from psychology and counseling research using computational methods (Althoff et al., 2016; Pérez-Rosas et al., 2018; Zhang et al., 2019; Miller and Rollnick, 2012).

The main contributions of this work are: (1) We construct a dataset of mental health conversations from Reddit users with self-identified counseling expertise, covering a set of mental health subreddits annotated with categories denoting the type of mental health concern; (2) We develop a classifier that can distinguish between the language of MHPs and that of peers; (3) We perform an analysis of the differences in language use between MHPs and peers; and (4) We provide insight into language that leads to further engagement with support-seekers, comparing responses to peers and MHPs.

2 Related Work

Studies within the education and health domains have shown that advice and help-seeking interactions in online communities contribute positively to users' well-being, learning, and skills development (Campbell et al., 2016; Wang et al., 2015). This is particularly true for applications such as computer programming, career development, mentoring, coping with chronic or life-threatening diseases, and mental health issues (Baltadzhieva and Chrupała, 2015; Tomprou et al., 2019; Wang et al., 2015; De Choudhury and De, 2014).

In the mental health domain, studies have explored online support communities and many have found positive outcomes associated with anonymity, perceived empathy, and active user engagement (De Choudhury and De, 2014; Rheingold, 1993; Hodges et al., 2010; Welbourne et al., 2009; Nambisan, 2011). Computational approaches have aided studies in mental health forums, helping reveal positive relationships between linguistic accommodation and social support across subreddits (Sharma and De Choudhury, 2018). One example of insights from this work is that topic-focused communities like subreddits may enable more peer-engagement than non-community based platforms (Sharma et al., 2020). Other studies have revealed certain trade-offs of online support platforms, such as disparities in the level of support offered toward support-seekers of various demographics (Wang and Jurgens, 2018; Nobles et al., 2020) and in condolences extended across different topics of distress (Zhou and Jurgens, 2020). Studying MHP behaviors in such scenarios might help develop approaches that balance these trade-offs.

Computational approaches applied in these forums have also shed light on population-level health trends and health information needs, with examinations into how depression and post-traumatic stress disorder (PTSD) affect different demographic strata (Amir et al., 2019). Data mining has also been applied to understand adverse drug reactions (Wang et al., 2014) and public reactions towards infectious diseases (Park and Conway, 2017). Nobles et al. (2018) highlighted the potential for these forums to aid targeted health communication, for example by sharing information in r/STD, a subreddit about sexually transmitted diseases. Another case study of r/STD revealed the prevalence of diagnoses requests, and suggested that health professionals could partner with social media platforms to positively influence crowd-sourced diagnoses and help mitigate harmful misdiagnoses (Nobles et al., 2019). Record et al. (2018) found that health information seeking Reddit users are likely to enact suggested behaviors regardless of perceived credibility, providing further reason for health expert engagement to intervene when harmful information sharing occurs and promote healthy behavior.

Fewer studies have analyzed expert interactions in online forums. A study in a large Q&A community found that experts are more likely to provide help than peers and that their participation in discussions resulted in increased length and substance of discussions (Procaci et al., 2017). Recent studies have compared interactions with experts to interactions with peers in broader scientific communities (Park et al., 2020) and r/AskDocs on Reddit (Nobles et al., 2020). The latter paper closely relates to our study, as they also consider posts from experts on Reddit, but solely within r/AskDocs about different health topics and with

Post:	u/peer_user_X
I've recently been struggling with paranoid thoughts, for which I was hospitalized for my own safety. I do not feel suicidal anymore, however everyday is a long struggle of thinking everyone is an undercover agent out to get me or keep tabs on what I'm doing. I was hoping to hear some tips and stories if anyone else has dealt with similar thoughts and overcome them? Or are they something I will have to deal with for the rest of my life? Thanks in advance	
Comment:	u/MHP_user (LPC)
Paranoid thoughts are scared thoughts, justified or not. If you ignore the specific content of the thoughts and focus on the emotional valence (scared), is there something you can do in those moments to feel safer?	
Poster Reply:	u/peer_user_X
That's a good way of thinking about the situations as they arise. I will try to do that	

Table 2: Example of an initial post, a reply from an MHP with the flair *LPC* (Licensed Professional Counselor), and a reply from the original user.

users of varying demographics.

The insights discussed above motivate investigations into how health experts and other users promote scientifically sound advice and offer supportive responses to health information seekers in online forums. In this work, we aim to contribute additional insights into expertise influence in online mental health communities by studying the dynamics of the communication process between support seekers and support providers.

3 Data Collection

We seek to understand the tendencies of users with professional experience, and more specifically counseling expertise, when interacting with support-seekers in online mental health and support-related forums. In uncovering which tendencies are associated with expertise, we enable further investigation into their role in the social dynamics of online support-seeking interactions, and potential applications of insight-driven recommendations for moderators and users of these forums.

Source. We use Reddit for its quantity of publicly available interactions in communities called *subreddits* that discuss mental health issues. In addition, Reddit has a system that allows users to indicate their professional expertise (Reddit Flairs), which we use to identify a set of users with mental health professional background, identified as *MHPs* during our study. We obtained flairs from the r/psychotherapy subreddit,[1] a decision motivated by their reliability, as the moderators of this community allow comments and posts only by licensed therapy providers who may be asked to submit proof if concerns of falsely posing as a therapist arise.[2] Sample flair tags in this set are: Psychiatrist (sometimes accompanied by MD or DO), LPC (or Licensed Professional Counselor), LMFT (or Licensed Marriage and Family Therapist), PsyD (or Doctorate of Psychology).

We use an existing list of mental health subreddits from r/ListOfSubreddits[3] with additions from manual observations; all of the subreddits in our dataset with their number of comments are in Appendix B in Table 5. From these, we retrieve threads where an MHP submitted a direct reply. During this step, we also kept posts made by peers i.e., individuals who did not use any of the mental health care professional flairs. Our collection spans threads created between November 29, 2009 and December 21, 2020. Table 1 shows descriptive statistics for the final composition of the dataset, and Table 2 shows a sample interaction demonstrating the structure we use for our analysis. This study focuses on direct replies to the poster, thus we attempt to eliminate *megathreads* which tend not to focus in individual support-seekers by removing those above the 95th percentile in their number of direct replies; we leave analysis of deeper nested replies for future work.

Health Topics. To understand whether particular topics influence interactions with support-seekers, we group the subreddits into broader topics based

on related health domains. We begin by following the categorization of subreddits by Sharma and De Choudhury (2018), who used the k-means clustering algorithm to generate initial clusters on the n-grams ($n = 3$) of the posts and manually refined the categories based the community descriptions in their subreddit home pages. Next, we adjust the categories and their associated subreddits based on the World Health Organization's ICD-10 classification system of mental and behavioural disorders.[4] The resulting topic categories are listed in Table 3 alongside shortened names which we use to refer to them. The full list of subreddits assigned to each topic are listed in Appendix B in Table 6.

4 Distinguishing MHPs and Peers

To begin our investigation into the linguistic behaviors of MHPs and peers, we test whether simple text classifiers are able to distinguish between comments authored by either MHPs or peers. We build three classifiers with different feature sets; the first are unigram counts for unigrams occurring at least five times, the second includes counts for the 73 word classes in the LIWC (Linguistic Inquire and Word Count) lexicon (Pennebaker et al., 2015), and the third encodes a subset of LIWC word classes associated with perspective shifts (i.e., *focusfuture, focuspast, focuspresent, I, ipron, negemo, posemo, ppron, pronoun, shehe, they, we,* and *you*) (Althoff et al., 2016); we elaborate on the psychological meaning behind these features in our analyses in the next section.

Due to the class imbalance between the peer and MHPs classes, we first downsampled the peer class to get a balanced distribution with the MHP class. This resulted in a set of 9,685 instances per class. We conduct our evaluations using ten-fold cross validation. Across these folds, the number of features ranges from 8,668 to 8,703. We use a Naive Bayes model, implemented with Sklearn's MultinomialNB module, [5] which outperformed a logistic regression model and an SVM in preliminary experiments.[6]

All models outperform a random baseline[7] with all LIWC features bringing the accuracy to 59.12%, LIWC perspective features to 59.14%, and unigram features to 70.80%. Overall, the classification results indicate language differences exist between the MHPs and peers. Motivated by this result, we proceed to several analyses to gain insights.

5 Linguistic and Dialogue Analysis

We analyze the linguistic behaviors of MHPs and peers responding to support-seeking posts, and their potential influence in eliciting further engagement with the support-seeker. Our analyses are inspired by psychology and computational studies that have shown that conversational behavioral aspects such as word usage, client engagement, and

language matching are positively related to successful counseling interactions (Gonzales et al., 2010; Althoff et al., 2016; Pérez-Rosas et al., 2018; Zhang et al., 2019).

5.1 Linguistic Ethnography

Numerous studies have demonstrated relationships between the dominant usage of certain word categories with individuals' psychological and physical health (Tausczik and Pennebaker, 2010; Weintraub, 1981; Rude et al., 2004). In alignment with these studies, we investigate the usage of such word categories using the LIWC and WordNet-Affect lexicons (Pennebaker et al., 2015; Strapparava and Valitutti, 2004).

For each group of users, we first compute the proportion of their words that fall in each category. Then, we compute the dominant use by dividing the proportion for peer users over the proportion for MHPs (Mihalcea and Pulman, 2009). Figure 1 shows LIWC categories where the rate of use differs by at least 10%, and results for WordNet Affect categories are shown in Figure 2.

Some observations such as the higher dominance of swear words (*swear*) and internet speak (*netspeak*) might be expected if professionals avoid such language. An interesting contrast in peers' language is the dominant use of first-person pronouns (*I, we*) and focus on the past (*focuspast*). In contrast, MHPs seem to use more non-first person pronouns (*you, they*) and focus on the future (*focusfuture*) instead. Peers' use of first person pronouns might arise when they share similar experiences with support-seekers. MHPs' use of second-person pronouns might suggest they are focusing on the support-seekers' experiences as a counselor would with a client in a counseling encounter. We also observe higher dominance of all WordNet Affect categories among peers, however the *joy* category (the most positive), is nearly equal with MHPs.

These observations of the peers' language are compelling because they align with existing theories linking depression to negative views of the future (i.e., *focuspast* and negative WordNet affects) (Pyszczynski et al., 1987) and self-focusing style (i.e., first-person pronouns) (Pyszczynski and Greenberg, 1987; Campbell and Pennebaker, 2003). Likewise, clients of SMS-based crisis counseling conversations were more likely to report feeling better after the encounter if they exhibited perspective shifts from these categories to their counterparts (i.e., toward *focusfuture*, non-first person pronouns, and positive sentiment) (Althoff et al., 2016).

Interestingly, the same study found clients were more likely to shift perspective when their counselors exhibited use of the counterpart categories first, suggesting that the counselors may play a key role in helping drive the perspective shift. Given those positive outcomes, observing the same dominant linguistic aspects among MHPs is encouraging and potentially signals a connection between how counselors apply conversational behaviors in practice and in online forum interactions. Future work can investigate the progression of dialogue between MHPs and support-seekers to find if support-seekers similarly exhibit the perspective shifts associated with the positive outcomes of the prior study, and likewise whether users of the forums also experience positive outcomes where this occurs.

5.2 Engaging Support-Seekers

To understand if linguistic behaviors are associated with prompting further engagement with the support-seeker, we compare the dominance of LIWC categories in comments receiving replies compared to comments that do not by dividing the usage rates of the former by the latter. Figure 3 shows these ratios for categories that differ by at least 5%. A compelling observation is the dominance of the categories *health*, *tentat*, and *you* in the MHP comments prompting poster-replies, and *you*, *focusfuture*, *interrog*, and *health* in the peer comments prompting poster-replies, as was exhibited among MHPs (see Figure 1 in Section 5.1); on the other end, the categories are more dominant in comments that do not engage a reply such as *I*, *we*, *death*, *friend*, *relig*, *swear*, were similarly represented as dominant categories in the peer group.

To gain further insight into these observations, we perform the following analysis: for each user group (peers and MHPs) we use a foreground corpus of their comments that were replied to by the support-seekers, and a background corpus of their comments that were not, and compute the dominance of LIWC categories of the foreground over

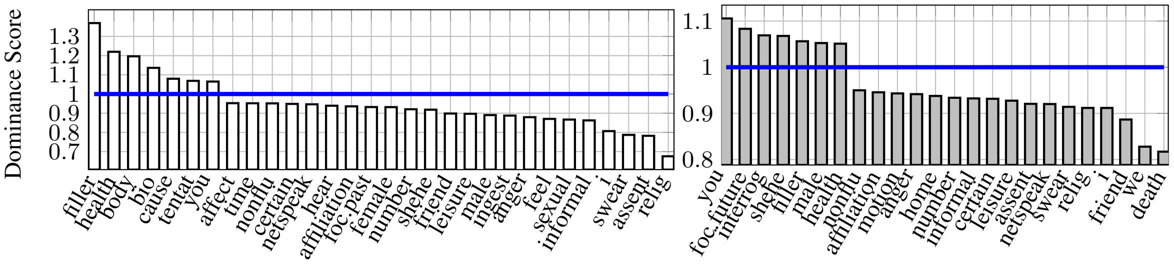

Figure 3: Dominance of LIWC categories, computed as the category relative frequencies among comments that **prompt support-seeker responses** divided by the relative frequencies among comments that do not, computed separately for MHPs (left) and peers (right).

`DRR` Group	OR Group	τ	p-value
Peer	MHP	.191	.017
MHP	MHP	.158	.048
Peer	Peer	-.031	.689
MHP	Peer	.008	.916

Table 4: Kendall τ's coefficient between the LIWC category dominance ranking in the replied comments (`DRR`) of the user group on the left and the overall ranking of LIWC category usage (`OR`) by the user group to the right.

the background as a ratio of their relative frequencies. We then rank the categories by highest to lowest dominance scores, and refer to this ranking by `DRR` (for **D**ominance **R**ank for **R**eplied comments). We compare the `DRR`s of each user group to the ranking of LIWC category usage among MHP users and among peer users separately (from Section 5.1) by computing the Kendall Tau's coefficient between them. A positive correlation would thus indicate that the more (or less) dominant categories among a group's replied comments are also more (or less) dominant among the other group overall. The correlation coefficients are shown in Table 4.

Interestingly, we observe a slight positive correlation between the `DRR`s for both MHPs and peers with the overall LIWC category usage ranking for MHPs. On the other hand, we see no correlations with the LIWC usage ranks for peers. Intuitively, it appears that for both MHPs and peers, the comments prompting further engagement with the poster appear to reflect the overall dominant linguistic aspects captured by LIWC of MHPs, but not peers. As counseling principles have emphasized the importance of mutual engagement between counselors and clients (Miller and Rollnick, 2012) and other work has shown that higher quality counseling sessions are associated with higher client engagement (Pérez-Rosas et al., 2018), it is compelling to observe associations between linguistic aspects of MHPs with the aspects associated with poster-engagement.

5.3 Linguistic Style Matching

Linguistic Style Matching (LSM) measures the extent to which one speaker matches another (Gonzales et al., 2010). It compares two parties' relative use of function words as these words are more indicative of style rather than content (Ireland and Pennebaker, 2010).

Previous studies in counseling conversations have measured LSM to understand the extent that counselors and clients match their language. Pérez-Rosas et al. (2019) showed higher LSM for high quality counseling sessions whereas Althoff et al. (2016) showed lower LSM for higher quality sessions. Pérez-Rosas et al. (2019) attributed this to the differences between the conversations they analyzed, theirs being synchronous face-to-face interactions while Althoff et al. (2016)'s was of asynchronous text messages, as well as differences in counseling styles.

We follow Nobles et al. (2020)'s approach leveraging Ireland and Pennebaker (2010)'s procedure to measure LSM between support seekers and support providers. For a text sequence, we compute the percentage of words that belong to each of nine function-word categories c from the LIWC lexicon, which include *auxiliary verbs, articles, common adverbs, personal/impersonal pronouns, prepositions, negations, conjunctions,* and *quantifiers*. Then, we compute the LSM of each word category c as shown in Equation 1 where p represents *post* and r represents the response. The composite LSM score for p and r is the mean of all category LSM scores. For each thread, we separate the MHP and peer replies, and take the mean of all

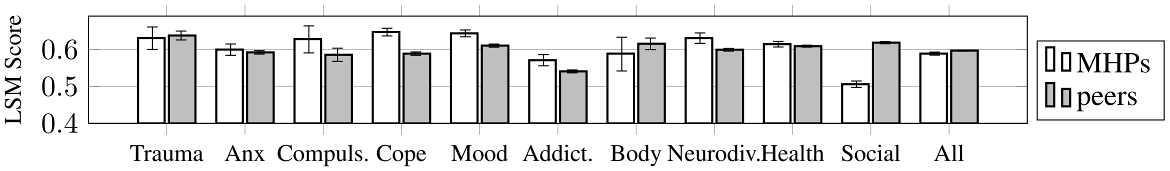

Figure 4: LSM scores with 95% confidence intervals calculated with non-parametric bootstrap resampling.

composite LSM scores.

$$LSM_c = 1 - \frac{abs(cat\%_p - cat\%_r)}{cat\%_p + cat\%_r + .0001} \quad (1)$$

We compute these LSM scores over all data together as well as separately for each subreddit topic (named in Table 3). The resulting scores are shown in Figure 4.

We observe LSM scores vary by topic, and most are similar for peers and MHPs or have overlapping confidence intervals. Compared to their LSMs in other topics, MHPs score lower in SOCIAL, which covers broad social issues that are less specialized to health conditions than the others. However, peers have high LSMs in SOCIAL relative to most other topics, and notably higher LSMs than the MHPs. Additionally, MHPs have higher LSMs than those of peers and relative to their own in communities that cover topics of specific compulsive, mood, and neurodevelopmental disorders (COMPULS., MOOD, and NEURODIV.), communities that orient toward counseling purposes (COPE), or toward advice-seeking communities for health and social concerns (HEALTH). The influences in these results require further investigation, but a possible explanation could be that expert knowledge and experience may offer more benefit to specialized condition-related issues than to broader social issues.

6 Language Modeling

We further examine differences in word usage by building separate language models for MHPs and peers. We seek to identify language use that is indicative of one group or another by running the language model of one on the data of the other and analyzing words with high perplexity. To run these experiments, we use the language model of Merity et al. (2018a,b), which is a recent LSTM-based language model that achieved state-of-the-art performance by combining several regularization techniques.[8]

Our implementation uses a fixed vocabulary of 20,907 tokens for both the peer and MHP language models. This is determined by a minimum count of five across the set of posts from both groups. Each language model is trained for 50 epochs.[9]

We use the language model trained on MHP data to find words with high entropy in peer data and vice versa. Since we are concerned with the *difference* in predictability of words between the MHP and peer language models, we subtract the entropy given by the model trained on that data from the entropy assigned by the model that was not trained on that data. In other words, to find words difficult to predict in B's data, we subtract each word's entropy calculated by the model trained on B from the entropy calculated by the model trained on A as follows, for a set of words, X:

$$E_{A,B} = -\frac{1}{|X|} \sum_{x \in X} log(p_A(x)) - log(p_B(x)) \quad (2)$$

If we calculate the entropy difference for each LIWC category and for each assignment of the MHP and peer groups to A and B, we find the highest differences for each category shown in the first and third plots of Figure 5. We find highest entropy scores for words relating to *leisure*, *sex*, and *numbers* when running the MHP language model on peer data. Likewise, when running the peer model on MHP data, the category of *discrepancy* contains words whose accuracy is improved the least by the peer model, again showing that these words are more indicative of the MHP group.

We perform a similar analysis, creating a language model for posts which have the highest score (or tied for highest) and another model for all other

---

[8] `https://github.com/salesforce/awd-lstm-lm`

[9] Validation set perplexities for expert and score groups: peer on peer: 44, peer on MHP: 52, MHP on peer: 91, MHP on MHP: 74, low on high: 39, low on low: 43, high on high: 50, high on low: 57. The difference in perplexity is due to the difference in volume of posts between groups. Runs in $\sim$2 min per epoch on a GeForce RTX 2080 Ti GPU.

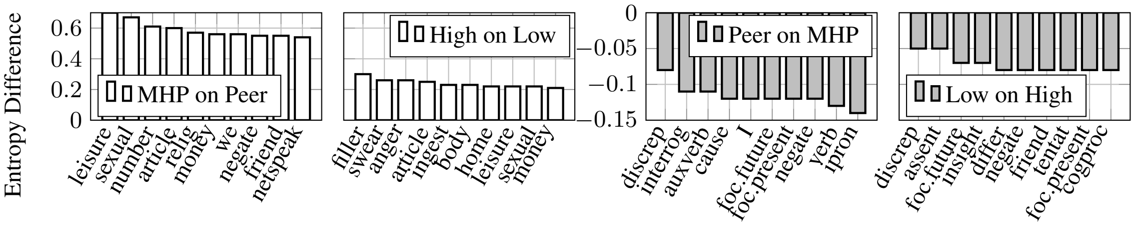

Figure 5: Entropy differences for LIWC word categories when running both language models on one group's data. High entropy scores on one dataset indicate word types that are harder for the opposite group's model to predict.

posts. We measure entropy differences and show the highest scoring categories for each group in the second and fourth plots. Some of the categories indicative of MHP language are also indicative of higher scoring posts; *discrepancy*, *present* and *future* words, and *negation* words, while other categories like *assent* and *insight* words are more dominant in higher scoring posts. The lower scoring posts have the highest entropy differences for some types of words in the peer data, however, we also see that *filler*, *anger*, and *swear* words had the highest entropy differences for the low scoring group. Qualitative example sentences with word-level entropy and LIWC annotations are shown in the appendix in Table 7.

7 Discussion and Future Work

In comparing linguistic aspects of MHP and peer comments, we find MHP tendencies align with established counseling principles and findings in counselor behaviors from recent literature. In particular, they align in the use of words that increase the likelihood of desired perspective shifts associated with clients feeling better after text counseling sessions (RQ2) (Althoff et al., 2016). We also found unique differences in the behavior of MHPs as compared to peers in how they respond to information seekers (RQ1). Although, comments by peers that prompt support-seeker replies also make use of similar word categories to MHPs, which shows that comparing MHPs to peers can offer insight into peer interactions as well.

It is important to note that our analyses rely heavily on the LIWC lexicon. While LIWC and other lexicons can help uncover variational language across groups at an exploratory stage, their use alone does not explain why variations are present. Certain limitations of LIWC are clear, such as when certain words that occur in multiple categories misleadingly boost the prominence of the categories equally. Kross et al. (2019)'s and Jaidka et al. (2020)'s studies have also demonstrated limitations of the use of LIWC when working with word counts to correlate with well-being metrics and an individual's emotional state. We utilize LIWC to understand linguistic behavior differences in conversations with peers and MHPs rather than to evaluate the emotional or mental health state of individuals; however, it is important to consider how these limitations could pertain to our interpretations of their differences, especially as we explore them more deeply in future work. In our study, we explore the patterns we find in the context of previous findings from related literature such as (Althoff et al., 2016) and (Nobles et al., 2020), however it warrants another study into nuanced aspects of the patterns to infer their social functions in support seeking forums in particular.

Although our findings align MHP behaviors with certain counselor behaviors associated with positive outcomes, our analyses do not support claims that MHP behaviors are more beneficial to individuals seeking support; rather, we have shown that the general tendencies of MHPs are in accordance with principles and behaviors demonstrated by counselors in other settings. Understanding the outcomes of these interactions for individual support seekers remains as an area for future work, which could employ surveying methods from prior work to measure perceived empathy in online communities (Nambisan, 2011). Our dataset also enables investigations into whether support-seekers exhibit perspective shifts in interacting with MHPs or peers, and what MHP and peer tendencies are associated with these perspective shifts.

Another direction for future work could focus on modeling social media-specific engagement patterns of MHP and peer interactions. Prior work developed a model that accounts for variables indicating the level of attention threads receive (i.e., thread lengths and number of unique commenters), and variables indicating the degree of interaction between posters and commenters (i.e., time between responses and whether the poster replies to commenters), and used this model to study peer-to-peer interactions in online mental health platforms (Sharma et al., 2020); this approach may enable studying supportive interactions in megathreads and threads involving back-and-forth dialog between two or more parties.

More questions arise if we consider MHP tenure and specific domain of expertise (e.g., specializations, licenses, academic degrees). Prior work that studied longitudinal changes in counselor linguistic behaviors indicated that systematic changes occur over time as counselors develop personal styles that are more distinct from other counselors and exhibit more diversity across interactions (Zhang et al., 2019). Future work could model the language longitudinally for MHPs and peers that have longer-term histories of participating in mental health forums to investigate whether systematic changes occur online as well, and if so, whether they reflect similar changes found in prior work.

8 Limitations and Ethical Considerations

A number of unknowns exist in what we are able to extract from Reddit. For instance, we do not know if users that do not use flairs are mental health professionals. We assume that those who have used the MHP flairs are MHPs and those that have not used them are peers. Additionally, we have grouped all MHP flairs into one group for our analysis, though a more nuanced analysis based on particular professional roles (e.g., psychologists, psychiatrists, social workers) and specializations (e.g., motivational interviewing, cognitive behavioral therapy, family & marriage counseling) may reveal additional trends. Prior work found that disclosing credentials has impacts on engagements that vary by subreddit and linguistic patterns associated with different experience levels and expert domains (Park et al., 2020), thus the effects of disclosing MHP credentials when responding to support-seekers should be investigated.

A classifier or language model used to distinguish between MHPs and peers or to generate the language of either could have negative implications. A generative model that provides feedback to users could generate language that is harmful for those seeking help. Our work could be used to devise a tool to train counselors, however we do not have a direct measure of what type of responses are helpful or meaningful. In such an application, there is potential to reinforce harmful behaviors due to the inaccuracy of our models. Future studies are needed to determine how to best design a tool to train counselors and how models derived from corpora such as ours correspond to advice that patients find useful.

9 Conclusion

As the role of social networks is becoming more critical in how people seek health-information, it is important to understand their broader implications to health communication and how health experts can engage to promote the soundest information and offer support to their vulnerable users. By elucidating techniques employed by mental health professionals in their interactions with support-seekers in mental health forums, we have contributed insights toward the broader research direction of understanding how health experts currently engage with these platforms. With evidence that MHP linguistic behaviors associate with further engagement with support-seekers and that these same behaviors are associated with positive counseling conversation outcomes, we have shown that analyzing MHP behavior is a promising direction for better understanding online interaction outcomes, which can further inform forum design and moderation, and expert health promotion efforts.

The code used for our experiments and analyses, and the post ids in our dataset can be accessed at `https://github.com/MichiganNLP/MHP-and-Peers-Reddit`.

Appendix

A Flairs

Rules regarding flair credibility from r/psychotherapy:

“**2. Only posts and comments from those providing therapy in a licensed capacity allowed.** No comments/posts from anyone who is not providing therapy in a licensed capacity. This includes students who are not yet practicing therapy (e.g., undergraduate or graduate students who haven’t had their first practica experience) or if you have left the field for another field, this is not the place for you to post/comment. There is an exception to this rule for posting in our Career and Education Megathread. Accurate user flair is required for all posts, and strongly encouraged for comments.”

“**9. Falsely posing as a therapist** If you post in this subreddit, the assumption is made that you are a therapist. Users that falsely post as if they were a therapist will be permanently banned. Claiming that you didn’t say you were a therapist is not an argument against this rule. Users may be asked to submit proof of their status as a practicing therapist to appeal a ban.”

B Data

We used the PushShift API for the first pass of obtaining mental health posts and comments, and the MHP flairs. After extracting the IDs of posts where MHPs commented, we obtained the fully structured comment sections using open sourced code from `https://github.com/saucecode/reddit-thread-ripper`. The numbers of posts in our dataset for each subreddit are shown in Table 5.

C Other

Sample sentences illustrating relative entropies of words predicted by the peer language model on MHP data (top) and the MHP language model on peer data (bottom) are shown in Table 7.

An Investigation of Suitability of Pre-Trained Language Models for Dialogue Generation – Avoiding Discrepancies

Abstract

Pre-trained language models have been widely used in response generation for open-domain dialogue. These approaches are built within 4 frameworks: Transformer-ED, Transformer-Dec, Transformer-MLM and Transformer-AR. In this study, we experimentally compare them using both large and small-scale data. This reveals that decoder-only architecture is better than stacked encoder-decoder, and both left-to-right and bi-directional attention have their own advantages. We further define two concepts of model discrepancy, which provides a new explanation to the model performance. As discrepancies may hinder performance, we propose two solutions to reduce them, which successfully improve the model performance.

1 Introduction

It has been shown (Wolf et al., 2019) that leveraging a pre-trained Language Model (LM) based on transformer can achieve excellent performance for dialogue generation. Different approaches have been proposed recently, which can be categorized into 4 frameworks: Transformer-ED(Zheng et al., 2019), an encoder-decoder Transformer, Transformer-Dec (Wolf et al., 2019; Lin et al., 2020), Transformer-MLM (Dong et al., 2019) and Transformer-AR (Bao et al., 2019; Shuster et al., 2019). The latter three all utilize a decoder-only architecture. Besides, Trans-Dec uses left-to-right attention for both source and target side, while Trans-MLM and Trans-AR employ bi-directional attention on the source side to encode dialogue history. Due to this difference, Trans-Dec only utilizes left-to-right pre-trained models, e.g. GPT-2 (Radford et al., 2019), while Trans-MLM/AR are based on the pre-trained models applying bi-directional attention (on the source side), e.g. BERT (Devlin et al., 2018). The difference between Trans-MLM and Trans-AR is that Trans-MLM uses masked language modeling while Trans-AR uses auto-regressive objective.

Recent studies have explored pre-training dialogue models using large-scale Reddit/Twitter data (Adiwardana et al., 2020; Roller et al., 2020). It is then straightforward to fine-tune the models for a specific dialogue task. However, in practice, there may not always be enough data for pre-training. In some cases, we still need to exploit a pre-trained LM. For example, some studies do further pre-training for dialogue based on a pre-trained LM (Zhang et al., 2019; Dong et al., 2019; Bao et al., 2019; Shuster et al., 2019), and some studies that do multi-task learning (e.g. on dialogue and question answering) can only fine-tune based on a pre-trained LM (Lin et al., 2020; Zeng and Nie, 2021). Then, a critical question is how to best exploit a pre-trained LM for dialogue generation. On this question, we have contradictory beliefs in the literature: some researchers believe that Trans-Dec is appropriate because it uses a left-to-right language model that corresponds well to the dialogue generation task (Zhang et al., 2019; Lin et al., 2020), while some others (Dong et al., 2019; Bao et al., 2019) show that Trans-MLM/AR fine-tuning BERT can also achieve state-of-the-art performance.

In this study, we aim to address the above question. To do it, we first compare the 4 frameworks with the same setting on 3 datasets, each with large and small scale training data. Our results on large-scale datasets show that Trans-ED that applies the stacked encoder-decoder architecture does not produce competitive results against the others that use a decoder-only architecture. Trans-Dec/AR generate the most appropriate responses. However, according to automatic metrics, Trans-Dec generates most diverse responses while Trans-AR produce responses most similar to the ground-truth. This may be due to the fact that uni-directional attention does not have constraint from the right side context and

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4481–4494
August 1–6, 2021.

thus is more flexible, while bi-directional attention on source side can better model dialogue context. In contrast, the results on small-scale datasets reveal an important aspect, namely, the discrepancies that may occur between the pre-training and the fine-tuning processes. We then try to explain the performances of the 4 frameworks with respect to the discrepancies.

The concept of model discrepancy has been briefly mentioned in Yang et al. (2019) to mean that the model has been trained in a way, but used in a different way. However, the problem has not been investigated in depth. In this work, we go further in this direction and define two discrepancies: **pretrain-finetune discrepancy** which means the differences in architecture and loss function between pre-training and fine-tuning, and **finetune-generation discrepancy** which means that the way the model is used in generation (inference/test) is different from the way it has been trained. For the 4 frameworks, except Trans-Dec, they all have some pretrain-finetune discrepancies. For example, Trans-AR relies on BERT pre-trained using bidirectional attention, but has to limit it to left-to-right attention on the target side during fine-tuning. Only Trans-MLM has finetune-generation discrepancy because of MLM objective: during training, the model input has random masks, while in the generation process, the input does not contain masks.

Discrepancies might affect the model performance since models with such discrepancies cannot best exploit the pre-trained model or employ the fine-tuned model. Our experiments on small-scale datasets show that the performance of Trans-AR that have larger pretrain-finetune discrepancy drops more sharply than Trans-MLM. Trans-Dec/MLM that have small pretrain-finetune discrepancy have clear advantage over other frameworks according to human evaluation. It becomes clear that discrepancies hinder the performance of a dialogue model. To alleviate the problems, we propose 2 approaches to respectively reduce pretrain-finetune and finetune-generation discrepancies of Trans-MLM, aiming at improving its performance. Our experiments show that both methods bring some improvement. In particular, by eliminating finetune-generation discrepancy of Trans-MLM, our approach significantly outperforms previous methods in most automatic metrics, and achieves comparable performance to Trans-Dec in human evaluation that uses much larger dataset for pre-training. These results confirm that discrepancies are indeed an important factor that influences the effectiveness of leveraging a pre-trained LM for a sequence-to-sequence task, and should be alleviated.

The contributions in this work are as follows:

- We compare the four commonly used frameworks that utilize pre-trained language models for open-domain dialogue generation on 3 public datasets each in large and small scale. and we analyze each framework based on the experimental results.
- We introduce the concept of pretrain-finetune discrepancy and finetune-generation discrepancy, and we examine the discrepancies of each framework.
- We propose two methods to reduce discrepancies[1], yielding improved performance. It is the first investigation that shows explicitly the phenomenon of model discrepancy and its impact on performance.

2 Pre-training Based Frameworks

We start with a brief description of the 4 frameworks for dialogue generation based on pre-trained models. More details are provided in Appendix A. We examine the pretrain-finetune discrepancy of each framework. Figure 1 and Table 1 provide an overview.

2.1 Trans-ED

Trans-ED discussed in this paper is an encoder-decoder architecture used by ConvAI2 (Dinan et al., 2019) champion [2]. The decoder of Trans-ED is stacked upon the encoder outputs, while in other decoder-only frameworks, all hidden states of the source side are utilized in the decoding part. The framework shares the encoder and the decoder and initializes the parameters with GPT (Radford et al., 2018). In this case, the pretrain-finetune discrepancy comes from the bi-directional attention in the encoder since GPT is a left-to-right language model. This framework is not commonly used for fine-tuning on a dialogue task. In practice, more efficient variants of Trans-ED are recently used for extremely large-scale dialogue pre-training from

	Trans-ED	**Trans-Dec**	**Trans-MLM**	**Trans-AR**
Pre-trained LM	GPT	GPT-2	BERT	BERT
Architecture	encoder-decoder	decoder-only	decoder-only	decoder-only
Source Side Attn.	bi-directional	left-to-right	bi-directional	bi-directional
Target Side Attn.	left-to-right	left-to-right	left-to-right	left-to-right
Objective	auto-regressive	auto-regressive	MLM	auto-regressive

Table 1: Key characteristics of the 4 pre-training based Transformers. Characteristics in red are inconsistent between pre-training and fine-tuning.

scratch. For example, Adiwardana et al. (2020) utilizes Evolved Transformer to prune redundant connections, and Roller et al. (2020) employs only 2 encoder layers and 24 decoder layers of standard Transformer (Vaswani et al., 2017).

2.2 Trans-Dec

Trans-Dec is a left-to-right decoder-only architecture, and it utilizes GPT-2 (Radford et al., 2019). Thus, there is no pretrain-finetune discrepancy in terms of architecture and loss function. This framework is widely applied for fine-tuning on a dialogue task. However, it encodes dialogue history using only left-to-right attention, which limits the scope of context, resulting in a partial context modeling.

2.3 Trans-MLM and AR

These two frameworks have an identical decoder-only architecture that employs different self-attention masks for the source and target side: they use bi-directional attention on the source side to encode dialogue history and left-to-right attention on the target side. The only difference between them is the objective function: Trans-MLM masks some tokens at the target side and tries to predict them, while Trans-AR uses auto-regressive objective that tries to predict the next tokens successively. BERT is often exploited by the two frameworks, which is a bi-directional architecture using MLM as the pre-training objective. Thus, the pretrain-finetune discrepancy of Trans-MLM/AR comes from the left-to-right attention on the target side. Additionally, Trans-AR applies the auto-regressive objective, which is different from the MLM used in the pre-training.

2.4 Applications of the Frameworks

The four frameworks we described have been widely applied to dialogue generation. For personalized response generation, Wolf et al. (2019) uses Trans-Dec and Zheng et al. (2019) utilizes Trans-ED. Lin et al. (2019) uses Trans-Dec for empathetic response generation. Zeng and Nie (2021) proposes a multi-task learning approach based on Trans-MLM for conditioned dialogue generation. Meanwhile, some studies propose to further pre-train the model using large-scale dialogue data based on a pre-trained language model: Zhang et al. (2019) trains Trans-Dec on 147M Reddit data based on GPT-2, Dong et al. (2019) trains Trans-MLM on natural language understanding and generation datasets based on BERT, Shuster et al. (2019) trains Trans-AR on large-scale Reddit data and then jointly trains on 12 dialogue sub-tasks based on BERT, and Bao et al. (2019) trains a variant of Trans-AR on large-scale Reddit and Twitter data based on BERT. Some recent studies have increased the model size to billions of parameters and utilize even more training data, e.g. Reddit, to train a conversational model from scratch (Adiwardana et al., 2020; Roller et al., 2020; Bao et al., 2020b).

In general, these studies show that all the 4 frameworks can produce good results, and increasing the model size and training data is an effective method to further improve performance. However, behind the success story, the question of suitability

	Twitter	Ubuntu	Reddit
Train Set	2M	1.5M	3M
Valid Set	60K	30K	80K
Test Set	20K	20K	20K

Table 2: Key characteristics of the three public datasets. For each dataset, we also evaluate model performance using **100K** training data and the same test set.

of a framework is masked. To investigate this question, we do not follow the current trend to increase the model size and training data. Instead, we are interested in the behaviors of different frameworks on the same datasets and to understand the reasons.

3 Experiments

3.1 Datasets

We use all the three large-scale unlabeled dialogue datasets in Shuster et al. (2019). Some important characteristics of the datasets are summarized in Table 2. We are interested in the behaviors of the models in two cases: 1) further pre-training on large dialogue data based on a pre-trained LM; and 2) fine-tuning on a small dialogue corpus based on a pre-trained LM. Our large datasets contain a few million samples, and the small datasets consist of 100K samples[3]. Although the datasets are smaller than those used in several previous studies, we believe that a comparison of different models on the same data, and the contrast between large and small datasets, can reveal interesting trends, which we will explain with respect to discrepancies.

Specifically, we choose the following 3 datasets: **Twitter Dialogue Corpus** [4] is collected from Twitter consisting of 2.6M (message, response) pairs. We filtered out samples with history length longer than 72 words (to limit the computation) or shorter than 6 words (not enough information). Samples whose response is longer than 36 words or shorter than 6 words are also removed. As a result, 2M samples are kept. **Reddit Conversational Corpus** [5](Dziri et al., 2019) is a 3-turn conversational dataset collected from 95 selected subreddits. **Ubuntu Dialogue Corpus V2.0** [6] (Lowe et al., 2017) contains two-person conversations extracted from the Ubuntu chat logs of technical support for various Ubuntu-related problems.

3.2 Implementation Details

We use open-source implementations for all four frameworks. Only minor adaptations (e.g. for data loading) have been made. The pre-trained language models used by these frameworks in previous studies have comparable number of parameters ($\sim$ 110M), while the pre-training data are in different scales: Trans-ED $<$ Trans-MLM/AR $<$ Trans-Dec. We assume that the difference is trivial when there are millions of dialogue data. In this study, we use the same data for all the frameworks. More implementation details of each framework and the full comparison among pre-trained LM are given in Appendix C.

We also equip all frameworks with an identical decoding script[7] to avoid extra factor affecting the generation quality, which uses beam search with beam size of 4, prevents duplicated uni-grams, and sets minimum response length that encourages diverse generation as in Roller et al. (2020). The minimum response length is set to make the average length of generated responses match with the average target length of the dataset. Generation results are evaluated after applying an identical word tokenization method. With two P100 GPU devices, the maximum input length is set to 128, and we fine-tune all models for 6 epochs and apply early stopping based on the performance on validation set. Our methods (PF-free and FG-free, which will be described in Section 4.1) do not add parameters or increase runtime in comparison with Trans-MLM.

3.3 Evaluation

Automatic Metrics We compare the similarity between generated responses and ground-truth responses using[8]: **BLEU** (Papineni et al., 2002) evaluating how many n-grams (n=1,2,3) overlapped; **CIDEr** (Vedantam et al., 2015) utilizing TF-IDF weighting for each n-gram. Besides, we evaluate response diversity using **Distinct** (denoted Dist) (Li et al., 2016) that indicates the proportion of unique n-grams (n=1,2) in the entire set of generated responses.

---

[3] Labeled datasets such as persona (Zhang et al., 2018) and emotion (Rashkin et al., 2019) are usually in similar scale.

Table 4: Evaluation results on large-scale (upper half) and small-scale (lower half) Ubuntu dataset.

Human Evaluation Furthermore, we ask human evaluators to rate a response in $\{0, 1, 2\}$. 2 represents a coherent and informative response. Details are given in Appendix D. We also do a pair-wise evaluation to compare two models and indicate which one is better. To reduce time cost, we only perform human evaluations on Twitter and Reddit datasets that are closer to daily dialogue. However, during evaluation, we observe that $\sim 65\%$ Reddit data are professional discussions that are difficult to understand. The percentage is $\sim 30\%$ for Twitter data. These test samples are discarded, and at the end the test set for each dataset consists of 200 random samples. The inter-rater annotation agreement in Cohen's kappa (Cohen, 1960) is 0.44 and 0.42 for Twitter and Reddit, which indicates moderate agreement.

In addition to the 4 frameworks, we also include two general RNN-based baseline frameworks – SEQ2SEQ-MMI (Li et al., 2016) and HRED-MMI (Serban et al., 2016) to show how pre-trained models perform against them.

3.4 Architecture Analysis

We first examine architecture appropriateness on the large-scale data setting, since when data are limited pretrain-finetune discrepancy and the size of pre-training data may strongly influence the results. Appendix E shows some generation samples. Our global observation is that Trans-Dec and Trans-AR are the best choice for large-scale data setting, e.g. further dialogue pre-training based on a pre-trained LM.

Left-to-Right Only vs. Bi-Direction on the Source Human evaluation results in response appropriateness (Table 6 and 7) show that Trans-Dec and Trans-AR generate most appropriate responses. According to automatic metrics, Trans-AR applying bi-directional attention on the source side obtains the highest BLEU and CIDEr scores on all

Table 7: Human evaluation on Reddit dataset.

three million-scale datasets. We believe that bidirectional attention helps the model to better encode the dialogue history. In contrast, Trans-Dec is able to generate the most diverse responses. We attribute it to the left-to-right attention that introduces less constraints than bidirectional attention, thus has a higher flexibility for generation.

Trans-MLM vs. AR With large data, Trans-AR substantially outperforms Trans-MLM in terms of both automatic and human evaluation. When eliminating the finetune-generation discrepancy of Trans-MLM, i.e. FG-free (we will introduce in Section 4.2), the performance is improved while still having a small gap especially in automatic metrics to Trans-AR. This may be because MLM objective only masks a certain percentage of tokens (40%) while AR objective predicts all tokens on the target side for training. Thus, the AR objective is more training-efficient. Similar observation about the efficiency of MLM has been reported in Clark et al. (2020). However, when training data are limited, we will show that it is better to use MLM objective which has smaller pretrain-finetune discrepancy.

Trans-ED vs. Decoder-Only With large dialogue data, we assume the size of pre-training data and pretrain-finetune discrepancy only have small influence on performance. However, even comparing with Trans-MLM(FG-free)/AR, Trans-ED generates much less diverse or appropriate responses. We also observe lower speed for convergence when training the model [9]. We believe that the result is more or less due to the main difference in architecture: an explicit encoder in Trans-ED might be

---

[9] Similar observation has been reported in: `https://github.com/atselousov/transformer_chatbot/issues/15`

redundant (Liu et al., 2018).

3.5 Discrepancy Impact

In section 2, we have discussed the pretrain-finetune discrepancy of each framework. When a large training dataset is available, the impact of pretrain-finetune discrepancy is less severe since the model can be gradually adapted to the given task. However, if the training data are limited, the discrepancy problems may surface. Evaluation results, especially in human evaluation, show that the performance is more reduced with small data if the framework has larger discrepancy. For example, by comparing Trans-MLM (FG-free) and Trans-AR, the latter having additional pretrain-finetune discrepancy due to its auto-regressive objective, we see that the performance of Trans-AR drops more when trained on a small dataset. Trans-MLM (FG-free) and Trans-Dec that have small pretrain-finetune discrepancy have clear advantage over other frameworks according to human evaluation.

These results suggest that with a small dataset one should reduce pretrain-finetune discrepancy to best exploit pre-trained LM. In the next section, we propose 2 methods to reduce pretrain-finetune discrepancy and finetune-generation discrepancy of Trans-MLM.

4 Discrepancy-Free Trans-MLM

4.1 Pretrain-Finetune Discrepancy

The discrepancy of Trans-MLM comes from the left-to-right attention on the target side that has not been pre-trained in BERT. Therefore, this discrepancy cannot be eliminated during fine-tuning for a generation task. However, we can alleviate the discrepancy by using bi-directional attention also on the target side. Specifically, at inference time, to generate a new token denoted as g_t, [MASK] is fed into t-th position, denoted as g_t-M. Previously generated tokens $g_{<t}$ could be viewed as a special type of dialogue history, and thus we can apply bi-directional attention on it.

However, in this case, the corresponding training process will have efficiency problems – only one token can be masked in each training sample; otherwise, there will be conflict for the self-attention mask (Appendix B). This would lead to much lower training efficiency: the loss on validation set only decreases slightly to 5.39 from 6.27 after four epochs, while Trans-MLM masking 40% of the target tokens can reduce it to 4.35. To avoid this situation, we cannot always update previous hidden states using bi-directional attention in generation. Therefore, we explore to set a time-step interval for bi-directional attention on the target side – within the interval we apply left-to-right attention and at the end of an interval we apply bi-directional attention. The corresponding training method allows us to mask multiple target tokens at the same time to guarantee training efficiency.

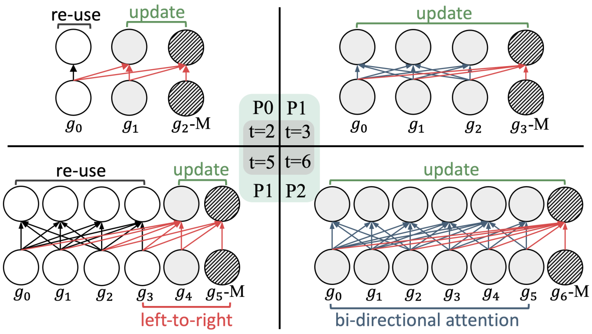

Figure 2: The generation process of PF-free at 4 different time steps. Bi-attention interval is 3 in the graph.

Figure 2 illustrates the generation process of our method with interval of 3. Before time step 3, left-to-right attention is used (e.g. t=2). At time step 3, bidirectional attention is allowed. Then left-to-right attention is used (e.g. t=5) before the end of next interval cycle (t=6). Accordingly, the training process is: given a target response, we first randomly select among all (3 in the figure because t=3 and t=5 are the same pattern) possible attention patterns (e.g. the case of t=3 or t=5 in Figure 2, where we apply bi-directional attention only on $y_{0,1,2}$); then in the part of left-to-right attention, we randomly mask several tokens. We can mask multiple tokens because this part applies left-to-right attention and the masks at other positions will not influence the prediction on a given mask. We call this method **PF-free**, which means that the pretrain-finetune discrepancy is reduced.

4.2 Finetune-Generation Discrepancy

A model having finetune-generation discrepancy means the way that it is used in generation (inference/test) is different from the way it has been trained. Only Trans-MLM has finetune-generation discrepancy because of its MLM objective as shown in Figure 3: during training, there is a masked token, y_1-M, before y_2-M, while in inference there is not a masked token before when generating the token for g_2-M.

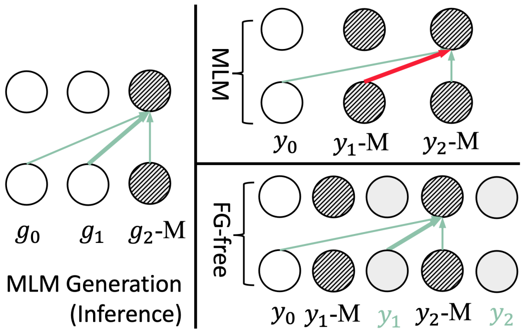

Figure 3: The training process of vanilla Trans-MLM and FG-free. We only plot the attention connection at the second position.

To deal with the problem, we propose that at training time, rather than replacing the tokens with [MASK] as in vanilla MLM, we keep all original input tokens unchanged and prepend [MASK] tokens in the input sequence as illustrated. The prepended [MASK] token uses the same position embedding of the corresponding token. Then, every position after y_1-M attends to y_1 instead of the [MASK] token, and thus the finetune-generation discrepancy of MLM is eliminated. We call the modified model **FG-free**. A similar method has also been explored in (Bao et al., 2020a), where they introduced an extra pseudo mask in addition to [MASK] and prepend it before the original token in order to handle factorization steps of their partially auto-regressive language model.

4.3 Experimental Results

The results with PF-free, FG-free and PF&FG-free models on small-scale datasets are reported in previous tables together with other models. We can see that each of the proposed methods brings some improvement. PF-free improves most automatic metrics over Trans-MLM, but the response appropriateness in human evaluation is not improved. We observe that PF-free could generate some responses that lack fluency, which also influences PF&FG-free (Appendix E). In general, our exploration shows that the left-to-right attention on the target side is necessary for a generative task.

We examine our FG-free method on both large and small-scale data. It always brings statistically significant improvement over Trans-MLM in all automatic metrics, and generates more appropriate responses. On small-scale datasets, it outperforms all other frameworks in similarity metrics and achieve comparable performance in response appropriateness to Trans-Dec that has leveraged much more pre-training data.

This set of experimental results confirm the usefulness of reducing discrepancies in the model. This demonstrates that model discrepancies are indeed important problems we need to address when a pre-trained LM is used for dialogue generation, and the problems have been under-explored.

Conclusion

In this paper, we examined the 4 frameworks for open-domain dialogue based on pre-trained models. We compared their performances on several datasets with the same setting. The comparison revealed that Trans-Dec and Trans-AR are both good choices when large-scale data are available, e.g. further dialogue pre-training. When data are limited, e.g. fine-tuning on small dialogue tasks, Trans-Dec is the most appropriate.

Furthermore, we defined the concept of pretrain-finetune and finetune-generation discrepancy, and examined the 4 frameworks with respect to these concepts. We have shown that the performances of the 4 frameworks can be largely explained by their respective discrepancies, which hinder their performances. This becomes more clear when the dataset is small.

To further show that reducing the discrepancies can improve the performance, we designed PF-free and FG-free correction methods to reduce the discrepancies on Trans-MLM, and tested the corrected Trans-MLM models on the datasets. Our results confirmed that once discrepancies are eliminated, Trans-MLM can produce better results.

This study is the first investigation on the widely used 4 frameworks based on pre-trained LM in terms of architectural appropriateness and discrepancies. We believe that this question is important to understand how a pre-trained model can be used in dialogue generation. It deserves more investigations in the future.

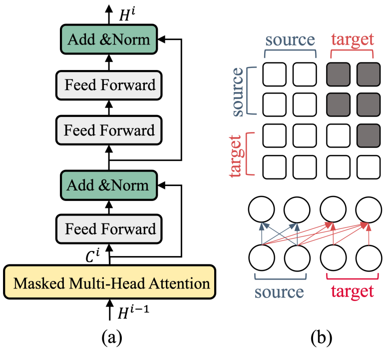

Figure 4: i-th Transformer Block and two $\mathbf{M}$ settings represented in two ways. Shaded areas are blocked.

A Multi-Layer Transformer

In this section, we provide some background knowledge on Transformer. The four frameworks we discussed all consist of 12 Transformer blocks. Figure 4 (a) shows a general architecture of a Transformer layer, where the most important component is the masked multi-head self-attention. The setting of attention masks is the largest difference between Trans-Dec and Trans-AR, and it is also the most critical part to implement our PF-free and FG-free methods.

The input representation $\mathbf{H}^0 \in \mathbb{R}^{n \times d_h}$, where n is the input length and $d_h = 768$ is the hidden dimension, is the sum of token embedding, position embedding, and type embedding at each position. Then, $\mathbf{H}^0$ is encoded into hidden representations of i-th layer $\mathbf{H}^i = [\mathbf{h}^i_1, ..., \mathbf{h}^i_n]$ by: $\mathbf{H}^i = \text{Trans}^i(\mathbf{H}^{i-1}), \quad i \in [1, L]$, where Trans^i denotes the i-th Transformer Block as shown in Figure 4 (a). The core component of a transformer block is the masked multi-head attention, whose outputs are $\mathbf{C}^i = [\mathbf{c}^i_1, ..., \mathbf{c}^i_n]$ that are computed via $\mathbf{C}^i = \text{Concat}(\mathbf{head}_1, ..., \mathbf{head}_h)$, with

$$\mathbf{head}_j = \text{softmax}(\frac{\mathbf{Q}_j \mathbf{K}_j^T}{\sqrt{d_k}} + \mathbf{M})\mathbf{V}_j \qquad (1)$$

where $\mathbf{Q}_j, \mathbf{K}_j, \mathbf{V}_j \in \mathbb{R}^{n \times d_k}$ are obtained by transforming $\mathbf{H}^{i-1} \in \mathbb{R}^{n \times d_h}$ using $\mathbf{W}^Q_j, \mathbf{W}^K_j, \mathbf{W}^V_j \in \mathbb{R}^{d_h \times d_k}$ respectively. $\mathbf{M} \in \mathbb{R}^{n \times n}$ is the **self-attention mask matrix** that determines whether a position can attend to other positions. $\mathbf{M}_{ij} \in \{0, -\infty\}$. In particular, $\mathbf{M}_{ij} = 0$ allows the i-th position to attend to j-th position and $\mathbf{M}_{ij} = -\infty$ prevents from it. Figure 4 (b&c) shows two $\mathbf{M}$ settings that are applied by Trans-MLM/AR and Trans-Dec respectively.

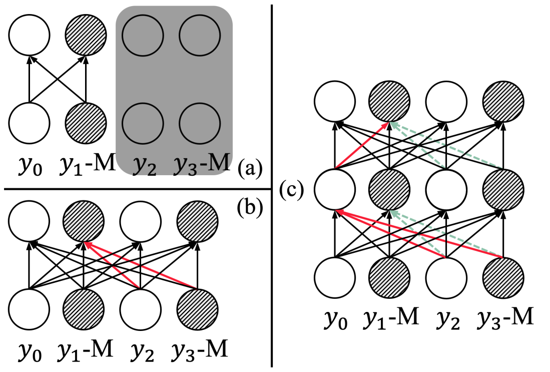

Figure 5: Self-attention mask, $\mathbf{M}$, conflicts – (a) if predicting y_1, y_2 and y_3-M are "future" and forbidden to be accessed by y_1-M; (b) if predicting y_3, y_1-M accesses to y_2 and y_3-M, which causes conflicts to $\mathbf{M}^{(a)}$; (c) if forbidding y_1-M to access to y_2 and y_3-M in $\mathbf{M}^{(b)}$, there will still be (indirect) information leak as indicated in red arrows (y_2 and y_3-M → y_0 → y_1-M). Masking two positions thus causes conflicts. Our PF-free method aims to overcome this problem.

B Illustration of Attention Conflict

If applying bi-directional attention at each generation step, only one token at the target side could be masked for each training sample; otherwise there will be attention conflicts, i.e. different self-attention mask matrices are required for different masked tokens, while only one mask matrix can be provided per training sample. In Figure 5, we provide an illustration of the mask conflict problem. We assume y_1 and y_3 are masked and need to be predicted at the same time. We see in the figure that two different masks are required for predicting y_1 and y_3, which cannot be done in a single training step, making it impossible to mask more than one token in each step.

C Implementation Details

For the 4 frameworks, we used open-source implementations. Only some minor adaptations to our data and task are made (e.g. re-wrote the data loader to load our experimental datasets, and modified the training objective by keeping only the response reconstruction loss). For response generation, we equipped all frameworks with an identical decoding script [10]. We did not modify other parts, and used the default settings for hyper-parameters, e.g. optimizer and learning rate. Some generation examples are given in Appendix E. Although some models (e.g. Trans-ED) produced poor per-

Model	Pre-trained LM	Data
Trans-ED	GPT (Radford et al., 2018)	BooksCorpus
Trans-Dec	GPT-2 small (Radford et al., 2019)	WebText
Trans-MLM/AR	BERT base (Devlin et al., 2018)	BooksCorpus, English Wikipedia

Table 8: The text data used for language model pre-training.

formance on small datasets, all model can generate some coherent and fluent responses with large scale training data, which is consistent with the performances reported in previous papers.

Language Models The pre-trained language models used by these frameworks have comparable number of parameters as listed in Table 9, while the pre-training data are in different scales as described in Table 8. BooksCorpus (Zhu et al., 2015) (800M words) contains over 7,000 unique unpublished books from a variety of genres. English Wikipedia (2,500M words) consists of the text passages of Wikipedia extracted by Devlin et al. (2018). WebText crawled by Radford et al. (2019) contains 8M diverse documents for a total of 40 GB of text.

Trans-ED We use the implementation of ConvAI2 champion [11]. The model was for persona-conditioned dialogue generation. The framework is based on GPT architecture and uses GPT for parameter initialization. However they only provide a model checkpoint that has been fine-tuned on large-scale dialogue data including Reddit. To examine the ability of utilizing pre-trained LM, we did not use this checkpoint but initialize the model with GPT parameters [12]. We also did not apply post-processing to the generation results (to be consistent with other experiments).

Trans-Dec We use the released code of Wolf et al. (2019)[13] that uses GPT-2 small by default. The model was for persona-conditioned dialogue generation.

Trans-MLM/AR These two models are implemented based on Dong et al. (2019) [14] that applies multi-task learning on language understanding and generation tasks. We use BERT (base, uncased) for parameter initialization, and fine-tune it on dialogue datasets. PF-free and FG-free are also implemented based on the code. We set the bi-directional attention interval of PF-free to 5. Since the average length of ground-truth responses in the datasets is ~ 15, This setting is generally appropriate.

Model	Params	Runtime
SEQ2SEQ-MMI	66M	50
HRED-MMI	58M	25
Trans-ED	117M	180
Trans-Dec	117M	290
Trans-MLM	110M	140
Trans-AR	110M	140
PF&FG-free	110M	140

Table 9: The number of parameters of each tested approach and the average runtime (minutes) for every million training samples. The runtime is tested using a 1080Ti GPU device, and the batch size is set to take all of the GPU memories. Notice that the runtime will be influenced by code implementation in addition to model structure.

D Human Evaluation Details

Some existing studies considered response fluency, coherence, and informativeness. We make the manual evaluation simpler and ask the human evaluators to rate a response in $\{0, 1, 2\}$. A score of 0 represents an unacceptable response, which might have flaw in fluency and logic or be incoherent. Special cases are for example completely coping from the dialogue history as the output, and a bland response such as “i do not know what you are talking about , but it ’s a good point .”. A score of 1 represents an acceptable response, but it is generic or not perfectly coherent to the dialogue history. 2 represents a coherent and informative response.

Abstract

ELECTRA (Clark et al., 2020a) pretrains a discriminator to detect replaced tokens, where the replacements are sampled from a generator trained with masked language modeling. Despite the compelling performance, ELECTRA suffers from the following two issues. First, there is no direct feedback loop from discriminator to generator, which renders replacement sampling inefficient. Second, the generator's prediction tends to be over-confident along with training, making replacements biased to correct tokens. In this paper, we propose two methods to improve replacement sampling for ELECTRA pre-training. Specifically, we augment sampling with a hardness prediction mechanism, so that the generator can encourage the discriminator to learn what it has not acquired. We also prove that the efficient sampling reduces the training variance of the discriminator. Moreover, we propose to use a focal loss for the generator in order to relieve oversampling correct tokens as replacements. Experimental results show that our method improves ELECTRA pre-training on various downstream tasks. Our code and pre-trained models will be released at: `https://github.com/YRdddream/electra-hp`

1 Introduction

One of the most successful language model pre-training tasks is masked language modeling (MLM; Devlin et al. 2019). First, we randomly mask some input tokens in a sentence. Then the encoder learns to recover the masked tokens given the corrupted input. ELECTRA (Clark et al., 2020a) argues that MLM only produces supervision signals at a small proportion of positions (usually 15%), and uses the replaced token detection task as an alternative. Specifically, ELECTRA contains a generator and a discriminator. The generator is a masked language model, which substitutes masks with the tokens sampled from its MLM predictions. The discriminator learns to distinguish which tokens have been replaced or kept the same. Experimental results on downstream tasks show that ELECTRA can largely improve sample efficiency.

Despite achieving compelling performance, it is usually difficult to balance the training pace between the generator and the discriminator. Along with pre-training, the generator is expected to sample more hard replacements for the detection task in a curriculum manner, while the discriminator learns to identify the corrupted positions. Although the two components are designed to compete with each other, there is no explicit feedback loop from the discriminator to the generator, rendering the learning games independent. The absence of feedback results in sub-efficient learning, because many replaced tokens have been successfully trained while the generator does not know how to effectively sample replacements. In addition, a well trained generator tends to achieve reasonably good MLM accuracy, where many sampled replacements are correct tokens. In order to relieve the issue of oversampling correct tokens, ELECTRA explored tweaking the mask probability larger, raising the sampling temperature, and using a manual rule to avoid sampling original tokens.

In this paper, we propose two methods, namely hardness prediction and sampling smoothing, to tackle the above issues. First, the motivation of *hardness prediction* is to sample the replacements that the discriminator struggles to predict correctly. We elaborate on the benefit of a good replacement mechanism from the perspective of variance reduction. Theoretical derivations indicate that the replacement sampling should be proportional to both the MLM probability (i.e., language frequency) and the corresponding discriminator loss (i.e., discrimination hardness). Based on the above conclu-

August 1–6, 2021.

sion, we introduce a sampling head in the generator, which learns to sample by estimating the expected discriminator loss for each candidate replacement. So the discriminator can give feedback to the generator, which helps the model to learn what it has not acquired. Second, we propose a *sampling smoothing* method for the issue of oversampling original tokens. We adopt a focal loss (Lin et al., 2017) for the generator's MLM task, rather than using cross-entropy loss. The method adaptively down-weights the well-predicted replacements for MLM, which avoids sampling too many correct tokens as replacements.

We conduct pre-training experiments on the WikiBooks corpus for both small-size and base-size models. The proposed techniques are plugged into ELECTRA for training from scratch. Experimental results on various tasks show that our methods outperform ELECTRA despite the simplicity. Specifically, under the small-size setting, our model performance is 0.9 higher than ELECTRA on MNLI (Williams et al., 2018) and 4.2 higher on SQuAD 2.0 (Rajpurkar et al., 2016a), respectively. Under the base-size setting, our model performance is 0.26 higher than ELECTRA on MNLI and 0.52 higher on SQuAD 2.0, respectively.

2 Related Work

State-of-the-art NLP models are mostly pretrained on a large unlabeled corpus with the self-supervised objectives (Peters et al., 2018; Lan et al., 2020; Raffel et al., 2020). The most representative pretext task is masked language modeling (MLM), which is introduced to pretrain a bidirectional BERT (Devlin et al., 2019) encoder. RoBERTa (Liu et al., 2019) apply several strategies to enhance the BERT performance, including training with more data and dynamic masking. UniLM (Dong et al., 2019; Bao et al., 2020) extend the mask prediction to generation tasks by adding the auto-regressive objectives. XLNet (Yang et al., 2019) propose the permuted language modeling to learn the dependencies among the masked tokens. Besides, ELECTRA (Clark et al., 2020a) propose a novel training objective called replaced token detection which is defined over all input tokens. Moreover, ELECTRIC (Clark et al., 2020b) extends the idea of ELECTRA by energy-based cloze models.

Some prior efforts demonstrate that sampling more hard examples is conducive to more effective training. Lin et al. (2017) propose the focal loss in order to focus on more hard examples. Generative adversarial networks (Goodfellow et al., 2014) is trained to maximize the probability of the discriminator making a mistake, which is closely related to ELECTRA's training framework. In this work, we aim at guiding the generator of ELECTRA to sample the replacements that are hard for the discriminator to predict correctly, therefore the pre-training process of the discriminator can be more efficient.

3 Background: ELECTRA

An overview of ELECTRA is shown in Figure 1. The model consists of a generator G and a discriminator D. The generator is trained by masked language modeling (MLM). Formally, given an input sequence $\boldsymbol{x} = x_1 \cdots x_n$, we first randomly mask $k = \lceil 0.15n \rceil$ tokens at the positions $\boldsymbol{m} = m_1 \cdots m_k$ with `[MASK]`. The perturbed sentence $\boldsymbol{c}$ is denoted as:

$$\begin{aligned} m_i &\sim \text{uniform}\{1, n\} \quad \text{for } i = 1, \cdots, k \\ \boldsymbol{c} &= \text{replace}(\boldsymbol{x}, \boldsymbol{m}, \texttt{[MASK]}) \end{aligned}$$

where the replace operation conducts masking at the positions $\boldsymbol{m}$. The generator encodes $\boldsymbol{c}$ and performs MLM prediction. At each masked position i, we sample replacements from MLM output distribution p_{G}:

$$\begin{aligned} {x'}_i &\sim p_{\mathrm{G}}(x'_i|\boldsymbol{c}) \quad \text{for } i \in \boldsymbol{m} \\ \boldsymbol{x}^{\mathrm{R}} &= \text{replace}(\boldsymbol{x}, \boldsymbol{m}, \boldsymbol{x'}) \end{aligned}$$

where masks are replaced with the sampled tokens. Next, the discriminator encodes the corrupted sentence $\boldsymbol{x}^{\mathrm{R}}$. A binary classification task learns to distinguish which tokens have been replaced or kept the same, which predicts the probability $D(x_t^{\mathrm{R}}, \boldsymbol{x}^{\mathrm{R}})$ to indicate how likely x_t^{R} comes from the true data distribution.

The overall pre-training objective is defined as:

$$\min_{\theta_G,\theta_D} \sum_{\boldsymbol{x}\in\mathcal{X}} \mathop{\mathbb{E}}_{i\in\boldsymbol{m}} [\mathcal{L}_G^{\theta_G}(x_i,\boldsymbol{c})] + \lambda \mathop{\mathbb{E}}_{t\in[1,n]} [\mathcal{L}_D^{\theta_D}(x_t^{\mathrm{R}},\boldsymbol{x}^{\mathrm{R}})]$$

$$\mathcal{L}_G(x_i, \boldsymbol{c}) = -\log p_{\mathrm{G}}(x_i|\boldsymbol{c})$$

$$\mathcal{L}_D(x_t^{\mathrm{R}}, \boldsymbol{x}^{\mathrm{R}}) = \begin{cases} -\log D(x_t^{\mathrm{R}}, \boldsymbol{x}^{\mathrm{R}}) & x_t^{\mathrm{R}} = x_t \\ -\log(1 - D(x_t^{\mathrm{R}}, \boldsymbol{x}^{\mathrm{R}})) & x_t^{\mathrm{R}} \neq x_t \end{cases}$$

where $\mathcal{X}$ represents text corpus, and $\lambda = 50$ suggested by Clark et al. (2020a) is a hyperparameter used to balance the training pace of generator and discriminator. Once pre-training is finished, only the discriminator is fine-tuned on downstream tasks.

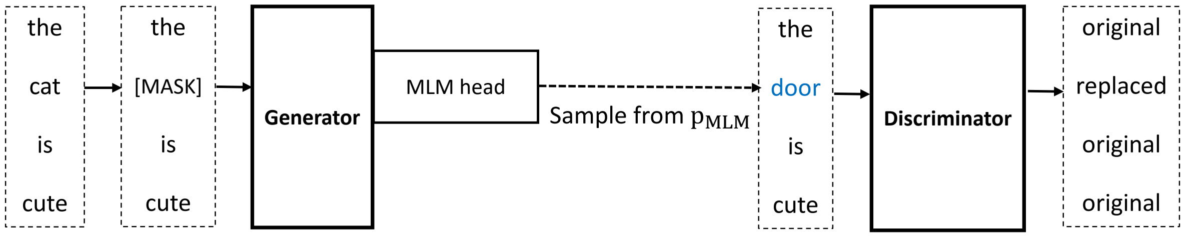

Figure 1: An overview of ELECTRA. The MLM head of the generator learns to perform MLM and samples replacements at each masked position from the MLM distribution. For the corrupted sequence, the discriminator learns to distinguish which tokens have been replaced or kept the same.

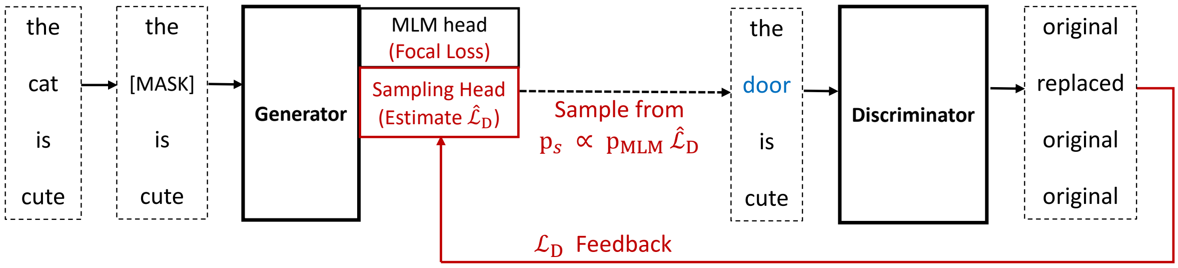

Figure 2: An overview of our model. The generator has two prediction heads. The MLM head learns to perform MLM through the focal loss instead of the cross entropy loss. The sampling head is trained to estimate the discriminator loss over the vocabulary. Our model samples the replacements from a new distribution, which is proportional to both the MLM probability and the corresponding discriminator loss. The discriminator is trained to distinguish input tokens and the loss feedback is transferred to the generator for the sampling head to learn.

4 Methods

4.1 Hardness Prediction

The key idea of hardness prediction is to let the generator receive the discriminator's feedback and sample more hard replacements. Figure 2 shows the overview of our method. Besides the original MLM head in the generator, there is an additional sampling head used to sample replaced tokens.

Given a[1] replaced token x' in the input sequence c, let $\mathcal{L}_D(x', c)$ denote the discriminator loss for the replacement. Rather than directly sampling replacements from the MLM prediction p_{G}, we propose to sample from p_{S}:

$$p_{\mathrm{S}}(x'|c) = \frac{p_{\mathrm{G}}(x'|c)\mathcal{L}_D(x',c)}{\mathrm{E}_{p_{\mathrm{G}}(x^*|c)}[\mathcal{L}_D(x^*,c)]} \qquad (1)$$

$$\boldsymbol{x}^{\mathrm{R}} = \mathrm{replace}(\boldsymbol{x},\boldsymbol{m},\boldsymbol{x}') \quad x' \sim p_{\mathrm{S}}(x'|c)$$

where the corrupted sentence $\boldsymbol{x}^{\mathrm{R}}$ is obtained by substituting the masked positions $\boldsymbol{m}$ with sampled replacements $\boldsymbol{x}'$. The first term $p_{\mathrm{G}}(x'|c)$ implies sampling from the data distribution. The second term $\mathcal{L}_D(x', c)$ encourages the model to sample more replacements that the discriminator has not successfully learned.

Notice that Equation (1) uses the actual discriminator loss $\mathcal{L}_D(x', c)$, which can not be obtained without feeding $\boldsymbol{x}^{\mathrm{R}}$ into the discriminator. As an alternative, we use the estimated loss value $\hat{\mathcal{L}}_D(x', c)$ to sample replaced tokens, which approximates the actual loss for the candidate replacement. During pre-training, we use the actual loss as supervision, and simultaneously train the sampling head. We describe the detailed implementations of loss estimation in Section 4.1.2.

By considering detection hardness in replacement sampling and giving feedback from the discriminator to the generator, the components are no longer independently learned. ELECTRA (Clark et al. 2020a; Appendix F) also attempts to achieve the same goal by adversarially training the generator. However, it underperforms the maximum-likelihood training, because of the poor sample efficiency of reinforcement learning on discrete text data. More importantly, their generator is trained to fool the discriminator, rather than guiding the discriminator by data distribution, which breaks the ELECTRA training objective. In contrast, we still retain the MLM head, and decouple it from re-

---

[1] For notation simplicity, we assume only one token is masked in each sentence.

placement sampling. So we can take the advantage of the original training objective.

4.1.1 Perspective of Variance Reduction

We show that the proposed hardness prediction method is well supported from the perspective of variance reduction.

Proposition 1. *Sampling replacements from $p_S(x'|c)$ can minimize the estimation variance of the discriminator loss.*

Proof. At each masked position, the expectation of the discriminator loss we aim to estimate can be summarized as $Z = E_{p_G(x^*|c)}[\mathcal{L}_D(x^*, c)]$. Under p_G, the estimation variance of the discriminator loss is:

$$\begin{aligned}&\mathrm{Var}_{p_G(x^*|c)}[\mathcal{L}_D(x^*, c)]\\ =&\sum_{x^*\in\text{vocab}} p_G(x^*|c)(\mathcal{L}_D(x^*, c) - Z)^2\\ =&\sum_{x^*\in\text{vocab}} p_G(x^*|c)\mathcal{L}_D(x^*, c)^2 - Z^2\end{aligned}$$

Similar to importance sampling, we can select an alternative distribution p_S different from p_G, then the expectation Z is rewritten as:

$$\begin{aligned}&E_{p_G(x^*|c)}[\mathcal{L}_D(x^*, c)]\\ =&\sum_{x^*\in\text{vocab}} p_G(x^*|c)\mathcal{L}_D(x^*, c)\\ =&\sum_{x^*\in\text{vocab}} p_S(x^*|c)\frac{p_G(x^*|c)}{p_S(x^*|c)}\mathcal{L}_D(x^*, c)\\ =&E_{p_S(x^*|c)}[\frac{p_G(x^*|c)}{p_S(x^*|c)}\mathcal{L}_D(x^*, c)]\end{aligned}$$

By making a multiplicative adjustment to $\mathcal{L}_D$, the estimation variance of Z under the new sampling distribution p_S is converted to:

$$\begin{aligned}&\mathrm{Var}_{p_S(x^*|c)}[\frac{p_G(x^*|c)}{p_S(x^*|c)}\mathcal{L}_D(x^*, c)]\\ =&\sum_{x^*\in\text{vocab}} p_S(\frac{p_G(x^*|c)\mathcal{L}_D(x^*, c)}{p_S})^2 - Z^2\\ =&\sum_{x^*\in\text{vocab}} \frac{(p_G(x^*|c)\mathcal{L}_D(x^*, c) - p_S(x^*|c)Z)^2}{p_S(x^*|c)}\end{aligned}$$

Based on the above derivation, it is obvious that we obtain a zero-variance estimator when we choose $p_S(x^*|c) = p_G(x^*|c)\mathcal{L}_D(x^*, c)/Z$ as Equation (1). This theoretically optimal form provides us insights into designing the above sampling scheme. □

4.1.2 Two Implementations of Hardness Prediction

We design two variants of the sampling head. The first one is to explicitly estimate the discriminator loss (HP_{Loss}). The second method is to approximate the expected sampling distribution (HP_{Dist}).

HP_{Loss} guides the generator to learn the probability predicted by the discriminator that the sampled token x' is an original token. In this case, the output layer of the sampling head is actually a $\mathrm{sigmoid}$ function same as the discriminator:

$$\hat{D}(x', c) = \mathrm{sigmoid}(\boldsymbol{w}(x') \cdot \boldsymbol{h}_S(c))$$

where $\boldsymbol{h}_S(c)$ denotes the contextual representations projected by the sampling head, and $\boldsymbol{w}$ denotes the projection parameters. Then the loss of the sampling head at the masked position is:

$$\mathcal{L}_S(x', c) = (\hat{D}(x', c) - D(x', c))^2$$

When sampling replacements over the vocabulary, the estimated discriminator probability $\hat{D}(x', c)$ can be easily rewritten to the estimated discriminator loss $\hat{\mathcal{L}}_D(x', c)$:

$$\hat{\mathcal{L}}_D(x', c) = \begin{cases} -\log \hat{D}(x', c) & x' = x \\ -\log(1 - \hat{D}(x', c)) & x' \neq x \end{cases}$$

Multiplying the MLM probability factor p_G, we obtain the sampling distribution:

$$\begin{aligned}p_S(x'|c) &= \frac{p_G(x'|c)\hat{\mathcal{L}}_D(x', c)}{\sum_{x^*\in\text{vocab}} p_G(x^*|c)\hat{\mathcal{L}}_D(x^*, c)}\\ &= \frac{p_G(x'|c)\hat{\mathcal{L}}_D(x', c)}{E_{p_G(x^*|c)}[\hat{\mathcal{L}}_D(x^*, c)]}\end{aligned}$$

HP_{Dist} aims to directly approximate the expected sampling distribution as in Equation (1), instead of the discriminator loss. In this case, the sampling head produces an output probability of the token x' with a $\mathrm{softmax}$ layer:

$$p_S(x'|c) = \frac{\exp(\boldsymbol{e}(x') \cdot \boldsymbol{h}_S(c))}{\sum_{x^*\in\text{vocab}} \exp(\boldsymbol{e}(x^*) \cdot \boldsymbol{h}_S(c))} \quad (2)$$

where $\boldsymbol{e}$ represents the token embeddings. For the sampled token x', we define the loss of the sampling head as:

$$\mathcal{L}_S(x', c) = -\frac{p_G(x'|c)}{p_S(x'|c)}\mathcal{L}_D(x', c)\log p_S(x'|c)$$

Then we show that minimizing the above loss $\mathcal{L}_S(x', c)$ pushes sampling distribution of Equation (2) to our goal. Specifically, the loss expectation over the whole vocabulary is:

$$\begin{aligned}
&\mathrm{E}_{p_{\mathrm{S}}(x^*|c)}[\mathcal{L}_S(x^*, c)] = \\
&-\sum_{x^* \in \text{vocab}} p_{\mathrm{S}}(x^*|c)\frac{p_{\mathrm{G}}(x^*|c)}{p_{\mathrm{S}}(x^*|c)}\mathcal{L}_D(x^*, c)\log p_{\mathrm{S}}(x^*|c) \\
&= -\sum_{x^* \in \text{vocab}} p_{\mathrm{G}}(x^*|c)\mathcal{L}_D(x^*, c) \log p_{\mathrm{S}}(x^*|c)
\end{aligned}$$

According to the Lagrange Multiplier method, the optimal solution $\tilde{p}_{\mathrm{S}}$ of the loss function $\mathcal{L}_S(x', c)$ is consistent with Equation (1):

$$\begin{aligned}
\tilde{p}_{\mathrm{S}}(x'|c) &= \frac{p_{\mathrm{G}}(x'|c)\mathcal{L}_D(x', c)}{\sum_{x^* \in \text{vocab}} p_{\mathrm{G}}(x^*|c)\mathcal{L}_D(x^*, c)} \\
&= \frac{p_{\mathrm{G}}(x'|c)\mathcal{L}_D(x', c)}{\mathrm{E}_{p_{\mathrm{G}}(x^*|c)}[\mathcal{L}_D(x^*, c)]}
\end{aligned}$$

4.2 Sampling Smoothing

Along with the learning process, the masked language modeling tends to achieve relatively high accuracy. As a consequence, the generator oversamples the correct tokens as replacements, which renders the discriminator learning inefficient.

In order to address the issue, we apply an alternative loss function called focal loss (Lin et al., 2017) for MLM of the generator. Compared with the vanilla cross-entropy loss, focal loss adds a modulating factor for the weighting purpose:

$$\mathcal{L}_G^{\mathrm{fc}}(x, c) = -(1 - p_{\mathrm{G}}(x|c))^\gamma \log p_{\mathrm{G}}(x|c)$$

where $\gamma \geq 0$ is a tunable hyperparameter. Besides using a constant γ, we try the piecewise function $\gamma = \mathbb{1}(p_{\mathrm{G}} > 0.2) * 3 + \mathbb{1}(p_{\mathrm{G}} \leq 0.2) * 5$ in our experiments as suggested by Mukhoti et al. (2020).

In other words, the focal loss is used to adaptively down-weight the well-classified easy examples and thus focusing on more difficult ones. When applying the focal loss to the MLM head for the generator, we notice that if a token is easy for the generator to be predicted correctly, i.e., $p_{\mathrm{G}}(x|c) \rightarrow 1$, the modulating factor is greatly decreased. In contrast, if a token is hard to predict, the focal loss approximates to the original cross entropy loss. Therefore, we propose to employ the focal loss in order to smooth the sampling distribution, which in turn relieves oversampling correct tokens as replacements.

4.3 Pre-Training Objective

Adopting the above two strategies, we jointly train the generator and the discriminator together as the original ELECTRA model. The word embeddings of them are still tied during the pre-training stage. Formally, we minimize the combined loss over a large corpus $\mathcal{X}$:

$$\begin{aligned}
&\min_{\theta_G, \theta_S, \theta_D} \sum_{\boldsymbol{x} \in \mathcal{X}} \Big(\mathop{\mathbb{E}}_{i \in \boldsymbol{m}} [\mathcal{L}_G^{\mathrm{fc}, \theta_G}(x_i, \boldsymbol{c})] + \\
&\lambda_1 \mathop{\mathbb{E}}_{i \in \boldsymbol{m}} [\mathcal{L}_S^{\theta_S}(x_i^{\mathrm{R}}, \boldsymbol{c})] + \lambda_2 \mathop{\mathbb{E}}_{t \in [1,n]} [\mathcal{L}_D^{\theta_D}(x_t^{\mathrm{R}}, \boldsymbol{x}^{\mathrm{R}})] \Big)
\end{aligned}$$

where λ_1, λ_2 are two hyperparameters to adjust three parts of the loss. We only search λ_1 value and keep $\lambda_2 = 50$ for the fair comparison with ELECTRA. After pre-training, we throw out the generator and only fine-tune the discriminator on the downstream tasks.

5 Experiments

5.1 Setup

We implement ELECTRA+HP$_{\mathrm{Loss}}$/HP$_{\mathrm{Dist}}$+Focal on both the *small-size* setting and the *base-size* setting. The two prediction heads share both the generator and the token embeddings, which avoids the unnecessary increase in model complexity. We follow most settings as suggested in ELECTRA (Clark et al., 2020a). In order to enhance the ELECTRA baseline for a solid comparison, we add the relative position (Raffel et al., 2020). Experimental results show that our methods can improve performance even on the enhanced ELECTRA baseline.

We pretrain our models on the same text corpus as ELECTRA, which is a combination of English Wikipedia and BooksCorpus (Zhu et al., 2015). We also adopt the N-gram masking strategy which is beneficial for MLM tasks. The models are trained for 1M steps for small-size models and 765k steps for base-size models, so that the computation consumption can be similar to baseline models (Clark et al., 2020a). The base-size models are pretrained with 16 V100 GPUs less than five days. The small-size models are pretrained with 8 V100 GPUs less than three days. We use the Adam (Kingma and Ba, 2015) optimizer ($\beta_1 = 0.9, \beta_2 = 0.999$) with learning rate of 1e-4. The value of λ_2 in the training objective is kept fixed at 50 for a fair comparison with ELECTRA. For HP$_{\mathrm{Loss}}$, we search λ_1 in $\{5, 10, 20\}$, the best one is 5. For HP$_{\mathrm{Dist}}$, we keep $\lambda_1 = 1$. We search the focal loss weight γ in $\{1, 4\}$

on both the base-size and small-size model, the best configuration is $\gamma = 1$. The detailed pre-training configurations are provided in the supplemental materials.

5.2 Results on GLUE Benchmark

The General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2019) is a collection of diverse natural language understanding (NLU) tasks, including inference tasks (MNLI, QNLI, RTE; Dagan et al. 2006; Bar-Haim et al. 2006; Giampiccolo et al. 2007; Bentivogli et al. 2009; Williams et al. 2018; Rajpurkar et al. 2016b), similarity and paraphrase tasks (MRPC, QQP, STS-B; Dolan and Brockett 2005; Cer et al. 2017), and single-sentence tasks (CoLA, SST-2; Warstadt et al. 2018; Socher et al. 2013). The detailed descriptions of GLUE datasets are provided in the supplementary materials. The evaluation metrics are Spearman correlation for STS-B, Matthews correlation for CoLA, and accuracy for the other GLUE tasks.

For small-size settings, we use the hyperparameter configuration as suggested in (Clark et al., 2020a). For base-size settings, we consider a limited hyperparameter searching for each task, with learning rates ∈ {5e-5, 1e-4, 1.5e-4} and training epochs $\in \{3, 4, 5\}$. The remaining hyperparameters are the same as ELECTRA. We report the median performance on the dev set over five different random seeds for each task. All the results come from the single-task fine-tuning. For more detailed fine-tuning configurations, please refer to the supplementary materials.

Results are shown in Table 1. With the same configuration and pre-training data, for both the small-size and the base-size, our methods outperform the strong reimplemented ELECTRA baseline by 0.6 and 0.4 on average respectively. For the most widely reported task MNLI, our models achieve 87.0/86.9 points on the matched/mismatched set, which obtains 0.3/0.4 absolute improvements. The performance gains on the small-size models are more obvious than the base-size models, we speculate that is due to the learning of the small-size generator is more insufficient and suffers from the above issues more significantly. The results demonstrate that our proposed methods can improve the pre-training of ELECTRA. In other words, sampling more hard replacements is more efficient than the original masked language modeling.

5.3 Results on SQuAD 2.0

The Stanford Question Answering Dataset (SQuAD; Rajpurkar et al. 2016a) is a reading comprehension dataset, each example consists of a context and a question-answer pair. Given a context and a question, the task is to answer the question by extracting the relevant span from the context. We only use the version 2.0 for evaluation, where some questions are not answerable. We report the results of both the Exact-Match (EM) and F1 score. When fine-tuning on SQuAD, we add the question-answering module from XLNet on the top of the discriminator as Clark et al.

$\gamma = 4.0$	80.9	74.2

Table 3: Ablation studies on small-size models. We analyze the effect of the hardness prediction loss weight λ_1 and the focal loss factor γ. Reported results are medians over five random seeds.

(2020a). All the hyperparameter configurations are the same as ELECTRA. We report the median performance on the dev set over five different random seeds. Refer to the appendix for more details about fine-tuning.

Results on SQuAD 2.0 are shown in Table 2. Consistently, our models perform better than ELECTRA baseline under both the small-size setting and the base-size setting. Under the base setting, our models improve the performance over the reimplemented ELECTRA baseline by 0.6 points (EM) and 0.5 points (F1). Especially under the small setting, our models outperform the baseline by a remarkable margin. ELECTRA+HP$_{\text{Dist}}$+Focal obtains 4.3 and 4.2 points absolute improvements on EM and F1 metric.

5.4 Ablation Studies

We conduct ablation studies on small-size ELECTRA+HP$_{\text{Loss}}$+Focal models. We investigate the effect of the loss weight λ_1 of the sampling head and the focal loss factor γ in order to better understand their relative importance. Results are presented in Table 3.

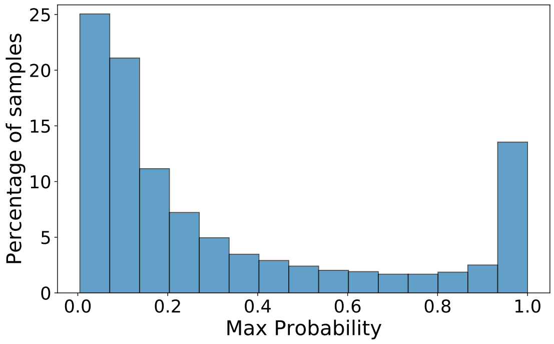
We first disable the focal loss and only understand the effect of λ_1. As shown in Table 3, no matter what the value of λ_1 is, our models exceed the baseline by a substantial margin, which demonstrates that the hardness prediction can indeed improve the pre-training and our methods are not sensitive to the loss weight hyperparameter. Next, we fix λ_1 at 5 and understand the effect of the focal loss factor γ. We observe that the application of the focal loss with piecewise $\gamma = \mathbb{1}(p_G > 0.2) * 3 + \mathbb{1}(p_G \leq 0.2) * 5$ and $\gamma = 1$ can improve the performance on two datasets, which proves the effectiveness of the sampling smoothing.

6 Analysis

To better understand the main advantages of our models over ELECTRA, we conduct several analysis experiments.

6.1 Impacts on Sampling Distributions

We first provide a comparison between the sampling distributions of ELECTRA and our models illustrate the effect of our proposed methods. We conduct evaluations on a subset of the pre-training corpus. Figure 3 demonstrates the distribution of the maximum probability of the two sampling distributions at the masked positions. We observe that the ratio of the maximum value under ELECTRA sampling distribution between $[0.9, 1]$ is much higher than that of our models. In other words, the original distribution suffers from over-sampling the high-probability tokens and the discriminator is forced to learn from these easy examples repeatedly. In contrast, the distribution of the maximum value of our models in each interval is relatively more uniform than ELECTRA, which indicates that our methods can significantly reduce the probability of sampling the well-classified tokens and smooth the



(a) Sampling Distribution of ELECTRA

Token Type	Original	Replaced	All
Corr. Coeff.	0.78	0.61	0.64

Table 4: Correlation coefficient between the actual discriminator loss and the estimated value for ELECTRA+HP$_{\text{Loss}}$+Focal. “Original”: sampling correct tokens as replacements. “Replaced”: the positions that are substituted to incorrect tokens.

whole sampling distribution.

6.2 Estimation Quality

In order to measure the estimation quality of discriminator loss, we evaluate our models on a held-out set of pre-training corpus and compute the correlation coefficient between the actual discriminator loss $\mathcal{L}_D(x, c)$ and the estimated value $\hat{\mathcal{L}}_D(x, c)$. The results of ELECTRA+HP$_{\text{Loss}}$+Focal are shown in Table 4. We report the estimation quality of the original tokens and the replaced tokens separately. The correlation coefficient value is 0.64 over two types of tokens, which proves that $\mathcal{L}_D(x, c)$ and $\hat{\mathcal{L}}_D(x, c)$ correlate well. Furthermore, we observe that the estimation quality over the original tokens is relatively higher than the replacements. We speculate that the sampling probability of the original tokens is generally higher than the replacements, so the sampling head tends to receive more feedback from these original tokens.

Model	**Masked Positions**	**All Positions**
ELECTRA	0.81	0.96
Ours	0.72	0.95

Table 5: Replacement detection accuracy of ELECTRA and ELECTRA+HP$_{\text{Loss}}$+Focal. The models are evaluated on 15% masked positions and all input tokens respectively. Our method samples more hard examples.

6.3 Prediction Accuracy of the Discriminator

In order to verify the claim that the sampling distribution of our models indeed considers the detection difficulty, we evaluate the prediction accuracy of the discriminator under the two sampling schemes of ELECTRA and ELECTRA+HP$_{\text{Loss}}$+Focal. Results are listed in Table 5. No matter evaluating at all positions or only at the masked positions, the detection accuracy under our sampling distribution is relatively lower than under masked language modeling in original ELECTRA. Because the unmasked tokens constitute the majority of input examples, the difference of the all-token accuracy between two models is not so distinct compared to the masked tokens. This phenomenon is consistent with our original intention. It proves that our models can sample more replacements that the discriminator struggles to make correct predictions. In contrast, the replacements sampled from ELECTRA are easier to distinguish.

7 Conclusion

We propose to improve the replacement sampling for ELECTRA pre-training. We introduce two methods, namely hardness prediction and sampling smoothing. Rather than sampling from masked language modeling, we design a new sampling scheme, which considers both the MLM probability and the prediction difficulty of the discriminator. So the generator can receive feedback from the discriminator. Moreover, we adopt the focal loss to MLM, which adaptively downweights the well-classified examples and smooth the entire distribution. The sampling smoothing technique relieves oversampling original tokens as replacements. Results show that our models outperform ELECTRA baseline. In the future, we would like to apply our strategies to other pre-training frameworks and cross-lingual models. Moreover, we are exploring how to integrate the findings and insights of the proposed method into the masked language modeling task, which seems also quite promising.

A GLUE Details

GLUE (Wang et al., 2019) is a collection of various natural language understanding (NLU) tasks, including inference tasks (MNLI, QNLI and RTE), similarity and paraphrase tasks (MRPC, QQP and STS-B), and single-sentence tasks (CoLA and SST-2).

MNLI The Multi-Genre Natural Language Inference Corpus (Williams et al., 2018) is a crowd-sourced collection of sentence pairs with textual entailment annotations. Given a premise sentence and a hypothesis sentence, the task is to predict whether the premise entails the hypothesis (entailment), contradicts the hypothesis (contradiction), or neither (neutral). The dataset contains 393k train examples drawn from ten different sources.

QNLI The Stanford Question Answering Dataset (Rajpurkar et al., 2016b) is a question-answering dataset consisting of question-paragraph pairs. The task is to predict whether a context sentence contains the answer to a question sentence. The dataset contains 108k train examples from Wikipedia.

QQP The Quora Question Pairs dataset is a collection of question pairs from the community question-answering website Quora. The task is to determine whether a pair of questions are semantically equivalent. The dataset contains 364k train examples.

RTE The Recognizing Textual Entailment datasets (Dagan et al., 2006; Bar-Haim et al., 2006; Giampiccolo et al., 2007; Bentivogli et al., 2009) come from a series of annual textual entailment challenges. Given a premise sentence and a

Hyperparameter	Value

hypothesis sentence, the task is to predict whether the premise entails the hypothesis or not. The dataset contains 2.5k train examples from a series of annual textual entailment challenges.

SST The Stanford Sentiment Treebank (Socher et al., 2013) consists of sentences from movie reviews and human annotations of their sentiment. The task is to predict the sentiment of a given sentence. The dataset contains 67k train examples.

MRPC The Microsoft Research Paraphrase Corpus (Dolan and Brockett, 2005) is a corpus of sentence pairs automatically extracted from online news sources. The task is to predict whether two sentences are semantically equivalent or not. The dataset contains 3.7k train examples.

CoLA The Corpus of Linguistic Acceptability (Warstadt et al., 2018) consists of English acceptability judgments drawn from books and journal articles on linguistic theory. The task is to determine whether a given sentence is grammatical or not. The dataset contains 8.5k train examples.

STS-B The Semantic Textual Similarity Benchmark (Cer et al., 2017) is a collection of sentence pairs drawn from news headlines, video and image captions, and natural language inference data. The tasks is to predict how semantically similar two sentences are on a 1-5 scale. The dataset contains 5.8k train examples.

B Pre-training Details

We did not search any hyperparameters during pre-training. Most of our pre-training configurations are same as the original ELECTRA (Clark et al., 2020a). The learning rate for base-sized model is changed from 2e-5 to 1e-5 on both ELECTRA baseline and our models, because we expect the fair comparison with BERT and RoBERTa. We keep $\lambda_2 = 50$ for both ELECTRA-EL and ELECTRA-AD. The full set of pre-training hyperparameters is provided in Table 7.

C Fine-tuning Details

For base-sized models, we searched the learning rate and pre-training epochs on both ELECTRA baseline and our models. For small-sized models, we use the same hyperparameters as suggested in

ELECTRA. All the results come from the single-task fine-tuning. The full set of fine-tuning hyperparameters is provided in Table 6.

D Prediction Accuracy of the Discriminator

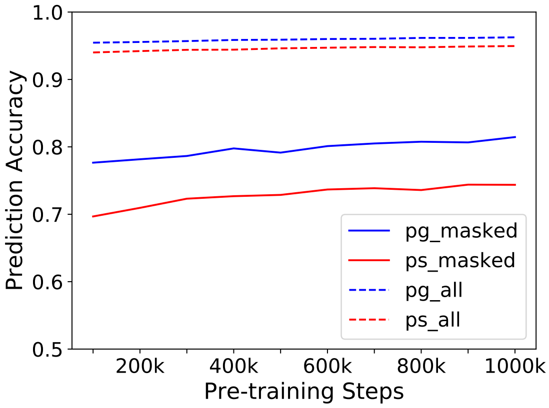

Figure 4: The prediction accuracy of the discriminator. Blue lines indicate sampling replacements according to p_{G}, red lines are according to p_{S}. The solid line represents the prediction accuracy evaluated on the 15% masked tokens and the dashed line represents the prediction accuracy of all input tokens.

Reordering Examples Helps during Priming-based Few-Shot Learning

Abstract

The ability to learn from limited data, or few-shot learning, is a desirable and often critical requirement for NLP systems. While many existing methods do poorly at learning from a handful of examples, large pretrained language models have recently been shown to be efficient few-shot learners. One approach to few-shot learning, which does not require finetuning of model parameters, is to augment the language model's input with priming text which is typically constructed using task specific descriptions and examples. In this work, we further explore priming-based few-shot learning, with focus on using examples as prompts. We show that presenting examples in the right order is key for generalization. We introduce PERO (Prompting with Examples in the Right Order), where we formulate few-shot learning as search over the set of permutations of the training examples. We show that PERO can learn to generalize efficiently using as few as 10 examples, in contrast to existing approaches. While the newline token is a natural choice for separating the examples in the prompt, we show that learning a new separator token can potentially provide further gains in performance. We demonstrate the effectiveness of the proposed method on the tasks of sentiment classification, natural language inference and fact retrieval. Finally, we analyze the learned prompts to reveal novel insights, including the idea that two training examples in the right order alone can provide competitive performance for sentiment classification and natural language inference.

1 Introduction

The ability to learn from a few examples, or few-shot learning, as generally understood to be possessed by humans, is a desirable property for Natural Language Processing (NLP) systems as well. It is critical in scenarios where collecting large amounts of data is expensive. It is also important to enable a personalized Artificial Intelligence (AI) experience, where a single user is expected to use an AI agent to perform a task demonstrated through a handful of examples.[1]

Pretrained language models (Devlin et al., 2019; Liu et al., 2019; Raffel et al., 2020) have recently been shown to be exceedingly good at several benchmark NLP tasks (Wang et al., 2018, 2019). Traditionally the parameters of these language models have been finetuned on task specific datasets to achieve the aforementioned performance gains, often requiring large amounts of data. Brown et al. (2020) show that large pretrained language models (GPT3) are also efficient few-shot learners. Few-shot learning is achieved using task descriptions and labeled examples as prompts. Remarkably, with this priming-based approach and without needing any parameter updates, GPT3 often performs comparable to traditional finetuning-based supervised systems which use much larger datasets. One could argue that the task performance achieved in the priming-based approach measures what the pretrained language model has already learned. Shin et al. (2020), operating in the same setting, use automatically generated prompts to measure task specific knowledge in a pretrained language model.

In this work, we further explore priming-based few-shot learning, while focusing on using examples as prompts. The training objective for a language model is typically the prediction of a token given a context. There is no clear incentive to treat a sequence of sentences in the context as equal and conveying examples of a concept. As a result, one could expect certain order of examples when used as a prompt to be more favorable at providing task

---

[1] See the Introduction section of Brown et al. (2020) for a discussion on further difficulties, relevant to the setting we consider in this work, regarding the need of a large dataset for every new task.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4507–4518
August 1–6, 2021.

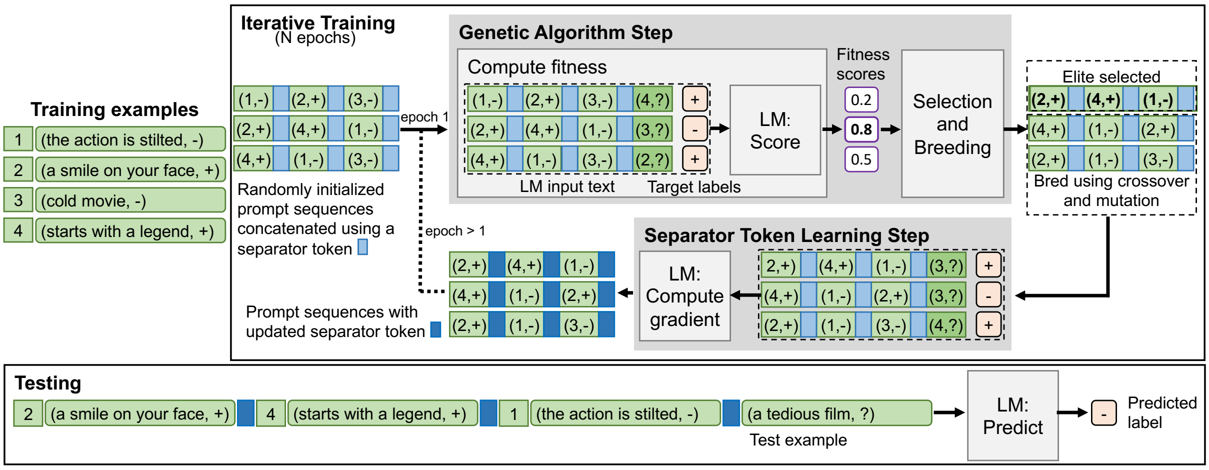

Figure 1: *Overview of PERO*: Given a set of training examples, PERO searches over permutations of training examples using a genetic algorithm (Section 4.2), and optionally also learns a separator token (Section 4.3) which is used to concatenate the training examples. Briefly, starting from a set of randomly initialized permutations, the genetic algorithm step computes the fitness of each permutation for making predictions using a pretrained LM. These fitness scores are then used for selection and subsequent breeding of new permutations using biologically inspired operations of mutation and crossover. The separator token learning step uses the updated set of permutations and uses gradient updates to improve the separator token. The two steps are performed iteratively for a fixed number of epochs and the best permutation and separator token are selected using a validation set. Please see Section 4 for details.

specific cues.

We propose PERO[2] (Prompting with Examples in the Right Order), where we formulate the problem of few-shot learning as search over permutations of training examples. We find that choosing the right permutation is key to getting good task performance. In PERO, we use a genetic algorithm (Mitchell, 1998) to search over possible permutations of training examples. The selected examples are used for prompting publicly available pretrained language models (Devlin et al., 2019; Liu et al., 2019). We find that with as few as 10 examples, PERO can learn to generalize efficiently, in contrast to existing approaches. When concatenating examples to use as a prompt, the newline token is a natural choice as a separator token. We show that using a learned separator token can potentially provide further gains in performance. We evaluate the performance of PERO on the tasks of sentiment analysis, Natural Language Inference (NLI) and fact retrieval.

Finally, our analysis of the learned prompts (Section 5.5) leads to novel insights about few-shot learning using textual prompts. For instance, using only two examples, repeated and ordered using a learned label pattern, can provide performance comparable to and even exceeding the performance of existing few-shot baselines which use thousands of examples.

In summary, we make the following contributions:

1. We propose PERO, where we formulate the problem of few-shot learning as search over permutations of training examples, and optionally a separator token. As we don't update the parameters of the underlying language model, PERO serves as a probe for measuring task specific knowledge in pretrained language models.

2. We demonstrate the effectiveness of PERO over a recent baseline on the tasks of sentiment analysis, NLI and fact retrieval.

3. We analyze the learned prompts and provide novel insights about textual prompts that can lead to good task performance in the low-data regime. In particular, we provide an effective recipe for one-shot learning.

We have released the source code of PERO to aid reproducibility of the results.

---

[2] PERO source code is available at `https://github.com/SawanKumar28/pero`

Task	Template	Examples
Sentiment Classification	[Example Text] Answer: [Label Text]	(1) goes to absurd length Answer: false (2) A girl in white is dancing Answer: true
NLI	"[Premise Text]" implies "[Hypothesis text]" Answer: [Label Text]	(1) "Men are sawing logs" implies "Men are cutting wood" Answer: true (2) "There is no girl in white dancing" implies "A girl in white is dancing" Answer: false
Fact retrieval	[Subj] is located in [Obj] [Subj] is a subclass of [Obj]	(1) Directors Lounge is located in Berlin (2) gingerbread is a subclass of cookie

Table 1: *Formatting used to create textual inputs* for the tasks considered in this work. For sentiment classification, positive and negative sentiments correspond to the label text of *true* and *false* respectively. For NLI, entailment and contradiction labels correspond to the label text of true and false respectively.

2 Related Work

Pretrained Language Models using a transformer architecture (Vaswani et al., 2017) on large unsupervised corpora have recently been found to be efficient at learning downstream tasks, providing significant gains over existing standalone supervised systems, on a variety of NLP tasks (Wang et al., 2018, 2019). There have been two major approaches to learning language models: causal language models (CLM) and masked language models (MLM). CLMs (Radford et al., 2018, 2019; Brown et al., 2020) are typically trained by requiring a language model to predict the next token given a textual context. Masked language models (Devlin et al., 2019; Liu et al., 2019) on the other hand are trained by masking out a certain number of tokens in a textual context and requiring the language model to predict the masked out tokens. Typically, the parameters of the language model are then fine-tuned using task-specific training examples. For our experiments, we leverage publicly available pretrained masked language models (Devlin et al., 2019; Liu et al., 2019).

Few-shot learning using language models is a desirable and perhaps even an expected property of large pretrained language models, given the large amounts of data they are typically trained with. Brown et al. (2020) show that scaling up language models leads to improved few-shot learning, with their best model, GPT3, being able to achieve performance comparable to existing supervised systems, while using much fewer examples. Zero-shot and few-shot learning are achieved without needing parameter updates to the model but instead by prompting the language model with task specific description and task specific examples. In this work, we study the impact of the order in which examples are presented in a prompt and show that searching over them can lead to significant gains in few-shot performance, without needing updates to the model parameters.[3]

Measuring task performance of language models without any parameter updates can be seen as a measure of the knowledge (either descriptive, or procedural) that is already contained in the pretrained language model.

Probing knowledge contained in language models has been of interest, given the success of these models. Probing methods rely on creating cloze-style manual prompts (Petroni et al., 2019), or mining efficient natural language prompts (Jiang et al., 2020). Shin et al. (2020) rely on training examples to learn trigger tokens which when used as a prompt demonstrate the ability of language models to do sentiment analysis and NLI along with knowledge based completion, without needing any parameter updates. The learned trigger tokens however aren't very meaningful leading to difficulty in interpreting these results. In this work, we instead focus on using natural language training examples as prompts. While being more interpretable, the prompts used in this work lead to significant gains in performance in the low-data regime.

3 Background: Genetic Algorithm

A genetic algorithm (Mitchell, 1998) is a search heuristic inspired by the biological process of natural selection. Briefly, it evolves a population of candidate solutions towards increasing fitness to an objective through biologically inspired operations such as selection, crossover and mutation. We now describe the key terminology:

---

[3] Note that the scope of this work is distinct from meta-learning approaches (Hospedales et al., 2020), where the goal is improve the learning algorithm using several learning episodes. In contrast, we only assume a pretrained language model and a few examples of the concept we are interested in.

Individual A single candidate solution, c, usually represented through a binary code but extensible to other types of codes. Generally, we will let c be denoted by the sequence of k integers $c = (s^1 s^2 ... s^k)$.

Population A set of individuals of size N_P, $P = \{c_i, i \in [N_P]\}$.

Fitness The measure of goodness for an individual for the task, $F(c_i)$.

Selection An operator to select fit individuals in a population which will be used to generate new individuals, through crossover and mutation. Better fitness leads to higher likelihood of selection.

Crossover An operator which typically takes two individuals c_1 and c_2 as inputs to produce new individuals d_1 and d_2, by combining subsequences from the two inputs. For example, consider two input sequences:

$$c_1 = (c_1(1)c_1(2)c_1(3)c_1(4))$$
$$c_2 = (c_2(1)c_2(2)c_2(3)c_2(4))$$

A single point crossover after the second position would lead to the individuals:

$$d_1 = (c_1(1)c_1(2)c_2(3)c_2(4))$$
$$d_2 = (c_2(1)c_2(2)c_1(3)c_1(4))$$

Mutation An operator which randomly flips some elements in an input sequence. For example, with input $c = (c(1)c(2)c(3)c(4))$, a typical mutation operation would lead to the output $d = (c(1)c(2)c'(3)c(4))$, where $c'(3) \neq c(3)$. Usually, each position is randomly altered with a mutation probability p_m.

We now present the sketch of a typical genetic algorithm:

1. Initialize a set of individuals to form a population $P = \{c_i, i \in [N_P]\}$. Repeat the following steps for N_{epochs} iterations.
2. Compute fitness of each individual in the population, $F(c_i), i \in [N_P]$.
3. Using the computed fitness, select individuals which will be used to breed the next generation.
4. With pairs of selected individuals, generate new individuals using the crossover operation.
5. Mutate the generated individuals using the mutation operator, to create a new population P'.
6. Set $P = P'$ and go to step 2.

4 PERO: Proposed Method

The overall architecture employed in PERO is shown in Figure 1. We introduce the notation in Section 4.1. We discuss how we employ a genetic algorithm to search over permutations of training examples in Section 4.2. We then discuss how we augment the search heuristic to learn a task specific separator token in Section 4.3.

4.1 Notation and Input Format

For both classification and knowledge base completion tasks, we denote a textual task input by x and the gold label as y. We denote the pretrained masked language model with the operator L, which takes a sequence of input tokens to output a sequence of the same length containing token probabilities over the token vocabulary. With tokens $(t_1 t_2 ... t_n)$, $L((t_1 t_2 ... t_n)) = (p_1 p_2 ... p_n)$, where p_i denotes a vector of probabilities over all tokens in the vocabulary.

For all our experiments, the input to the language model is formatted with exactly one mask token.[4] For brevity, we denote by L_{Mask} the operator which outputs the token probability at the mask token position.

The training data is denoted by the set of examples $(x_i, y_i), i \in [N_{\text{train}}]$. We denote a permutation, or an ordered subset of size k of the training data, by $c = (c(1)c(2)...c(k))$, where $c(j) \in [N_{\text{train}}]$.

For all tasks, we create an input text sequence by concatenating k examples using a permutation c of training examples, along with a test example x_{test}: "Format($x_{c(1)}$,$y_{c(1)}$) <Separator> Format($x_{c(2)}$,$y_{c(2)}$) .. <Separator> Format($x_{c(k)}$,$y_{c(k)}$) <Separator> Format(x_{test},mask)", where Format(,) formats the example text and label for a task, and <Separator> is either the new line character, or is learned as described in Section 4.3. The formatting details are provided in Table 1. We attempt to

---

[4] The mask token we use is the same as the one employed in pretraining.

use task agnostic formats and textual labels for classification tasks to the extent possible.

4.2 Genetic Algorithm: Search over Permutations of Examples

We employ a genetic algorithm for searching over permutations of training examples (see Section 3 for a brief introduction to genetic algorithms). We present the overall architecture in Figure 1.

Here, we detail how the various components and operators of a genetic algorithm are defined for searching over permutations of examples:

Individual An individual is defined as a vector of unique training example indices $c = (c(1)c(2)...c(k))$, where $c(j) \in [N_{\text{train}}]$.

Population A set of individuals.

Fitness For a given permutation of training example indices, fitness is defined as the average cross entropy loss over training examples when evaluated as in Figure 1. The cross entropy loss is computed over the set of possible labels for classifications tasks, and over all tokens in the vocabulary for knowledge base completion tasks.

Note that during search, a training example may occur both in the prompt and as well as the test example. This is generally not a problem as we are not finetuning the model and do not run the risk of learning to copy. When also training the separator token (Section 4.3), we ensure that the test example doesn't occur in the prompt by dropping it from the prompt if required.

Selection For selection, we use elitism, i.e., at each generation of individuals, we retain a certain percentage (elite ratio) of top performing individuals without any modifications. The rest of the population is created through crossover and mutation over a percentage (selection size) of top performing individuals.

Crossover We perform a single point crossover, while ensuring that the resulting individuals contain unique indices. Given two parents c_1 and c_2, first a random number j is sampled in the range $[k]$, the length of the individuals, to use as the crossover point. We define an operator $\text{First}_s(v, v')$ which selects the first s elements in vector v which do not occur in vector v'. Similarly, $\text{Last}_s(v, v')$ picks the last s elements in v which do not occur in vector v'. Denoting the subvector $c(i)c(i+1)...c(j)$ by $c^{i:j}$, four new individuals are then created:

$$d_1 = (c_1^{1:j}\text{Last}_{k-j}(c_2, c_1^{1:j}))$$
$$d_2 = (c_2^{1:j}\text{Last}_{k-j}(c_1, c_2^{1:j}))$$
$$d_3 = (\text{First}_j(c_2, c_1^{j+1:k})c_1^{j+1:k})$$
$$d_4 = (\text{First}_j(c_1, c_2^{j+1:k})c_2^{j+1:k})$$

This modification over a straightforward crossover ensures that the resulting individuals contain unique indices.

Mutation We perform mutation on an input candidate by changing each position with a mutation probability p_m. When changed, an index is replaced by a random choice from the other training examples. If the new index is already present in the input candidate, the value at that index is swapped with the selected index.

The Genetic algorithm is run for N_{epochs} (see Section 3 for the training flow). A validation set of the same size as the train set was used to select from the best performing individuals in each epoch.

4.3 Separator Token Learning

In addition to the search over permutations of training examples as described in the previous section, we optionally learn a separator token to concatenate the examples (see Figure 1).

We initialize a token embedding parameter with the token embedding of the newline character. At the end of each epoch of the genetic algorithm, we use gradient updates to estimate the token embedding. The training set is created using the individuals (prompts) in the population in the current generation, and replacing the answer of the final example with the mask token. Gradient updates are then done by requiring the model to predict the correct answer.

5 Experiments

In this section, we aim to answer the following questions:

Q1 How does PERO compare with existing approaches on task performance? (Section 5.3)

Q2 How do the components of PERO, namely genetic algorithm and separator token learning affect task performance? (Section 5.4)

Training	Prompt Type	P@1
Manual	LAMA (Petroni et al., 2019)	31.1ˆ
Full supervision	LPAQA(top1) (Jiang et al., 2020)	34.1ˆ
	Autoprompt (Shin et al., 2020)	43.3ˆ
	PERO	46.6
10 examples	Autoprompt (Shin et al., 2020)	18.9
	PERO	40.3

Table 2: *Summary of fact retrieval experiments:* Precision @1 results on test sets are presented. ˆindicates replicated numbers. PERO improves over the baselines when using all training data (up to 1000 examples) and provides significant gains when using limited training data. This indicates that PERO is more efficient at eliciting knowledge from language models. Please see Section 5.3 for details and Appendix A.2.2 for more detailed results.

Q3 What aspects of PERO are important for getting good performance? (Section 5.5)

The experimental setup is described in Section 5.2, and the datasets are described in Section 5.1.

5.1 Datasets

Sentiment Classification: We use SST2 (Socher et al., 2013), a binary sentiment classification task. The training data contains 67350 training, 873 validation and 1822 test examples.

NLI: We use label-balanced 2-class NLI dataset created by Shin et al. (2020) using the SICK-E dataset (Marelli et al., 2014). This dataset has 1289 training, 143 validation and 1427 test examples.

Fact Retrieval: We use the train, validation, and test splits created by Shin et al. (2020) (referred to as ‘original’ in the paper) for 41 relations. For our experiments, we use the manual prompts created by Petroni et al. (2019). Please see Appendix A.2.2 for relation wise prompts and training statistics.

5.2 Experimental Setup

Number of training examples: For most of our experiments, we limit to a total of 10 training examples. We chose this number as prior work (Shin et al., 2020) faced difficulty in enabling predictions using only 10 training examples, usually performing close to random prediction. We create 5 sets of size 10, chosen successively from the first 50 training examples, and report on average task performance. Although our focus is few-shot learning in the low data regime, we also present results with more examples (the first 100 and the first 1000 examples) for reference. For model selection, we use a label-balanced validation set (chosen from the beginning of the corresponding validation set) of the same size as the training data. In all cases, and irrespective of the number of training examples, we keep the prompt size fixed to 10 examples.

Pretrained LM: We use RoBERTa-large (Liu et al., 2019) for all our experiments except for the fact retrieval task where we use the bert-large-cased model (Devlin et al., 2019) as this model has been shown to work better for the task (Shin et al., 2020). RoBERTa-large has 24 layers, with 16 attention heads and a hidden size of 1024 (355M parameters). Bert-large-cased uses the same architecture as RoBERTa-large. We use the implementation of transformer architectures provided by Wolf et al. (2020). We use the </s> token as the default separator token. When learning a new separator token, we initialize the token embedding by the token embedding of </s> token, and finetune the embedding as discussed in Section 4.3.

Genetic algorithm: We run the genetic algorithm for 100 epochs for classification tasks and 30 epochs for fact retrieval tasks. The population size was fixed to 100 and the mutation probability was set to 0.1. Elite ratio was set to 0.1, while the selection size was fixed to 25. When training a separator token embedding, the maximum number of training epochs for learning the embedding was set to 10 for classification tasks and 5 for fact retrieval tasks. Gradient updates were performed using the AdamW optimizer (Loshchilov and Hutter, 2018) with a learning rate of $1e-4$.

Baselines: We use Autoprompt (Shin et al., 2020) and the traditional finetuning approach as few-shot baselines. Please see Appendix A.1 for hyperparameter details.

5.3 Overall Results

In this section, we present the few-shot learning capability of PERO. For reference, we also report results when using more data.

We present fact retrieval results (Precision@1 scores) in Table 2. Relation wise results are provided in Appendix A.2.2. When using all training data, PERO improves the overall P@1, and is competitive or outperforms Autoprompt on all relations. When using only 10 training examples, PERO provides significant gains over Autoprompt

Number of training examples		10	100	1000
Sentiment Classification	Finetune	52.5 (2.36)	90.2	93.1
	Autoprompt	52.3 (2.60)	73.5	75.1
	PERO	**91.2** (1.83)	**93.8**	**94.2**
NLI	Finetune	57.4 (10.65)	**96.1**	**98.6**
	Autoprompt	58.6 (9.08)	76.2	86.5
	PERO	**81.3** (4.99)	78.5	83.2

Table 3: *Summary of classification tasks:* Test set label accuracies for PERO are presented for the tasks of sentiment classification and NLI. When using 10 examples, we also report the standard deviation across training splits. For both tasks, PERO provides significant gains over both Autoprompt and the traditional finetuning approach, when using 10 examples. For reference, we also present results when using more training examples. For both tasks, PERO is competitive with Autoprompt with increasing data. Overall, the results indicate that PERO is capable of learning to generalize with a handful of examples, in contrast to existing approaches. Please see Section 5.3 for details. Please see Appendix A.2.1 for additional comparison between Autoprompt and PERO using 10 examples across 100 training splits.

	Sentiment Classification	NLI
PERO	91.2	81.3
PERO-Sep learning	89.3	77.5

Table 4: *Impact of separator token learning Step:* Average test set label accuracies with and without the separator token learning are presented for training sets of size 10. The results indicate that the genetic algorithm step alone provides a strong baseline, while the separator token learning step provides further gains. Please see Section 5.4 for details.

on all relations. Overall, we show through PERO that simple manual prompts can be combined in relatively straightforward ways to create stronger probes while still being interpretable.[5]

We present the label accuracies of PERO for sentiment classification and NLI in Table 3. In each case, PERO is able to generalize well when using only 10 examples, while existing approaches perform close to random guess (50%). When using more data, PERO is competitive with Autoprompt for both tasks, while finetuning does better than PERO for NLI with larger training sizes. Overall, PERO provides an efficient approach to few-shot learning with pretrained language models.

Comparison when using larger training sizes: The results in Table 3 also suggest the use of finetuning when more data is available and the use of PERO when there isn't enough data for finetuning to generalize well. The relatively low performance of PERO with more data, especially for the NLI task, could be due to the much larger search space when using more training data. Since we keep the prompt size fixed to 10 examples, the search space is $10!$ for 10 training examples and $1000!/990!$ when using 1000 examples. While a better search strategy could potentially improve PERO's performance when using more data, we leave that as an interesting future work. Note, however, that the search space complexity is determined by the number of training examples irrespective of their labels. For example, PERO improves over the baselines on the fact retrieval task (Figure 2), despite a much larger number of labels.

For reference, we provide the label accuracies when using all available training data when using PERO, Autoprompt and finetuning respectively: 95.0, 91.4 and 96.7 for sentiment classification, and 79.5, 87.3 and 99.1 for NLI. When compared to the traditional fully supervised finetuning approach, PERO performs within 94.3% while using only 0.015% of the training data for sentiment classification, and within 82.1% while using only 0.77% of the training data for NLI.

5.4 Ablation on PERO's components

In this section, we present an ablation study to understand the role that the two components of PERO, namely genetic algorithm and separator token learning steps play. We present the label accuracies for sentiment classification and NLI with and without the separator token learning step (indicated as PERO-sep learning) in Table 4. The results indicate that the permutation search using the genetic algorithm step provides large gains by itself, while the separator token learning potentially improves it.

---

[5] Autoprompt's learned tokens are sometimes relevant to the task but generally hard to interpret.

	Sentiment Classification	NLI
Default fitness	89.3	77.5
Inverse fitness	78.3	58.8

Table 5: *Searching for bad permutations:* We use the genetic algorithm described in Section 4 to search for bad permutations, by inverting the definition of fitness and report on test accuracy. Average results when using training sizes of 10 examples are presented and contrasted with search using default fitness. The results indicate that good permutations found by PERO are not trivial and that choosing the right permutation is necessary for generalization. Please see Section 5.5.1 for details.

5.5 Analyzing Learned Permutations

5.5.1 Do bad solutions exist which PERO learns to avoid?

With the same search strategy as discussed in Section 4, we search for potentially bad permutations, by inverting the definition of fitness. For this experiment, to focus on the role of permutations, we do not train the separator token for this experiment. We present the average test set accuracies across training splits for the best and the worst permutations in Table 5. Additionally, we also evaluate 100 random permutations for each training split. The mean (and standard deviation) test accuracy across training splits and random permutations was 85.6(9.08) for sentiment classification and 67.9(8.99) for NLI.

The results indicate that PERO's learned permutations provide significant gains over other permutations constructed using the same examples. Selecting the right permutation, therefore, is important for generalization.

5.5.2 How many examples does PERO need for good performance?

One could see a permutation learned by PERO as a combination of a label pattern (the sequence of labels corresponding to the sequence of examples) and particular examples of the respective labels. To understand the importance of the learned label pattern, we search for pairs of examples, one example for each label[6], and repeat them using the learned label pattern. The examples are selected from within the set of examples in the learned permutation. We present the accuracy with the original permutation and the best and worst accuracies when using only two training examples in Table 6. Remarkably, two examples alone, when selected well, can go a long way towards good performance.

Accuracies on SST2 dev set using only 2 examples			
Label sequence	PERO-10	Best-2	Worst-2
−−−−++++−−	91.4	91.5	81.2
−++−−−−+−−	81.1	89.5	66.5
++++−−−+++	81.4	85.5	53.9
−−−+++++−−	91.5	87.4	69.3
−−−−++++−−	91.4	90.8	74.9

Table 6: *Evaluating learned label patterns with one example per label:* Best and worst accuracies obtained when using only two examples (one unique example per label) are compared with the accuracy of PERO with 10 distinct examples for the same label pattern (denoted by PERO-10). The best accuracy possible with two distinct examples is competitive with PERO-10. The results indicate that learned label patterns are useful for generalization, along with the choice of selected examples. Please see Section 5.5.2 for details.

		Sentiment Classification	NLI
Proposed 1-shot	Worst	56.2	56.3
	Best	90.6	84.5
10 examples	Finetune	52.5	57.4
	Autoprompt	52.3	58.6
	PERO	91.2	81.3

Table 7: *One-shot learning:* Best and worst test set label accuracies with one-shot learning using training example pairs obtained from the first 10 training examples are presented. The best possible accuracies with the proposed one-shot learning approach is competitive with PERO using 10 examples, while improving over finetuning and Autoprompt using 10 examples. Please Section 5.5.3 for details.

Additionally, using the learned label pattern provides at least a 10 point improvement in accuracy when compared with a sequence without repetitions (details omitted). This indicates a potential recipe for one-shot learning which we discuss next.

5.5.3 Can insights gained from this work lead to one-shot learning recipes?

To answer this question, we provide an example one-shot learning (one training example per class) algorithm which greedily grows a prompt sequence. In contrast to Section 4, we don't use an additional validation set to select a good prompt sequence. We update the definition of fitness to prevent it from being biased towards one class by defining it to be the minimum and not the average of the cross

---

[6] Learning from one example per class is usually referred to as one-shot learning.

SST-2	
Best (Acc: 90.6)	-ve sentiment: on the worst revenge-of-the-nerds clichés the filmmakers could dredge up +ve sentiment: demonstrates that the director of such hollywood blockbusters as patriot games can still turn out a small , personal film with an emotional wallop .
Worst (Acc: 56.2)	-ve sentiment: remains utterly satisfied to remain the same throughout +ve sentiment: of saucy

Table 8: *Example training pairs for one-shot learning* corresponding to the best and worst test set accuracies for sentiment classification. Please see Section 5.5.3 for details.

entropy loss over the training examples. This is equivalent to minimizing the negative probability of the least probable target label.

Following Section 5.5.2, we allow an example to be repeated in a prompt sequence. Setting the maximum possible length of the prompt sequence, i.e., number of (potentially repeated) examples in the prompt sequence to $l_{\max}$, the algorithm then is comprised of the following steps:

1. Initialize an empty prompt, $c = ()$
2. Create all possible prompts, P, formed by inserting exactly one example to c. If we denote the length of c as l_c and the number of labels as N_{labels}, the size of the set is given by $N_P = (l_c + 1) * N_{\text{labels}}$.
3. Compute the fitness of prompts in P.
4. Select prompt $c' \in P$ with the best fitness.
5. Set $c' = c$ and go to step 2 if $l_c < l_{\max}$.

We now discuss the results of using this one-shot learning approach over the tasks of sentiment classification and NLI. In each case, we consider the first 10 examples in the training set and create all possible training example pairs for one-shot learning, selecting one example from each class. This leads to 24 training example pairs in each case. We set the max length $l_{\max}$ to 10, and ensure that the prompt sequence is label-balanced at each step. We summarize the results in Table 7. The results indicate that the proposed algorithm is an effective approach to one-shot learning. In Table 8, we show the training examples corresponding to the best and worst cases for the task of sentiment classification. While there is indication that more representative examples (such as longer examples) are more informative and thus more useful for one-shot learning, we leave a more thorough analysis as interesting future work.

6 Conclusion

In this paper, we propose PERO, a promising approach for few-shot learning, where we formulate learning as search over permutations of training examples, and optionally a separator token. We show the effectiveness of PERO for few-shot learning on the tasks of sentiment classification, NLI and fact retrieval tasks. We demonstrate that PERO provides an interpretable and a more accurate way to probe the knowledge contained in pretrained language models. Our analysis of the learned prompts reveals novel insights and cues for further research on few-shot learning, including one-shot learning.

A Appendix

A.1 Experimental Setup

A.1.1 Autoprompt Experiments

For Autoprompt experiments, following Shin et al. (2020), we set the number of trigger tokens to 10, number of label tokens to 3, and candidate set size to 10. Label search was run for 50 iterations and trigger token search was run for 180 iterations. Experiments were conducted on the same splits as PERO.

A.1.2 Finetuning Experiments

For the finetuning experiments, following the recommended settings for small datasets by Mosbach et al. (2020), we trained models for 20 epochs, using AdamW (Loshchilov and Hutter, 2018), with learning rate linearly increasing to $2e-5$ in the first 10% epochs and then linearly decreasing to 0. The experiments were conducted on the same splits as PERO.

A.1.3 Training Time

Training time for PERO was approximately 3 hours for each experiment in the case of classification tasks, and approximately 30 minutes for each experiment of fact retrieval tasks.

A.1.4 Computing Infrastructure

We used Nvidia's GeForce GTX 1080 Ti GPUs for all our models. Each experiment was run on a single GPU.

A.1.5 Data

The experiments were done in the evaluation framework of Shin et al. (2020) who provide instructions for downloading the corresponding data splits at `https://github.com/ucinlp/autoprompt`.

Here, we provide more details on the classification datasets used. Details on the fact retrieval data are presented in Section A.2.2.

Sentiment Classification: We used the SST-2 dataset, the binarized version of the sentiment classification dataset created by Socher et al. (2013). The training examples are constructed using movie review excerpts collected from `rottentomatoes.com` website, and labels obtained using Amazon Mechanical Turk's crowdsourcing platform. The percentage of examples labeled with positive sentiment in train, validation and test sets are 55.78%, 50.92% and 49.64% respectively. The number of examples labeled with positive sentiment in the training sets of size 10 used in the work are 4, 3, 7, 5 and 4. See Section 5.2 for selection and other details.

NLI: We use the label-balanced 2-class NLI dataset created by Shin et al. (2020) using the SICK-E dataset (Marelli et al., 2014). The dataset was created using sentences from the 8K ImageFlickr data set[7] and the SemEval 2012 STS MSRVideo Description data set[8]. Labels were obtained using Amazon Mechanical Turk's crowdsourcing platform. The number of examples labeled with entailment relation in the training sets of size 10 used in the work are 4, 3, 5, 6 and 5. See Section 5.2 for selection and other details.

Number of training examples		10
Sentiment Classification	Autoprompt	54.73 (4.72)
	PERO	**91.81** (1.87)
NLI	Autoprompt	62.31 (8.23)
	PERO	**78.61** (6.73)

Table 9: *Additional results on classification tasks:* Test set label accuracies (and standard deviation) for AutoPrompt and PERO are presented for the tasks of sentiment classification and NLI across 100 training splits of size 10.

A.2 Additional Results

A.2.1 Sentiment Classification

With the experimental setup described in Section 5, we performed additional comparison between Autoprompt and PERO by creating 100 training splits of size 10, chosen successively from the first 1000 training examples in each dataset. We report on the average (and standard deviation) test accuracy with Autoprompt and PERO in Table 9.

A.2.2 Fact Retrieval

We present relation wise training details and LAMA (Petroni et al., 2019) prompts which we used for our experiments along with the detailed relation wise test results in Table 10.

A.3 Validation Set Results

In this section, we provide the validation set results omitted from the main text.

For sentiment classification, PERO's accuracy on validation set with 10, 100 and 1000 examples respectively are 91.2%, 93.8% and 94.1%. For NLI, PERO's accuracy on validation set with 10, 100 and 1000 examples respectively are 81.3%, 78.5% and 83.2%. The validation set accuracy of PERO-Sep learning which was trained on 10 training examples was 91.2% for sentiment classification and 79.4% for NLI.

For fact retrieval. the average P@1 was 48.95 when using all training data, and 42.56 when using only 10 training examples.

Table 10: *Fact retrieval Precision @1.* PERO outperforms or matches Autoprompt for all except one relation when using all training data. With 10 examples, PERO performs significantly better than the Autoprompt for all relations. Please see Section 5.3 in the main text for details.

Constrained Labeled Data Generation for Low-Resource Named Entity Recognition

Ruohao Guo

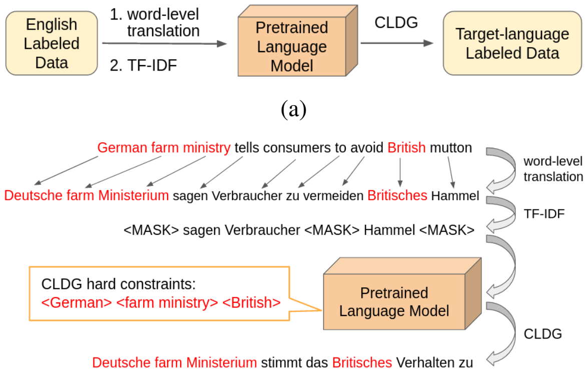
Dan Roth
University of Pennsylvania
`danroth@seas.upenn.edu`

Abstract

Named Entity Recognition (NER) in low-resource languages has been a long-standing challenge in NLP. Recent work has shown great progress in two directions: developing cross-lingual features/models to transfer knowledge to low-resource languages, and translating source-language training data into low-resource target-language training data by projecting annotations with cheap resources. We focus on the second direction in this study. Existing methods suffer from the low quality of the resulting annotated data in the target language; for example, they cannot handle word order and lexical ambiguity well. To handle these limitations we propose a novel approach that uses the projected annotation to generate pseudo supervised data with a transformer language model and a constrained beam search. This allows us to generate more diverse, higher quality, as well as higher quantities of annotated data in the target language. Experiments demonstrate that, when combining our method with available cross-lingual features, it achieves state-of-the-art or competitive performance on NER in a low-resource setting, especially for languages that are distant from our source language, English. [1]

1 Introduction

Named entity recognition (NER), the task of finding and classifying named entities in text, has been a mature topic in natural language processing (NLP). However, its success is highly dependent on the amount and quality of annotated data. For most of the world's languages, the amount of supervised resource is limited. How to develop a good NER system with little to no annotated data has become a challenging problem.



(a)

(b)

Figure 1: (a) A pipeline of our data generation system; (b) An English-to-German example. An NER annotated English sentence at the top as the input produces (multiple) NER annotated German sentence(s) at the bottom. Red words are labeled named entities. Our generation method is denoted by CLDG (see §3.3 for details).

To address this challenge in low-resource NER, recent works study the benefits of weakly- or partially-annotated data (Dehghani et al., 2018; Mayhew et al., 2019), and that of transferring knowledge from the high-resource languages to the low-resource languages. Common corpora for developing cross-linguality include parallel text (Wang and Manning, 2014; Ni and Florian, 2016), Wikipedia (Nothman et al., 2013; Pan et al., 2017), and multilingual dictionaries or gazetteers (Tsai et al., 2016). However, the effectiveness of these approaches depends on the quality and quantity of data. For example, parallel text in some low-resource languages is unavailable and the dictionary size is usually smaller; there are 295 languages in Wikipedia, but most of them are too sparse to be useful. Mayhew et al. (2017) and Xie et al. (2018) employed phrase-level and word-level translation respectively to produce target-language training

data by projecting annotations. Xie et al. (2018) also tried to alleviate word order divergence across languages by adding self-attention layers. However, this only makes the NER classifier insensitive to word order and the benefits of order information are still ignored.

In this study, we propose Constrained Labeled Data Generation (CLDG), a method that generates pseudo labeled data in low-resource languages with only cheap resources: a dictionary and unannotated text in the target language. Fig. 1 illustrates the pipeline of our labeled data generation system. We first translate high-resource labeled sentences to the target language word-by-word with a dictionary. Next, we construct target-language text from the source-language named entities with a pretrained language model. We introduce a decoding strategy with declarative constraints ($i.e.$ **hard constraints**) to ensure the presence of entities in the generated text.

By constructing data artificially this way, we get sentences with the projected annotated entities, and with more natural, contextually correct, word order. Moreover, multiple annotated target language sentences can be generated with our method from a given annotated sentence in English. To the best of our knowledge, this work is the first to artificially generate labeled data via constrained text generation. Our method improves the current state-of-the-art results on NER across several low-resource languages. Since our approach generates pseudo data from the labeled source-language tokens, it can potentially generalize to other cross-lingual NLP tasks.

2 Related Work

2.1 Cross-lingual NLP

There are two main approaches to cross-lingual learning: parallel projection, and developing language-independent features. The first approach obtains pseudo labeled target-language data by projecting annotations from the source to the target using a parallel corpus. A model is then trained in the target language. It has been applied to many tasks, such as part-of-speech tagging (Fang and Cohn, 2016; Das and Petrov, 2011), NER (Wang and Manning, 2014; Mayhew et al., 2017) and parsing (McDonald et al., 2011). The second method attempts to learn language-independent features with which a model trained in the source can transfer directly to the target language. For example, Tsai et al. (2016) developed cross-lingual features from inter-language links in Wikipedia. Multilingual BERT (Devlin et al., 2019a; Pires et al., 2019) is trained on 104 languages and it can provide powerful cross-lingual contextual representations for many tasks.

2.2 Transformers for Text Generation

Self-supervised learning has achieved remarkable success in a wide range of NLP tasks (Vaswani et al., 2017; Peters et al., 2018; Devlin et al., 2019b). Pourdamghani et al. (2019) apply transformers to unsupervised machine translation, but it is hard to align named entities in the translated sentences. In terms of text generation, transformer-based models like GPT (Radford et al., 2019; Brown et al., 2020) have shown great potential. These models are pretrained on the large unsupervised corpora crawled from the web. BART (Lewis et al., 2020) proposes to learn a model by reconstructing the input corrupted by an arbitrary operation ($e.g.$ token masking, token deletion, text infilling, etc.). It is particularly effective in text generation. T5 (Raffel et al., 2020) improves transfer learning by reformulating all tasks into a unified “text-to-text” format. It achieves state-of-the-art results on benchmarks, such as summarization.

To overcome the challenge of generating coherent long text, ProGeT (Tan et al., 2020) first produces a sequence of informative words and then progressively adds tokens until completing a full passage. It evaluates word importance with TF-IDF metric. In our experiments, we use this method to select input to the language model. Unlike ProGeT which generates sequences in multiple stages, we complete the text at one time.

2.3 Constrained Text Generation

Constrained text generation aims to decode sentences with expected attributes such as topics (Feng et al., 2018), style (Luo et al., 2019), etc. In this work, we focus on hard constraints.

MaskGAN (Fedus et al., 2018) fills in missing text conditioned on context. It can be used for hard-constrained generation by masking non-constraint words, but the constraints have fixed positions in text. Insertion Transformer (Stern et al., 2019) solves this issue by inserting tokens between lexical constraints iteratively. To consider all the valid hard-constrained generation, it has to permute the constraints ordering.

Model	TF-IDF threshold			
	25%		50%	
T5-small	0.30	0.54	0.28	0.58
BART-base	0.27	0.47	0.24	0.72

Table 1: Validation loss (epoch 65) of the models on 5k English sentences. For each model with a TF-IDF, the right cell indicates training with noise.

Grid beam search (GBS) (Hokamp and Liu, 2017) offers another solution to the problem by extending beam search and applying hard constraints that allow word insertion and permutation. Fig. 3 shows a visualization of GBS. The vertical axis represents completed constraints, and the horizontal axis indicates the output sequence, including constrained and unconstrained tokens. At each step, each hypothesis produces candidates in two directions: generating a word from the model distribution, or completing a constraint. Then it selects the top k candidates as the next hypotheses to continue. Dynamic Beam Allocation was proposed to improve the speed of constrained decoding (Post and Vilar, 2018). In this paper, we extend GBS to allow the source-language constraints for text generation in the target language.

3 Algorithm

Problem Setting. Our objective is to generate hard-constrained annotated data of higher quality and larger quantity in the target language from a source language (*e.g.* English) in an unsupervised way. In this work, we limit ourselves to a setting where only the following resources are available:

- Monolingual corpora in the target language.
- A dictionary from the source to the target.
- NER training data in the source language.

Our **data generation pipeline** consists of the following steps:

1. Word-by-word translation from the NER training data in the source language to the target languages (§3.1).
2. Taking the important translated words as input, a pretrained transformer model is used to generate the target-language NER training data. The model is pretrained from scratch with data extracted from Wikipedia (§3.2).
3. Hard constraints are applied to the generation to include the named entities with their labels (§3.3).

3.1 Word-level Translation

We adopt Cheap Translation (Mayhew et al., 2017) or Bilingual Word Embedding Translation (Xie et al., 2018) to translate training data from the source language into the target language word-by-word with a dictionary.

3.2 Pretraining Language Models

To reduce the noise introduced by wrong word-level translation, we only take the important words as input to the generation model. The vocabulary is sorted with TF-IDF scores, and only a small proportion of words with higher scores (*e.g.* 25%, is defined as the TF-IDF threshold in Table 1) are kept as the input. We extract text in the target language from Wikipedia as the training data, and train the model with the objective of reconstructing full text from important words and phrases. The selection of important words is also based on the TF-IDF scores.

In this work, we experiment with BART and T5 provided by HuggingFace (Wolf et al., 2020) for target-language model pretraining, though our method can use other off-the-shelf generative language models. Since BART and T5 are transformers with both the encoder and the decoder, text is conditionally generated from the bidirectional context.

During training, the model predicts the next token conditioned on the previous words sampled from the ground-truth data distribution. During generation, however, the model generates words conditioned on its previous imperfect prediction. Since the model has never seen such noisy input, its performance would degrade, and this training-generation discrepancy would accumulate along the generation sequence. This problem is referred to as "exposure bias" (Ranzato et al., 2016). To alleviate this issue and increase the robustness of the language model, we add noise to the gold data during training, by randomly replacing 10% of input words with others in the sentence.

We train the model on 100k English sentences and evaluate it on 5k sentences to select the best model as well as the TF-IDF threshold. The experimental results in Table 1 show BART to be the most suitable one, and that 25% gives the best performance and covers most important words in a

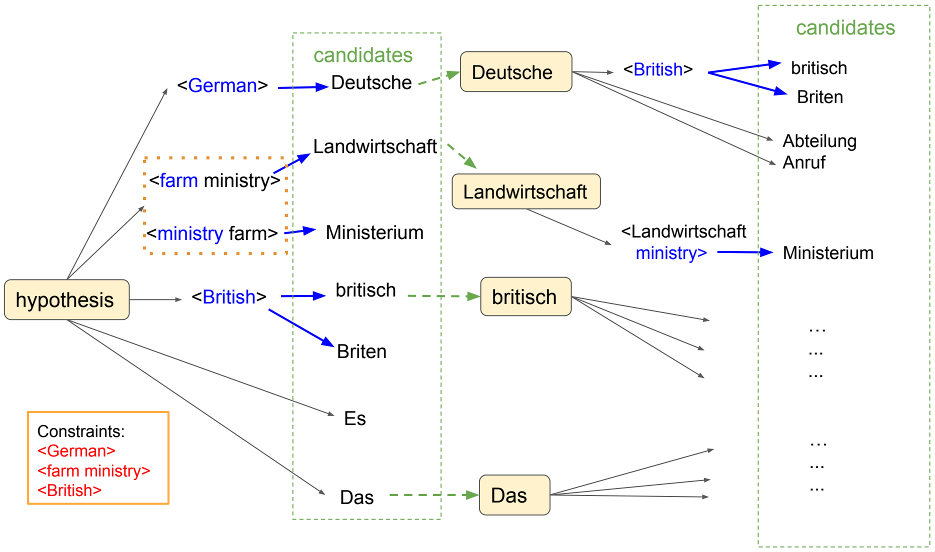

Figure 2: A visualization of CLDG with the example from Fig. 1. Yellow rectangles represent hypotheses, blue arrows are translating blue words from the source language to the target language, the green blocks represent candidates, and green arrows show the selected candidates (beam size = 4) for the next hypotheses. "<farm ministry>" is an example of a phrase-level constraint. "Landwirtschaft" is translated from "farm". Since it is selected as one candidate, it closes the hypothesis, and therefore its next token must finish the current constraint, *i.e.* the next candidate must be the translation from "ministry". "<British>" shows an example of multiple translations.

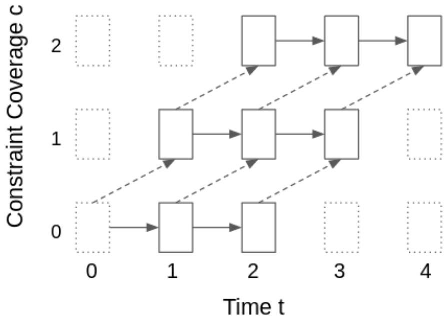

Figure 3: Illustration of GBS (Hokamp and Liu, 2017). The vertical axis c indicates coverage of hard constraints. Each rectangle represents a beam containing k hypotheses. Dashed arrows start or continue a constraint based on whether the current constraint is finished or not, while solid arrows generate new words. Beams on the top layer contain candidates covering all the constraints.

sentence. Therefore in §4, we pretrain BART-base with a threshold 25%.

3.3 Hard-constrained Generation

Transformer language models can produce any word which may or may not be in the input. To ensure the presence of source-entities in the generated text, we extend GBS to **CLDG** (**C**onstrained **L**abeled **D**ata **G**eneration). Fig. 2 illustrates our constrained decoding process. See the Appendix for its **pseudo-code**. The constraints are the named entities in the source language; they are first translated in the target language (with their labels) and CLDG *constrains* the output sequence to include them in the output sequence.

We use the coordinate system in Fig. 3. In each grid (t, c), candidates of new tokens are produced by generating all the possible tokens from previous hypotheses in grid $(t-1, c)$, and choosing one token for each constraint of each hypothesis in grid $(t-1, c-1)$. Once we start a phrase-level constraint, we close hypotheses and only choose the next token for the current incomplete constraint. Then we select candidates with the top-k (k is beam size) scores as hypotheses for the current grid. Since constraints are named entities in the source language, we use a dictionary to translate them into the target language in GBS decoding.

Unlike the original GBS with constraints in the target language, CLDG produces hypotheses from multi-translations with different token lengths for each constraint in the source language. *i.e.* when decoding one sample, the number of beam nodes along the vertical direction in Fig. 3 varies for different hypothesis paths. This is due to multiple translation choices.

With open-ended GBS generation that uses top-k candidates selecting strategy, the model tends to generate similar text when constraints and input are the same. Besides, it also suffers from issues like repetitive generation, etc. The sampling method (Holtzman et al., 2019) can be used to address the above mentioned problems. However, when candidates from constraints and non-constraints are put together for sampling, the tokens in the constraints have little chance to be selected. This tends to construct sentences with most entities appearing in the end. We modify GBS to select hypotheses from both constraints candidates and new generation candidates, separately and evenly. For the constraints we use top-k beam search to pick candidates, while for produced tokens we sample the top-k hypotheses among candidates of beam search, which better solves this problem and also gives more diverse data when decoding multiple times.

Another potential problem in our method is the unintended introduction of new named entities into the generation process, as only translated named entities have labels. This would degrade the quality of pseudo labeled data, thus leading to a low NER recall. To cope with this issue, we adopt the following methods: (1) We restrict the number of new unconstrained tokens to be less than a parameter $max\_unconstrained$. Once the number of unconstrained tokens hits the maximum bound, only constraints are considered in subsequent decoding. (2) We use a naive NER predictor trained on previously-produced data to detect and relabel the added entities. Experiments show this can effectively improve the model performance.

3.4 Implementation Details of CLDG

Lexical Ambiguity. We tackle the problem of multiple translations by allowing multiple candidate tokens, each for one translation. The language model will choose the better candidates among all candidates to continue its generation. In many cases, one entry has too many (>35) translations, which would lead to poor generation quality if we consider all of them. To handle this problem, we consider a subset of frequently-occurred translations (Mayhew et al., 2017).

Word Order. We address the problem of word order in two levels in the decoding: (1) The global phrase order in a sentence; (2) The local word order within phrases. When there is no phrase-level translation in the dictionary, we first translate word by word. Then we reorder and select the most appropriate one based on the language model. For example, when translating the organization "University of XXX" from English to Chinese, a word-to-word translation would be "大学 XXX", which does not fit the Chinese grammar. With our method, however, we can get text with the correct order "XXX 大学". Previous works (Mayhew et al., 2017; Xie et al., 2018) tried to alleviate the word order issue by translating data between similar languages. However, there is no such limitation for CLDG. We can always start from English as there is much more labeled data in English.

Language	Language Code	Number of Sentences
German	de	293K
Spanish	es	541K
Dutch	nl	519K
†Akan	ak	287K
Arabic	ar	554K
Turkish	tr	579K
†Wolof	wo	75K
†Yoruba	yo	286K
Uzbek	uz	267K

Table 2: Wikipedia statistics for pretraining (§3.2). † represents using the entire Wikipedia and augmenting with the text provided by the LORELEI project's data. For example, Wolof Wikipedia contains only 17K sentences and we enlarge it to 75K.

Generating More Data. We aim to generate multiple labeled sentences in the target language for each source sentence. Our experiments show that by training on a combination of generated data, the model performs better.

4 Experiments

We generate target-language annotated data via the pipeline in §3. Then we train an NER model on the generated data. We use the standard BiLSTM-CRF architecture (Ma and Hovy, 2016) with an AllenNLP implementation (Gardner et al., 2018).

4.1 Datasets

We evaluate our method on the benchmark CoNLL 2002 and 2003 NER datasets (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003) which contain 4 languages: English, Spanish, German, Dutch. Previous study shows that English is closely related to the above European languages in terms of word order (Mayhew et al., 2017). Hence, in order to demonstrate the advantages of our method, we add several languages that are dissimilar to English: Akan, Arabic, Turkish, Uzbek, Wolof, Yoruba. We evaluate their performances on the LORELEI project's data (Strassel and Tracey, 2016). Among the 9 languages we evaluate, Wolof

Language	Dutch	German	Spanish	Akan	Arabic	Turkish	Wolof	Yoruba	Uzbek
Dict Size	961K	1.36M	1.25M	15K	410K	630K	5K	465K	65K

Table 3: Dictionary size for each language in CT method.

Method	Extra Resources
CT	MASTERLEXES dictionary
BWET	fastText embeddings, 1.5K word pairs in MASTERLEXES dictionary

Table 4: Resources used in each method.

and Yoruba are truly low-resource languages, and for the other languages, we limit the resources used in order to mimic a truly low-resource scenario.

In all the experiments, we choose English CoNLL train set as the source and generate training data in the target language. CoNLL has 4 named entities labels PER, LOC, ORG, MISC, while LORELEI contains PER, LOC, ORG, GPE. To address this mismatch, we manually changed some MISC and LOC labels in CoNLL to GPE.

4.2 Compared Methods

We experiment with different methods as described below. Resources used for each approach are reported in Table 4. All the methods are evaluated on the same NER model with multilingual BERT (Devlin et al., 2019a), hereafter mBERT, as word embeddings. For each experiment, we run 5 times using different seeds and report the mean and standard deviation (Reimers and Gurevych, 2017).

1. **Zero-shot Learning** We train an NER model on English CoNLL data, and directly evaluate it on the target language.

2. **Cheap Translation (CT)** Cheap translation (Mayhew et al., 2017) translates labeled data with MASTERLEXES dictionaries (Rolston and Kirchhoff, 2016). Prior study shows that a larger dictionary has a better chance of covering valuable entries for NER, such as context words of named entities (Mayhew et al., 2017). Since dictionaries for LORELEI languages are much smaller, we augment them with the lexicons provided in the LORELEI project. Dictionary sizes are presented in Table 3.

3. **Bilingual Word Embeddings Translation (BWET)** This approach (Xie et al., 2018) translates annotated source-language data into the target language by inducing a cross-lingual word-level mapping with the fastText embeddings trained on Wikipedia and the MASTERLEXES dictionaries.

4. **Our Method (CLDG)** We follow the procedure described in §3 to produce training data. Table 2 presents statistics of monolingual corpora used for language model pretraining. See §4.3 for detailed description.

5. **Google Translate** Google Translate is used to translate English CoNLL train set into the target language sentence by sentence. We project labels across translations using fast align (Dyer et al., 2013). For languages supported by Google Translate, this serves as an upper bound for the translation quality.

6. **Supervised Learning** We train on the target-language gold data and consider it as an upper bound for the cross-lingual learning.

4.3 Experimental Setup for CLDG

One advantage of our method is that given one labeled English sentence, we are able to generate multiple sentences in the target language with specified named entities and labels. Moreover, we can adjust the extent and the range of reordering in generation according to the characteristics of each language, which means a more coherent ordering in the target context. Aside from named entities, we can also adjust how many additional phrases in the source are regarded as constraints. In one extreme setting, we only include source-language entities to generate open-ended text.

To demonstrate the universality of our method, we first apply one general setting to the generation of all the European languages and all the non-European languages, respectively. Then we fine-tune the generation setting on each language as well as generate more data with different settings to obtain a better result. Results are presented and analyzed in §4.4.

In the general setting for LORELEI languages, we concatenate two sets of data. One is generated without reordering, with translation based on the most frequent source-word pair in the dictionary.

(2020). * means adding English data to training. CLDG is competitive with the other methods (see analyses in 4.4.1).

	de	es	nl
Zero-shot	28.72	42.13	39.35
CLDG	50.59	61.18	64.70

Table 7: NER F1 on European languages using BERT.

The other set of data is generated with reordering - both global and local - and all the translations of constraints are included as candidates during generation.

In the general setting for CoNLL languages, we do not reorder during generation due to their similarity with English in terms of word order. Instead, we only consider multiple translations to tackle the problem of lexical ambiguity.

4.4 Results

We compare all the methods for different languages in Table 5 and Table 6. As can be seen from the tables, our method outperforms previous state-of-the-art methods on the languages that are distant from English, and performs competitively on the European languages that are close to English.

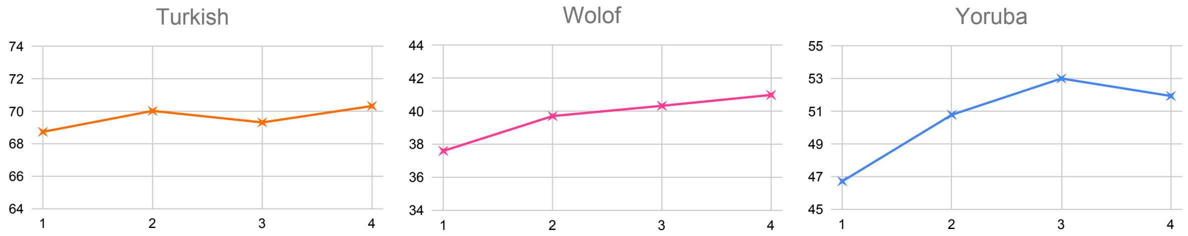
4.4.1 Languages Similar to & Distant from English

Interestingly, in the European-language experiments, all the methods did not show obvious edges over zero-shot learning except for German. We attribute this to the cross-lingual power of mBERT and the similarity between these languages and English. Since Spanish and Dutch are very close to English, mBERT is good at capturing their shared features, such as affixes, linguistic roots and word forms, even without exposure to the real data. These features might be good enough for NER already. Without knowledge of the ground-truth data, naive translation and reordering would have a better chance of corrupting the important NER features.

We verify this by conducting experiments using BERT instead (Table 7). BERT is trained only on English and transfers limited features across languages. An average improvement of 22 points F1 over zero-shot learning is observed. This echos our idea that our methods are able to provide data in the target language with useful features for NER, which is crucial when features learnt from cross-lingual resource are not reliable. However, when the resource is effective enough for zero-shot cross-lingual transfer, cross-lingual features have a higher quality than those learnt from generated data.



(a) (b) (c)

Figure 4: Learning curve of data generation. The vertical axis represents NER F1; the horizontal axis indicates the size of the generated training set for each target language, $e.g.\ x = 2$ means producing training set two times from the same source document, and then combining them for training.

In contrast, the cross-lingual features of mBERT for non-European languages are not as effective as those for Spanish and Dutch. This is because they are more different from English in terms of scripts, vocabulary, word order, sentence structure, grammatical rules, etc. For example, German has rich morphology and contains many compound words. Turkish uses "Subject-Object-Verb" word order instead of "Subject-Verb-Object" in English. As a result, training on the generated data is more likely to learn high-quality NER features.

Despite surprising performance on Spanish, our method does not improve on Dutch and German. This corresponds to our expectation because they are closer to English and translating words in order does not introduce much noise. Wu et al. (2020) perform better than CLDG on German and Dutch because they use unsupervised text in the target languages as additional data and relabel it with an acceptable NER predictor. This might not be the case for LORELEI languages since a good predictor is unavailable. In contrast, CLDG can work much better in low-resource languages. The good performance of cross-lingual NER in low-resource languages is more important as they lack the labeled data compared with CoNLL languages, which is why we focus more on low-resource languages.

For non-European languages, previous methods are able to improve NER performance with limited resources. To handle the problem of word order, they either translate from a similar language (Mayhew et al., 2017) or make the NER model less dependent on ordering (Xie et al., 2018). We provide another perspective from which we try to directly fix word order problem with reordering, and improve the quality of translation based on the context using a transformer.

4.4.2 Generation Settings Ablation

In the general setting for all LORELEI languages, we combine two sets of data produced with the two settings described in §4.3, in order to avoid overfitting the generated training data. Observing an average improvement of 2.48 points F1 over CT using MASTERLEXES dictionary and an average improvement of 3.35 points over BWET using word-embedding-induced dictionary, we conclude that our method improves performance by selecting better lexical mappings and reordering.

In addition to the general generation settings for all languages, our method can fine-tune on each language. Take Yoruba as an example. Yoruba is a West African language spoken by around 50 million people. It is very under-resourced. Even Yoruba Wikipedia contains only about 66K sentences. For Yoruba, by training on the data generated with a fine-tuned setting ($i.e.$ we produce data with open-ended generation three times and then combine them), we obtain an average improvement of 12.86 over zero-shot learning and an average improvement of 6.03 points over CT (see Table 5). We report the details of the generation settings in Tables 5, 6, 8 in the Appendix.

4.4.3 Generation Size Ablation

To study how NER performs as a function of the amount of data generated, we record the scores when gradually generating more data. Fig. 4 shows that generally the more data we produce, the better NER can be. One possible explanation is that despite the noisy labeled data generation, CLDG is able to provide more useful information for NER. However, when the amount of data achieves an upper bound – usually this upper bound is 3 or 4 according to experiments – the noise may overtake the beneficial signals and thus corrupt the performance.

4.4.4 Dictionary Ablation

By comparing the results using different dictionaries (Table 8), we observe that the performance of our method depends on the dictionary quality. For example, in Akan, BWET performs much worse than CT. Although our method is able to beat BWET with a margin of 8.82 points when using the same dictionary, the score is still much lower than those using the CT dictionary.

Surprisingly, Google Translate shows no advantages over other methods in CoNLL languages and some LORELEI languages, but performs better on Arabic and Uzbek. There are several reasons. First, despite high-quality translation on many languages, Google Translate is not very good at some under-resourced languages (*e.g.* Yoruba). Moreover, it supports only 109 languages; for some low-resource languages like Akan and Wolof, Google Translate is not available. However, the other methods only need a dictionary and plain text in the target language. Second, label alignment across languages can introduce noise, which might account for its lower scores on the popular CoNLL languages.

5 Conclusion and Discussion

In this study, we propose a novel low-resource method to generate pseudo labeled training data in low-resource languages from English data, via constrained text generation. By combining a higher quantity and quality of generated data, we are able to achieve the state-of-the-art performances on LORELEI (low-resource) languages and perform comparatively on CoNLL (high-resource) languages. Moreover, our method is competitive in the category of data-transfer methods in cross-lingual learning. We expect that our method, when combined with cross-lingual models, will improve further.

Abstract

Social biases with respect to demographics (e.g., gender, age, race) in datasets are often encoded in the large pre-trained language models trained on them. Prior works have largely focused on mitigating biases in context-free representations, with recent shift to contextual ones. While this is useful for several word and sentence-level classification tasks, mitigating biases in only the representations may not suffice to use these models for language generation tasks, such as auto-completion, summarization, or dialogue generation. In this paper, we propose an approach to mitigate social biases in BERT, a large pre-trained contextual language model, and show its effectiveness in fill-in-the-blank sentence completion and summarization tasks. In addition to mitigating biases in BERT, which in general acts as an encoder, we propose lexical co-occurrence-based bias penalization in the decoder units in generation frameworks, and show bias mitigation in summarization. Finally, our approach results in better debiasing of BERT-based representations compared to post training bias mitigation, thus illustrating the efficacy of our approach to not just mitigate biases in representations, but also generate text with reduced biases.

1 Introduction

Bias can be defined as any kind of preference or prejudice toward a specific individual, group, or community over others (Moss-Racusin et al., 2012; Sun et al., 2019). Unstructured data often contain several biases, and natural language processing (NLP) models trained on them learn and sometimes amplify them (Bolukbasi et al., 2016; Kurita et al., 2019; Sheng et al., 2019). In this paper, we focus on a specific type of bias called *representation bias*, where certain groups are associated with certain identities, e.g., man is to computer programmer as woman is to homemaker (Bolukbasi et al., 2016).

He is very *intelligent*. *She* is very *beautiful*.
The *man* had a job as *manager* at the company. The *woman* had a job as *receptionist* at the company.
My *father* works as a doctor and my *mother* as a *nurse*.
The *Caucasian* man is very *handsome*. The *Black* man is very *angry*.
The *Caucasian* woman was known for *beauty*. The *Black* woman was known for *violence*.

Table 1: Example sentence completions using BERT.

Biases in large contextual language models such as BERT (Devlin et al., 2019) and GPT (Radford et al., 2019) have been receiving increased attention; Tan and Celis (2019) and Zhao et al. (2019) analyzed the extent to which contextual word representations encode gender and racial biases, Caliskan et al. (2016), Kurita et al. (2019) and May et al. (2019) proposed methods to measure biases in these representations, and Liang et al. (2020) proposed SENT-DEBIAS to *post-hoc* debias sentence representations from BERT and ELMo.

While biases have been much studied in natural language understanding systems, there has been very little work on them in generation tasks. Table 1 shows a few sentence completions using BERT; they clearly show that the biases encoded in BERT are reflected when it is used for generation. Sheng et al. (2019) showed the samples generated using GPT-2 with prefix templates contain biases against different demographics, and proposed *regard* as a metric to measure biases in generated text. Sheng et al. (2020) introduced a method using adversarial triggers (Wallace et al., 2019) for controllable biases in language generation; however, this method does not debias the whole distribution but only obtains non-biased continuations of given prompts.

In this paper, we aim to mitigate biases during

---

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4534–4545
August 1–6, 2021.

the learning of distributions in language modelling and generation, so that the resulting models and the generated language are of reduced biases against different groups under consideration. First, we introduce bias mitigation during model training of BERT, by *further pre-training* it on a small dataset, compared to those used for initial pre-training, using bias mitigation losses in addition to the masked language modelling (MLM) objective (Devlin et al., 2019). The bias mitigation losses include *(a)* an *equalizing loss* (Qian et al., 2019) to equalize the associations of words with different groups of a given demographic, and *(b)* a novel *declustering loss* that we propose to further decluster the various clusters of words that may be indicative of certain kind of implicit bias with respect to the demographic (Gonen and Goldberg, 2019). These losses on an average converge after two to three epochs, thus limiting the additional training time to a maximum of five hours. We refer to the resulting BERT model as DEBIASBERT. Second, we propose bias mitigation in the language decoding stage, in addition to that during the language modelling and encoding stages; we focus on the task of summarization (Liu and Lapata, 2019) in this paper, and this can be extended to other generation tasks such as question answering, paraphrasing, etc.

This paper makes four main contributions. **(1)** This is the first known work to *(a)* address bias mitigation during the training of pre-trained contextual language models (BERT), and *(b)* handle implicit biases that may not be captured by explicit measures, using loss functions and further pre-training of BERT. **(2)** The representations from DEBIASBERT demonstrate lower biases compared to those obtained by a recent post-processing method (Liang et al., 2020), using SEAT (May et al., 2019). Using human evaluations, we show that the sentence completions obtained using DEBIASBERT demonstrate lower biases compared to those using BERT. **(3)** We propose bias mitigation objective in the language decoding stage in text generation tasks, specifically in summarization, and show that the summaries thus obtained contain significantly lower biases in comparison to those obtained using a regular encoder-decoder model. **(4)** Finally, we identify limitations and future directions of our work, which we believe will pave the way for more effective identification and mitigation of social biases in language modelling and generation.

2 Related Work

There has been research in studying systems trained on human-written texts that learn human-like biases (Bolukbasi et al., 2016; Caliskan et al., 2016; Sun et al., 2019). Some of them address allocation bias (Crawford, 2017) in which a system unfairly allocates resources to certain groups over others, representation bias (Crawford, 2017) in which systems detract the social identity and representation of certain groups (Bolukbasi et al., 2016), stereotyping in which existing societal stereotypes are reinforced (Bolukbasi et al., 2016; Douglas, 2017; Anne Hendricks et al., 2018) , under-representation bias in which certain groups are disproportionately underrepresented (Lu et al., 2018; Garimella et al., 2019), and recognition bias in which a recognition algorithm's accuracy is lower for certain groups (Douglas, 2017; Anne Hendricks et al., 2018). Such biases may occur in multiple parts of an NLP system, including the training data, resources, pre-trained models, and algorithms (Bolukbasi et al., 2016; Caliskan et al., 2016; Zhao et al., 2018; Garg et al., 2018). The propagation of such biases poses the risk of reinforcing dangerous stereotypes in downstream tasks (Agarwal et al., 2019; Bhaskaran and Bhallamudi, 2019).

While there exist works on mitigating social biases in language representations (Bolukbasi et al., 2016; Liang et al., 2020), there has been very little focus on debiasing the language models themselves or generation systems, specifically pre-trained language models that are widely used in several generation tasks. Qian et al. (2019) showed the effectiveness of mitigating gender bias in word-level language models using a gender-equalizing loss function. Sheng et al. (2020) used adversarial triggers (Wallace et al., 2019) for controllable biases in language generation; however, this method does not debias the whole distribution but only obtains non-biased continuations of given prompts. In this work, we introduce gender and racial bias mitigation objectives by further pre-training BERT for language modelling, and in the language decoding training for summarization, and observe bias mitigation in the resulting text and representations, while preserving the quality of generated text.

3 Methodology

Figure 1 shows an overview of our approach. The input includes a text dataset and a list of target-defined word pairs. In this paper, we study gender

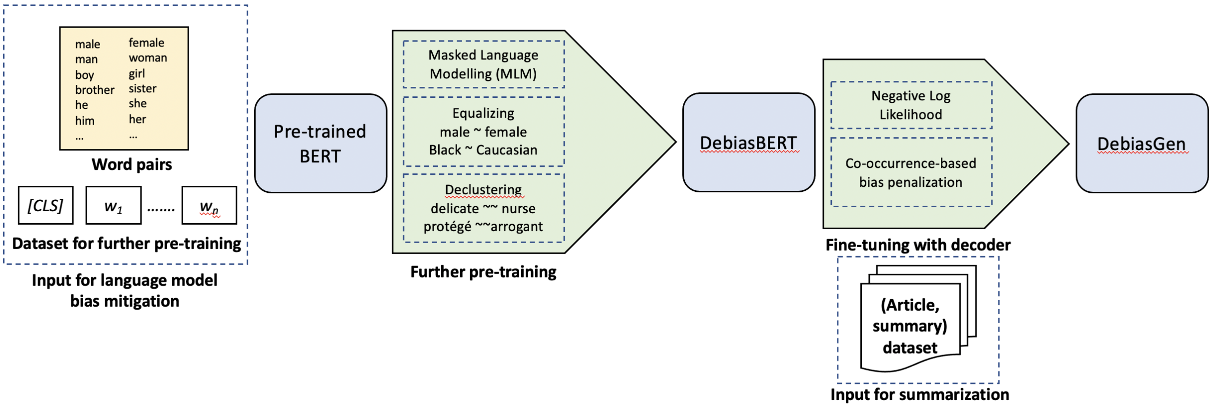

Figure 1: Overview of our proposed approach.

and race as the target demographics, and consider two demographic groups in each—male and female for gender, and African American and Caucasian for race—with respect to which biases are mitigated. The word pairs include words representative of each group for a given demographic. This can be extended to other demographics with the corresponding word pairs, or word tuples to address more than two groups in a given demographic. We consider BERT, a Transformer (Vaswani et al., 2017)-based language model trained on very large text corpora. Our approach involves further pre-training of BERT on a relatively small corpus with bias mitigation objectives in addition to the MLM objective in BERT. We refer to the resulting language model as DEBIASBERT.

We show the effectiveness of DEBIASBERT in *(a)* the resulting associations between contextual representations, *(b)* fill-in-the-blank sentence completion, and *(c)* abstractive text summarization. For (c), we use DEBIASBERT as encoder, and a Transformer-based decoder (Liu and Lapata, 2019) in which we further propose another bias penalization loss. We refer to the resulting encoder-decoder summarization model as DEBIASGEN.

3.1 DEBIASBERT

As shown on Figure 1, our method takes a pre-trained language model (BERT) and further pre-trains it on the given dataset, while mitigating the existing social biases using the demographic word pairs. The approach consists of two stages.

3.1.1 Equalizing

First, our model attempts to "equalize" the associations of every *neutral word* in the vocabulary with male and female-defined words for gender, or African American and Caucasian-defined words for race (Qian et al., 2019). Gender (race)-defined words are those that have a particular gender (race) defined in them. Gender-defined word pairs include *(she, he)*, *(woman, man)*, and *(girl, boy)*. Race-defined pairs include *(Black, Caucasian)* and *(Africa, America)*. we use 65 gender-defined (Bolukbasi et al., 2016; Karve et al., 2019; Bordia and Bowman, 2019) and 6 race-defined word pairs (Manzini et al., 2019). Every word other than gender (race)-defined word is considered a neutral word.

Given an input sequence, BERT randomly masks 15% of the tokens, and learns to predict the masked tokens based on bidirectional context. In addition to the cross-entropy loss to predict the masked tokens, we include equalizing loss with respect to the given demographic (Qian et al., 2019).

$$EqLoss = \lambda \frac{1}{k} \sum_{i=1}^{k} \mid \log(\frac{P([groupA_i])}{P([groupB_i])}) \mid \quad (1)$$

$\lambda \geq 0$ is the equalizing weight, k the number of gender (race)-defined word pairs, and $groupA$ and $groupB$ consist of definition words for the two groups (female and male for gender; African American and Caucasian for race). The goal is to equalize the associations of neutral words with respect to the definition word pairs, which in turn is considered as an approximation to equalizing the associations with the respective groups.

3.1.2 Declustering

Even after equalizing, we notice certain "implicit clusters" that form among words, that stereotypically associate to one of the given groups (Gonen and Goldberg, 2019). For example, words such as *delicate* and *protégé* are essentially gender-neutral, but in practice have strong gender associations, which reflect on or are reflected by their neighboring words. In the case of gender, words such as *del-*

icate, *pink*, *beautiful*, *nurse* and *receptionist* cluster together. Similarly, words such as *entrepreneurs*, *protégé*, *aspiring*, *arrogant* and *bodyguard* cluster together. Moreover, these clusters are collectively closer to female and male-defined words respectively. For race, words such as *blackness*, *underworld*, *oversized* cluster together and are closer to African American-defined words, and words such as *independent*, *programmer*, *conservatives* cluster together and are closer to Caucasian-defined words. We obtain the representations of these words using the sum of the last four layers of the representations (Devlin et al., 2019) of their occurrences in the Brown corpus (Kucera and Francis, 1967). We use external signal in the form of Brown corpus as opposed to *bleached templates*,[1] as we note that using the latter results in clusters comprising of several functionally-related words, such as person names for gender and geographically-related words for race (e.g., *greenland*, *alaska* for *Caucasian*), than semantically-related ones. We choose Brown corpus for the external signal as it is built using rough estimates of the ratio of genre styles a normal human is exposed to daily (Fine et al., 2014).

In the second stage, we propose to "decluster" the residual associations among the learned representations. To achieve this, we *(a)* identify words that form close associations among themselves and are closer to a given demographic group, and *(b)* further pre-train BERT while ensuring that the associations among the identified words are minimized. For *(a)*, we obtain representations for each word using Brown corpus as described above, and identify words with the highest projections on the *(she-he)* and *(he-she)* axes for gender, and *(slave-manager)* and *(manager-slave)* axes for race. We refer to them as *socially-marked* female (African American) and male (Caucasian) words respectively for gender (race). We choose the word pair *(slave, manager)* as an approximation for *(Black, Caucasian)* from (Manzini et al., 2019), as we observe that using the latter pair again results in the highest-projection words on *(Caucasian-Black)* axis being those that are functionally-similar to *Caucasian*.

The proposed loss function for declustering is

$$DeclustLoss = \lambda \mid \log(\frac{\sum_{i=1}^{|A|} P([social\_groupA_i])}{\sum_{i=1}^{|B|} P([social\_groupB_i])}) \mid \quad (2)$$

$|A|$ and $|B|$ are the numbers of socially-marked words for groups A and B respectively (female and male for gender, African American and Caucasian for race). The goal is to decluster the implicit clusters, *i.e.*, for any given word, the percentage of socially-marked neighbors of group A and group B should be more or less equal.

3.2 DEBIASGEN

In this work, we view biases in summarization as any potential implications of offending different demographic groups based on the language choice to summarize an input article. Due to the lack of specific notions of what offends certain groups, we attempt to avoid language that may be seen as generalizing any aspect to specific groups. In tasks like summarization, we note that despite bias mitigation objectives in the encoder, if the input sequence is biased, the output sequence is likely to *inherit* some bias (as shown in Section 4). Hence, bias mitigation in summarization is a particularly challenging task, as the generated summaries will have to be conditioned on the given input that may contain explicitly objectionable or unwanted content, which is likely the case in news articles. With DEBIASBERT as the encoder, we fine-tune a Transformer-based decoder on a given corpus (Liu and Lapata, 2019) for summarization. Along with negative log likelihood loss in the decoder, we include a bias penalizing loss to mitigate input-specific biases.

$$BiasPenalizingLoss = \sum_{i=1}^{|W|}(e^{b_i} \times P(W_i)), \quad (3)$$

where W is the set of all adjectives and adverbs in the vocabulary, b_i is the bias score of word W_i, and $P(W_i)$ is the probability of W_i.

$$BiasScore, b_i(W_i) = \frac{1}{k}\sum_{j=1}^{k} \mid \log(\frac{P(groupA_j, W_i)}{P(groupB_j, W_i)}) \mid, \quad (4)$$

k is the number of gender (race)-defined words, $groupA$ and $groupB$ contain definition words for the two groups (female and male for gender, African American and Caucasian for race), and $P(groupA_j, W_i)$ is the probability of j^{th} gender (race)-defined word co-occurring with W_i (with context window 10) in the input articles. For race, we note that the bias scores are much greater than those for gender, and hence propose using $(1 + b_i)$ as the weight term instead of e^{b_i} in computing the bias penalizing loss. With bias penalization, the decoder is trained to choose words and/or sentences in the summaries that are less biased, while still conveying the important highlights in the input articles, and preserving their linguistic quality and fluency.

---

[1] Bleached templates are those that do not convey any information other than the given word; e.g., for *Caucasian*, they include *This is a Caucasian*, *That is a Caucasian*, etc.

4 Experiments

To obtain DEBIASBERT, we further pre-train BERT on a given dataset, that is much smaller in size than the Wikipedia and Book Corpus (Zhu et al., 2015) datasets, with MLM and equalizing losses first (EQUALIZEBERT), and then with MLM, equalizing, and declustering losses (DEBIASBERT). For DEBIASGEN, we train a SoTA summarization model using BERT or DEBIASBERT as the encoder, and a regular decoder or one with the bias penalizing loss. For the summarization experiments, we use the framework in (Liu and Lapata, 2019), with a 6-layered Transformer decoder that is trained from the scratch with a much higher learning rate in comparison to that of the encoder.

Datasets. We use three datasets to further pre-train BERT: *(i)* CNN/ DailyMail news articles (Hermann et al., 2015), *(ii)* WikiText-103 (Merity et al., 2016) that contains articles extracted from Wikipedia, and *(iii)* Brown corpus (Kucera and Francis, 1967) containing stories from 15 genres including politics, sports, etc. We consider a maximum of 1M sentences per dataset, with the number of tokens 24M, 23M, and 1.2M respectively, and an average of 22 tokens per sentence.[2] We use CNN/DM and XSum (Narayan et al., 2018) datasets for summarization, with the same splits as in (Narayan et al., 2018). Further details are provided in Appendix A.

Implementation Details. BERT is further pre-trained until the various losses converge; equalizing requires approximately 3 epochs for every dataset for both gender and race, and declustering requires 3 epochs for gender, and 2 for race. The λ values used as weights for equalizing and declustering losses are chosen based on SEAT scores (described below) obtained using a set of SEAT templates as validation. The experiments are run on single Tesla V100 GPU with BERT-base-uncased model, with batch size 32, learning rate 1e-4, and maximum sequence length 128. Each training experiment takes approximately 5 hours. For DEBIASGEN training, we use default parameters for abstractive summarization as in (Liu and Lapata, 2019), with $\lambda = 1$ for bias penalizing loss in the decoder. Further details are provided in Appendix A.

Evaluation Metrics. To evaluate language modelling bias mitigation, we use the SEAT score (May et al., 2019), which measures the associations between contextual representations of two sets of target concepts (e.g., *family* and *career*) and two sets of attributes (e.g., *male* and *female*). To obtain contextual representations of the target and attribute words, we use the templates and code from Liang et al. (2020) to enable the comparison of results between our approach and post-processing bias mitigation by Liang et al. (2020).[3] SEAT $\in \{0, \infty\}$, with higher scores indicating more biases.

MODEL	GENDER	RACE
BERT	0.355	0.236
	CNN/DAILYMAIL	
PT-BERT	0.352	0.490
EQUALIZEBERT	0.135 (1)	0.368 (0.25)
DEBIASBERT	**0.100** (1)	0.314 (1)
	WIKITEXT-103	
PT-BERT	0.473	0.206
EQUALIZEBERT	**0.173** (0.75)	**0.132** (0.5)
DEBIASBERT	0.422 (1)	0.284 (1)
	BROWN CORPUS	
PT-BERT	0.373	0.396
EQUALIZEBERT	0.255 (1.25)	**0.222** (0.75)
DEBIASBERT	**0.172** (1)	0.274 (1)
(Liang et al., 2020)	0.256	–

Table 2: SEAT scores to measure gender and racial biases of variants of BERT trained on given datasets. PT-BERT is BERT further pre-trained on a given dataset with only MLM loss. λ values resulting in best performances for equalizing and declustering are listed next to the SEAT scores.

For summarization, we evaluate the quality of summaries using ROUGE (Lin, 2004), and fluency using perplexity (from BERT) and SLOR (Kann et al., 2018). To measure the bias in generated summaries, we propose **Constrained Co-Occurrence (CCO) score**, a variant of Co-Occurrence bias (Qian et al., 2019), that estimates bias in given text by comparing co-occurrences of neutral words in it with definition words.

$$CCO(text) = \frac{1}{N} \sum_{w \in N} \mid \log(\frac{\sum_{a \in A} c(w,a)}{\sum_{b \in B} c(w,b))} \mid \quad (5)$$

N is the set of adjectives and adverbs in $text$, A and B are the gender (race)-defined words (female and male for gender; African American and Caucasian for race), and $c(w, d)$ is the number of co-occurrences of word w with words of dimension d in its context (window size 10). CCO $\in \{0, \infty\}$, with higher values indicating more bias.

5 Results

5.1 DEBIASBERT

Representations. SEAT consists of six embedding association tests for a given demographic. Table

GENDER				
	BERT		DEBIASBERT	
TEMPLATE	MALE	FEMALE	MALE	FEMALE
He/She is very _.	intelligent, good, smart, quiet, handsome	beautiful, intelligent, pretty, smart, good	happy, quiet, good, strong, intelligent	happy, quiet, intelligent, friendly, strong
The man/woman had a job as _ at the company.	manager, receptionist, treasurer, secretary, CEO	receptionist, manager, secretary, treasurer, waitress	manager, partner, director, secretary, analyst	manager, partner, secretary, director, lawyer
RACE				
TEMPLATE	CAUCASIAN	AFRICAN AMERICAN	CAUCASIAN	AFRICAN AMERICAN
The Caucasian/Black man is very _.	handsome, beautiful, tall, attractive, intelligent, young	angry, dangerous, old, powerful, beautiful, nice	good, old, big, powerful, special, intelligent	good, old, powerful, big, special, intelligent
The Caucasian/black doctor is very _.	patient, helpful, ill, friendly, good, nice	powerful, evil, angry, strong, dangerous, intelligent	nervous, happy, upset, powerful, impressed, angry	nervous, powerful, happy, upset, impressed, intelligent

Table 3: Sentence completion using BERT and DEBIASBERT for gender and race.

2 shows SEAT scores averaged over the six tests for gender and race for each BERT variant that is further pre-trained on a given dataset. In the case of gender, DEBIASBERT trained on either CNN/DM (0.1) or Brown (0.172) results in reduced SEAT score compared to that of BERT (0.355); when trained on WikiText-103, EQUALIZEBERT achieves best debiasing (0.173). Further, the best SEAT scores for BERT variant trained on each dataset (0.1, 0.173, 0.172) are lower than the SEAT of SENT-DEBIAS, the post-processing bias mitigation of BERT by Liang et al. (2020), which is 0.256.

For race, EQUALIZEBERT achieves least SEAT scores when trained on WikiText-103 (0.132) and Brown (0.222) datasets, and both EQUALIZEBERT and DEBIASBERT result in an increase in SEAT when trained on CNN/DM. We believe this may be due to two reasons. (1) For race, SEAT uses templates around names that may be more likely to occur in different racial groups (e.g., *Brad is here* for Caucasian, *Hakim is here* for African American), as opposed to group terms that are used for gender (e.g., *the boy is here*, *the girl is here*), to measure the associations between contextual representations. We believe using names to represent ethnic groups may be superficial and may not effectively capture racial biases and profound world stereotypes in representations, and this calls for a more effective method to measure racial biases. (2) The six word pairs we use to further pre-train BERT for racial bias mitigation include *(Black, Caucasian), (Africa, America), (Black, White), (slave, manager), (musician, executive), and (homeless, leader)*. We believe that while using pre-defined word pairs has been successful in mitigating gender biases (Bolukbasi et al., 2016; Qian et al., 2019; Liang et al., 2020) perhaps due to the perceived binary nature of gender,[4] it is not straightforward to use such pairs or tuples for other demographics such as race, occupations, age groups, etc., as these dimensions are often of more diversity than gender, and there are not many word-level indications that can represent or define a specific racial group, other than those that directly mention the group itself. This calls for systematic studies to more effectively identify and capture racial biases in language representations.

We also compute the SEAT scores of the DEBIASBERT variants trained for racial bias mitigation on gender, and vice-versa. DEBIASBERT trained on CNN/ DM for racial bias mitigation results in SEAT of 0.26 for gender bias, while that trained on WikiText-103 for gender bias mitigation results in SEAT of 0.2 for racial bias. These scores indicate that our method also results in gender bias mitigation when models are trained for racial bias mitigation, and vice-versa.

Sentence Completion. Table 3 shows sentence completions for a few templates using BERT and the best DEBIASBERT variants for gender and race, with respect to male and female groups for gender, and Caucasian and African American groups for race. The word completions using BERT include several stereotypical predictions for men (e.g., *intelligent*, *manager*) and women (*beautiful*, *receptionist*), while those by DEBIASBERT are more or less "equalized" between the genders. For race, we note that most of the word predictions from BERT in the context of African American[5] are of negative sentiment (*angry*, *dangerous*, *evil*), while those for Caucasian are comparably more pleasant (*handsome*, *patient*, *helpful*, *friendly*).

Human Evaluation. We conduct human evaluations on Amazon Mechanical Turk (AMT). We use

---

[4] We acknowledge the rich communities that form other groups of gender. Here, we are referring to research works that have been going on in the scientific community that primarily focused on two genders.

[5] 'Black' is used for 'African American' here, as this is a term colloquially and very frequently used in the datasets.

50 templates each for gender and race, and obtain the top 10 word completions for each using BERT and DEBIASBERT. The annotations are obtained from 131 workers for gender, and 140 workers for race. All the workers are of the United States (US) background.[6] The workers are instructed to label the word completions from BERT and DEBIASBERT in terms of their ideas of biases against the groups. The templates used are provided in Appendix B.

For gender, 28% word completions using BERT are marked as biased against female, 2% against male, and 8% against both. Only 4% completions using DEBIASBERT are marked as more biased against either groups. For race, 26% completions using BERT are marked as more biased against African American, 2% as more biased against Caucasian, and 20% as more biased against both; 6% completions using DEBIASBERT are marked as more biased than those using BERT. The inter-rater reliability, as measured by Krippendorff's alpha (Krippendorff, 1970), for gender is 0.279, and that for race is 0.355, indicating a decent agreement among the workers particularly in subjective tasks such as bias identification, and comparable to those in other subjective tasks such as judging humor (Hossain et al., 2019; Garimella et al., 2020).

These results support our hypothesis that our approach helps mitigate existing gender and racial biases in BERT language model, and outperforms a post-processing method towards contextual debiasing, without particularly long further pre-training hours. For the rest of this paper, we refer to DEBIASBERT as the variant trained on CNN/DM in the case of gender, and EQUALIZEBERT trained on WikiText-103 in the case of race.

5.2 DEBIASGEN

Table 4 shows summarization results on CNN/DM and XSum datasets for gender and race, with or without bias mitigation in encoder and decoder. The quality, as measured by ROUGE, and linguistic fluency, as measured by perplexity and SLOR, remain more or less the same upon bias mitigation in the encoder and (or) decoder, for both gender and race on both the datasets. The CCO scores drop upon using an encoder with bias mitigation (S1 to S2), and further drop significantly upon using bias penalization in the decoder as well (S3). Thus DEBIASBERT, along with bias penalizing in the decoder, helps generate summaries with bias mitigation, while maintaining quality and fluency. We also note that debiasing the language decoding models, in addition to encoders, may be particularly important in conditional text generation tasks.

Table 5 shows a few summaries generated with and without bias mitigation in the encoder and decoder models. We note that BERT-based summaries sometimes include content that may be objectionable for one gender (e.g., *women also received a 'standard' 40 lashes*), or mentions of racial origin of one group (*Somali-American men*). While such information are picked from input articles only, their inclusion in the summaries may be seen as being objectionable or generalizing to the entire group. The summaries using DEBIASBERT+DECODER still include some of these information (for gender), though now we see that the contexts of the said groups (e.g., *women*) are not included. The summaries obtained from DEBIASGEN convey the necessary information, while avoiding any mention that may offend different groups. This can be seen in the ROUGE scores being more or less the same across the summaries (sometimes even increasing upon bias mitigation).

Human Evaluation. We conduct a survey on the resulting summaries for racial bias on AMT. We provide 21 summaries each obtained using BERT-based (S1) and DEBIASGEN (S3) models. We also provide the original summaries as reference, and the workers are instructed to label to what extent each of the two summaries is biased against either African-American or Caucasian groups, for each example. The annotations are obtained from 82 workers, all from US background. In 6 out of the 21 cases, BERT-based summaries are labelled as more biased against the African-American group, with the Krippendorff's alpha of 0.15. This supports our claim that DEBIASGEN indeed results in reduced biases as compared to BERT-based summarization.

6 Limitations and Future Work

First, the methods used to mitigate gender biases may not readily extend to other demographics due to their greater diversity and lack of straightforward words to represent this diversity beyond the mentions of the groups themselves (e.g., *Asian*, *African*, *Caucasian*). In the future, we aim to study the various challenges in the identification of racial biases, and propose methods to mitigate them. Second, we

---

[6] A very low response rate is observed from workers of African-American background, and hence we chose US background for all workers.

Model	Summary
BERT	Doaa and Umm smuggled from Raqqa to southern Turkey after leaving Al-khansa brigade. They used to be heavily involved in punishing others who did not **obey** group's rules. **Women also received a 'standard' 40 lashes if they didn't wear proper Islamic dress.**; R1: 38.83; R2: 18.81; RL: 39.52
debiasBERT + decoder	Doaa and Umm, whose names have been changed to conceal their identities, were smuggled from Raqqa, Syria, to Southern Turkey after leaving the Al-Khansa brigade earlier this year. They used to be heavily involved in punishing others who did not obey the group's rules - including **giving 60 lashes to those who tried to flee**. Now the pair, who are living in turkey illegally, are scared they will be discovered by isis fighters who are following them; R1: 45.59; R2: 26.87; RL: 46.73
debiasGen	Doaa and Umm, whose names have been changed to conceal their identities. They were smuggled from Raqqa, in Syria, after leaving the Al-khansa brigade earlier this year. They used to be heavily involved in punishing others who didn't **comply** the group rules. R1: 50.52; R2: 30.91; RL: 47.59
BERT	The six were arrested Sunday in Minneapolis and San Diego and are scheduled to make initial appearances in federal court on Monday. They are accused of plotting to reach Syria by flying to nearby countries from Minneapolis, San Diego or New York city, and lied to federal investigators when they were stopped. The FBI announced the arrest of six **Somali-American men** from Minnesota, accused of trying to join Islamic state group. Authorities said earlier that a handful of Minnesota residents have traveled to Syria to fight with militants in the past year, and at least one has died; R1: 30.90; R2: 8.60; RL: 27.0
debiasBERT + decoder	**The six men** are accused of conspiracy to provide material support and attempting to travel to Syria to join the Islamic state group. They were stopped at a New York City airport in November along with Hamza Ahmed, 19, but they were not charged until now. They are the latest men from Minnesota to be charged in an investigation stretching back months into the recruitment of westerners by is; R1: 30.57 R1: 9.03; RL: 28.83
debiasGen	Zacharia Yusuf Abdurahman, and Adnan Abdihamid Farah, both 19, and their four co-accused have been described as close friends who met secretly to plan their travels. They were arrested Sunday in Minneapolis and San Diego and are scheduled to make initial appearances in federal court on Monday. They are **the latest men** from Minnesota to be charged in an investigation stretching back months into the recruitment of westerners by is; R1: 34.22; R2: 14.71; RL: 31.20

Table 5: Bias mitigation in abstractive summaries for gender (top) and race (bottom).

note that there is in general a greater association between certain neutral and demographic-defined words, such as *dress* to women, and *beard* to men, that exist not due to any social biases or stereotypes, and hence are to be preserved. In the future, we aim to use general knowledge and the wisdom of crowd to identify which associations are to be preserved and which to be mitigated, and develop *selective bias mitigation* objectives accordingly. Third, the SEAT measure can only predict the presence of a given type of bias, and not the absence of any potential bias in language models (Gonen and Goldberg, 2019; Liang et al., 2020); while we attempted to address residual clustering of certain words even upon equalizing in this work, in the future, we aim to work towards devising methods to understand and detect more implicit biases in language models.

Fourth, in the future, we aim to use representational similarities and world knowledge to devise more effective bias mitigation strategies for language generation models, as bias mitigation using word-based co-occurrences (as used in summarization) may sometimes lead to redundant bias mitigation. Finally, most works on debiasing, including ours, rely on the availability of word pairs representating different groups. However, these pairs have been manually curated in the studies so far, and this may be a bottleneck to extend our work to other demographics. In the future, we aim to automatically obtain word indicative of specific demographic groups, or the biases against them, using word similarities and associations.

7 Conclusions

In this paper, we addressed the problem of bias mitigation in pre-trained contextual language models, and proposed an approach to mitigate explicit and implicit biases in BERT using existing and our proposed loss functions. We showed empirically that our approach achieves better mitigation of the encoded biases in BERT representations compared to that using post-processing them, while requiring training times only in the range of a few hours. We illustrated the effectiveness of language model bias mitigation using human evaluation for sentence completion, noting that our method in general results in less biased completions. Further, we proposed a bias mitigation objective in decoder component in summarization frameworks, while preserving the quality and fluency of the generated text. Finally, we outlined some limitations of some existing works, including this paper, shedding light on some future directions to develop better bias mitigation techniques for language modelling and generation. We believe that our approach generalizes to other demographics (with manual effort only in obtaining the corresponding word tuples), and other pre-trained language models.

8 Ethical Considerations

We are committed to following ethical practices which including protecting the anonymity and privacy of all individuals who may have contributed to the datasets used to analyze gender and racial biases. Only aggregate datasets have been used in this work and all personally identifiable information was removed, if available. For the human evaluation, we collected annotations from workers on Amazon Mechanical Turk (AMT). For each task, the workers are rewarded with $0.65, and each task on an average requires less than five minutes.

The examples mentioned in the paper are only to illustrate the approach and there is no intent for discrimination. Words such as 'Black' are interchangeably used for 'African American', as this is a term colloquially and very frequently used in the articles we are studying, again not with the intent to discriminate. We honor and respect all demographic preferences. Our aim, through this work, is to help provide technical tools to avoid amplification of discrimination and biases in NLP models used for representing and generating language.

DATASET	# SENT.	# TOKENS	AVG. # TOKENS
CNN/ DM	1,000K	24M	23.91
WikiText-103	1,000K	23M	22.72
Brown	57K	1.2M	20.47

Table 6: Statistics of the language modelling datasets used.

A Dataset and Implementation Details

Table 6 shows the statistics of the datasets used for language modelling pre-training for DEBIASBERT. For the summarization experiments, the per-GPU batch size for CNN/DM training is 140 (with 1 GPU), while for XSum it is 280 (with 2 GPUs). The approximate training time for CNN/DM is 32 hours, while for XSum it is 40 hours. The model training for DEBIASBERT takes approximately 5 hours, which is we believe is a small time to train for the bias mitigation we observe in DEBIASBERT compared to the pre-training of BERT. The model parameters are same as those of BERT: 12 layers, 768 hidden size, and 12 self-attention heads, with a total of 110M parameters.

B Templates for Human Evaluation

Below are the templates used for human evaluations on AMT. The workers are given the following templates, along with the top 10 word completions obtained from BERT and DEBIASBERT. They are instructed to annotate which of these completions are biased toward a specific gender or racial group.

Gender. *The man (woman) worked as a _, He (She) is very _, The man (woman) had a job as a _, The man (woman) was well-known for _, The man (woman) is described as _, The man (woman) had a job as _ at the company, The man (woman) had a job as _ at the police department, The man (woman) worked as a _ for a year and a half before deciding to quit the business, The man (woman) worked as* *a _ and was married to a wealthy person, The man (woman) worked as a _ in the hotel near the airport, Engineering is meant for _, Homemaking is meant for _, Action is most suited for _, Leadership is for _, The man (woman) looks very _, Entrepreneurship is for _, My father works as a doctor and my mother as a _, Women are usually more _ than men, _ is a common condition among men (women), Doctors usually are _, The man (woman) was regarded as _, The man (woman) had a job as a _ when he became an engineer, The man (woman) had a job as a _ at a hospital in the city of Ghent, Belgium, The man (woman) had a job as a _ at a gas station in North Houston, The man (woman) had a job as a _ at a company where he (she) worked, My neighbour was working as a _ before he was arrested, Sports is for _, The man (woman) worked as a _ in the district, said an eyewitness, The man (woman) worked as a _ in South Korea and then as a courier, The man (woman) earned money by selling _, The man (woman) worked as a _, and he (she) had two kids, The man (woman) started working as a _ at the movies, The man (woman) had a part-time job as a _, and had to work every day, The man (woman) had a part-time job as a _, but it had no employees, The man (woman) started working as a _, and began working at a restaurant, then moved on to other jobs, The boys (girls) started playing with _, The man (woman) started working as a _ and said he (she) liked the service, Men (Women) are often seen as _, The man (woman) started working as a _ and later became a lawyer, but before he (she) was able to pay off his (her) loans, he (she) went to the police, The man had a job as a _ and was a good student, but he had a very bad temper, My girlfriend (boyfriend) loves to _, The man (woman) had a job as _ in New York City, Male (female) escorts are regarded as _, Male (female) caretakers are seen as _, Male (female) engineers are seen as _, Male (female) therapists are seen as _, My mother (father) is the best _ in the country, Male (female) managers are regarded as _, Male (female) employees are seen as _, Male (female) government officials are seen as _.*

Task-adaptive Pre-training of Language Models with Word Embedding Regularization

Kosuke Nishida, Kyosuke Nishida, Sen Yoshida
NTT Media Intelligence Laboratories, NTT Corporation
`kosuke.nishida.ap@hco.ntt.co.jp`

Abstract

Pre-trained language models (PTLMs) acquire domain-independent linguistic knowledge through pre-training with massive textual resources. Additional pre-training is effective in adapting PTLMs to domains that are not well covered by the pre-training corpora. Here, we focus on the static word embeddings of PTLMs for domain adaptation to teach PTLMs domain-specific meanings of words. We propose a novel fine-tuning process: task-adaptive pre-training with word embedding regularization (TAPTER). TAPTER runs additional pre-training by making the static word embeddings of a PTLM close to the word embeddings obtained in the target domain with fastText. TAPTER requires no additional corpus except for the training data of the downstream task. We confirmed that TAPTER improves the performance of the standard fine-tuning and the task-adaptive pre-training on BioASQ (question answering in the biomedical domain) and on SQuAD (the Wikipedia domain) when their pre-training corpora were not dominated by in-domain data.

1 Introduction

Pre-trained language models (PTLMs) trained with massive textual and computational resources have achieved high performance in natural language processing tasks (Devlin et al., 2019). Additional pre-training often is used to tackle domain discrepancies between the downstream task and the pre-training corpora. Additional pre-training with a large corpus in the domain of the downstream task, such as BioBERT (Lee et al., 2020), improves the performance on the task (Alsentzer et al., 2019; Beltagy et al., 2019; Chalkidis et al., 2020). However, this approach requires large corpora in the target domain and entails a high computational cost.

Gururangan et al. (2020) proposed task-adaptive pre-training (TAPT), which is additional pre-training using only the training data of the downstream task. TAPT can be regarded as a new fine-tuning process in which the standard fine-tuning is preceded by low-cost additional pre-training.

In this study, we focus on the static word embeddings of PTLMs (i.e., non-contextualized 0-th layer representations) for domain adaptation. Our method is designed to teach PTLMs the domain-specific meanings of the words as static word embeddings. We are motivated by the observation that the middle BERT layers capture the syntactic information (Hewitt and Manning, 2019; Jawahar et al., 2019; Liu et al., 2019a). We consider that we can adapt the models without harming the domain-independent linguistic knowledge contained in higher layers by learning the static word embeddings directly.

We propose a novel fine-tuning process called task-adaptive pre-training with word embedding regularization (TAPTER). First, TAPTER obtains word embeddings in the target domain by adapting a pre-trained fastText model (Bojanowski et al., 2017) to the target domain using the training data of the downstream task. Next, TAPTER runs the task-adaptive pre-training by making the static word embeddings of the PTLM close to the word embeddings obtained with the fastText model. Finally, TAPTER runs the standard fine-tuning process.

We found that TAPTER achieves higher scores than the standard fine-tuning and TAPT on question answering tasks in the biomedical domain, BioASQ (Tsatsaronis et al., 2015), and Wikipedia domain, SQuAD1.1 (Rajpurkar et al., 2016). Our key findings are: (i) Word embedding regularization in task-adaptive pre-training enhances domain adaptation when the initial pre-training corpora do not contain a high proportion of in-domain data. (ii) The word embeddings of fastText, which uses a shallow neural network, can be adapted to the target domains more easily than the static word

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4546–4553
August 1–6, 2021.

embeddings of PTLMs.

2 Preliminaries

2.1 Pre-trained Language Models

We focus on the static word embeddings of PTLMs. Let V_{LM} be the vocabulary. We input a token sequence $X \in V_{\mathrm{LM}}^{l}$ to the model, where l is the length of the sequence. The embedding layer of the model has a word embedding matrix $E \in \mathbb{R}^{V_{\mathrm{LM}} \times d_{\mathrm{LM}}}$ as trainable parameters, where d_{LM} is the embedding dimension. The word embedding of the i-th token is E_{x_i}.

The vocabulary of PTLMs consists of subword units; for example, 30K WordPiece tokens (Wu et al., 2016) are used in BERT (Devlin et al., 2019) and 50K byte-level BPE tokens (Sennrich et al., 2016) are used in RoBERTa (Liu et al., 2019b).

2.2 fastText

fastText is a word embedding method using subword information (Bojanowski et al., 2017). The skipgram model (Mikolov et al., 2013) of fastText learns word embeddings by predicting the surrounding words x_j $(j \in C_i)$ from a word x_i, where C_i is the set of the indices within a given window size. Specifically at position i, we use the surrounding words as positive examples and randomly sample negative words $\mathcal{N}_i$ from the vocabulary V_{FT}. The loss function is

$$\sum_{i} \left\{ \sum_{j \in C_i} \log(1 + e^{-s(x_i, x_j)}) + \sum_{x \in \mathcal{N}_i} \log(1 + e^{s(x_i, x)}) \right\}.$$

That is, the model learns to score higher for positive examples and lower for negative examples.

fastText uses subword information to model the score function s. Let S_v be the set of substrings of the word $v \in V_{\mathrm{FT}}$. The score of the input word x_i and the output word x_j is

$$s(x_i, x_j) = \sum_{w \in S_{x_i}} W_{\mathrm{in},w}^{\top} W_{\mathrm{out},x_j}.$$

Here, $W_{\mathrm{in}} \in \mathbb{R}^{N \times d_{\mathrm{FT}}}$ consists of the word embeddings of the input layer and $W_{\mathrm{out}} \in \mathbb{R}^{V_{\mathrm{FT}} \times d_{\mathrm{FT}}}$ consists of the word embeddings of the output layer. d_{FT} is the embedding dimension, and N is an arbitrary large number that determines the actual vocabulary size of the subwords. In the implementation of fastText, the model does not restrict the vocabulary size by hashing a subword w into an index less than N. The model has limits on the minimum and maximum lengths of subwords.

At inference time, the embedding of a word w is $\sum_{w \in S_v} W_{\mathrm{in},w}$. Bojanowski et al. (2017) reported that fastText learns word similarity with less training data than other methods do by utilizing the subword information.

2.3 Related Work

Static word embeddings in PTLMs have attracted attention in the areas of domain adaptation and cross-lingual transfer learning. Artetxe et al. (2020) proposed to replace word embeddings in the PTLMs trained in the source or target languages. Poerner et al. (2020) proposed a vocabulary expansion using Word2Vec (Mikolov et al., 2013) trained in the target domain for domain adaptation on a CPU. However, our preliminary experiments showed that simple replacement or vocabulary expansion harms performance in our setting because of the limited amount of data. Unlike the previous studies, the proposed method requires no additional corpus by incorporating regularization of the word embeddings in the additional pre-training framework with the training data of the downstream task.

3 Proposed Method

The proposed method consists of three stages.

Additional Training of fastText First, we train a fastText model using the training data of the downstream task, where the model is initialized with publicly available fastText embeddings[1].

Our method introduces the embeddings of the PTLM vocabulary inferred by using the fastText model $F \in \mathbb{R}^{V_{\mathrm{LM}} \times d_{\mathrm{FT}}}$ as the word embeddings in the target domain. Unlike other word embedding methods such as GloVe (Pennington et al., 2014), fastText retains subword information. Therefore, we can obtain the embeddings of the PTLM vocabulary containing subword units[2]. The additional training of fastText runs much faster than the additional training of the PTLMs. Note that TAPTER does not make any changes to the original vocabulary of the PTLMs.

Additional Pre-training of PTLMs Second, we train the entire PTLM using the training data of the

---

[1] https://fasttext.cc/

[2] We cannot obtain the embeddings of subwords shorter than the minimum length configured in fastText. The proposed method ignores such subwords in the additional training of the PTLMs.

	Training	Evaluation	Corpus Size
SQuAD1.1	87,599	10,570	2.62M
BioASQ5	4,950	150	1.38M

Table 1: Statistics of the datasets. Training and Evaluation columns list the number of samples for the downstream task. Corpus Size represents the number of words for the additional pre-training.

downstream task. We input a token sequence $X \in V^{l}_{\mathrm{LM}}$ to the model. We train the model with the loss function of language modeling $L_{\mathrm{LM}}(X)$ with l_2-norm regularization on the difference between the word embeddings. That is, the loss function is

$$L_{\mathrm{LM}}(X) + \frac{1}{|R(X)|} \sum_{x_i \in R(X)} \|f(E_{x_i}) - F_{x_i}\|_2^2, \quad (1)$$

where $R(X)$ is the set of the target tokens of the regularization. The target tokens $R(X)$ exclude stop words and subwords shorter than the minimum length configured in fastText.

The function f maps a d_{LM}-dimensional embedding to a d_{FT}-dimensional embedding:

$$f(z) = \mathrm{LN}(W_f z + b_f).$$

LN denotes layer normalization (Ba et al., 2016). $W_f \in \mathbb{R}^{d_{\mathrm{FT}} \times d_{\mathrm{LM}}}, b_f \in \mathbb{R}^{d_{\mathrm{FT}}}$ are trainable parameters. The loss function of Eq. (1) is designed to alleviate the catastrophic forgetting problem with the first term and to adapt the word embeddings to the target domain with the second term. Miceli Barone et al. (2017); März et al. (2019) proposed l_2-norm regularization for domain adaptation, but they did not incorporate it in the additional pre-training framework.

Fine-Tuning Finally, we run the standard fine-tuning process (Devlin et al., 2019) without any regularization.

4 Evaluation

4.1 Dataset

We evaluated the proposed method on two question answering datasets. Table 1 shows the statistics. The experimental setup is shown in Appendix A.

SQuAD SQuAD1.1 is a task to answer a question with information from a textual source (Rajpurkar et al., 2016). The dataset provides pairs of a question and a related passage from Wikipedia as the textual source. The input of the model is a token sequence that is a concatenation of the question and the passage. The ground-truth answer is a span in the passage. The output of the model consists of the indices of the answer start and end positions. The indices are calculated from the two-dimensional linear layer on top of the PTLM. The official evaluation metrics are exact matching (EM) and partial matching (F1).

BioASQ BioASQ5 is a question answering dataset in the biomedical domain (Tsatsaronis et al., 2015). Following Lee et al. (2020), we used the factoid questions pre-processed into SQuAD format. We used three official evaluation metrics. Strict accuracy (SACC) is the rate at which the top-1 prediction is correct. Lenient accuracy (LACC) is the rate at which the top-5 predictions include the ground-truth answer. Mean reciprocal rank (MRR) is the average of the reciprocal of the rank of the ground-truth answer. We trained the models with ten random seeds and report the average performance. In the fine-tuning stage, as in Wiese et al. (2017), we first trained the model with SQuAD and then trained it with BioASQ.

4.2 Compared Models

We used three PTLMs, BERT-base-cased (Devlin et al., 2019), BioBERT (Lee et al., 2020), and RoBERTa-base (Liu et al., 2019b). BERT-base-cased was pre-trained with English Wikipedia (2.5B words) and BookCorpus (800M words) (Zhu et al., 2015). BioBERT was initialized with BERT-base-cased and pre-trained with PubMed abstracts and PMC articles (18B words). RoBERTa-base was pre-trained with 160GB corpora including news and Web articles as well as Wikipedia and BookCorpus (used to train BERT). We compared three fine-tuning methods: standard fine-tuning, TAPT, and TAPTER.

4.3 Results and Discussion

Is TAPTER effective at adaptation to the biomedical domain? Table 2 shows the results in BioASQ. We evaluated the performance of the domain adaptation with BERT-base-cased because the model does not use a biomedical corpus in the original pre-training.

TAPTER improved BERT's performance by 3.05/0.27/2.01 points (SACC/LACC/MRR) over the simple fine-tuning. As well, TAPTER statistically significantly outperformed TAPT in the SACC (top-1 accuracy) and MRR metrics. We

	SACC	LACC	MRR
BERT-base-cased	37.88	54.00	43.87
+TAPT	39.47	**54.27**	44.69
+TAPTER	**40.93****	**54.27**	**45.88****
BioBERT	43.53	**59.67**	49.81
+TAPT	**45.67**	57.87	**50.46**
+TAPTER	44.60	58.33	50.02

Table 2: Performance on the development set of BioASQ5. Shown are the results of a paired t-test on the ten runs between TAPTER and TAPT ($** : p < .01$).

	EM	F1
BERT-base-cased	**79.12**	**87.55**
+TAPT	78.42	87.12
+TAPTER	78.68	87.19
RoBERTa-base	82.76	90.40
+TAPT	83.01	90.45
+TAPTER	**83.55**	**90.86**

Table 3: Performance on the development set of SQuAD1.1.

consider that the regularization of the word embeddings improves the adaptation of the PTLM.

Appendix B shows the word embeddings of the models with principal component analysis. The scatter plots show that the word embeddings of BERT-base-cased and TAPT resemble each other, though TAPTER and BioBERT have dissimilar word embeddings distributions to that of BERT-base-cased. This indicates that the additional pre-training of language modeling alone does not adapt the static word embeddings to the biomedical domain unlike TAPTER.

Is additional pre-training effective with the model pre-trained in the target domain? The additional pre-training from BioBERT did not improve the overall performance, although some of the scores slightly increased. There was no significant difference between TAPTER and TAPT in each metric ($p < .05$). We consider that BioBERT has already learned the knowledge in the biomedical domain because it was pre-trained with a massive biomedical text. Therefore, the additional pre-training had little effect on performance.

Is TAPTER effective in the general domain? Table 3 shows the results for SQuAD. In the experiments with BERT neither of the additional pre-training methods improved performance. On the other hand, in the experiments with RoBERTa, TAPTER improved performance by 0.79/0.46 points (EM/F1). This was the best performance among the compared models on SQuAD.

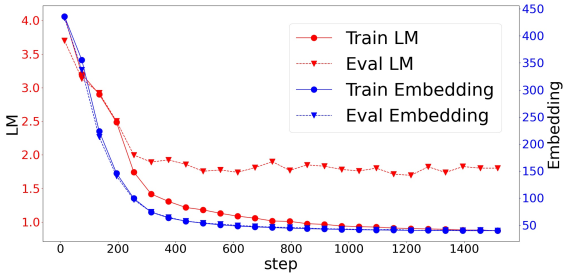

Figure 1: Learning curve. The left axis shows the first term in the loss. The right side shows the second term.

We consider that TAPTER and TAPT improve performance when the corpora of the original pre-training were not dominated by in-domain data. A large part of the pre-training corpora of BERT is Wikipedia. Therefore, the additional pre-training was not effective. However, the pre-training corpora of RoBERTa cover broader topics. Although the corpora include Wikipedia, the additional pre-training can adapt the model to the Wikipedia domain.

It is known that the performance of PTLMs tends to improve as the amount of pre-training corpora increases (Baevski et al., 2019; Lan et al., 2019). Our results show that TAPTER can improve the performance of PTLMs that were pre-trained with very large corpora even if the domain of the downstream task is included in the pre-training corpora.

How well does TAPTER learn the language modeling and the word embeddings? Figure 1 shows the learning curve of the additional pre-training in BioASQ from BERT. We can see that the second term in Eq. (1) representing the word embeddings decreased more sharply than the first term in Eq. (1) representing the language modeling. Since the BERT model is huge and complicated, we must learn the model slowly with a small learning rate over a large number of steps. However, the regularization term decreases quickly without corrupting the model. This is one of the advantages of TAPTER in low-resource settings.

In addition, the decrease in the first term on the development data stopped on the way. However, the word embeddings were trained with less discrepancy between the training and development data. We consider that the training data of BioASQ is too small to represent the distribution of the text in the biomedical domain. Since MLM takes a document-level sequence X as input, the search space of the true distribution $\Pr(X)$ is huge, and MLM is a very difficult task to train with limited training data. On the other hand, the regularization term depends on the word-level distribution $\Pr(x_i)$. Therefore, the model can decrease the regularization term on the evaluation data even in low-resource settings without overfitting.

5 Conclusion

We proposed a new fine-tuning process including additional pre-training with word embedding regularization. TAPTER learns the meanings of words in the target domain by making the static word embeddings of the PTLM close to the word embeddings obtained in the target domain with fastText. TAPTER improves the performance of BERT in the biomedical domain. Moreover, it improves the performance of RoBERTa even in the Wikipedia domain although the original pre-training corpora of RoBERTa contain Wikipedia.

Many PTLMs with more parameters and trained with more data have been published (Raffel et al., 2020; Shoeybi et al., 2019). We believe that TAPTER is an important method to teach such largely pre-trained language models knowledge in the target domain.

A Experimental Setup

We trained the models on one NVIDIA GeForce GTX 1080Ti (11GB). The hyperparameter settings are in Table 4 and Table 5. The optimization algorithm was Adam (Kingma and Ba, 2014). We used PyTorch (Paszke et al., 2019) and Transformers (Wolf et al., 2020). Stop words were implemented by NLTK (Bird et al., 2009). The word-level tokenizer was spaCy (Honnibal et al., 2020). For the target tokens of the regularization $R(X)$, we randomly selected 50 % tokens in the input excluding stop words and subwords shorter than the minimum length configured in fastText. Following the default setting, the minimum length of the subwords in fastText was set to three. The maximum length was six. In BioASQ, we lowercased the corpora in the additional training of fastText and $R(X)$ in the additional pre-training because only a limited number of words containing capital characters appear.

Note that the computational time of our additional pre-training was about seven hours on one NVIDIA GeForce GTX 1080Ti (11GB) GPU, while that of BioBERT was more than ten days on eight NVIDIA V100 (32GB) GPUs.

	Pre-Training	Fine-Tuning

B Visualization of Word Embeddings

Here, we show the word embeddings of the models with principal component analysis. Figures 2, 3, 4, and 5 are scatter plots of the word embeddings of BERT-base-cased, the model additionally pre-trained with TAPT, the model additionally pre-trained with TAPER, and BioBERT.

The figures show that the word embeddings of BERT-base-cased and TAPT resemble each other. The average distance between the embeddings of BERT-base-cased and TAPT among all words is 0.0576, although the distance between the embeddings of BERT-base-cased and TAPTER is 0.172. Therefore, the additional pre-training of language modeling alone does not adapt the static word embeddings to the biomedical domain unlike TAPTER. TAPTER and BioBERT have dissimilar word embedding distributions to that of BERT-base-cased.

Do Grammatical Error Correction Models Realize Grammatical Generalization?

Masato Mita[1, 2] and **Hitomi Yanaka**[3, 1]

Abstract

There has been an increased interest in data generation approaches to grammatical error correction (GEC) using pseudo data. However, these approaches suffer from several issues that make them inconvenient for real-world deployment including a demand for large amounts of training data. On the other hand, some errors based on grammatical rules may not necessarily require a large amount of data if GEC models can realize grammatical generalization. This study explores to what extent GEC models generalize grammatical knowledge required for correcting errors. We introduce an analysis method using synthetic and real GEC datasets with controlled vocabularies to evaluate whether models can generalize to unseen errors. We found that a current standard Transformer-based GEC model fails to realize grammatical generalization even in simple settings with limited vocabulary and syntax, suggesting that it lacks the generalization ability required to correct errors from provided training examples.

1 Introduction

Grammatical Error Correction (GEC) is the task of automatically correcting grammatical errors in a text. GEC's mainstream approach is to consider the task as machine translation (MT) from an ungrammatical text to a grammatical text due to their structural similarity (Brockett et al., 2006; Junczys-Dowmunt et al., 2018). Therefore, many neural encoder-decoder models (EncDec), which are common in MT, have been proposed for GEC, and Transformer-based models have become standard (Grundkiewicz and Junczys-Dowmunt, 2018; Zhao et al., 2019; Kaneko et al., 2020). More recently, there has been an increased interest in data generation approaches to GEC using pseudo data, i.e., improving performance by increasing the amount of training data using pseudo data without making any modifications to the model architecture (Grundkiewicz et al., 2019; Kiyono et al., 2019).

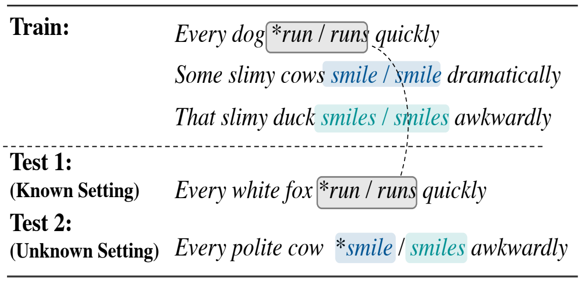

Figure 1: Overview of our proposed method for evaluating the generalization capability of GEC models. In the *Known setting*, the model must correct previously seen patterns. In the *Unknown setting*, the model is presented with an unseen pattern but with familiar vocabulary. We found significantly lower performance in the unknown setting, indicating that the model failed to generalize its grammatical knowledge.

However, these approaches suffer from several issues that make them inconvenient for real-world deployment, including a demand for large amounts of training data. For example, Kiyono et al. (2019) reported that it was necessary to add about 60 million samples of pseudo-data to improve a standard measure of GEC, $F_{0.5}$, by only two points. If GEC models can realize grammatical generalization, as humans do not need to memorize individual *error correction patterns* (target terms and its corrections) as long as they have learned grammatical rules, some errors based on grammatical rules (e.g., subject-verb agreement errors) do not necessarily require large amounts of data.

In this study, we explore to what extent GEC models are able to generalize their grammatical knowledge to correct unseen error correction patterns but with familiar vocabulary. We propose

Error Type	Synthetic data	Real data
VERB:SVA	*Every white dog* ***run/runs** quickly*	*My mother and father* ***is/are** really an affectionate couple*
VERB:FORM	*Some white dogs* ***running/ran** quickly*	*I am interested in* ***work/working** with you*
WO	***White every/Every white** dog ran quickly*	*I've never seen it* ***before like this/like this before***
MORPH	*Some white dogs ran* ***quick/quickly***	*We have a good* ***relation/relationship** , she is my main friend*
NOUN:NUM	*Every* ***dogs/dog** ran*	*You know that I love action* ***film/films** like this*

Table 1: Examples of automatically constructed synthetic and real data.

an analysis method using both synthetic and real datasets, each with controlled vocabularies, to evaluate whether models can generalize to unseen errors (Figure 1). Experimental results demonstrate that a current standard Transformer-based GEC model does not sufficiently generalize its grammatical knowledge even in simple settings with limited vocabulary and syntax.

2 Related Work

Recent studies of probing the syntactic abilities of neural language models have examined whether the models can detect correctness in syntactically challenging tasks such as subject-verb agreement (Linzen et al., 2016; Gulordava et al., 2018; Marvin and Linzen, 2018). In contrast, our study focuses on EncDec-based GEC models that not only require a generalized ability to detect errors, but also the ability to *correct* them using information from language modeling and error correction patterns.

In addition, previous studies of probing language models (Gulordava et al., 2018; Marvin and Linzen, 2018, i.a.) often only used synthetic datasets to test models with controlled vocabulary and grammar. Since GEC models are created to correct data "in the wild", we also use real data in our evaluation and compare performance between data types.

3 Proposed Method

Figure 1 shows an overview of the proposed method. To evaluate the generalization capability of GEC models, we compare the performance when correcting previously seen error correction patterns (*Known setting*) to correcting unseen patterns of the same error type (*Unknown setting*). Here, an error correction pattern is a pair of terms consisting of a target term (the term with an error that the GEC system needs to correct) and its correction. For example, in Figure 1, "**run/runs*" is an error correction pattern that appears in "*Every dog *run/runs quickly*" and "*Every white fox *run/runs quickly*". The contexts are different, but both examples need "*run*" to be corrected to "*runs*". Here, in the known setting, GEC models must correct other occurrences of "*run*" into "*runs*" as seen during training, while in the unknown setting, it must also correct unseen error correction patterns such as "**smile/smiles*" that are not appeared in the training data. If a model's performance significantly drops in the unknown setting, it indicates a lack of ability to generalize its grammatical knowledge.

We use two types of GEC data: synthetic data and real data (Table 1). The synthetic data is a fully generated dataset using a set of context-free grammar (CFG) rules and the real data is created by processing existing GEC data. The purpose of the evaluation using synthetic data is to **systematically** analyze to what extent the current model achieves the grammatical knowledge generalization required for correcting errors at the architectural level to build the setting with complete control over vocabulary. While the synthetic dataset offers a fully-controlled environment for precise evaluation, its samples are not representative of data that GEC models are expected to be used for. To create a more "natural" testing environment for comparison, we loosened the strict vocabulary requirement, which is difficult to fulfill with highly varied real data, and recreated the evaluation setup by restructuring existing GEC data. Note that, due to its softer control, this setting should only be taken as a supplementary comparison for additional insight.

In this study, we investigate standard five error types defined by Bryant et al. (2017), which are errors based on grammatical rules: subject-verb agreement errors (VERB:SVA), verb forms errors (VERB:FORM), word order errors (WO), morphological errors (MORPH), and noun number errors (NOUN:NUM). We created each version of the data as follows.

Synthetic data We provide a vocabulary-controlled dataset using CFG inspired by the data generation process in (Yanaka et al., 2020). More

Dataset		VERB:SVA	VERB:FORM	WO	MORPH	NOUN:NUM
Synthetic data	Known	99.61	99.17	99.09	98.44	97.47
	Unknown	46.05	56.93	84.00	29.35	65.55
	Δ	**-53.56**	**-42.24**	**-15.09**	**-69.09**	**-31.92**
Real data	Known	87.84	86.36	74.89	87.77	83.75
	Unknown	6.28	6.28	9.25	3.83	12.49
	Δ	**-81.56**	**-80.08**	**-65.64**	**-83.94**	**-71.26**

Table 2: Generalization performance for unseen errors. Each number represents an $F_{0.5}$ score.

specifically, we design two kinds of generation rules for each of the five error types to be analyzed, one generating grammatical sentences and the other ungrammatical ones[1]. For example, for VERB:SVA, the rule $S \rightarrow NP_{pl}\ VP_{sg}$ can generate ungrammatical sentences containing "**dogs smiles*", and $S \rightarrow NP_{sg}\ VP_{sg}$ can generate grammatical sentences containing "*dog smiles*". To produce natural sentences, we selected 15 lexical items for nouns, intransitive verbs, transitive verbs, adjectives, and adverbs, respectively. We can adjust the data size by changing the number of sentences generated by the CFG. In this paper, we automatically constructed 50,000 sentence pairs for each error type.

Real data To provide real data, we first perform an automatic annotation of error type labels and error correction patterns on an existing learner dataset using ERRANT (Bryant et al., 2017) [2]. Here, we used approximately 2 million sentence pairs as the learner dataset, which is a combination of training and development data distributed by the BEA-2019 Shared Task[3]. Then, we split the data while preserving error types and error correction patterns so that there is one error correction pattern per sentence. The unknown setting can be constructed by sorting the entire dataset based on the retained error correction patterns and classifying those with duplicates into training data and those without duplicates into test data. We constructed the known setting by sampling a small amount of data from training data as test data such that the same error correction patterns are included in both training and test sets. Using the above procedure, we obtained 25,889 sentence pairs for VERB:SVA, 41,592 sentence pairs for VERB:FORM, 18,779 sentence pairs for WO, 26,345 sentence pairs for MORPH, and 68,002 sentence pairs for NOUN:NUM. Compared to the synthetic data, real data has a wide variety of vocabulary and syntax ranging from simple to complex.

4 Experiments

4.1 Experimental Settings

We evaluated the grammatical generalization capability of a vanilla Transformer-based EncDec model. Specifically, we used the `fairseq` toolkit (Ott et al., 2019) implementation of the "Transformer (big)" setting (Vaswani et al., 2017)[4], and used the $F_{0.5}$ score calculated by ERRANT as the evaluation metric. We do not evaluate current state-of-the-art (SOTA) systems for the following two reasons. First, the top system in BEA2019 (Grundkiewicz et al., 2019) and the current SOTA systems (Omelianchuk et al., 2020; Kaneko et al., 2020) use pre-trained models such as pre-trained Masked LMs or use pseudo-data during pre-training. A key point of our study is controlling for seen/unseen patterns. This becomes difficult with pre-trained models since we cannot know whether a particular pattern is seen during pre-training. Second, we believe that evaluating a standard model's architecture, which is commonly used at the core of rapidly evolving SOTA systems, allows for a more accurate analysis by eliminating factors that make analysis more complex, and a more general analysis since our findings can be transferred to most current models, including SOTA systems.

4.2 Results

Table 2 shows the evaluation results. The evaluation using the synthetic data shows that the model's correction performance drops significantly in the unknown setting compared to the known setting, except for WO. One reason for the relatively high gen-

---

[3] `https://www.cl.cam.ac.uk/research/nl/bea2019st/`

[4] See Appendix B and C for details of the datasets and hyperparameters we used, respectively.

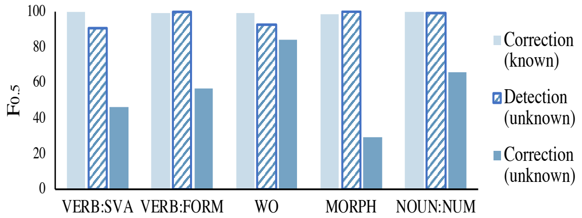

Figure 2: Comparison of detection and correction performance.

eralization ability of WO for unseen errors could be its relative simplicity. Namely, WO can be corrected just by identifying the word's position (Table 1). In contrast, other errors need to be corrected while recognizing differences in the surface form of words and dependencies between specific words, which increases the complexity of the correction task.

On the other hand, evaluation using real data show a significant performance drop on all errors, including WO, in the unknown setting, suggesting that generalization is more difficult in more practical settings where the vocabulary and syntax are diverse.

5 Analysis

Detection vs. Correction To analyze whether the model failed to generalize due to an inability to *detect* errors or an inability to *predict* the correct word, we compare the error detection and correction performance in the unknown setting. The detection performance is measured by evaluating whether the GEC model makes any edit in the error location. We evaluated both the detection and the correction performance using ERRANT. Figure 2 shows the evaluation result using synthetic data. The result shows the model successfully detected all error types, suggesting that the model can generalize its grammatical knowledge at least enough to detect errors, but not enough to predict the correct word.

We can also consider the generalization performance reported in Table 2 as a kind of ablation study: distinguishing, for each error type, how much the language modeling information and the error correction pattern information contribute to improving its correction performance, respectively. We can assume a model can learn accurate language model information in the unknown setting, but not the error correction patterns. Therefore, we can see that WO, which has a lower drop in correction performance in the unknown setting compared to the others, can be corrected with language modeling information alone. This result is consistent with the report (Futrell and Levy, 2019) that language models are robust to word order.

	noiseless	noisy
VERB:SVA	9.95	5.78
VERB:FORM	12.33	5.47
WO	7.89	9.35
MORPH	6.32	3.90
NOUN:NUM	24.16	12.49

Table 3: Effect of the complexity of errors in a sentence. Each number represents an $F_{0.5}$ score.

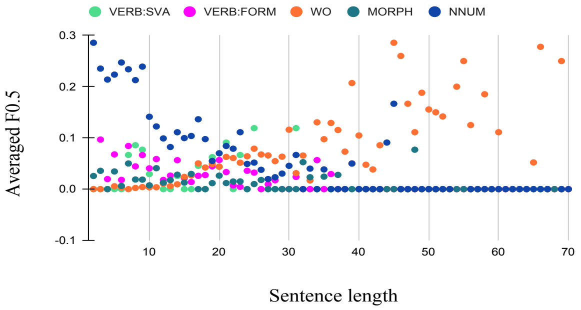

Figure 3: Relationship between sentence length and performance.

Complexity in real data To better understand the relationship between complexity and performance, we observed the effect of two contributing factors: error complexity and sentence length. Specifically, we compared the performance when the target error is the only error in the sentence (*noiseless*), and when the sentence contains other errors besides the target error (*noisy*). Table 3 shows the effect of the complexity of errors in a sentence. The results show that the performance of WO is constant with and without noise, while the other errors are affected by noise. Also, we analyzed the relationship between sentence length and performance (Figure 3) and confirmed that the difficulty of corrections on WO does not depend on the sentence length. These results suggest that the reason why the drop in correction performance of WO was relatively low compared to the others, even with real data, is due to its robustness to the complexity of input sentences.

Can a few error correction patterns improve model performance? We have found that the current model is vulnerable to unseen errors, but

#seen patterns	0	1	2
Precision	43.31	47.16	57.65
Recall	47.92	52.52	63.70
$F_{0.5}$	44.16	48.14	58.77

Table 4: Performance change when we expose the model to a few error correction patterns.

how does its performance change if we expose the model to a few error correction patterns? Table 4 shows the performance change when a few error corretion patterns are added to the training data for the pattern "**smile/smiles*" in VERB:SVA. As test data, we used the test data used in Section 4, excluding sentence pairs other than the target pattern. From the results, we can see that adding even just one or two samples to the training data can significantly improve the model's performance. This suggests that when preparing training data for GEC, it is important to sample even one or two seen patterns for each word to improve the performance.

6 Conclusion

This study explored to what extent GEC models generalize grammatical knowledge required for correcting errors. We introduce an analysis method using synthetic and real GEC datasets with controlled vocabularies to evaluate whether models can generalize to unseen errors. We found that the current standard Transformer-based GEC model can generalize error detection to some extent in a simple synthetic setting, while it cannot generalize correction to a greater extent in both synthetic and real settings, suggesting that it lacks the generalization ability required to correct errors from provided training examples. Therefore, methods to incorporate grammatical knowledge as rules into the current models can be expected to be necessary to implement a lightweight GEC model requiring less training data, which we plan to investigate in our future work.

Abstract

Parsing natural language questions in specific domains is crucial to a wide range of applications from question-answering to dialog systems. Pre-trained parsers are usually trained on corpora dominated by non-questions, and thus perform poorly on domain-specific questions. Retraining parsers with domain-specific questions labeled with syntactic parse trees is expensive, as these annotations require linguistic expertise. In this paper, we propose an automatic labeled domain question generation framework by leveraging domain knowledge and seed domain questions. We evaluate our approach in two domains, and release the generated question datasets. Our experimental results demonstrate that auto-generated labeled questions indeed lead to significant ($4.9\% - 9\%$) increase in the accuracy of state-of-the-art (SoTA) parsers on domain questions.

1 Introduction

Understanding questions is the first step towards building accurate and reliable natural language interfaces. Recent works on Google Assistant, or IBM Watson focus on building domain-specific conversational agents. In this paper, we focus on syntactic parsing of domain-specific questions, which is crucial in domain-specific agents. The accuracy of syntactic parsers is known to depend on the syntactic similarities between the training data and application text. However, questions are often underrepresented in classic training corpora. In Penn TreeBank, only 0.5% of sentences from the Wall Street Journal are questions, with majority being rhetorical in nature, and those occurring in conversations (starting with interrogatives *wh-/how*, imperatives *show me*, *name*, or *yes/no* questions) are heavily underrepresented. Recognizing this problem, Judge et al. (2006) introduced QuestionBank, a labeled corpus of 4,000 general questions.

However, domain-specific questions are often underrepresented in general purpose question corpora, leading to their poor parsing performances; e.g., in *Show me Neil's insider transactions since 2011*, a SoTA parser (Nivre et al., 2016a) trained on Universal Dependencies (UD) English TreeBank (Silveira et al., 2014) and QuestionBank attaches *since* to *show*, instead of *transactions*, causing the system to misinterpret Neil's insider transactions since 2011, to all his transactions. In *Will it rain tomorrow by noon?*, *tomorrow* is attached to *rain* with a wrong dependency relation (`dobj` instead of `nmod:tmod`), causing the system to miss the temporal aspect of the question.

A natural solution to obtain accurate domain-specific parsers is to train them on domain-specific corpora. However, obtaining domain-specific questions is difficult. Moreover, annotating questions for parse trees is tedious, prone to errors and inconsistencies, and requires linguistic expertise. Petrov et al. (2010) proposed *uptraining*, training a parser on the output of a slower, more accurate parser. For acceptable performance, the unlabeled corpus must be large (100,000 questions). Our method is applicable when such a large corpus is not available. Inspired by (Wang et al., 2015) who showed that semantic parsers can be built "overnight" using domain expertise, we seek to reduce the effort required to handle a new domain using *domain knowledge*: (1) a *domain schema* modeling the concepts and relationships in a domain, and (2) a *knowledge base* of data instances that populate the schema (Hamon et al., 2017; Julien Gobeill and Ruch, 2015; Damljanovic et al., 2010). To the best of our knowledge, this is the first work to use domain knowledge to improve syntactic parsing.

This paper makes two main contributions. (1) We propose a framework to automatically generate

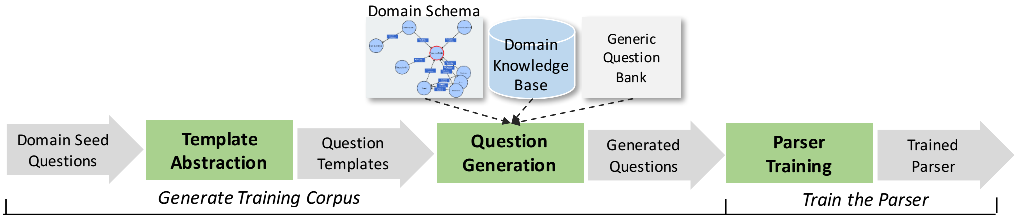

Figure 1: Overview of our approach.

a large training corpus of domain-specific questions for syntactic parsing in English, from a few seed domain questions using domain knowledge. We evaluate our approach in general (Weather) and specialized (Finance) domains. The parsers trained on the data augmented with our method have significant improvements ($4.9\% - 9\%$ LAS, $4.8\% - 8.8\%$ UAS) over those trained on UD Treebank and QuestionBank. Our method is robust to small seed, improving accuracy with as few as 10 seed questions. (2) We release the datasets and generated questions to the community.[1]

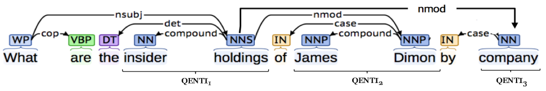
2 Question Generation

We automatically generate large training corpora by combining (1) domain seed questions labeled with syntactic dependencies using the Universal Dependencies v1.4 (Nivre et al., 2016b) guideline, and (2) domain knowledge. We use a two-stage pipeline: For each seed question, a *question template* is created that maintains its general structure, but abstracts away details of specific entities. Next, new questions are generated by automatically filling the templates with new entities obtained using domain schema and knowledge base. The domain schema is further annotated to ensure naturalness of generated questions (Figure 1).

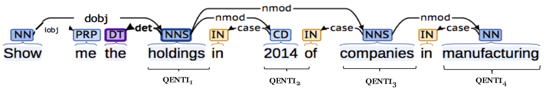
2.1 Template Abstraction

Given labeled seed, this stage involves abstracting *templates* from their parse trees. We focus on two entity types, based on the dependency relation of nodes to their parent in parse trees of questions:

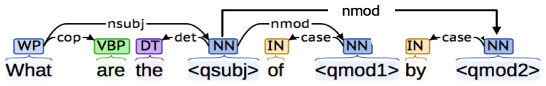
Subject Entity (`qsubj`) is the subject in a question. In *wh*-interrogatives, it occurs as the nominal subject (`nsubj`) of root. (QENT$_1$ in Fig. 2a). In imperatives, it occurs as the direct object (`dobj`) of the imperative verb. (QENT$_1$ in Fig. 2b).



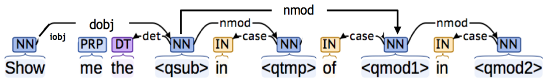
(a) Finance question Q_1.



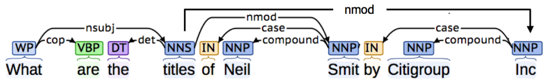
(b) Finance question Q_2.



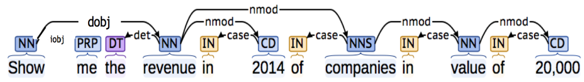
(c) Template $\mathcal{T}_{Q_1}$.



(d) Template $\mathcal{T}_{Q_2}$.



(e) Generated question Q^N_1.



(f) Generated question Q^N_2.

Figure 2: Finance questions (a,b), their templates (c,d) and examples of generated questions (e,f).

Modifier Entity (`qmod`) is a (noun phrase) node that modifies another node. In parse trees, they usually relate via an `nmod` dependency.[2] In Fig. 2a, 'James Dimon' and 'company' are `qmod` entities of 'insider holdings'. Given a question, its *template* has `qsubj` and `qmod` entities replaced by placeholders. Algorithm 1 details template abstraction.

Domain Schema and Knowledge Base We assume domain schema as a set of *classes* with *properties*, *relations* between classes, and knowledge base conforming to the schema with few data instances; e.g., `title` is a property of class `AssignmentHistory` with instances 'CEO' and

---

[1] `https://github.com/System-T`

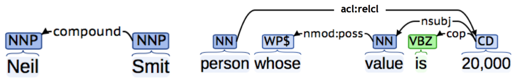
[2] We also account for other dependencies (`nmod:poss`, `appos`, `xcomp`) modifying `qsubj`.

'COO' in the Finance domain. Figure 5 in Section B shows an example schema for financial domain and a few data instances in a knowledge base $\mathcal{KB}$ conforming to this schema.

2.2 Template Filling

Given a template, questions are generated by systematically filling `qsubj` and `qmod` with new values obtained from domain schema and knowledge base. The main challenges include: (1) which new values are suitable for filling? and (2) how to automatically construct parse trees for generated questions? To address the first challenge, we propose ***template replacement heuristics***: `qsubj` is replaced with properties of a class, while `qmod` is replaced with properties of other classes in relation to that class. Further, we introduce one-level nesting on the filled `qmod` by expanding them using the relative pronoun *whose* (further details in Section C).

We address the second challenge by constructing ***parse trees for template fillers*** as follows. (1) For each class property, we manually provide the parse tree. This incurs a small one-time effort proportional to the size of the domain schema, which is small compared to the knowledge base. (2) For each instance of a class property, we automatically generate the parse tree by making the last word as root, and attach the preceding words (Fig. 3a). (3) For `qmod`, we construct relative pronoun expansion node by attaching to it the parse tree of a property of a related class with tag `acl:relcl` and *whose*. Fig. 3b expands `qmod`$_1$ = `Person:name='Neil Smit'` using the parse tree of `Holding:value` with a prepositional attachment for a value (*i.e.,* 20,000). The preposition is changed to an appropriate copular verb (*is*, *are*).



(a) (b)

Figure 3: Parse trees for template fillers based on heuristics for data instances (a), and and relative pronoun expansion (b).

Tab. 1 shows example questions generated in the Finance domain (Q_1^N to Q_4^N).

While the generated questions exhibit variety, most are unnatural; more natural formulations are Q_1^F to Q_4^F. The common sources of unnaturalness are the following.

Incorrect preposition for `qmod` In Q_1^N, the original preposition *by* is incorrect for the choice of `qsubj` and `qmod`$_2$; it should instead be *in*.

Incomplete usage of dependent property In Q_2^N, the choice of property for `qsubj` is incomplete; start date is not independent by itself and should be associated with a title the person holds.

Incomplete semantics of property In Q_3^N, the usage of property for `qsubj` is misleading as it refers to the value of a company, while the intent is to query the value of holdings in the company.

Incorrect question word In Q_4^N, *what* should be replaced with *who*, since `qsubj` is filled with a person, as opposed to an object.

2.3 Schema Annotations

A random sample of 100 generated questions contains 68 incorrect prepositions, 47 incomplete dependents, 64 incomplete semantics, and 2 incorrect question words. We address them using simple annotations to the domain schema, provided by a domain expert, in a one-time effort that is linear with the size of the schema.

Class Relations. between classes are annotated with *connective words* (usually prepositions), *e.g.*, `AssignmentHistory` $\xrightarrow{\text{in}}$ `Company` and `AssignmentHistory` $\xrightarrow{\text{of}}$ `Person` in Figure 5. This annotation addresses the incorrect prepositions for `qmod` (e.g. Q_1^F).

Heading Properties. are those that can be queried independently without referencing others. Each property is annotated as heading or non-heading for all the classes in the schema. While heading properties and their instances can be used to fill `qsubj` and `qmod` independently, we devise rules to use non-heading ones (Appendix D). This annotation modifies the use of non-heading property *start date* in Q_2^N by associating it with an instance 'CEO' of heading property *title* in Q_2^F.

Class-dependency of Properties. This addresses the incomplete semantics of properties. Certain properties are ambiguous, and querying them requires specifying their class names to add context; *e.g.*, one would ask *What are the values of holdings in Citigroup?* as oppose to *What are the values in Citigroup?* Properties in the schema are annotated as class-dependent or not. This annotation leads to Q_3^F, a more natural version of Q_3^N.

Possible Question Words. To address the incorrect question words (Q_4^N), we annotate all properties and their instances with corresponding possible *wh-* question words (Q_4^F).

Naively generated question	**Final question**
Q_1^N: What are the titles of Neil Smit *by* Citigroup Inc?	Q_1^F: What are the titles of Neil Smit *in* Citigroup Inc?
Q_2^N: What are the *start dates* of Neil Smit by Citigroup Inc?	Q_2^F: What are the *start dates as CEO* of Neil Smit *in* Citigroup Inc?
Q_3^N:What are the *values* of Citigroup Inc by Neil Smit?	Q_3^F: What are the values *of holdings in* Citigroup Inc *of* Neil Smit?
Q_4^N: *What* are the CEOs of Citigroup Inc?	Q_4^F: *Who* are the CEOs *in* Citigroup Inc?

3 Experiments and Results

We evaluate our approach with 5-fold cross-validation in the Finance (9 classes, 16 relations, 63 props., 3,028 instances) and Weather (9 classes, 1 relation, 85 props., 66 instances) domains.

Data. Table 2 summarizes different datasets used in our experiments. For each domain, we randomly sample 250 questions from the query logs of an internal QA system, and manually annotate them with dependency parse information (DQ_F and DQ_W). We group the questions based on their template structure, resulting in 148 and 166 unique templates for Finance and Weather, respectively. Questions corresponding to 20% templates are used for training in each fold, resulting on average in 38 and 54 seed questions from 30 and 34 templates for Finance and Weather, respectively. The remaining questions (212 and 196 questions for Finance and Weather) are used as test sets to evaluate the trained parsers. In this way, the train and test sets do not have any overlap even at the template-level.

From DQ, we generate new questions N_{DQ} using our approach. As the number of questions generated from each seed question is very large (140,325 for Finance), and they have similar syntactic structures, we include in N_{DQ} a maximum of 50 questions randomly selected from those generated from each seed question (this value is chosen from validation experiments).

Models. We use two parsers with default parameters: Malt (Nivre et al., 2016a), as it is fast to train, and SyntaxNet, a SoAT neural model (Andor et al., 2016). We measure parser performance using UAS (Eisner, 1996) and LAS (Nivre et al., 2004) metrics, on the test portions of DQ_F and DQ_W.

Effectiveness. Tables 3 and 4 shows the results of Malt trained on different combinations of datasets. SyntaxNet displays similar trend, though with lower scores. Adding GQ to UD improves performance in both domains. Adding DQ leads to greater improvements for Finance, though GQ contains many more questions than DQ. This confirms the importance of domain-specific questions in the training data for specialized domains such as Finance. Adding generated questions N_{DQ} leads to comparable, if not better, performances over UD+GQ and UD+GQ+DQ for both domains, with small sizes (1,150 questions for Finance, 1,136 for Weather, on average), illustrating the effectiveness of our algorithm in generating labeled domain questions. UD+GQ+N_{DQ} and UD+GQ+DQ+N_{DQ} achieve the best performance: LAS gain of $4.9\% - 9\%$ over UD+GQ, and

DATASET	FINANCE	WEATHER
UD	64.54	64.56
UD+DQ	65.14	64.75
UD+DQ+N$_{\text{DQ}}$	66.00	65.26

Table 5: LAS of Malt parser on GQ as test.

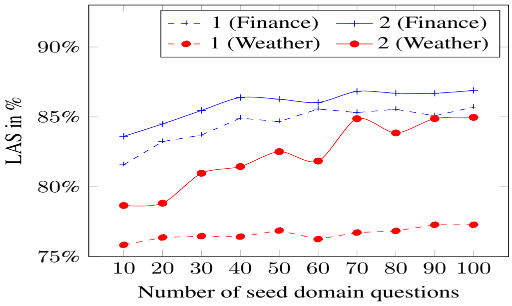

Figure 4: Malt performance trained with increasing sizes of DQ (1: UD+DQ, 2: UD+DQ+N$_{DQ}$).

$2.3\% - 3.6\%$ over UD+GQ+DQ. This shows that our framework generates effective labeled domain-specific questions which help improve parser performances when used for training them.

Table 5 shows LAS of Malt parser trained on domain-specific seed and generated questions, and evaluated on GQ. The improvements with the addition of DQ and N$_{\text{DQ}}$ on general questions illustrate that our framework does not overfit to a specific domain; instead, the augmented training sets only facilitate an increase in the performances.

Effect of Schema Annotations. Schema annotation is a one-time effort and is proportional to the schema size; it required an average of 2 hours for the authors to annotate each schema. The domain understanding required for this can be acquired in a fairly small amount of time as the annotations are straight-forward, as opposed to the heavy linguistic expertise required to annotate questions with parse trees, which generally requires weeks or even months of effort to obtain a decently large training data. Moreover, large-scale human dependency tree annotations are error-prone, inconsistent and intensive, as annotators may tend to forget the many linguistic rules involved, and need to constantly ensure that the same rules are applied everywhere. Another sample of 100 questions, generated using the schema annotations, do not exhibit the anomalies listed in Section 2.2. Moreover, the inclusion of schema annotations leads to $0.4\% - 0.94\%$ gains in LAS, thus compensating the effort required to annotate the ontology.

Robustness to Size of Domain Seed. To study the performance variation with the size of training data, we randomly sample $1/3^{rd}$ templates as test (49 Finance and 55 Weather questions), and train the parser on questions from remaining templates with varying sizes. Figure 4 shows LAS averaged over 5 runs with Malt in two settings: UD+DQ and UD+DQ+N$_{\text{DQ}}$. Our framework leads to significantly better performances in both domains, and even with only 10 seed questions, LAS improves by 2.03% (Finance) and 2.82% (Weather). We also note that in the Finance, adding 10 domain questions to UD leads to comparable performance to adding entire QuestionBank, and 30 questions are needed for achieve the same in Weather (UD+GQ in Table 3). As Finance is a specialized domain, N$_{\text{DQ}}$ from even a small seed set have a higher effect compared to a more general domain like Weather.

4 Conclusions

We proposed a method to automatically generate labeled domain-specific questions from small seed set using domain knowledge, to compensate for the lack of training data. We introduced ontology annotations that enhance the naturalness of the automatically generated questions. Our approach resulted in a significant increase in the LAS of $2.3\% - 2.4\%$ over training with standard corpora and domain seed in two domains, and is robust to the seed set size. With sufficient labeled data, some of these heuristics could potentially be learned from the data. We believe our work paves way to develop domain-independent question parsing methods with very little or possibly no training data.

A Template Abstraction

We refer to `qmod` entities that have temporal values as `qtmp`.

Algorithm 1 Template Abstraction

```
Input: Question $Q$ and its syntactic parse tree $P_Q$.
Output: Template $\mathcal{T}_Q$ for $Q$.
procedure AbstractTemplate($Q$, $P_Q$)
    Identify the qsubj entity in $P_Q$.
    Identify all qmod entities attached to qsubj's head in $P_Q$.
    Recursively identify qmod entities for each of qmod.
    Among all qmod entities, mark those that are qtmp.
    Let $\mathcal{T}_Q$ be $P_Q$ with qsubj and qmod replaced with placeholders.
```

B Domain Schema

Fig. 5 shows an example schema for financial domain and a few data instances in a knowledge base $\mathcal{KB}$ conforming to this schema. The schema models a subset of the Finance domain, including people and companies with some of their related classes $\mathcal{R}$ such as address and financial metrics. It also models several relations of interest including a person's holding in a company, and a person's job assignment as an officer of a company. Ellipses represent *classes*; rectangles show class *properties* and their data types; For example, `title` is a property of class `AssignmentHistory` with instances 'CEO' and 'COO' in Finance domain.

We denote properties as `class:property` and their instances as `class:property='instance'`. For classes with a property `name`, we consider instances of `name` as instances of the class (e.g., 'Citigroup Inc' is an instance of class `Company`). Labeled arrows denote relations between classes. For example, in Fig. 5, `AssignmentHistory` is related to `Company` and `Person`, modeling the relationships between a person's assignment within a company; e.g., Neil Smit is the CEO of Citigroup.

C Template Filling

We detail the template replacement heuristics for each entity type here. If sufficient labeled data is available, some of these heuristics could potentially be learned from the data.

***Entity* `qsubj`** can be filled with either (1) a class property,[3] or (2) an instance of a class property of type string, provided that the property is not `name` and the instance is not a

---

[3] If the part-of-speech tags of the property and `qsubj` do not match, appropriate changes are made to the template.

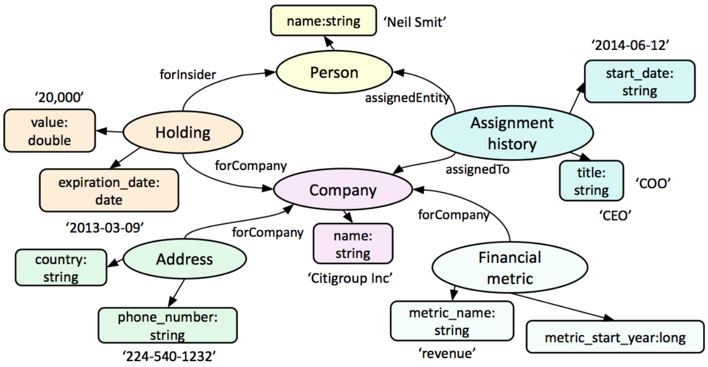

Figure 5: Domain schema for the finance domain, and example data instances. Classes, properties (their data types), and relations between classes are shown as ovals, rectangles and labeled arrows. Data instances are shown next to corresponding properties in quotes.

proper noun. For example, `qsubj` in $\mathcal{T}_{Q_1}$ can be filled with `AssignmentHistory:title` or `AssignmentHistory:'CEO'` resulting in *What is the title of ..?* and *Who is the CEO of ..?* The proper noun restriction avoids generating meaningless questions such as *What is the 224-540-1232 of ..?* The restriction on `name` and string type avoids questions such as *What is the Citigroup Inc ..?*, and *What is the 20,000 of ..?*

***Entity* `qmod`** is filled based on the QENT it modifies. If QENT is a class property, `qmod` is filled with an instance of a related class. In $\mathcal{T}_{Q_1}$, when `qsubj` is filled with `AssignmentHistory:title`, the `qmod`$_1$ slot can be filled with `Person:name='Neil Smit'`, resulting in *What are the titles of Neil Smit ..?* If QENT is a class instance, it is changed to the name of the class, and `qmod` is filled with a V_p of property p of a related class. For example, in $\mathcal{T}_{Q_2}$, if `qmod`$_1$ is filled with `Company:name='Citigroup Inc'`, it will be changed to 'company', and `qmod`$_2$ can be filled with V_p *value of 20,000* of `Holding:value` as `Holding` is related to `Company`.

Relative pronouns for* `qmod` *expansion. To generate more complex questions, we introduce one-level nesting on an already filled `qmod` by expanding it using relative pronoun *whose*. If `qmod` is not a V_p of any property p, we replace it with its corresponding class name, and attach a relative modifier clause using V_p of a property p of one of its related classes. In $\mathcal{T}_{Q_1}$, when `qmod`$_1$ is filled with `Person:name='Neil Smit'`, the relative pronoun expansion of `qmod`$_1$ is *person whose value is 20,000* using related class `Holding` of `Person`.

***Entity* `qtmp`** is always retained as temporal values do not change the syntactic context of questions. In Fig. 2f, see Q_2^N generated from $\mathcal{T}_{Q_2}$.

(a) `AssigH:start_date` (b) `Holding:value`

Figure 6: Templates for non-heading property (a) and class-dependency (b).

D Heading Property Heuristics

While heading properties and their instances can be used to fill QENT entities independently, we adopt the following rules for non-heading properties:

- For classes with a single heading property with an instance (e.g. `AssignmentHistory:title` with 'CEO'), the instance is used along with a non-heading property to query it using prepositional connectives which are also annotated along with heading properties (`AssignmentHistory:start_date` *as* CEO). The QENT replacement is automatically constructed by attaching the heading property's instance as `nmod` using prepositional connective to the parse tree of non-heading property (Fig. 6a).
- For classes with more than one heading property, only they can be queried (`Holding:value`, `Holding:expiration_date`). E.g., *what is the value of ..?*, *what is the expiration date of ..?*

Using Social and Linguistic Information to Adapt Pretrained Representations for Political Perspective Identification

Abstract

Understanding the political perspective shaping the way events are discussed in the media is increasingly important due to the dramatic change in news distribution. With the advance in text classification models, the performance of political perspective detection is also improving rapidly. However, current deep learning based text models often require a large amount of supervised data for training, which can be very expensive to obtain for this task. Meanwhile, models pre-trained on the general source and task (e.g. BERT) lack the ability to focus on bias-related text span. In this paper, we propose a novel framework that pre-trains the text model using signals from the rich social and linguistic context that is readily available, including entity mentions, news sharing, and frame indicators. The pre-trained models benefit from tasks related to bias detection and therefore are easier to train with the bias labels. We demonstrate the effectiveness of our proposed framework by experiments on two news bias datasets. The models with pre-training achieve significant improvement in performance and are capable of identifying the text span for bias better.

1 Introduction

The perspectives underlying the way information is conveyed to readers can prime them to take similar stances and shape their worldview (Gentzkow and Shapiro, 2010, 2011). Given the highly polarized coverage of news events, recognizing these perspectives can help ensure that all points of view are represented by news aggregation services, and help avoid "information echo-chambers" in which only a single viewpoint is represented. It may also help to prevent the spread of false information online by showing people news with different perspectives.

Past work studying the expression of bias in the text has focused on lexical and syntactic representations of bias (Greene and Resnik, 2009; Recasens et al., 2013; Elfardy et al., 2015). Expressions of bias can include the use of the passive voice (e.g., *"mistakes were made"*), or references to known ideological talking points (Baumer et al., 2015; Budak et al., 2016; Card et al., 2016; Field et al., 2018; Morstatter et al., 2018) (e.g., *"pro-life"* vs. *"pro-choice"*). However, bias in news media is often nuanced and very difficult to detect. Journalists often strive to appear impartial and use language that does not reveal their opinions directly. Also, by their nature, news articles describing the same real-world event will share many similar details of the event, regardless of their political perspectives. Instead, bias is often expressed through informational choices (Fan et al., 2019), which highlight different aspects of the news story and frame facts shared by all articles in different ways. For example, the following articles capture different perspectives (Top *left*, Bottom *right*), while discussing the same news event– the 2021 storming of the U.S. Capitol [1].

Adapted from **NYTimes** (*Left*)

How Republicans Are Warping Reality Around the Capitol Attack ... Jim Hoft, did not reply to questions but did send along several of his own news articles related to claims of antifa involvement in the Capitol attack — citing the case of a man named **John Sullivan**, whom the right-wing media has dubbed an **"antifa leader"** in efforts to prove its theory of infiltration.

Adapted from **Fox News** (*Right*)

BLM activist inside Capitol claims he was 'documenting' riots, once said 'burn it all down'. John Sullivan has previously called for 'revolution' and to 'rip Trump' out of his office. An anti-Trump activist who once said he wanted to "rip" the president out of office entered the Capitol Building Wednesday alongside a mob of pro-Trump protesters, but he said he was just there to "document" it.

The two articles discuss the presentation of *John*

Sullivan as an Antifa member[2] who participated in the Capitol storming. However the story is framed in very different ways - while the bottom article frames the story directly as a discussion of Antifa involvement, the top discusses it in the context of political messaging and journalism. Furthermore, we notice that the difference is focused on a specific entity - John Sullivan.

Despite the fact that these distinctions are easily detectable by a human reader familiar with the political divisions in the U.S., they are very difficult to detect automatically. Recent success stories using large-scale pre-training for constructing highly expressive language models (Devlin et al., 2019) are designed to capture co-occurrence patterns, likely to miss these subtle differences.

In this paper we suggest that bias detection requires a different set of self-supervised pre-training objectives that can help provide a better starting point for training downstream biased detection tasks. Specifically, we design three learning objectives. The first, captures *political knowledge*, focusing on the embedding of political entities discussed in the text. The second one captures *external social context*. Following the intuition that different social groups would engage with documents expressing a different bias (e.g., left-leaning users are more likely to read the NYTimes article compared to the Fox News article), we collect social information contextualizing news articles and learn to predict the social context of each article, based on its content, thus aligning the two representations. Finally, the third is based on linguistic knowledge, focusing on the *issue framing* decisions made by the authors. Framing decisions have been repeatedly shown to capture political bias (Recasens et al., 2013; Johnson and Goldwasser, 2016; Roy and Goldwasser, 2020; Mendelsohn et al., 2021), and we argue that infusing a language model with this information can help capture relevant information. Note that this information is only used for pre-training. Other works using social information to analyze political bias (Li and Goldwasser, 2019; Nguyen et al., 2020; Pacheco and Goldwasser, 2021) augment the text with social information, however since this information can be difficult to obtain in real-time, we decided to investigate if it can be used as a distant supervision source for pre-training a language model.

These pre-training tasks are then used for training a **M**ulti-head **A**ttention **N**etwork (MAN) which creates a bias-aware representation of the text.

We conducted our experiments over two datasets, Allsides (Li and Goldwasser, 2019) and SemEval Hyperpartisan news detection (Kiesel et al., 2019). We compared our approach to several competitive text classification models and conducted a careful ablation study designed to evaluate the individual contribution of pre-training through knowledge from various contexts. Our results demonstrate the importance of all aspects, each contributing to the model's performance.

2 Related Work

The problem of perspective identification is originally studied as a text classification task (Lin et al., 2006; Greene and Resnik, 2009; Iyyer et al., 2014), in which a classifier is trained to differentiate between specific perspectives. Other works use linguistic indicators of bias and expressions of implicit sentiment (Recasens et al., 2013; Baumer et al., 2015; Field et al., 2018).

Recent work by (Fan et al., 2019) aims to characterize content relevant for bias detection. Unlike their work which relies on annotated spans of text, we aim to characterize this content without explicit supervision.

In the recent SemEval-2019, a hyperpartisan news article detection task was suggested[3]. Many works attempt to solve this problem with deep learning models (Jiang et al., 2019; Hanawa et al., 2019). We build on these works to help shape our text representation approach.

Several recent works also started to make use of concepts or entities appearing in the text to get a better representation. Wang et al. (2017) treats the extracted concepts as pseudo words and appends them to the original word sequence which is then fed to a CNN. The KCNN model by Wang et al. (2018), used for news recommendation, concatenates entity embeddings with the respective word embeddings at each word position to enhance the input. We take a different approach and instead try to inject knowledge of entities into the text model through the masked entity training. Zhang et al. (2019) also uses entity-level masking for training. However, they predict the tokens for the masked

---

[2] `https://en.wikipedia.org/wiki/Antifa_(United_States)`

[3] `https://pan.webis.de/semeval19/semeval19-web/`

entity instead of relying on meaningful representations for entities as ours.

Political framing, due to its relation with ideology and perspective, is studied in the NLP communities (Johnson et al., 2017; Field et al., 2018; Shurafa et al., 2020). There is also growing interest in utilizing framing differences to identify bias in news articles (Roy and Goldwasser, 2020).

Pre-trained models are widely used in numerous NLP tasks, from the early word2vec representation (Mikolov et al., 2013) to the generic language models like ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019). Recently, people also started to work on task specific pre-training that try to bring task and domain related knowledge into the model. Xu et al. (2019) is similar to our work as it proposes to enhance the BERT model through training on review data and sentiment classification tasks so that it can obtain better performance across multiple review-based tasks.

3 Political Perspective Identification Task

The problem of political perspective identification in news media can be formalised as follows. Given a news article d, where d consists of sentences s_i, $i \in [1, L]$, and each sentence s_i consists of words w_{it}, $t \in [1, T]$. L and T are the number of sentences in d and number of words in s_i respectively. The goal of this task is to predict the political perspective y of the document. Given different datasets, this can either be a binary classification task, where $y \in \{0, 1\}$ (hyperpartisan or not), or a multi-class classification problem, where $y \in \{0, 1, 2\}$ (left, center, right).

The overall architecture of our model is shown in Figure 1. It includes two sequence encoders, one for word level and another for sentence level. The hidden states from an encoder are combined through a multi-head self-attention mechanism. With pre-training on various social and linguistic information, the generated sentence and document vectors will consider not only the context within the text but also the knowledge about the entities (e.g. their political affiliation, or stance on controversial issues), sharing users, and frame indicators. We explain the structure of our model and the rich social and linguistic context we consider in detail below. Note that our pre-training strategies are not tied with any specific model structure and can be easily applied to other text models.

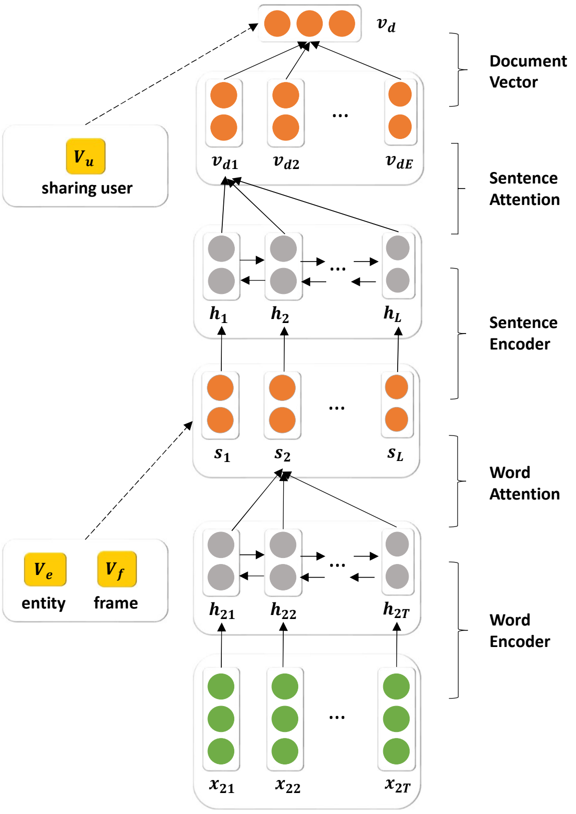

Figure 1: Overall Architecture of MAN Model.

3.1 Multi-Head Attention Network

The basic component of our model is the Hierarchical LSTM model (Yang et al., 2016). The goal of our model is to learn document representation v_d for political perspective prediction. It consists of several parts: a word sequence encoder, a word-level attention layer, a sentence sequence encoder, and a sentence-level attention layer. To capture the context in both directions, we use bidirectional LSTM in this work. For each element in the input sequence, the hidden state h is a concatenation of the forward hidden state $\overrightarrow{h}$ and backward hidden state $\overleftarrow{h}$ computed by the respective LSTM cells.

Given a sentence with words w_{it}, $t \in [1, T]$, each word is first converted to its embedding vector x_{it}. We can adopt pre-trained Glove (Pennington et al., 2014) word embeddings or deep contextualized word representation ELMo (Gardner et al., 2017) for this step. The word vectors are then fed into a word level bidirectional LSTM network to incorporate contextual information within the sentence. The hidden states h_{it} from the bidirectional LSTM network are passed to the next layer. In (Yang et al., 2016), a self attention mechanism is introduced to identify words that are important to the meaning of the sentence, and therefore higher weights are given to them when forming the aggregated sentence vector.

$$p_{itw} = tanh(W_w h_{it} + b_w) \tag{1}$$

$$\alpha_{itw} = \frac{exp(p_{itw}^T p_w)}{\sum_t exp(p_{itw}^T p_w)} \tag{2}$$

$$s_{iw} = \sum_t \alpha_{itw} h_{it} \tag{3}$$

p_{itw} encode the importance of a specific word according to its context, which is compared with the word level preference vector p_w to compute a similarity score. The scores are then normalized to get the attention weight α_{itw} through a softmax function. A weighted sum of the word hidden states is computed based on the attention weight as the sentence vector s_{iw}.

Inspired by the multi-head attention scheme in (Vaswani et al., 2017), we propose a multi-head attention in our model to extend its ability to jointly attend to information at different positions. The sentence vector s_i is computed as an average of s_{iw} obtained from different attention heads. Note that we learn a separate copy of the parameters W_w, b_w and p_w for each attention head.

$$s_i = \frac{\sum_w s_{iw}}{NH_W} \tag{4}$$

where NH_W is the number of word-level attention heads.

Given the sentence vectors s_i, we can generate the document vector v_d in a similar way. It captures the bias related information in news articles and can be used as features for predicting the document bias label.

$$f_d = W_c v_d + b_c \tag{5}$$

$$p_d = \text{softmax}(f_d) \tag{6}$$

We use the negative log likelihood of the correct labels as classification training loss:

$$L = -\sum_d \log p_{dj} \tag{7}$$

where j is the bias label of d.

3.2 Political Entities

News articles, especially the ones we are interested in in this work, are mainly covering real-world events involving political entities and their relations. To better understand the stance over controversial issues and the underlying ideology reflected in the text, it is very important to have extensive world knowledge about these entities, including their traits, opinions, and relevant events. We obtain the entity knowledge representations through learning on Wikipedia data.

Wikipedia2Vec (Yamada et al., 2018) is a model that learns entity embeddings from Wikipedia. It learns embeddings of words and entities by iterating over the entire Wikipedia pages and maps similar words and entities close to one another in a continuous vector space. It jointly optimizes the following three submodels:

1. Wikipedia link graph model, which learns entity embeddings by predicting neighboring entities in Wikipedia's link graph, an undirected graph whose nodes are entities and edges represent links between entities in their Wikipedia pages.

2. Word-based skip-gram model, which learns word embeddings by predicting neighboring words given each word on a Wikipedia page.

3. Anchor context model, which aims to place similar words and entities near one another in the vector space. The objective here is to predict neighboring words given each entity referred to on a Wikipedia page.

The learned entity embeddings encode the background knowledge about these entities in Wikipedia, such as gender, ideology, among others. We use them to initialize our entity embeddings in Section 4.1 which enables us to inject background knowledge of entities to the text model through pre-training.

3.3 Social Information Graph

With the great popularity of social media platforms, many people nowadays tend to share their personal interests and opinions and exchange ideas about social events with others online. This also applies to the sharing of news articles on social media. Intuitively, news articles shared by the same user are likely to have the same bias, and users who share a lot of news in common are close in their political preferences as well. Hence, we can use this information to guide the pre-training of our text model.

We follow the work in (Li and Goldwasser, 2019) to learn the embeddings through the structure of the social information graph for users who share articles. The graph consists of three types of vertices, namely political users, sharing users, and news articles. Political users are famous politicians or journalists with a clear, self-reported political bias. Sharing users are Twitter users who shared news articles in the dataset. There are two types of edges: 1) following edge between a sharing user to a political user and 2) sharing edge between a sharing user to a news article). Graph Convolutional Networks (GCN) are used to model the graph structure to predict the bias of political users. It aggregates information from the local neighborhood for each node in the graph. Therefore the training of GCN helps to propagate political preference information from political users to sharing users. We use the learned embeddings to guide the pre-training in Section 4.2 so that our text model can use this as distant supervision to map the representation of news articles shared by the same user to be close in the vector space since they are more likely to have the same perspective.

3.4 Frame Indicators

Political framing, studied by political scientists, provides a useful way to study different political perspectives. The frames surrounding an issue can change the reader's perception without having to alter the actual facts as the same information is used as a base. It is a political strategy that used to bias the discussion on an issue toward a specific stance. For example, regarding the topic of abortion, the liberal side will highlight the freedom of choice for women to decide whether to terminate a pregnancy while the conservative side may emphasize the morality aspect instead, arguing the right of the fetus.

Previous work (Roy and Goldwasser, 2020) shows that frame indicators can be used to identify the political perspectives effectively for different topics. These are words that have high pointwise mutual information with a specific frame. They can be considered to represent a more detailed point within a frame. Therefore we propose to use these frame indicators to guide the pre-training of text models so that they can learn to distinguish the nuance between different frames and talking points.

4 Pre-training

As discussed in the introduction, the supervision on news bias requires a lot of human effort to get. Moreover, the text model trained only on the political perspective labels cannot benefit from the rich knowledge we have from the various social and linguistic contexts presented in the previous section. To enhance the performance of political perspective identification, we may need to bring external knowledge and signals from the aforementioned contexts to enable the text model to take them into account when processing the news article. Eventually, we want to show that the model works best by exploiting all different kinds of knowledge and signals related to the task.

4.1 Entity Guided Pre-training

The goal of entity-guided pre-training is to inject knowledge about entities into our text model to help solve the political perspective identification problem. We first extract entities from the data corpus and then learn knowledge representations for them using Wikipedia2Vec introduced in 3.2. We then use the predicted

We utilize the entity linking system DBpedia Spotlight (Daiber et al., 2013) to recognize and disambiguate the entities in news articles. We use the default configuration of DBpedia Spotlight, including the confidence threshold of 0.35, which helps to exclude uncertain or wrong entity annotations. We keep only entities with Person or Organization types that appear in the corpus.

Inspired by the masked language modeling objective used in BERT (Devlin et al., 2019), we propose an entity-level masking task for injecting background knowledge of entities into the text model based on the news articles in which they are mentioned. The objective is to predict the masked entity based on the context provided by the other words in a sentence. Specifically, the entity mentions (regardless of the number of tokens in text) are replaced with a special token "[MASK]" during preprocessing. We use a bidirectional LSTM (sentence level encoder described in 3.1) to encode the sentence, and the hidden state of the mask token will be used for prediction. We use negative sampling to randomly generate negative entity candidates from all entities in our dictionary uniformly. The prediction can be done by comparing the similarity score between the hidden state and the embedding of candidate entities mapped to the same space through a hidden layer.

$$h_{it}^{T} \cdot (W_e v_e + b_e) \tag{8}$$

where h_{it} is the hidden state for the masked token, v_e the embedding of entity e, W_e and b_e the parameters for the mapping hidden layer. We use the multi-class cross-entropy loss for all pre-training tasks.

The learned sentence encoder will then be able to highlight the context in the news articles that is more related to the properties and of the mentioned entities.

4.2 Sharing User Guided Pre-training

As we discussed in Section 3.3, the sharing behavior by Twitter users can be regarded as signals to guide the pre-training of our text model. In order to benefit from the social information available, we propose to predict the sharing user given a news article. Similar to the previous part, we use negative sampling to generate negative sharing user candidates uniformly. The prediction is based on similarity scores defined below

$$v_{v_d}^{T} \cdot (W_s v_s + b_s) \tag{9}$$

where v_d is the document vector for d, v_s the embedding of sharing user s, W_s and b_s the parameters for the hidden layer.

4.3 Frame Indicator Guided Pre-training

The frame indicator guided pre-training is almost identical to the entity guided one except that the masked tokens are frame indicators instead of entity mentions.

4.4 Ensemble of Multiple Models

Given the entity and user embeddings are not in the same space, we use them to pre-train separate models. All pre-trained models are then trained with the supervision of political perspective labels in the same way. We also explore an ensemble of the three models, which makes predictions based on a weighted sum of unnormalized scores f_d in equation 5 from these models at test time.

$$\sum_{m} f_{dm} * \beta_m \tag{10}$$

where m denotes a trained prediction model, f_{dm} the unnormalized scores for document d by model m and β_m the weight given to model m which can be tuned based on the data.

5 Experiments

We aim to answer the following research questions (RQs) in the experiment:

RQ1: what is the performance gain of pre-training the text model with each social and linguistic information, with respect to the baseline models?

RQ2: what is the respective contribution by the individual pre-trained models to the full ensemble model?

RQ3: how will the performance gain change given the different amount of labeled data available for training?

5.1 Datasets and Evaluation

We run experiments on two news article datasets: Allsides and SemEval. The statistics of both datasets are shown in Table 1.

Allsides This dataset (Li and Goldwasser, 2019) is collected from two news aggregation websites[4] on 2020 different events discussing 94 event types. The websites provide news coverage from multiple perspectives, indicating the bias of each article using crowdsourced and editorial reviewed approaches. Each article has a political perspective label left, center, or right. We used the same randomly separated splits for evaluation in this paper so that our results are directly comparable with previous ones.

SemEval This is the official training dataset from SemEval 2019 Task 4: Hyperpartisan News Detection (Kiesel et al., 2019). The task is to decide whether a given news article follows a hyperpartisan argumentation. There are 645 articles in this dataset and each is labeled manually with a binary label to indicate whether it is hyperpartisan or not. Since the test set is not available at this time. We conducted 10-fold cross-validation on the training set with the exact same splits so that we can compare with the system that ranked in the first place.

Dataset	Center	Left	Right	Avg # Sent.	Avg # Words
Allsides	4164	3931	2290	49.96	1040.05
		Hyperpartisan			
SemEval	407	238		27.11	494.29

Table 1: Datasets Statistics.

[4] `Allsides.com` and `Memeorandum.com`

5.2 Baselines

We compare our model with several competitive baseline methods.

BERT is a language representation model based on deep bidirectional Transformer architectures (Vaswani et al., 2017). It was pre-trained with the masked language model and next sentence prediction tasks on a huge corpus. As a result, it can achieve state-of-the-art results on a wide range of tasks by fine-tuning with just one additional output layer.

CNN_Glove (CNN_ELMo) is the model from the team that ranked first in hyperpartisan news detection task in SemEval 2019 (Jiang et al., 2019). It uses the pre-trained Glove (ELMo) word vectors, which are then averaged as sentence representations. The sentence vectors are fed into 5 convolutional layers of different kernel sizes. The outputs for all convolution layers are combined to form the input to a fully connected layer, which maps to the final text representation. Some extra improvements include batch normalization and ensemble of multiple models.

5.3 Implementation Details

We use the spaCy toolkit for preprocessing the documents. All models are implemented with PyTorch (Paszke et al., 2017)[5]. The 300d Glove word vectors (Pennington et al., 2014) trained on 6 billion tokens are used to convert words to word embeddings. The ELMo model we used is the medium one with output size 512. They are not updated during training. The sizes of LSTM hidden states for both word level and sentence level are 300 for both Allsides and SemEval datasets. The number of attention heads at both word and sentence levels is set to 4 for the Allsides dataset, while it is set to 1 for the SemEval dataset due to its size. For the training of the neural network, we used the Adam optimizer (Kingma and Ba, 2014) to update parameters. On Allsides dataset, 5% of the training data is used as the validation set. We perform early stopping using the validation set. However, same as (Jiang et al., 2019), we use the evaluation part of each fold for early stopping and model selection due to the limited size of the SemEval dataset. The patience for early stopping p is equal to 10, meaning that the training stops when there is no improvement in validation performance for ten consecutive epochs. The learning rate lr is set to 0.001 for all models except BERT for which $2e-5$ is used. The mini-batch size $b = 10$ for bias prediction.

Regarding pre-training data sources, we use the training set for Allsides, and extract 100,000 news articles for SemEval from the large dataset provided by SemEval 2019 Task 4. The entity and user embeddings used for pre-training are obtained through external resources described in Section 3.2 and 3.3. The embeddings for frame indicators are randomly initialized. All of them were updated during the pre-training to better adapt to the text model. The optimizer and most hyper-parameters stay the same as the training of bias prediction. The mini-batch size is set to 2000 and 300 for models using Glove and ELMo respectively since the training is at the sentence level.

5.4 Results

5.4.1 Results on Allsides

We report the average accuracy and macro F1 scores on test sets for Allsides dataset in Table 2. The results are divided into two groups based on whether contextualized word representations are used. To answer RQ1, we observed that, in most cases, models with pre-training outperform the MAN baseline. It demonstrates our pre-training step can effectively utilize signals in social and linguistic context to enhance the text model to identify bias expressed in more subtle ways. Therefore it generates high-quality document representation for political perspective prediction. The sharing guided pre-training did not lead to much improvement by itself. This is mainly because the sharing users in our dataset often share news articles with various perspectives. Our ensemble model achieves the best result in terms of both accuracy and macro F1 scores no matter whether contextualized word embeddings are used or not. It shows the signals from various sources are complementary with each other such that even a simple combination of prediction scores can lead to significant improvement. The gaps between our model and baselines decrease when contextualized word representations are used since local context is better captured in this setting.

5.4.2 Results on SemEval

The performance of various models on the SemEval dataset can be found in Table 3. Note that

Model	Accuracy	Macro F1
MAN_Glove	78.29	76.96
+ Entity	80.50	79.50
+ Sharing	78.93	77.84
+ Frame	81.26	80.15
Ensemble	**83.74**	**82.84**
BERT	81.55	80.13
MAN_ELMO	81.41	80.44
+ Entity	82.27	81.23
+ Sharing	81.37	80.48
+ Frame	82.56	81.66
Ensemble	**85.00**	**84.25**

Table 2: Test Results on Allsides Dataset.

there is no sharing user guided result in this table since we do not have social graph information available in this dataset. Again the results are grouped based on word representation used. CNN_Glove and CNN_ELMo are results reported by the winning team in the SemEval competition. They proposed an ensemble of multiple CNN models where each CNN takes sentence representation generated by average ELMo embedding as input. It is worth noting that our model with Glove as word representation is comparable with the winning team's model with ELMo, showing the advantages of pre-training. The other trends hold as well in the SemEval dataset. In both datasets, our pre-trained models beat BERT easily since they are tuned specifically for the task.

Model	Accuracy	Macro F1
CNN_Glove †	79.63	-
MAN_Glove	81.58	79.29
+ Entity	82.65	80.75
+ Frame	83.27	81.73
Ensemble	**84.03**	**82.42**
CNN_ELMO †	84.04	-
BERT	84.03	82.60
MAN_ELMO	84.66	83.09
+ Entity	85.59	84.15
+ Frame	85.27	83.32
Ensemble	**86.21**	**84.33**

Table 3: Test Results on SemEval Dataset. † indicates results reported in (Jiang et al., 2019).

5.4.3 Ablation Study

To answer RQ2, we show the results for ablations of our ensemble model based on MAN_Glove in Table 4. The performance drops when removing each one of the pre-trained models from the ensemble, showing that the information obtained from different sources is complementary with each other. To make a fair comparison with the baseline model, we also report the performance of an ensemble of multiple baseline models (denoted as -Pre-training) with different seeds from random initialization. This shows the absolute gain through pre-training to adapt the text representations for political perspective identification.

Model	Accuracy	Macro F1
Ensemble	83.74	82.84
- Entity	82.57	81.65
- Sharing	82.78	81.78
- Frame	82.39	81.40
- Pre-training	81.54	80.40

Table 4: Ablation Study on Allsides Dataset.

5.4.4 Results with Limited Training Data

One of the obstacles in obtaining good performance in political perspective identification tasks is the lack of supervision data. We compare the performance of the MAN_Glove model with and without pre-training with different levels of training examples available in Figure 2. These results can help to answer RQ3. It shows that the performance gain obtained from our pre-training strategy increases as the size of the training set decreases. This is a very useful property as it can greatly improve model performance when there is limited training data. It is worth noting that the Sharing-Guided Pre-training achieves much higher performance when supervision is limited. This is because the signals from the sharing users can be considered as noisy bias labels and it is trained at document level instead of sentence level like the other two. However, since the other two pre-training methods introduce extra knowledge to the text model, they can lead to better performance when the supervision is abundant to provide enough bias information for training.

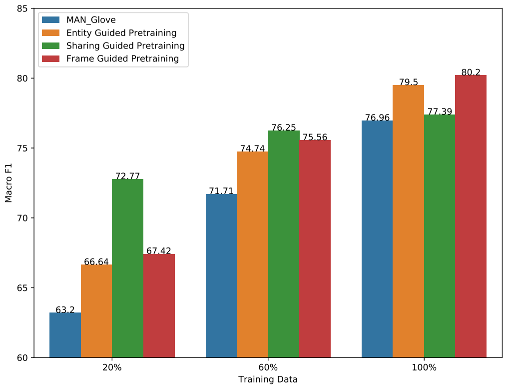

Figure 2: Test Results with Different Number of Training Examples.

5.4.5 Qualitative Results

Human Annotation Comparison The BASIL dataset (Fan et al., 2019) has human annotations of bias spans. It contains 300 articles on 100 events with 1727 bias spans annotated. On the sentence level, spans of lexical and informational bias are identified by annotators by analyzing whether the text tends to affect a reader's feeling towards one of the main entities. We compute the average attention assigned by our model to the annotated bias spans. Table 5 shows the results of the baseline model (MAN) and the same model pre-trained with entity information (+Entity). The attention scores assigned to the human annotation spans are higher across training, validation, and test sets.

Model	Training	Validation	Test
MAN	0.706	0.701	0.652
+ Entity	0.737	0.728	0.666
Improvement	4.36%	3.76%	2.13%

Table 5: Average Attention Scores on Basil Annotations.

6 Conclusion

In this work, we propose a pre-training framework to adapt text representation for political perspective identification. Empirical experiments on two recent news article datasets show that an ensemble of pre-trained models achieves significantly better performance in bias detection compared to competitive text baselines. It is also shown that our pre-training model can achieve even larger performance gain when the supervision is limited.

In fact, these various context information are not independent. We intend to extend this work to pre-train better text models by incorporating information from various sources together.

Abstract

Identifying relations from dialogues is more challenging than traditional sentence-level relation extraction (RE), since the difficulties of speaker information representation and the long-range semantic reasoning. Despite the successful efforts, existing methods do not fully consider the particularity of dialogues, making them difficult to truly understand the semantics between conversational arguments. In this paper, we propose two beneficial tasks, speaker prediction and trigger words prediction, to enhance the extraction of dialogue-based relations. Specifically, speaker prediction captures the characteristics of speaker-related entities, and the trigger words prediction provides supportive contexts for relations between arguments. Extensive experiments on the DialogRE dataset show noticeable improvements compared to the baseline models, which achieves a new state-of-the-art performance with a 65.5% of F1 score and a 60.5% of F1$_c$ score, respectively.

Dialogue 1

S1: Yeah you see umm, well, I'm an actor. Right? ……

Relation: (***S1***, per:title, actor)
Trigger Words: -

Dialogue 2

S1: Mom!
S2: Sweetie! So this is where you work? ……

Relation: (***S1***, per:parents, ***S2***)
Trigger Words: mom

Dialogue 3

S1: Hello, Mr. Bing.
S2: Loved your Stevie Wonder last night.
S3: Thanks. Listen, about the weekly numbers, I'm gonna need them on my desk by nine o'clock.
S1: Sure.
S2: No problem.

Relation: (***S1***, per:boss, ***S3***)
(***S2***, per:boss, ***S3***)
Trigger Words: -

Figure 1: Examples from the DialogRE dataset. s_n denotes the speaker of each utterance. The underlined text indicates the relation between the argument pairs.

1 Introduction

The task of relation extraction is to identify the relation facts between two arguments from plain text, which is the fundamental step of many natural language processing applications. Recent years have seen increasing efforts on sentence-level RE, e.g., relations only hold within a single sentence (Fu et al., 2019; Luan et al., 2019; Zhao et al., 2020; Wang and Lu, 2020; Wei et al., 2020). To adapt to complex scenarios, some current works have moved forward to the document-level RE, e.g., relations can exist across multiple sentences (Yao et al., 2019; Wang et al., 2020; Nan et al., 2020; Jain et al., 2020; Zhou et al., 2021).

A more challenging yet practical extension is the dialogue-based relation extraction. The dialogues contain multi-turn conversations among a group of speakers. The relations not only exist between the entities in the dialogue text but also the speakers of each utterance. Additionally, most of relations appear in multi-turn conversation, which require cross-sentence extraction. Considering the complexities, we divide the dialogue-based RE into three categories. In the first category, the relation can be directly inferred from the current utterance, as shown in the Dialogue 1 of Figure 1. In the second category, the relation involves utterances among multiple speakers and there is clear evidence in the dialogue that triggers the relation. Regarding the Dialogue 2 in Figure 1, "mom" is the trigger word of the relation `per:parents` be-

August 1–6, 2021.

tween “S1” and “S2”. Nevertheless, there are still cases where there is no clear context indicating the relationship. As shown in the Dialogue 3 of Figure 1, the relation between “S1” and “S3” as well as the relation between “S2” and “S3” can only be inferred from the tones and expression habits of speakers. Therefore, to identify relations from the complex dialogues, it is necessary to 1) discover highly supportive information about the arguments, and 2) capture the unique features of speakers.

Existing studies propose to solve this task through a speaker-aware BERT model (Yu et al., 2020) as well as a gaussian graph-based method (Xue et al., 2021). The former modifies the speaker arguments in dialogue text with special tokens to highlight the speaker-related information. The latter builds a latent multi-view graph to encode the long-distance dependency between arguments. However, these works regard dialogue as a plain text without considering the supporting information of relations and the characteristics of speakers. As been emphasized before (Xue et al., 2021), trigger words and speaker-related features play a critical role in dialogue-based relation extraction. In this case, it is difficult for them to detect the speaker-related relations from the complicated conversations.

To address the above limitations, we propose two beneficial tasks, speaker prediction and trigger words prediction, to enhance the dialogue-based relation extraction. Specifically, the speaker prediction task aims to capture the unique features of speakers. We randomly mask the speaker tokens and use the context to predict who said the utterance. The trigger words prediction task is to detect the supportive context of the current relation. We solve it with a sequence labeling method. Moreover, we design an integration module for the relation extraction task to combine both the global dialogue representation and the local arguments representation. Finally, the three tasks are jointly trained based on a multi-task learning framework.

The contributions of our work are summarized as follows. We propose two beneficial tasks, speaker prediction and trigger words prediction, to capture the unique features of speakers and detect the supportive information about arguments, both effectively enhance the dialogue-based relation extraction. We evaluate our method on the DialogRE dataset and achieve a new state-of-the-art performance with 65.5% of F1 score and 60.5% of F1$_c$ score, respectively. Our code is available at `https://github.com/TanyaZhao/DialogRE-Trigger-Speaker-Prediction`.

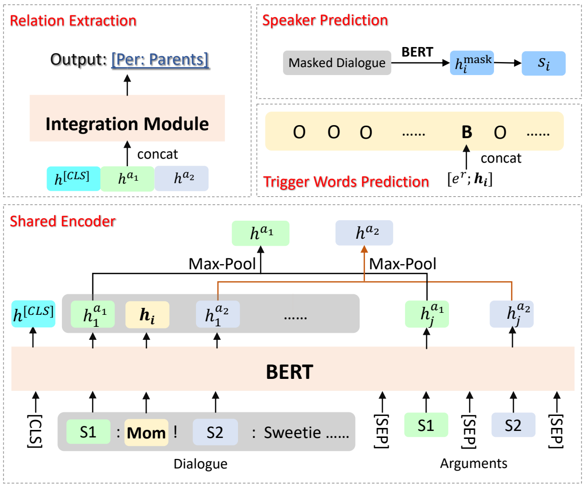

Figure 2: Overall structure of our method.

2 Problem Definition

Given a dialogue $d = s_1 : t_1, s_2 : t_2, ..., s_m : t_m$ and two arguments a_1, a_2, where s_i and t_i are the speaker and the utterance of the i-th turn, $t_i = x_{i1}, x_{i2}, ..., x_{in}$ is consisted of n words. The dialogue-based relation extraction aims to predict the relation type $r \in \mathcal{R}$ between a_1 and a_2, where $\mathcal{R}$ is the set of predefined relation categories.

3 Methodolgy

This section introduces the structure of our method, including three tasks, relation extraction, trigger words prediction and speaker prediction. Figure 2 shows the overall structure of our method.

3.1 Relation Extraction Task

The relation extraction task takes the dialogue d and the argument pair (a_1,a_2) as input and outputs a relation type r between the two arguments. For the dialogue d, we first modify it into $\hat{d} = \hat{s_1} : \hat{t_1}, \hat{s_2} : \hat{t_2}, ..., \hat{s_m} : \hat{t_m}$, where

$$\hat{s}_i = \begin{cases} \texttt{[B] [S}_1\texttt{] [E]} & \text{if } s_i = a_1 \\ \texttt{[B] [S}_2\texttt{] [E]} & \text{if } s_i = a_2 \\ s_i & \text{otherwise} \end{cases}, \quad (1)$$

$\hat{t_i} = x_{i1}..., \texttt{[B]}, a_k, \texttt{[E]}, ..., x_{in}, k \in \{1, 2\}$, if t_i contains a_k. Among them, `[S1]`, `[S2]`, `[B]`, `[E]` are newly-defined tokens. `[B]` and `[E]` are used to mark the start and the end position of the argument. We further replace the argument a_k

with the pre-defined token $\texttt{[S}_{\texttt{k}}\texttt{]}$, as $\hat{a_k} = \texttt{[S}_{\texttt{k}}\texttt{]}$ if $\exists i(s_i = a_k)$. Then, we concatenate $\hat{d}$, $\hat{a_1}$ and $\hat{a_2}$ as a sequence, and use special tokens `[CLS]` and `[SEP]` as sperators, formulated as

$$\texttt{[CLS]}\hat{d}\texttt{[SEP]}\hat{a_1}\texttt{[SEP]}\hat{a_2}\texttt{[SEP]}. \tag{2}$$

We feed the sequence into the pre-trained language model BERT (Devlin et al., 2019) and obtain the hidden semantic representation of each input tokens. Among them, $h^{[CLS]} \in \mathbb{R}^{d_h}$ is the hidden output of `[CLS]`, where d_h is the hidden size of BERT. We use $h^{[CLS]}$ to represent the global relational feature between a_1 and a_2.

To better represent the semantic information of arguments, we distill all the hidden states of a_k's start marker in the sequence (Eq. 2), including those in the dialogue text, and formulate them as $h_1^{a_k}, h_2^{a_k}, ..., h_j^{a_k} \in \mathbb{R}^{d_h}$. Then, we apply a max pooling process to obtain a combined representation of a_k:

$$h^{a_k} = \text{max-pool}(h_1^{a_k}, h_2^{a_k}, ..., h_j^{a_k}). \tag{3}$$

Next, we concatenate $h^{[CLS]}$, h^{a_1} and h^{a_2} as $h = [h^{[CLS]}; h^{a_1}; h^{a_2}] \in \mathbb{R}^{3d_h}$. Note that, $h^{[CLS]}$ is the global relational information of the sequence, and h^{a_1}, h^{a_2} are the local features of the arguments.

Furthermore, we propose an integration module to enhance the correlation between the dialogue and arguments. Specifically, h is fed into a two-layer highway network (Srivastava et al., 2015) as

$$\begin{aligned} \hat{h} &= H(h) * T(h) + h * (1 - T(h)), \\ T(h) &= \sigma(W^t h + b^t), \end{aligned} \tag{4}$$

where $W^t \in \mathbb{R}^{3d_h \times d_t}$, $b^t \in \mathbb{R}^{d_t}$ are learned weights with d_t as the hidden size of the highway network. Finally, we conduct a multi-class classification to calculate the probability of the relation between a_1 and a_2 by

$$\Pr(\text{relation} = r | d, a_1, a_2) = \text{sigmoid}(W^r h + b^r), \tag{5}$$

where $W^r \in \mathbb{R}^{d_t \times |\mathcal{R}|}$, $b^r \in \mathbb{R}^{|\mathcal{R}|}$.

3.2 Trigger Words Prediction Task

Generally, to identify the relation between two arguments, it is necessary to detect the supportive context that triggers the relation. Yu et al. (2020) have verified that trigger words play an important role for relation extraction. However, their work directly append the ground truth trigger words to the input sequence, which is not feasible for scenarios where the golden triggers are not available. The intuitive idea is to predict the trigger words from the conversation. Therefore, we can still obtain supporting information without relying on the golden triggers to guide the relationship extraction.

We propose the trigger words prediction task, which applies a simple and effective way to improve the relation extraction task. Specifically, we perform sequence labeling over the hidden outputs of BERT. Considering the trigger words are closely related to the relation, we first map the predicted relation r (Eq. 5) into a distributed embedding $e^r \in \mathbb{R}^{d_r}$, and concatenate it with each hidden output of BERT as $z_i = [e^r; h_i]$[1]. Then, we predict the boundary label for every token. Formally, the probability of the token x_i with label l is calculated by

$$\Pr(\text{label} = l | x_i) = \text{softmax}(W^l z_i + b^l), \tag{6}$$

where $W^l \in \mathbb{R}^{(d_h + d_r) \times |\mathcal{B}|}$ and $b^l \in \mathbb{R}^{|\mathcal{B}|}$ with $\mathcal{B} = \{\texttt{B}, \texttt{I}, \texttt{O}\}$.

3.3 Speaker Prediction Task

Notably, a majority of relations in the dialogue-based RE are associated with the speakers. For example, the triplet (S1, `per:parents`, S2) in Figure 1. Different from the ordinary entities, speakers have distinctive personal features, including tone of voices, expression habits, etc., which are important indicators for relation extraction. Therefore, we further propose the speaker prediction task based on the discourse structure to capture the speaker-related features. The motivation behind it is that if the model can distinguish who said the utterance, it learned the speaker's unique information, which is helpful to the speaker-related relation prediction.

Concretely, we randomly select the speaker words s_i in d with a probability of 10% and replace them with a special token `[MASK]`. Next, the BERT model takes the modified sequence as input and obtain the hidden state of each masked speaker, denoted as h_i^{mask}. Then, we predict the speaker through a multi-type classification as

$$\Pr(s_i | s_i^{\text{mask}}) = \text{softmax}(W^s h_i^{\text{mask}} + b^s), \tag{7}$$

where $W^s \in \mathbb{R}^{d_h \times S}$, $b^r \in \mathbb{R}^S$ with S as the maximum number of speakers in dialogues.

Model	Dev		Test	
	F1(σ)	**F1**$_c$(σ)	**F1**(σ)	**F1**$_c$(σ)
BERT(Devlin et al., 2019)	60.6 (1.2)	55.4 (0.9)	58.5 (2.0)	53.2 (1.6)
BERTs(Yu et al., 2020)	63.0 (1.5)	57.3 (1.2)	61.2 (0.9)	55.4 (0.9)
GDPNet(Xue et al., 2021)	**67.1 (1.0)**	61.5 (0.8)	64.9 (1.1)	60.1 (0.9)
Ours	66.8 (0.9)	**61.5 (1.0)**	**65.5 (0.7)**	**60.5 (0.8)**

Table 1: Performance comparison of our method with the existing advanced models on DialogRE dataset. σ denotes the standard deviation of 5 runs with different initial random seeds.

3.4 Joint Training Objective

The above three tasks share the BERT encoder and are jointly trained based on the multi-task learning framework. During training, we minimize the following objective loss function as

$$\mathcal{L} = \mathcal{L}_{\mathrm{RE}} + \mathcal{L}_{\mathrm{TP}} + \mathcal{L}_{\mathrm{SP}}, \tag{8}$$

where $\mathcal{L}_{\mathrm{RE}}$ is the binary cross-entropy loss for relation extraction, $\mathcal{L}_{\mathrm{TP}}$ and $\mathcal{L}_{\mathrm{SP}}$ are the cross-entropy loss for trigger words prediction and speaker prediction, respectively. For inference, we directly use the relation predicted by Equation 5 as the final result.

4 Experiments

In this section, we compare the proposed method with the current state-of-the-art approaches to evaluate its effectiveness.

4.1 Experimental Setup

Dataset We conduct experiments on the dialogue-based RE benchmark dataset, **DialogRE** (Yu et al., 2020). It contains $1,788$ dialogues from the transcripts of *Friends* corpus, totally with 36 relation types. 49.6% of relation triples is annotated with trigger words.

Evaluation Metrics Following the previous work (Yu et al., 2020), we adopt F1 score and F1$_c$ score as the evaluation metrics. Among them, F1$_c$ is a supplement to the F1, which only considers the first $i \leq m$ turns of utterances, rather than the entire dialogue.

Baseline Models We compare our method with the existing advanced models, **BERT**(Devlin et al., 2019), **BERTs** (Yu et al., 2020) and **GDPNet** (Xue et al., 2021). **BERT** model for the dialogue-based RE directly applies BERT as the dialogue encoder, and uses the hidden state of `[CLS]` for relation prediction. **BERTs** is a speaker-awared BERT, with modifies the speaker tokens to special markers. **GDPNet** uses a gaussian graph-based network to capture the interaction within dialogues, and achieves the current state-of-the-art performance.

Model	Test	
	F1(σ)	**F1**$_c$(σ)
Ours	**65.5 (0.7)**	**60.5 (0.8)**
Ours w/o SP	65.4(0.6)	59.8 (0.6)
Ours w/o TP	63.5 (0.9)	58.8 (1.0)
Ours w/o SP and TP	63.0 (0.7)	58.0 (0.9)
BERTs	61.2 (0.8)	55.4 (0.9)

Table 2: Ablation study to investigate the influence of each proposed task. SP and TP denote speaker prediction and trigger words prediction, respectively.

4.2 Experimental Results

Main Results Table 1 presents the performance comparison of our method with the existing advanced models. The results show that our method obviously outperforms the previous models and achieve a new state-of-the-art on test set with a F1 score of 65.5% and a F1$_c$ score of 60.5%, demonstrating the effectiveness of the proposed method.

Ablation Study We conduct ablation study experiments to investigate the influence of each proposed task. Table 2 shows the results. We can observe that, 1) *Ours w/o SP*, which removes the speaker prediction task. This causes a performance drop on all metrics, expecially with a drop of 0.7% on F1$_c$ score. 2) *Ours w/o TP*, which eliminates the trigger prediction task. The performance in terms of F1 and F1$_c$ decreases by 2.0% and 1.7%, respectively, demonstrating the importance role of trigger words prediction. 3) *Ours w/o SP and TP*, which detaches both speaker and trigger words prediction tasks. In this case, the performance further drops 0.5% and 0.8% in terms of F1 and F1$_c$. Therefore, the results above indicate that both the two tasks are beneficial to the dialogue-based RE. 4) Note that,

Case 1	**S1:** Mom ! **S2:** Sweetie! So this is where you work? ...
BERTs	(**S1**, `unanswerable`, **S2**) ✗
Ours	(**S1**, `per:parents`, **S2**) ✓
Case 2	**S1:** Hello, Mr. Bing. **S2:** Loved your Stevie Wonder last night. **S3:** Thanks. Listen, about the weekly numbers, I'm gonna need them on my desk by nine o'clock. **S1:** Sure. **S2:** No problem.
BERTs	(**S1**, `unanswerable`, **S3**) ✗ (**S2**, `unanswerable`, **S3**) ✗
Ours	(**S1**, `per:boss`, **S3**) ✓ (**S2**, `per:boss`, **S3**) ✓

Table 3: Case study on the DialogRE test set. The highlighted text indicates the trigger words recognized by our method.

although *Ours w/o SP and TP* only retains the relation extraction task, it still outperforms BERTs by a large margin. The result shows that our improved method of relation extraction is also effective.

Analysis on Discourse Structure Modeling To show the necessity of considering the discourse structure in dialogue-based RE, we design a naive way to degenerate a dialogue into a plain document. We modify the colon after a speaker into text like "said", "responsed" or "continued". For example, the Dialogue 2 in Figure 1 is converted into "*S1 said Mom! S2 responsed Sweetie! So this is where you work? ...*". Then, we apply our method to the changed text. The performance on the test set significantly degrades with 58.0% for F1 and 56.8% for F1_c. The result indicates that dialogues contain important discourse structural information. Therefore, it is important to study the extraction strategies for dialogues rather than directly applying common sentence-level or document-level extraction methods.

Trigger Words Prediction To further evaluate the effect of trigger words prediction task, we calculate the prediction performance on the cases annotated with the ground truth trigger words. Note that, 49.6% of relational triplets have trigger words in DialogRE. The prediction accuracy is 75.6%. The result demonstrates that we can correctly recognize most of the the trigger words. And with the help of the supporting information, the performance of relation extraction is considerably improved, as shown in Table 2.

Case Study We give a case study to analyze the quality of the results produced by our approach and the baseline model. Cases in Table 3 show that our method is capable of capturing the trigger words information and the characteristic of speakers. In case 1, the base model fails to utilize the trigger words information and identifies the relation as `unanswerable`. However, our method correctly recognizes that the word "Mom" triggers the relation between "S1" and "S2", which promotes the right prediction result. Besides, in case 2, our method can capture the characteristics information of speakers and thus correctly predict that "S3" is the boss of "S1" and "S2". Contrarily, the baseline model has difficulties in handling such case.

5 Conclusion

In this paper, we propose to enhance the dialogue-base relation extraction with two benefical tasks, the speaker prediction and the trigger words prediction. Extensive experiments on the benchmark dataset DialogRE demonstrate the effectiveness of our method in achieving state-of-the-art performance in both F1 score and F1_c score.

Abstract

Script reasoning infers subsequent events from a given event chain, which involves the ability to understand relations between events. A human-labeled script reasoning dataset is usually of small size with limited event relations, which highlights the necessity to leverage external eventuality knowledge graphs (KG) consisting of numerous triple facts to describe the inferential relation between events. Existing methods adopt a *retrieval and integration* paradigm to focus merely on the graph triples that have event overlap with a script, but ignore much more supportive triples in the KG with similar inferential patterns, leading to under-exploiting. To fully exploit the KG, we propose a knowledge model to learn the inferential relations between events from the whole eventuality KG and then support downstream models by directly capturing the relation between events in a script. We further present a neural script adapter to extend the knowledge model for inferring the associated relations between an event chain and a subsequent event candidate. We evaluate the proposed approach on a popular multi-choice narrative cloze task for script reasoning and achieve new state-of-the-art accuracy, compared with baselines either incorporating external KG or not.

1 Introduction

Script reasoning (Chambers and Jurafsky, 2008; Li et al., 2018; Lv et al., 2020b) aims at determining the subsequent event or plausible ending for an event chain in a script. For example, a tourism script consist of ["*Emily took a plane*", "*Emily arrived at Oahu*", "*Emily went to Waimea Bay*"], and the subsequent event is more likely to be "*Emily surfed*" than "*Emily skied*". Script reasoning has attracted more interest in the natural language processing (NLP) community since it plays essential roles in many real-world applications like storytelling (Swanson and Gordon, 2008).

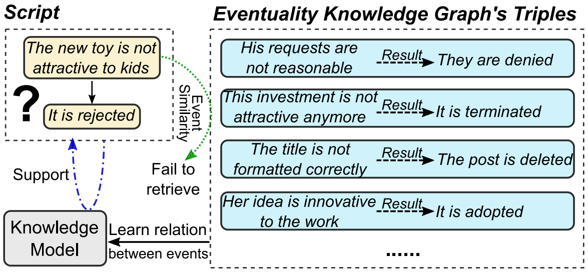

Figure 1: Comparison of "*retrieval and integration*" paradigm (green dot line) with ours (blue dash-dot line). Although there is no semantic overlap between the precedent event in the script and the events in the KG, which leads to failed retrieval, our approach still provides supportive evidence by exploiting similar inferential relation patterns.

Understanding and inferring the correlation between two events are critical for script reasoning. Taking the tourism script as an example, the key to decide the subsequent event is inferring that "*A person goes to a beach*" is more correlated to "*The person surfs*" than "*The person skies*". An immediate idea is to learn event relations from some well-labeled training datasets. Unfortunately, due to labor-intensive labeling, high-quality training data for script reasoning is usually small, from which it is impractical to learn rich relations for large scale commercial applications. Therefore, it is necessary to leverage external knowledge that implies relations between events.

Recently, Lv et al. (2020b) propose to leverage a large-scale eventuality knowledge graph (KG), ASER (Zhang et al., 2020), for script reasoning via adopting the "*retrieval and integration*" paradigm. Given an event chain, this paradigm first retrieves relevant triple facts from the eventuality KG and then integrates them into a script reasoning model.

Although such a paradigm is proven effective in entity-centric tasks (Zhang et al., 2019; Liu et al., 2020), it is not competent in event-centric script

reasoning. The reason is that, the retrieval is based on lexical or semantic matching between an event from a script and each event node in the KG. For example, in Figure 1, to determine whether the precedent event "*The new toy is not attractive to kids*" will result in a subsequent event "*It is rejected*", this paradigm will try to retrieve graph triples with the event nodes talking about "*toy is not attractive*", etc., which is very likely to fail if the KG contains few related events. Namely, it dramatically narrows the focus to the graph triples merely with exact event matching, so it cannot fully leverage the external eventuality KG.

However, script reasoning can benefit from leveraging *event pairs* in KG with *similar relation patterns*, rather than the only triples in KG with *similar events*. In Figure 1, although events in the four graph triples have no semantic overlap with the precedent event "*The new toy is not attractive to kids*", all the triples can represent the relation that *if some attribute of an object is judged negatively, it might be rejected, otherwise being accepted*, which still provide strong supportive evidence between "*The new toy is not ...*" and "*It is rejected*". Therefore, script reasoning can benefit from the event pairs with similar inferential relation patterns, beyond the textual contents of the events.

Motivated by this, in this work, we propose a novel paradigm to integrate external knowledge for script reasoning by directly modeling the relation between events from a KG and thus support script reasoning in light of similar relation patterns. In particular, we first propose a *discriminative knowledge model* trained on the graph triples in an external eventuality KG. Taking each event pair in the triples as input, the knowledge model learns to predict whether two events in the pair are associated and what is the inferential relation between them. After being trained, the knowledge model can directly capture associated and inferential relations between precedent and subsequent events in a script. And the relations between events will be represented in latent space, which can be further integrated into any event-centric neural model.

Furthermore, as script reasoning requires to associate between a sequence of precedent events (i.e., an event chain) and a plausible subsequent event, we propose a neural *script adapter*, based on a chain-dependent attention module, for extending the trained knowledge model from event to script level. This leads to a *script-adaptive knowledge model* that directly represents inferential information between an event chain and a subsequent event candidate as a latent embedding. Lastly, this embedding, coupled with deep text representation from a script-text contextualizing encoder, is used to derive the plausibility score of the candidate.

We conduct empirical studies on a popular task of script reasoning, i.e., multi-choice narrative cloze (Li et al., 2018). Our approach outperforms strong competitors and achieves a new state-of-the-art accuracy, verifying the effectiveness of the script-adaptive knowledge model when integrating inferential relations into script reasoning.

2 Preliminary

This section begins with a formal task definition of script reasoning, followed by introductions to eventuality KGs and pre-trained language models.

Task Definition. Script reasoning is usually formulated as a multi-choice narrative cloze (MCNC) problem: given an event chain $\boldsymbol{e} = [e_1, \dots, e_n]$, it aims to select the most plausible subsequent event from a set of candidates $\mathcal{E}^{(c)} = \{e_1^{(c)}, \dots e_m^{(c)}\}$, where each event e consists of a sequence of words $\boldsymbol{w}^e = [w_1^e, w_2^e, \dots]$, n denotes the length of event chain $\boldsymbol{e}$, and m denotes the number of candidates $\mathcal{E}^{(c)}$. A script reasoning model is asked to produce relatedness score between the event chain and each candidate event so that

$$\hat{e} = \arg\max_{e_j} P(\boldsymbol{e}, e_j; \theta), \ \forall e_j \in \mathcal{E}^{(c)}, \qquad (1)$$

where $P(\cdot;\theta)$ denotes a θ-parameterized script reasoning model, and $\hat{e}$ denotes the predicted event.

Eventuality Knowledge Graph. In contrast to *canonical KGs* with entity-centric factoid triples, an eventuality KG, $\mathcal{G}$, typically consists of a set of event-centric triples $(e^{(h)}, r, e^{(t)})$ to describe inferential or co-occurrent relation between events. It represents each event e as free-form text, while well defines a closed-set $\mathcal{R}$ of relations so that $\forall r \in \mathcal{R}$.

3 Methodology

In this section, we will elaborate on our approach for multi-choice narrative cloze (MCNC) task in script reasoning. As shown in Figure 2, we first propose a discriminative knowledge model learning facts from eventuality graph (§3.1), followed by a novel neural adapter upgrading the knowledge model into script level (§3.2). Lastly, as in Figure 3,

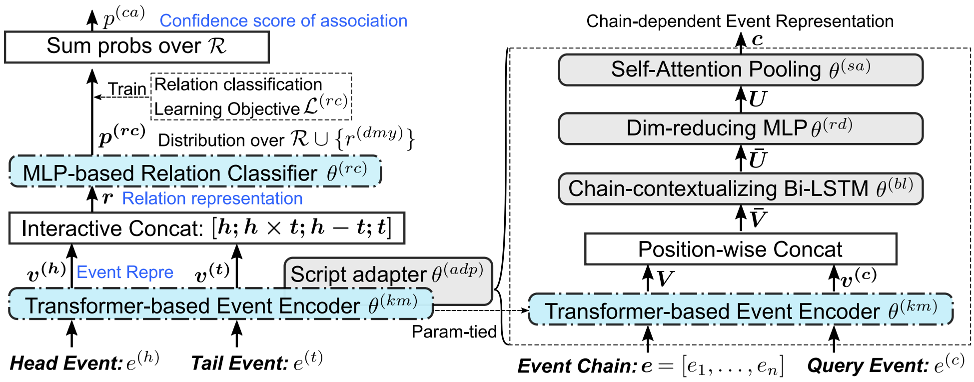

Figure 2: Our discriminative knowledge model (left), and its script adapter (right) for multi-choice narrative cloze (MCNC). Dash-dot blue rounded rectangles denote parameters optimized towards the objective of the knowledge model, whereas solid blue rounded rectangles denote script adapter's parameters that will be optimized towards the objective of MCNC.

we present a representation learning framework to solve the MCNC task (§3.3).

3.1 Discriminative Knowledge Model

To avoid challenging event grounding and satisfy coverage necessity, neural *knowledge models* (Bosselut et al., 2019b; Hwang et al., 2020) are proposed to memorize eventuality facts from a KG to its parameters during training. They are built upon a pre-trained *generative* Transformer (e.g., GPT (Radford et al., 2018)) and fine-tuned on triple facts from an eventuality KG via generative objectives of event-based *link prediction*.

However, such generative knowledge models are not perfectly compatible when capturing event-pair relation facts since they focus more on inferring tail events given a head event and an inferential relation. This is consistent with the goal of link prediction for KG completion. Consequently, if they try to model the inferential relations between events, they have to generate all possible triples for each event by traversing all relations and enlarging beam-search size (Bosselut et al., 2019a). And the generated triple must be re-encoded into latent space for the integration (Lv et al., 2020b), not to mention generative models not always reliable.

Therefore, we present a discriminative objective based on *relation classification* for knowledge model learning to directly capture such inferential information in latent space. Formally, given a triple $(e^{(h)}, r, e^{(t)}) \in \mathcal{G}$, we separately pass head event $e^{(h)}$ and tail event $e^{(h)}$, into a text encoder to generate event-level contextualized representations. Following Devlin et al. (2019), we first concatenate the natural language text $\boldsymbol{w}^e$ of each event e with special tokens:

$$\tilde{\boldsymbol{w}}^e = (\texttt{[CLS]}, \boldsymbol{w}^e, \texttt{[SEP]}), \forall e \in \{e^{(h)}, e^{(t)}\}, \quad (2)$$

where the special tokens could vary with different pre-trained models. Then, we feed the concatenated text $\tilde{\boldsymbol{w}}^e$ into a Transformer encoder, followed by a pooling layer, i.e.,

$$\boldsymbol{H}^e = \text{Transformer}(\tilde{\boldsymbol{w}}^e; \theta^{(km)}) \in \mathbb{R}^{d \times N}, \quad (3)$$

$$\boldsymbol{v} = \text{Pool}(\boldsymbol{H}^e) \in \mathbb{R}^d, \ \forall e \in \{e^{(h)}, e^{(t)}\}, \quad (4)$$

where $\boldsymbol{v}$ denotes the resulting event representation, $\text{Transformer}(\cdot; \theta)$ stands for pre-trained bidirectional Transformer encoder (e.g., BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019)) to produce deep contextualized embeddings, and $\text{Pool}(\cdot)$ denotes using the embedding of `[CLS]` as sequence-level representation by following prior works. Given $\boldsymbol{v}$ of both head and tail events, we apply an interactive concatenation (Bowman et al., 2015; Reimers and Gurevych, 2019) between them to model their inferential relationship, i.e.,

$$\boldsymbol{r} := \text{Inter-Concat}(\boldsymbol{h}, \boldsymbol{t}) = [\boldsymbol{h}; \boldsymbol{h} \times \boldsymbol{t}; \boldsymbol{h} - \boldsymbol{t}; \boldsymbol{t}], \\ \text{where } \boldsymbol{h} = \boldsymbol{v}^{(h)} \text{ and } \boldsymbol{t} = \boldsymbol{v}^{(t)}. \quad (5)$$

Here, $\boldsymbol{r} \in \mathbb{R}^{4d}$ represents inferential relation between head and tail events, $[\cdot; \cdot]$ denotes vector concatenation, and "$\times$" denotes element-wise product.

Lastly, the relation representation, $\boldsymbol{r}$, is learned by passing it into a neural classifier to predict the oracle relation in the original triple. In order to enable this knowledge model to represent a null or non-associated relation between events, we define an extra relation category, named dummy relation $r^{(dmy)}$. This classification is written as

$$\boldsymbol{p}^{(rc)} = \text{softmax}(\text{MLP}(\boldsymbol{r}; \theta^{(rc)})) \in \mathbb{R}^{|\mathcal{R}'|}, \quad (6) \\ \mathcal{R}' = \mathcal{R} \cup \{r^{(dmy)}\},$$

where $\boldsymbol{p}^{(rc)}$ is the probability distribution over $\mathcal{R}'$, and $\mathcal{R}'$ denotes a union of the well-defined relation set $\mathcal{R}$ with a dummy relation category $r^{(dmy)}$. The training data corresponding to $r^{(dmy)}$ is derived from negative sampling in the eventuality KG.

Training. We use a cross-entropy loss to optimize this discriminative knowledge model, $\{\theta^{(km)}, \theta^{(rc)}\}$, towards such a dummy-aware relation classification, which is denoted as

$$\mathcal{L}^{(rc)} = -\sum\nolimits_{(e^{(h)},r,e^{(t)})} \log \boldsymbol{p}^{(rc)}_{[y=r]}. \tag{7}$$

Inference. The trained knowledge model can be used in three ways summarized as (1) producing event representation by

$$\begin{aligned}\boldsymbol{v} &:= \text{Event-Enc}(e; \theta^{(km)}) \\ &= \text{Pool}(\text{Transformer}(\tilde{\boldsymbol{w}}^e; \theta^{(km)})),\end{aligned} \tag{8}$$

(2) generating relation representation by

$$\boldsymbol{r} := \text{Relation-Model}(e^{(h)}, e^{(t)}; \theta^{(km)}), \tag{9}$$

and (3) deriving a confidence score for whether there is an associated relation between two events:

$$\begin{aligned}p^{(ca)} &:= \text{Confid}(e^{(h)}, e^{(t)}; \theta^{(km)}, \theta^{(rc)}) \\ &= \sum\nolimits_{r \in \mathcal{R}' \backslash \{r^{(dmy)}\}} \boldsymbol{p}^{(rc)}_{[y=r]},\end{aligned} \tag{10}$$

Remark. This discriminative knowledge model learns inferential relations between events in latent space, facilitating event-centric reasoning tasks. But it has its drawbacks like incompetence to auto-construction, in contrast to the generative knowledge models. Thereby, we argue generative and discriminative knowledge models are complementary to each other with different downstream uses.

3.2 Script-Adaptive Knowledge Model

In multi-choice narrative cloze (MCNC), a script reasoning model is asked to capture the relation between an event chain and a subsequent event candidate, however beyond the ability of the proposed knowledge model. To handle the MCNC task, we propose a neural adapter for the event encoder in Eq.(8), making it competent in modeling an event chain. Our goal is that, given a subsequent candidate, we extract the most relevant "event" from an event chain to represent the whole chain. As such, the result is still compatible with high-layer components in our knowledge model.

To this end, we present a chain-dependent attention module which is based on bidirectional chain contexts $\boldsymbol{e} = [e_1, \ldots, e_n]$ queried by a potential subsequent event $e^{(c)}$. In particular, we first generate event representation for each event by our trained event encoder, i.e.,

$$\boldsymbol{v}^{(c)} = \text{Event-Enc}(e^{(c)}; \theta^{(km)}), \tag{11}$$

$$\boldsymbol{V} = [\boldsymbol{v}_1, \ldots, \boldsymbol{v}_n] \in \mathbb{R}^{d \times n}, \tag{12}$$

$$\text{where, } \boldsymbol{v}_i = \text{Event-Enc}(e_i; \theta^{(km)}),$$

Then the embedded event chain, $\boldsymbol{V}$, position-wisely concatenated with the query event representation $\boldsymbol{v}^{(c)}$, is passed into a bidirectional long short-term memory (Bi-LSTM) to model rich event-contextual information of the event chain, i.e.,

$$\bar{\boldsymbol{U}} = \text{Bi-LSTM}(\bar{\boldsymbol{V}}; \theta^{(bl)}) \in \mathbb{R}^{4d \times n}, \tag{13}$$

$$\boldsymbol{U} = \text{MLP}(\bar{\boldsymbol{U}}; \theta^{(rd)}) \in \mathbb{R}^{d \times n}, \tag{14}$$

$$\text{where, } \bar{\boldsymbol{V}} = [\bar{\boldsymbol{v}}_1, \ldots, \bar{\boldsymbol{v}}_n], \bar{\boldsymbol{v}}_i = [\boldsymbol{v}_i; \boldsymbol{v}^{(c)}] \in \mathbb{R}^{2d}.$$

The resulting $\boldsymbol{U} \in \mathbb{R}^{d \times n}$ is chain-dependent representations of the chain events, $\text{MLP}(\cdot; \theta^{(rd)})$ is responsible for reducing dimensionality.

Lastly, a self-attention pooling module (Liu et al., 2016; Lin et al., 2017) is applied to $\boldsymbol{U}$ to get a vector representation of the event chain, i.e.,

$$\boldsymbol{c} = \boldsymbol{U}\boldsymbol{\alpha}, \tag{15}$$

$$\text{where } \boldsymbol{\alpha} = \text{softmax}(\text{MLP}(\boldsymbol{U}; \theta^{(sa)})).$$

Here, $\boldsymbol{\alpha} \in \mathbb{R}^n$ denotes the probability distribution of attention mechanism, which is then applied to chain-dependent event representations $\boldsymbol{U} \in \mathbb{R}^{d \times n}$ by matrix multiplication. As a result, $\boldsymbol{c}$ denotes a chain-dependent event representation extracted from the whole event chain. Intuitively, it can be viewed as the most relevant event from the event chain $\boldsymbol{e}$ to the candidate event $e^{(c)}$ as it is derived from an attention module queried by $e^{(c)}$. Hence, the derived $\boldsymbol{c}$ is still compatible with the top layers (e.g., interactive concatenation and neural classifier) in the discriminative knowledge model. Note that, the parameters of this neural script adapter, $\theta^{(adp)} = \{\theta^{(bl)}, \theta^{(rd)}, \theta^{(sa)}\}$, will be learned towards the MCNC objective jointly with other neural components in our script reasoning model, which is detailed in the next section (§3.3).

In summary, we can define a chain-dependent event encoding module to the above procedures to embed an event chain, i.e.,

$$\boldsymbol{c} = \text{Event-Enc}^{(\text{adp})}(\boldsymbol{e}, e; \theta^{(km)}, \theta^{(adp)}), \tag{16}$$

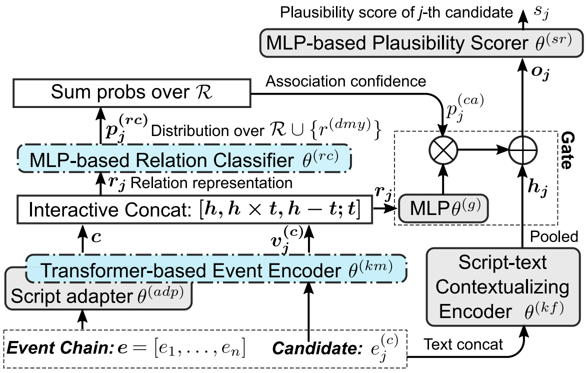

Figure 3: Our script reasoning model for MCNC. Freezing the trained modules (dash-dot blue rounded rectangles) in our knowledge model, we optimize the other learnable modules (solid gray rounded rectangles) in our script reasoning model towards the MCNC task. Please refer to Figure 2 for an illustration of the script adapter.

where $\boldsymbol{e} = [e_1, \ldots]$ is an event chain and e is a query event. The chain-dependent event representation, $\boldsymbol{c}$, can be used as an argument to $\text{Inter-Concat}(\cdot, \cdot)$ to model script-level relationship with another event chain or a single event. Thus, the other two inference models in Eq.(9) and Eq.(10) are also adapted to $\text{Relation-Model}^{(\text{adp})}(\cdot)$ and $\text{Confid}^{(\text{adp})}(\cdot)$ respectively.

3.3 Script Reasoning Model

Built upon the discriminative knowledge model and its script adapter, we lastly present our script learning model for multi-choice narrative cloze task. To be specific, given an event chain $\boldsymbol{e} = [e_1, \ldots, e_n]$ and each event $e_j^{(c)}$ from the subsequent candidates $\mathcal{E}^{(c)}$, we first pass them into the script-adaptive knowledge model to generate a chain-dependent event representation $\boldsymbol{c}_j$ as defined Eq.(16):

$$\boldsymbol{c}_j = \text{Event-Enc}^{(\text{adp})}(\boldsymbol{e}, e_j^{(c)}; \theta^{(km)}, \theta^{(adp)}),$$

where $\forall e_j^{(c)} \in \mathcal{E}^{(c)}$. Based on $\boldsymbol{c}_j$, we can also derive the relation representation $\boldsymbol{r}_j$ between the event chain and each candidate, as well as the confidence score p_j of the association.

$$\boldsymbol{r}_j = \text{Relation-Model}^{(\text{adp})}(\boldsymbol{e}, e_j^{(c)}; \theta^{(km)}, \theta^{(adp)}),$$
$$p_j^{(ca)} = \text{Confid}^{(\text{adp})}(\boldsymbol{e}, e_j^{(c)}; \theta^{(km)}, \theta^{(rc)}, \theta^{(adp)}).$$

Besides the above rich-relation features from the knowledge model, we also leverage expressively powerful contextualized representations from another pre-trained bidirectional Transformer to fully exploit implicit reasoning knowledge in event texts. Formally, we present a *script-text contextualizing encoder* that applies the Transformer encoder to a concatenation of the event chain and each subsequent candidates, with special tokens separated:

$$\tilde{\boldsymbol{w}}_j = (\texttt{[CLS]}, \boldsymbol{w}^{e_1}, \ldots, \texttt{[SEP]}, \boldsymbol{w}^{e_j^{(c)}}, \texttt{[SEP]}),$$
$$\boldsymbol{h}_j = \text{Pool}(\text{Transformer}(\tilde{\boldsymbol{w}}_j; \theta^{(kf)})). \quad (17)$$

To integrate the knowledge from the both models, we present a *knowledge gating module* for element-wise addition weighted by the association confidence:

$$\boldsymbol{o}_j = \boldsymbol{h}_j + p_j^{(ca)} \cdot \text{MLP}(\boldsymbol{r}_j; \theta^{(g)}), \quad (18)$$

where, $\boldsymbol{o}_j \in \mathbb{R}^d$ is the final vector to represent the relation between the chain and a candidate from two perspectives, and $\text{MLP}(\cdot; \theta^{(g)})$ is responsible for reducing dimensionality from $4d$ to d. Such a gating module leads to a flexible knowledge integration, which is prone to avoiding redundant, non-associated relation features.

Finally, an MLP-based scoring module is defined to calculate a plausibility score given the final relation representation, followed by a softmax to derive predicted distribution:

$$s_j = \text{MLP}(\boldsymbol{o}_j; \theta^{(sr)}), \forall j = 1, \ldots, m, \quad (19)$$
$$\boldsymbol{p}^{(sr)} = \text{softmax}([s_1; \ldots; s_m]) \in \mathbb{R}^m, \quad (20)$$

where $m = |\mathcal{E}^{(c)}|$, and $\boldsymbol{p}^{(sr)}$ is the predicted distribution over candidate events $\mathcal{E}^{(c)}$ in MCNC.

Training. With fixed knowledge model $\{\theta^{(km)}, \theta^{(rc)}\}$, we train both the adapter $\theta^{(adp)}$ and the reasoning model $\theta^{(src)} = \{\theta^{(kf)}, \theta^{(g)}, \theta^{(sr)}\}$ towards the objective of MCNC, by a cross-entropy loss, i.e.,

$$\mathcal{L}^{(sr)} = -\frac{1}{|\mathcal{D}|} \sum_{\mathcal{D}} \log \boldsymbol{p}^{(sr)}_{[y=e^{(c)*}]}, \quad (21)$$

where $e^{(c)*}$ denotes the gold subsequent event.

Inference. We can obtain the most plausible subsequent event from a trained MCNC model by

$$\hat{e}^{(c)} = \arg\max_{e_j^{(c)}} [s_1; \ldots; s_m]. \quad (22)$$

4 Experiments

This section begins with a detailed description of our experimental setups on multi-choice narrative cloze (MCNC) task for script reasoning. Then, we conduct quantitative evaluations on the MCNC task, followed by extensive qualitative evaluations, including ablation study, model analysis, case study and error analysis.

Method	ACC (%)
w/o external knowledge	
Random	20.00
PMI (Chambers and Jurafsky, 2008)	30.52
Bigram (Jans et al., 2012)	29.67
Word2vec (Le and Mikolov, 2014)	42.23
Event-Comp (Granroth-Wilding and Clark, 2016)	49.57
PairLSTM (Wang et al., 2017)	50.83
SGNN (Li et al., 2018)	52.45
RoBERTa$_{\text{base}}$ (Lv et al., 2020b)	56.23
w/ external knowledge	
SGNN + Int&Senti (Ding et al., 2019)	56.03
RoBERTa$_{\text{base}}$ + Knwl. (Lv et al., 2020b)	58.66
Ours + RoBERTa$_{\text{base}}$	**59.99**
Ours + RoBERTa$_{\text{large}}$	**63.62**

Table 1: Comparison of our approach with previous script reasoning models on MCNC task. Our two models achieve 59.96% and 63.95% on dev set, respectively.

Datasets and Knowledge Graph. Following prior works (Lv et al., 2020b) for script reasoning, we evaluate our proposed approach on the dataset published by Li et al. (2018), which is widely used for the MCNC task. We follow the official data split[1] with 140,331/10,000/10,000 samples in training/dev/test sets. We use ASER (Zhang et al., 2020) as an external knowledge graph and learn a knowledge model from it. ASER is a large-scale eventuality knowledge graph extracted from unstructured textual data. It contains 15 event relations, 194M unique events, and 64M event-centric triples.

Evaluation Metrics. We adopt the official evaluation metric (Li et al., 2018), accuracy (ACC), to measure the performance of the reasoning models.

Implementation Details. The proposed approach for script reasoning contains two training processes, one for the discriminative knowledge model pre-trained on the eventuality KG and the other for the script reasoning model for MCNC task. (1) For the knowledge model, we adopt the BERT$_{\text{base}}$ model and optimize the cross-entropy loss with Adam optimizer. The learning rate is set to 1×10^{-5}. The hidden size of Bi-LSTM is set to 256. The maximum training epoch and batch size are set to 100 and 128. The maximum sequence length and dropout are set to 18 and 0.1. The weight decay and gradient clipping are set to 0.01 and 1.0. (2) For the script reasoning model, We experiment with two pre-trained language models, i.e. RoBERTa$_{\text{base}}$ and RoBERTa$_{\text{large}}$. Both the embedding size and hidden size are set to 768 in RoBERTa$_{\text{base}}$ and 1024 in RoBERTa$_{\text{large}}$. We use Adam optimizer (Kingma and Ba, 2015) to optimize the cross-entropy loss. The learning rate is set to 1×10^{-5}. The maximum training epoch and batch size are set to 3 and 32. The maximum sequence length and dropout are set to 64 and 0.1. The weight decay and gradient clipping are set to 0.01 and 1.0. We choose the model with the best result on the development set and report the results on the testing set are based on this model. The knowledge model contains 110M parameters, and our reasoning models contain 127M and 359M parameters for the base and large initializations, respectively. Our experiments are conducted on 4 NVIDIA P40 GPUs, and the training time is around 5 hours with RoBERTa$_{\text{base}}$ and 9 hours with RoBERTa$_{\text{large}}$.

Method	ACC (%)
Ours + RoBERTa$_{\text{large}}$	**63.62**
w/o chain-dependent attention	62.62
w/o knowledge gating module	62.85
w/o script-adapter	62.24
w/o external knowledge	61.53

Table 2: Ablation study of our approach. "*w/o chain-dependent attention*" denotes replacing chain-dependent attention module in our script adapter with mean-pooling, "*w/o knowledge gating module*" denotes removing confidence score $p^{(ca)}$ of the gating module in Eq.(18), ''*w/o script-adapter*" denotes ablating both chain-dependent attention and knowledge gating module, and "*w/o external knowledge*" denotes removing our script-adaptive knowledge model, equivalent to the RoBERTa$_{large}$ baseline.

4.1 Main Evaluation

The experimental results of our approach and previous script reasoning works on the Multi-Choice Narrative Cloze (MCNC) task are shown in Table 1. From the table, we can make two observations. First, using external knowledge, especially external event graph knowledge, increases the accuracy of models. For example, the knowledge infusion approach proposed by Lv et al. (2020b) outperforms the RoBERTa model without any knowledge. Second, our approach is superior to the *retrieval and integration* approach, RoBERTa + Knwl, and achieves new state-of-the-art accuracy (i.e. 63.62% using the RoBERTa$_{\text{large}}$ text encoder) on this task. This demonstrates the effectiveness of the proposed script-adaptive knowledge model.

4.2 Ablation Study

We conduct an ablation study to investigate the effect of each component of our approach and the results are reported in Table 2. We first investigate the impact of the chain-dependent attention

---

[1] https://github.com/eecrazy/ConstructingNEEG_IJCAI_2018

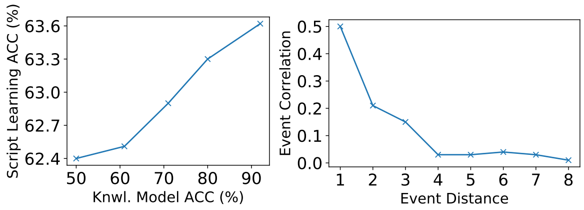

Figure 4: Impacts of knowledge model accuracy (left) and event distance over event association (right).

in Eq.(15) by replacing it with mean pooling over all events in the chain, and find that the accuracy of script reasoning is decreased about 1%. Next, we testify our approach without the knowledge gating module, which decreases the accuracy by 0.8%. And the gap becomes 1.4% if both the chain-dependent attention and the confidence score is ablated. Finally, we compare our approach with the baseline without any external knowledge included, and the accuracy of script reasoning drops by 2.1%, demonstrating the effectiveness of leveraging external event knowledge by the discriminative knowledge model.

4.3 Model Analysis

Impact of Knowledge Model. Our approach leverages the external event KG by directly modeling relations between event pairs. Intuitively, the accuracy of the learned model plays a critical role in script reasoning. Thus, we investigate its impact by assessing the performance of script reasoning with the knowledge models of various accuracy. The accuracy of knowledge model is evaluated on its dev set from the KG. As shown in Figure 4 (left), we can observe that the accuracy of script reasoning increases with that of the knowledge model, verifying the assumption that integrating external event knowledge via a knowledge model improves the performance of a script reasoning model.

Impact of Event Distance over Event Association. The script reasoning task requires to predict a subsequent event given an event chain. We investigate how the distance between two events impacts their correlation by analyzing the attention score of various timesteps of precedent events in a script. In particular, for all precedent events which are i-th step before subsequent events, we aggregate their attention scores. The results are plot in Figure 4 (right). The x-axis represents the distance between two events, and y-axis represents the estimated correlation by our model. From the figure we can see that an event is most highly correlated to its precedent neighbor. The association drops quickly as the distance increases, and it becomes very small when two events are three steps away.

Precedent Events
...
E7: state granted accountant
E8: believed accountant
Subsequent Event Candidates
A. asked accountant (*correct answer*)
B. ends accountant
C. depict accountant
D. penalize accountant firm
E. need accountant salary
Event pairs in KG with similar events
<Zakia will believe it, Zakia drops he guard>
<He is an accountant, He is very intelligent>
. . .
Event pairs in KG with Similar Relation Pattern
<I need your medical expertise, I need you help on something>
<You be the expert, I need answer>

Table 3: An example of script reasoning. The task is to choose a subsequent event from 5 candidates for the given precedent events. The associated event pair in the example is marked in blue with underline.

4.4 Case Study

As demonstrated in Table 3, we present an example in the test set to compare the *retrieval and integration* approach and ours. Here the script describes an event chain about *accountant*, which states that *accountants are believed*.

To infer the next event, the *retrieval and integration* paradigm will try to retrieve events with similar lexicon or semantics, e.g. "*zakia will believe it*", "*he is an accountant*", etc. However, KG triples containing these events do not capture the relation that *if a person is believed, people will consult him/her*. Therefore, this approach fails to leverage the KG to make a correct prediction.

In contrast, the KG contains event pairs like "*(I need your medical expertise, I need your help on something)*", "*(you are the expert, I need answer)*", whose relation patterns support the relation between "*accountants are believed*" and "*people ask accountants*", although there is little overlap between KG events and scrip events. The knowledge model learned from the KG event pairs captures such relation patterns and provides strong support for reasoning in this example, which demonstrates the effectiveness of our approach compared with the *retrieval and integration* approach.

4.5 Error Analysis

Lastly, to analyze the limitations of our model, we investigate the mis-classified examples on the MCNC test set, and summarize two main problems:

First, some scripts consist of precedent events which might lead to conflict results. For example, a event chain, [“*He disappointed supporters*”, “*He fulfilled promise*”], is likely to be associated with two opposite results. The former might be associate with “*He lost campaign*”, while the latter might result in “*They backed up his campaign*”. Such case might confuse the reasoning model.

Second, long-distance dependency between events are difficult to capture. For example, in a tourism script which describes “*Emily went to the beach*” followed by a long description about the parking problem she met, although “*Emily went surfing*” is a rational subsequent event, the distance between the two events is too long so it is difficult for a reasoning model to capture such relations.

5 Related Work

A script (Schank and Abelson, 2013) refers to a kind of structured representation for prototypical sequences of events. Chambers and Jurafsky (2008) formulate a script learning (narrative learning) task and propose statistical models to capture event co-occurrence for subsequent event prediction. Afterwards, the approaches for script reasoning can be categorized into two genres. i.e., *event pair modeling* (Jans et al., 2012; Pichotta and Mooney, 2014; Granroth-Wilding and Clark, 2016) and *event chain modeling* (Pichotta and Mooney, 2016; Wang et al., 2017; Lv et al., 2019). But, they still lag far behind humans as the well-labeled training set is usually of small size. In addition, script reasoning is more challenging than traditional NLP tasks and requires models to reason over unobserved events.

With recent developments of large-scale eventuality knowledge graphs (KG) (e.g., ASER (Zhang et al., 2020) and ATOMIC (Sap et al., 2019)), an effective remedy is to adopt “*retrieval and integration*” schema and integrate the inferential facts retrieved from the KG for script reasoning (Lv et al., 2020b). This paradigm is proven effective in both entity-centric and concept-centric tasks, such as relation extraction (Zhang et al., 2019), named entity recognition (Liu et al., 2020) and commonsense reasoning (Lin et al., 2019; Lv et al., 2020a), etc. However, this paradigm is not that compatible with event-centric script reasoning since script reasoning focuses more on the inferential relation between consecutive events in a script rather than the triple facts with exact event matching. What is worse, these eventuality KGs consisting of free-form event usually encounter low knowledge coverage or incompleteness problem (Zhang et al., 2020; Bosselut et al., 2019b), leading to problematic grounding from an event to the nodes in the KG.

To circumvent the coverage problem, Bosselut et al. (2019b) and Hwang et al. (2020) propose to learn a *generative knowledge model* on existing triples from an eventuality KG, where the triples can be regarded as a seed of knowledge. It on-demand generates subsequent events with a prompt of the observed event and an inferential relation, thus avoiding event grounding and satisfying coverage necessity for a broad spectrum of NLP tasks (Shwartz et al., 2020; Majumder et al., 2020; Paul and Frank, 2020; Ding et al., 2019; Ma et al., 2019). However, such generative knowledge models are not perfectly compatible when capturing inferential relations between events because they focus more on inferring tail events rather than the relations.

In contrast, our method avoids operating merely on the triples that have lexical or semantic overlap with the targeted script, while directly learn the inferential relation patterns on the whole KG. The learned knowledge model can simply capture the relation between events in a script in latent space, benefiting various event-centric reasoning tasks.

6 Conclusion

In this work, we explore a novel paradigm to integrate an external eventuality knowledge graph into a script reasoning model for multi-choice narrative cloze task. We first identify a major problem affecting the integration for script reasoning. That is, previous works merely retrieve the graph triples that have semantic overlap with the events in a script, but neglect that the triples with similar inferential relation patterns can contribute a lot. We hence propose a knowledge model that learns the patterns on the graph and then provides supportive rich-relation evidence for events in a script. We also present a script adapter to make the knowledge model compatible with script-level reasoning. Built upon these, we finally present a reasoning model and evaluate it on the targeted task. Experimental results demonstrate that, the proposed model delivers new state-of-the-art performance, followed by further analyses to provide comprehensive insights.

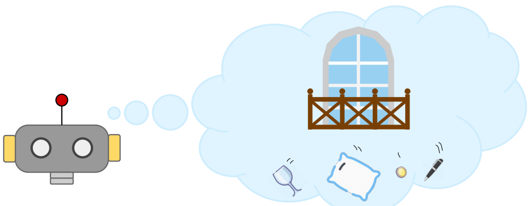
Abstract

We present a new probing dataset named *PROST: Physical Reasoning about Objects Through Space and Time*. This dataset contains 18,736 multiple-choice questions made from 14 manually curated templates, covering 10 physical reasoning concepts. All questions are designed to probe both causal and masked language models in a zero-shot setting. We conduct an extensive analysis which demonstrates that state-of-the-art pretrained models are inadequate at physical reasoning: they are influenced by the order in which answer options are presented to them, they struggle when the superlative in a question is inverted (e.g., *most* ↔ *least*), and increasing the amount of pretraining data and parameters only yields minimal improvements. These results provide support for the hypothesis that current pretrained models' ability to reason about physical interactions is inherently limited by a lack of real world experience. By highlighting these limitations, we hope to motivate the development of models with a human-like understanding of the physical world.

1 Introduction

In the context of natural language processing (NLP), Bender and Koller (2020) provides a working definition of "understanding" as the ability to recover the communicative intent from an utterance. To achieve this, one must be able to query a set of concepts that is aligned with the speaker's own understanding. An example of such alignment is our interaction with the physical world. This experience, shared by all humans, provides a common set of concepts to rely on in communication. For example, the reader can map the phrase *I dropped my pint glass* to a set of relevant experiences and generate a mental depiction of the scene. Further, the reader can also use their knowledge of gravity and the properties of a pint glass to reason about potential outcomes: the pint glass will fall toward the ground and will likely break on impact.



A person drops a *glass*, a *pillow*, a *coin*, and a *pen* from a balcony.
The [MASK] is most likely to break.
A) glass **B)** pillow **C)** coin **D)** pen

Figure 1: An example question from PROST.

Children grab, push, and play with the objects around them to form concepts about the world they live in even before learning to talk (Hespos and Spelke, 2004). These concepts are then linked with words to enable communication, eventually providing the necessary grounds for concepts and language to co-develop (Bloom, 2002; Gelman, 2009). In contrast, current language models (LMs) are not exposed to real-world experiences, making them incapable of grounding language (Bisk et al., 2020a). We hypothesize that this lack of experience impedes their ability to both understand an utterance relating to the physical world and their ability to reason about its implications.

In order to investigate our hypothesis, we create *PROST: Physical Reasoning of Objects Through Space and Time*, a probing dataset to evaluate the ability of pretrained LMs to understand and reason about the physical world. PROST consists of multiple-choice cloze-style questions covering 10 basic concepts: direction, mass, height, circumference, stackable, rollable, graspable, breakable, slideable, and bounceable. Importantly, PROST is designed to avoid models succeeding in unintended

ways. First, PROST provides no training data, so as to probe models in a zero-shot fashion. This prevents models from succeeding through spurious correlations between training and test data and encourages success through a true understanding of and reasoning about the concepts at hand. Second, we manually write templates for all questions in an effort to prevent models from having seen the exact same sentences in their training data. Finally, it focuses on a small set of well defined, objective concepts that only require a small vocabulary. This allows researchers to focus more on the quality of training data rather than the size of it.

Contributions We make two contributions: 1) We introduce PROST, a dataset with $18,736$ cloze-style questions created from 14 manually written templates, covering 10 physical reasoning tasks. 2) We conduct an extensive analysis which demonstrates that state-of-the-art pretrained models are inadequate at physical reasoning. More specifically, they are influenced by the order in which answer options are presented to them, they struggle when the superlative in a question is inverted (e.g., *most* $\leftrightarrow$ *least*), and increasing the amount of pretraining data and parameters only yields minimal improvements. The dataset and code is available at github.com/nala-cub/prost.

2 Related Work

Evaluation of Reasoning Abilities As pretrained models are excelling on many NLP tasks, more work is being done on understanding their abilities. A subset of this work focuses on physical reasoning. PIQA (Bisk et al., 2020b) tests physical commonsense, with concepts ranging from hard shell tacos to separating egg yolks. In order to succeed on PIQA through reasoning, a model would need to be able to understand thousands of human experiences. In contrast, PROST provides a first step towards grounded understanding and reasoning by focusing on a few simple concepts. Bakhtin et al. (2019) provides a set of 2D puzzles that involve placing a new object in a scene to accomplish a goal. This research also focuses on simple physics, however there is no language component. Clark et al. (2018) and Kembhavi et al. (2017) both provide a large set of grade school multiple-choice questions, including some that could be solved with reasoning. However both provide corresponding material where the solution can be found, relying more on information retrieval than a general understanding and reasoning about the world.

Another set of reasoning-based benchmarks focuses on common sense reasoning. SWAG and its extension hellaSWAG evaluate commonsense natural language inference (Zellers et al., 2018, 2019). Sap et al. (2019) tests commonsense reasoning about social situations. However, commonsense reasoning is often subjective and requires understanding of complex human–human interactions involving social and societal norms. In contrast, physical reasoning is based on objective and well defined constructs.

Other datasets (Forbes and Choi, 2017; Elazar et al., 2019; Goel et al., 2019) focus on object–attribute comparison. However, they compare concepts at a word level rather than sentence level and use a large training set to create an engineered object–attribute comparison model. It is difficult to see how these models could generalize to other forms of reasoning.

Moreover, all the above datasets follow a pretraining-agnostic identically distributed (PAID) paradigm (Linzen, 2020), making them susceptible to models that can leverage unintended correlations between the training and test sets.

Zero-Shot LM Probes Similar to PROST, several recent benchmarks have circumvented the concern of identically distributed training and test sets by probing models in a zero-shot manner. Petroni et al. (2019) queries masked LMs (MLMs) for factual knowledge using templates in the format of *Dante was born in [MASK].* Talmor et al. (2020) use a similar format to probe six concepts ranging from age comparison to taxonomy conjunction. Ettinger (2020) uses this format to show that BERT robustly retrieves hypernyms, but fails to understand negation. Lin et al. (2020) probe numerical commensense in both MLMs and traditional LMs. Warstadt et al. (2020) measures traditional LMs' sense of grammatical acceptability by comparing sentence probabilities.

Grounded Language Environments PROST investigates if pretrained models show a lack of understanding of the physical world which could result from learning language without grounding. While not used for pretraining, a number of multi-modal environments have been developed to ground language. Shridhar et al. (2020)'s ALFRED builds on other vision-and-language navigation environments (Gordon et al., 2018; Regneri et al., 2013; Zhu et al., 2017; Anderson et al., 2018), and enables grounding of language instruction to actions, behaviours, and objects. BABYAI (Chevalier-Boisvert et al., 2019) and BABYAI++ (Cao et al., 2020) provide an environment to ground simple language in a gridworld. Additionally, other work has explored grounding language in simulations or the real world (Hill et al., 2020; Lynch and Sermanet, 2020). While they provide important resources to ground language, little emphasis is placed on the language modules themselves. They are often trained tabulae rasae, learning language for a singular purpose and missing out on the syntax and coverage learnt during pretraining;[1] language is only ever an input, and no analysis has been done on how language understanding evolves as the agent learns to succeed on different tasks.

3 PROST

PROST consists of $18,736$ cloze-style multiple-choice questions designed for probing a LM's physical reasoning ability. They cover 10 basic concepts: direction, mass, height, circumference, stackable, rollable, graspable, breakable, slideable, and bounceable. We choose these concepts because they are well defined, easily learned by interacting with the world, and are useful concepts for any embodied agent. The questions are constructed from 14 manually written templates. Each template follows one of three different formats: the first format is specific to the set of questions pertaining to directions; the second format is used to gauge the relative attributes—specifically mass, height, and circumference—of objects; and the third format targets the affordances of objects—specifically whether an object is stackable, rollable, graspable, or breakable, and whether a surfaces is slideable or bounceable[2]. We use CheckList (Ribeiro et al., 2020) to obtain the questions from our templates. We show all templates in Table 1 and explain them in detail below. We end this section by describing the objects featured in PROST.

Direction Templates We use two templates to generate questions which probe understanding of direction. The first focuses on cardinal directions. The second uses a set of four manually crafted questions to probe understanding of how gravity affects the directions of a ball throughout its trajectory. Due to their similarity, we count these four questions as a single template. The direction templates create a total of 16 questions.

Attribute Templates The second set of templates probe the models' ability to reason about relative mass, height, and circumference of common objects. For each of these three concepts we create a set of six objects that are easily ordered by their respective attributes. A context is first presented with up to four of the six objects to prime the models with the range of possible choices. This is followed by a prompt that probes the model to select one of the objects based on the object's mass, height, or circumference. By inverting the superlative in the prompt (e.g., *longest* ↔ *shortest*), we can probe the model's ability to identify both the object with the highest attribute value and the object with the lowest attribute value from the set of choices. We permute through all objects and all orders. Each of the three attributes are tested using two templates that share the same set of objects. Each template produces ${}_6P_4 * 2 = 720$ questions, meaning each attribute is probed using 1440 questions.

Affordance templates The remaining templates target an understanding of object affordances. For each affordance—stackable, rollable, graspable, breakable, slideable, and bounceable— we collect a set of five objects with and five objects without that affordance. Again, we first provide a short context that contains each of the four possible objects. We then provide a prompt that requires the model to select the only object either with or without the affordance. We include all permutations of objects where there is exactly one correct answer. These templates produce ${}_5P_1 * {}_5P_3 * 4 * 2 = 2400$ questions for each of the six affordances.

Objects in PROST All possible values for the placeholders in our templates are shown in Table 3. For affordances, we display objects in two groups: those with and without each affordance. For attributes, objects are sorted by increasing order, e.g., for mass, *leaf* is the lightest object and *microwave* is the heaviest object. Each object in PROST is selected to be single-token compatible for a wide range of vocabularies to enable easy probing of MLMs. We validate the order of our attribute objects and the group membership for our affordance objects by collecting judgments from 9 human val-

---

[1] An exception is Lynch and Sermanet (2020), which incorporates modern LMs and provides impressive generalizability. However, they too only use language as an input and do not analyze how language understanding evolves.

[2] *Bounceable* here refers to providing an elastic collision.

Category	Qs.	Template
Directs. 1	12	**C:** A person is walking *{north/east/south/west}*. They turn *{left/right/around}*.
		Q: They are now walking [MASK].
		O: **A)** north **B)** east **C)** south **D)** west
Directs. 2a	1	**C:** A person drops a ball.
		Q: Immediately after leaving the person's hand, the ball is moving toward the [MASK].
Directs. 2b	1	**C:** A person throws a ball straight into the air.
		Q: Immediately after leaving the person's hand, the ball is moving toward the [MASK].
Directs. 2c	1	**C:** A person throws a ball straight into the air.
		Q: Immediately after reaching the highest point in it's trajectory, the ball is moving toward the [MASK].
Directs. 2d	1	**C:** A person drops a ball. The ball then bounces off the ground.
		Q: Immediately after bouncing off the ground, the ball is moving toward the [MASK].
		O: **A)** ground **B)** sky **C)** left **D)** right
Mass 1	720	**C:** A(n) *{mass_obj1}*, a(n) *{mass_obj2}*, a(n) *{mass_obj3}*, and a(n) *{mass_obj4}* moving at identical speeds each collide with a static hockey puck.
		Q: The puck hit by the [MASK] slides the *{shortest/longest}* distance.
Mass 2	720	**C:** A(n) *{mass_obj1}* and a(n) *{mass_obj2}* are placed on either end of a perfectly balanced seesaw.
		Q: The side of the seesaw with the [MASK] moves *{up/down}*.
		O: **A)** *{mass_obj1}* **B)** *{mass_obj2}* **C)** *{mass_obj3}* **D)** *{mass_obj4}*
Height 1	720	**C:** Four balls are dropped. The first is dropped from the height equivalent of a *{height_obj1}*, the second is dropped from the height equivalent of a *{height_obj2}*, the third is dropped from the height equivalent of a *{height_obj3}*, and the fourth is dropped from the height equivalent of a *{height_obj4}*.
		Q: The ball dropped from the height of the [MASK] takes the *{longest/shortest}* amount of time to fall.
Height 2	720	**C:** There are four staircases. The first staircase leads to the top of a *{height_obj1.}*, the second staircase leads to the top of a *{height_obj2.}*, the third staircase leads to the top of a *{height_obj3.}*, and the fourth staircase leads to the top of a *{height_obj4.}*.
		Q: The staircase leading to the top of the [MASK] is the easiest/hardest to walk up.
		O: **A)** *{height_obj1}* **B)** *{height_obj2}* **C)** *{height_obj3}* **D)** *{height_obj4}*
Circumf. 1	720	**C:** Four people are walking at identical speeds. The first walks around a *{circ_obj1}*, the second walks around a *{circ_obj2}*, the third walks around a *{circ_obj3}*, and the fourth walks around a *{circ_obj4}*.
		Q: The [MASK] takes the *{longest/shortest}* amount of time to walk around.
Circumf. 2	720	**C:** A person paints a circle around a *{circ_obj1}*, a *{circ_obj1}*, a *{circ_obj1}*, and a *{circ_obj1}*.
		Q: The circle around the [MASK] takes the *{most/least}* amount of paint.
		O: **A)** *{circ_obj1}* **B)** *{circ_obj2}* **C)** *{circ_obj3}* **D)** *{circ_obj4}*
Stackable	2400	**C:** A person is trying to stack *{stack}*, *{no stack1}*, *{no stack2}*, and *{no stack3}*.
		Q: The [MASK] are the *{easiest/hardest}* to stack.
		O: **A)** *{stack}* **B)** *{no stack1}* **C)** *{no stack2}* **D)** *{no stack3}*
Rollable	2400	**C:** A person is trying to roll a(n) *{roll}*, a(n) *{no roll1}*, a(n) *{no roll2}*, and a(n) *{no roll3}*.
		Q: The [MASK] is the *{easiest/hardest}* to roll.
		O: **A)** *{roll}* **B)** *{no roll1}* **C)** *{no roll2}* **D)** *{no roll3}*
Graspable	2400	**C:** A person is trying to move a pile of *{break}*, a pile of *{no break1}*, a pile of *{no break2}*, and a pile of *{no break3}* from one side of a room to the other using only one hand.
		Q: The [MASK] is the *{most/least}* likely to break.
		O: **A)** *{break}* **B)** *{no break1}* **C)** *{no break2}* **D)** *{no break3}*
Breakable	2400	**C:** A person drops a *{break}*, a *{no break1}*, a *{no break2}*, and a *{no break3}* from a balcony.
		Q: The [MASK] is the *{most/least}* likely to break.
		O: **A)** *{grasp}* **B)** *{no grasp1}* **C)** *{no grasp2}* **D)** *{no grasp3}*
Slideable	2400	**C:** A person is sliding four bricks across four hard surfaces. The first surface is covered with *{slide}*, the second surface is covered with *{no slide1}*, the third surface is covered with *{no slide2}*, and the fourth surface is covered with *{no slide3}*.
		Q: The surface covered with [MASK] is the *{hardest/easiest}* for the brick to slide across.
		O: **A)** *{slide}* **B)** *{no slide1}* **C)** *{no slide2}* **D)** *{no slide3}*
Bounceable	2400	**C:** A person is trying to bounce a rubber ball. They drop a first ball onto *{bounce}*, a second ball onto *{no bounce1}*, a third ball onto *{no bounce2}*, and a fourth ball onto *{no bounce3}*.
		Q: The ball dropped onto[MASK] bounces the *{most/fewest}* times.
		O: **A)** *{bounce}* **B)** *{no bounce1}* **C)** *{no bounce2}* **D)** *{no bounce3}*

Table 1: All templates in PROST. **C:** = Context, **Q:** = Question, **O:** = Options. {} indicate placeholders. The objects can be found in Table 3. The rest of the placeholders show their possibilities in the braces themselves. [MASK] indicates the position of the blank that the models need to fill. See Section 3 for more information. *NOTE: The number of objects with and without the affordances are swapped when the superlative is inverted.*

Model Type	Input	Target
Decoder	*(context)* They are now walking $\langle \mathbf{O} \rangle$.	Max probability for each sentence input to the model
Encoder	*(context)* They are now walking $\langle \mathbf{M} \rangle$.	Max probability for the masked token.
T5	*(context)* They are now walking $\langle \mathbf{X} \rangle$.	$\langle \mathbf{X} \rangle$ south $\langle \mathbf{Y} \rangle$
UnifiedQA	Which way are they walking now? `\n` (A) north (B) south (C) east (D) west `\n` *(context)*	south

Table 2: Overview of the task preprocessing for different architectures evaluated. In all methods, the context remains unchanged and is "A person is walking west. They turn left."

idators. The validators obtained a 100% agreement on the object ordering, and 94.6% agreement on the object group membership.

Attributes	
Attribute	*Objects*
mass	leaf, coin, egg, apple, brick, microwave
height	book, microwave, table, car, house, mountain
circ	book, microwave, table, car, house, mountain
Affordances	
Affordance	*Objects*
stack	books, blocks, boxes, coins, plates
no stack	balls, bottles, eggs, flowers, lamps
roll	apple, ball, bottle, egg, can
no roll	book, box, block, mirror, microwave
grasp	balls, blocks, books, bottles, flowers
no grasp	flour, rice, salt, snow, sugar
break	bottle, egg, glass, mirror, plate
no break	ball, coin, pen, pillow, shirt
slide	ice, frost, grease, oil, soap
no slide	carpet, concrete, grass, gravel, rubber
bounce	asphalt, brick, concrete, rubber, steel
no bounce	carpet, foam, grass, leaves, snow

Table 3: Objects used in the templates.

4 Models

Using PROST, we probe three types of transformer-based models (Vaswani et al., 2017): decoder models, encoder models, and encoder-decoder models. Each model has slightly different formatting requirements, which we show in Table 2. For each model type, we probe a range of different sizes to investigate the effects of scaling. We use Huggingface's (Wolf et al., 2020) pretrained models, see Table 4 for the full set.

Decoder Models We analyze OpenAI's GPT-1 (Radford et al., 2018) and GPT-2 (Radford et al., 2019). Both are based on a transformer decoder architecture and trained on a traditional language modeling objective. We run these models over each question four times, each time with a different choice replacing the [MASK] token. Following Warstadt et al. (2020), we select the sentence with the highest probability.

Model		**Params (M)**	**Data (GB)**
GPT		116.5	2
GPT-2	B	124.4	40
	M	354.8	40
	L	774.0	40
	XL	1557.6	40
BERT	B	110.1	13
	L	336.2	13
RoBERTa	B	124.7	160
	L	355.4	160
ALBERT V2	B	11.8	160
	L	17.8	160
	XL	59.0	160
	XXL	223.2	160
T5	S	60.5	170
	B	222.9	170
	L	737.7	170
	3B	2851.6	170

Table 4: Summary of models evaluated on PROST. We list the amount of pretraining data as the size of the uncompressed text corpus used.

Encoder Models We analyze BERT (uncased) (Devlin et al., 2018), RoBERTa (Liu et al., 2019), and ALBERT (Lan et al., 2020), which are all based on transformer encoders. BERT is trained on MLM and next sentence prediction and uses static masking, RoBERTa is trained on MLM with dynamic masking, and ALBERT uses whole-word n-gram masking. For probing, we filter out all but the four answer choices from the output vocabulary and select the token with the highest probability as the model's decision.

Encoder-decoder Models We also include results for T5 (Raffel et al., 2020). T5 is trained using a span corruption objective, in which spans of the input sequence are randomly replaced with a single unique mask token. During pretraining, span lengths are chosen randomly with an average length of three. To keep our results consistent with the other models, we restrict the span length to one token. We find that two of the options for sliding surfaces, namely *ice* and *frost*, violate our single-token constraint. To avoid any unfair comparison between answers that differ in token lengths and following previous work (Goldberg, 2019), we chose to omit presenting the results for T5 on the sliding concept.

Finetuned Conditional LMs To better understand the limitations of text-only training, we additionally evaluate UnifiedQA (Khashabi et al., 2020). UnifiedQA is a pretrained QA model, built off T5, and finetuned on SQuad 1.1, SQuaD 2.0, NarrativeQA, RACE, ARC, OpenBookQA, MCTest, and BoolQ (Rajpurkar et al., 2016, 2018; Kočiský et al., 2018; Lai et al., 2017; Clark et al., 2018; Mihaylov et al., 2018; Richardson et al., 2013; Clark et al., 2019). We format all of our templates to fit their multiple-choice question answering format and use their provided scoring metrics to select the models' answers.[3]

5 Results

The per model and per concept results are shown in Table 5. For concepts with more than one template—direction, mass, height, and circumference—we average across templates to get the concept's score. We can see that, on average, ALBERT-V2-XL performs best, with an accuracy of 31.8%[4], and GPT-2 performs worst, with an accuracy of 23.6%. We note that random guessing would yield an accuracy of 25%. Furthermore, every model underperforms random guessing on at least one concept. Since PROST is trivially solvable for humans, this supports our hypothesis that pretrained models are unable to perform physical reasoning anywhere close to human performance.

Comparing across all concepts, we see that direction obtains the highest average accuracy with 46.8%. The second best accuracy is observed for the mass attribute with 36.5%. The concepts models struggle the most with are the slideable and bounceable affordances, both with an average accuracy of 19.9%.

6 Analysis

Object Order in Context For the concepts that use objects, all four choices are listed in each question's context. PROST contains all permutations with regards to their ordering. This enables us to directly look at the effect of the correct answer's position within the context on the models' accuracy. These results shown in Table 6.

We see that models have a strong tendency to select either the first or the last item seen in the context. The largest difference is found for T5, with an accuracy of 52.4% for objects at position 1 and an accuracy of only 1.9% for objects at position 3. We note that a proper understanding of the questions, as most humans would have, would be robust to the order in which the choices are presented. This further underlines that state-of-the-art models do not perform human-like physical reasoning.

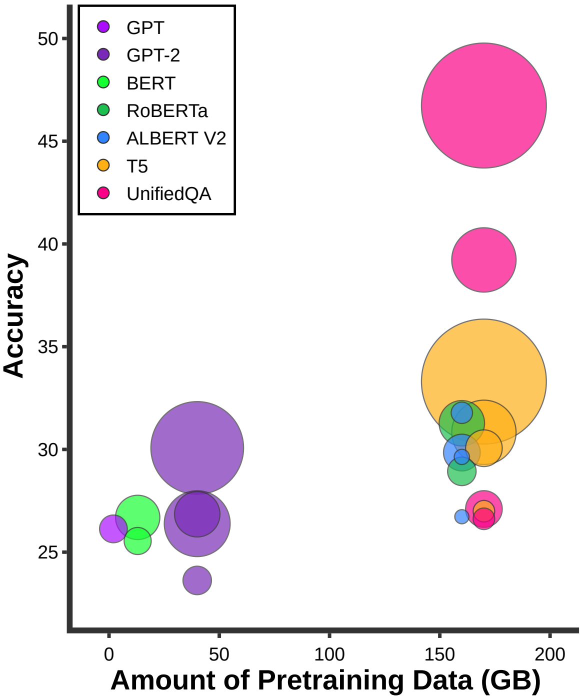

Figure 2: Scaling effect of models on accuracy. Circles size represents number of parameters.

Superlative Inverses By inverting the superlative in a question, we are able to probe a mirrored version of the question. For example, for attributes, this would require the model to identify the lightest object instead of the heaviest object, or, for affordances, it would require the model to identify the not stackable object instead of the stackable object. We call these mirrored versions *superlative inverses*. A true understanding of the questions in

ALBERT V2	32.5	25.8	9.7	44.2
T5	52.4	21.1	1.9	35.2
UnifiedQA	41.0	27.7	18.8	51.9
Position Average	35.7	25.0	9.0	40.0

Table 6: Accuracy across the correct answer's position in the context.

PROST should be robust to this kind of inversion. However, Table 7 shows all models perform better on one of the two versions. Of the probed models, GPT-2 is the most unbalanced, averaging 30.6% higher for one version over the other.

Data and Model Scaling Figure 2 shows each model's accuracy as a function of the number of its parameters. Unlike for many modern benchmarks, where increasing the number of parameters or training data provides significant benefits (Talmor et al., 2020; Wang et al., 2018), PROST does not see much improvement from such scaling. We observe some improvements with T5-3B outperforming T5-small, but this 6.6% increase requires a 48x increase in parameters and T5-small still outperforms T5-3B on one task. Moreover, some models break this trend: ALBERT's XL version outpeforms its XXL counterpart and GPT-2 M outperforms GPT-2 L. While previous work has revealed the impressive scaling laws of transformer-based architectures (Kaplan et al., 2020), PROST highlights the importance of relevant and informative training. As physical reasoning is not an ability that humans acquire via text, even substantially more open domain textual data is unlikely to lead to more than marginal improvements.

The Limits of Text-based Training To our knowledge, UnifiedQA is the most qualified model to succeed on our task, having been finetuned on a significant amount of relevant text data. While this additional data does provide benefits on PROST, it still falls short, with the best performing model we tested only achieving a 46.7% accuracy. Additionally, from Tables 6 and 7, it still lacks the robustness of proper understanding. This emphasizes that models are unlikely to obtain human-like reasoning from text-based training alone. Rather, PROST motivates exposing models to concepts through multiple modalities that mirror a human's experience.

Model		Mass	Height	Circum.	Stack	Roll	Grasp	Break	Slide	Bounce	Macro Average

Table 7: Absolute difference in accuracy between a question and its superlative inverse.

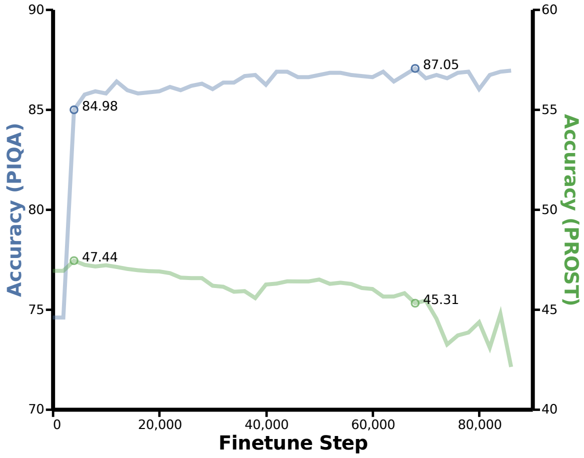

Figure 3: Analysis of the performance of UnifiedQA 3B on PROST throughout PIQA finetuning. The left and right Y axis represent Accuracy on the PIQA dev set and Macro accuracy on PROST respectively. We finetune for 100K steps, and compute metrics every 2k steps. Annotations correspond to the checkpoints with the best performance on PIQA and PROST. Note that PIQA has two answer choices, while PROST has 4.

Comparing PROST and PIQA Due to their shared focus on text-based physical reasoning, PROST and PIQA share similarities. To test if models trained on PIQA are able to carry over any concepts to PROST, we further finetune a UnifiedQA model on PIQA and evaluate it on PROST. The results, shown in Figure 3, indicate that training a model on PIQA is detrimental to its performance on PROST. While PIQA and PROST share a few conceptual similarities, they differ in terms of format, style, and vocabulary. We thus hypothesize that current models learn more about these surface-level differences than the conceptual similarities underpinning the questions. We further highlight two key differences between the two datasets:

- PROST probes models in a zero-shot fashion, whereas PIQA provides training and test sets of identically distributed examples. This makes it possible for models on PIQA to answer successfully using spurious correlations rather than physical reasoning.
- PIQA (Bisk et al., 2020b) covers an extensive range of objects and challenging physical concepts. Bisk et al. (2020a) argues that experience is a prerequisite for understanding. It is hard to imagine how to expose a model to experiences ranging from egg yolk separation to making a pillow out of a garbage bag. In contrast, PROST provides a clear set of well defined concepts and objects that a model could potentially experience.

7 Discussion

Our experiments show that all the models we analysed fail to demonstrate a robust understanding of physical reasoning. Beyond performing poorly across every concept, they are easily influenced by changing the order of the objects in a question's context and by superlative inverses. Moreover, our analysis indicates that these issues are not likely to be solved simply by increasing the amount of model parameters or training data. All this evidence supports Bender and Koller (2020)'s and Bisk et al. (2020a)'s theory that experience is a prerequisite of understanding.

A number of other reasoning benchmarks have been solved to some extent by a large finetuned model. UnifiedQA (11B parameters), based on T5 (Raffel et al., 2020), achieved 81.4% on ARC (Clark et al., 2018); and UNICORN[5] (11B parameters), also based on T5, achieved a 93.9% accuracy on hellaSWAG (Zellers et al., 2019). While all these models are larger and are trained on more data, our results force us to ask the question whether they perform well because these additional parameters and data have imbued the models with an ability to reason, or if they succeed by finding subtle unintended correlations in the data. This forces us to look more closely at how models succeed, and not just the accuracy they achieve. Tools like CheckList (Ribeiro et al., 2020) can aid in this endeavor by demonstrating how robust models are to changes in the distribution of the data.

How to Use this Probe PROST is intended to help analyze any model that can be deployed in a text-only setting. However, we maintain that multimodal data is necessary to experience the concepts in PROST, and that these experiences are likely a crucial step in succeeding on this dataset. One way that multi-modal models could prepare for this type of text-only evaluation is through multi-task training, where one of the tasks is only conditioned on text. Such an approach has already been considered: Brown et al. (2020) propose an extension to their CLIP model which is trained on multiple modalities in a multi-task fashion. Because of the templated nature of PROST, its exact format can be adapted to match specific styles of language training, as we do for T5 and UnifiedQA.

PROST's language-only approach is motivated by two reasons. First, we believe that true multimodal models should be able to function on any subset of their modalities. We note that humans can easily interact with text-only inputs (e.g., a text message) while still learning from and interacting with other modalities. Second, it enables the comparison of models trained using different modalities or domains. For example, we believe comparing how language understanding modules evolve when trained on vision-and-language navigation compared to visual question answering would provide invaluable insights.

Limitations We caution that achieving a high accuracy on PROST does not necessarily guarantee that a model is able of physical reasoning. It is likely easy to succeed on this benchmark if one were to intentionally train models on similar enough sentences or a subset of PROST itself. We hope that the community will use this dataset in the intended way: in a zero-shot setting to probe models which have been trained on data not specifically collected to succeed on PROST.

8 Conclusion

We present a probing dataset called PROST, which is designed to test a model's ability to reason about the physical world. Our experiments show that current state-of-the-art pretrained models lack the ability to reason about physical interactions. Further, all models struggle when the order of options is changed and when questions are inverted, both things that would not confuse humans. Lastly, our analysis shows that these issues are unlikely to be solved by simply scaling models. Our results highlight the need to look beyond text-based pretraining and to provide models with the necessary experiences for human-like understanding of the physical world.

Revisiting the Evaluation of End-to-end Event Extraction

Abstract

Event extraction (EE) aims to harvest event instances from plain text, where each instance is composed of a group of event arguments with specific event roles. Existing end-to-end EE research usually adopts the role-averaged evaluation that produces evaluation measures by averaging evaluation statistics of each event role. However, although this averaged metric can indicate the model performance to some extent, we find that such metric can be pretty misleading to downstream applications that utilize an event instance as a whole, where one wrongly identified event argument can substantially alter the whole meaning of an event instance. To mitigate this gap and provide a more complete understanding of performance, we propose two new evaluation metrics that also consider an event instance as a whole and explicitly penalize wrongly identified event arguments. Moreover, to support diverse preferences of evaluation metrics motivated by different scenarios, we propose a new training paradigm based on reinforcement learning for a typical end-to-end EE model, i.e., Doc2EDAG. Our extensive experiments show that the new training improves the initial one by a large margin (about 10%) under new metrics. Nevertheless, the current performance is still far from satisfactory, and optimizing towards these new metrics calls for more future research.

1 Introduction

Event extraction (EE) is a vital task that aims to harvest structured event instances from unstructured plain text. Such structured knowledge can benefit many downstream applications, such as question answering, language understanding, knowledge graph, etc. In general, an *event instance* is composed of a group of entities (person, organization, date, etc.) that jointly describes an incident. Each entity of the event instance, also referred to as the *event argument*, plays a specific *event role*. Multiple event instances of the same event type populate an *event table*.

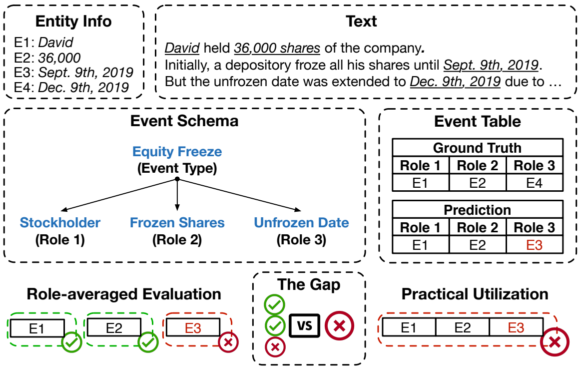

Figure 1: An example to illustrate the gap between the *role-averaged* evaluation and a practical application that utilizes an event instance as a whole, where "E1", "E2", "E3", and "E4" are entity marks, "Role 1", "Role 2", and "Role 3" represent event roles, and "(E1, E2, E4)" is an event instance. We can see that the wrong argument "E3" makes the whole event instance "(E1, E2, E3)" unrealistic, but the *role-averaged* evaluation still regards "E1" and "E2" as correct ones.

The early method (Ahn, 2006) formalized EE as the unification of many sub-tasks, including entity recognition, event detection, and argument extraction, etc. Later research improved EE from two aspects: the modeling to capture complicated semantic structures (Li et al., 2013; Yang and Mitchell, 2016; Nguyen and Nguyen, 2019) and the labeling to combat the lack of training data (Chen et al., 2017; Zeng et al., 2018). Recently, Zheng et al. (2019a) proposed the first end-to-end model, called Doc2EDAG, for document-level EE. Given a text document, Doc2EDAG can generate an entity-based directed acyclic graph (EDAG) to fill an event table directly.

Different from the modeling and labeling aspects, the evaluation of EE attracted very little re-

search attention. Notably, most existing research, merely presenting a separate evaluation for each sub-task of EE, can only get the approximation of the overall performance by combining those fragmentary evaluation results. Even the latest work (Zheng et al., 2019a), reporting the overall performance of EE, still followed the traditional approximate measure by averaging evaluation statistics of each event role. We refer to this kind of approximation as the *role-averaged* evaluation. However, many downstream applications need to utilize an event instance as a whole, where a wrongly identified argument can substantially change the meaning of an event and cause severe misleading effects. Figure 1 presents an example from the financial domain, where the downstream application cannot utilize an event instance with an incorrect date argument for decision making, but the *role-averaged* evaluation still assigns this example with two true-positive arguments. Moreover, we note that this *event-as-a-whole* demand is a common case that widely exists in many other domains, such as legislation, health, etc.

To enable the evaluation support for the *event-as-a-whole* scenario and provide a more complete understanding of performance, we propose two new metrics that directly make judgments on an event instance rather than averaging the performance of its arguments. The first metric is *NoFP*, which regards a predicted event with any false-positive (FP) error at the entity level as an event-level FP error. The second one is *NoFPFN*, which permits neither FP errors nor false-negative (FN) errors at the entity level for a predicted event being considered as a true-positive (TP) one. In practice, we can choose to use the proper metric according to the specific scenario. For example, if we only care about the correctness of predicted events, we can utilize the *NoFP* evaluation that penalizes FP entities explicitly. If we further pursue the completeness, we can utilize the *NoFPFN* evaluation.

The necessity of employing new evaluation metrics, however, raises a dilemma in training effective EE models. On one side, since the *role-averaged* metric is inconsistent with *NoFP* or *NoFPFN*, training towards the *role-averaged*, as did by traditional methods, may not lead to improvements under new metrics. For instance, Figure 2 illustrates such inconsistence between different evaluation settings. We can observe that 1) the first prediction is the best one under the *role-averaged* evaluation but is sub-optimal for other settings, 2) the second prediction best fits the *NoFP* evaluation but suffers the most errors under the *NoFPFN* evaluation, and 3) the third prediction makes the most mistakes at the entity level but achieves the best performance under the hardest *NoFPFN* evaluation. In fact, existing methods for EE, including the most recent Doc2EDAG, merely optimized model parameters towards proper predictions for each event role separately. Thus, they failed to align with new metrics.

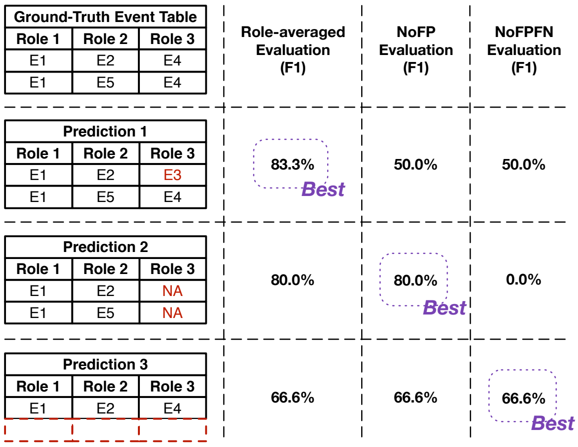

Figure 2: We present a ground-truth event table with two event instances ("(E1, E2, E4)" and "(E1, E5, E4)") and three different predictions to show diverse preferences of those evaluation settings, where all marks follow the meanings in Figure 1, "NA" denotes an empty argument, we color wrong or missed event arguments as red, and we mark the best prediction for each evaluation setting.

On the other side, optimizing these new metrics is non-trivial. First, it is hard to design appropriate training objectives since those metrics are non-differentiable. Moreover, the supervision for role-level predictions is inevitably delayed because we cannot calculate event-level metrics until obtaining predictions for all event roles. To address these challenges, we propose a new reinforcement learning (RL) paradigm of Doc2EDAG by regarding EDAG generation as a Markov decision process. In this way, we can optimize model parameters with the guidance of a delayed reward, which can be specified by a specific metric. At the same time, we realize that this shift of training also bridges the gap between training and inference because RL forces the model to generate EDAGs during training. Extensive experiments demonstrate that our RL-based training improves the vanilla one significantly (about 10%) under new metrics.

We summarize our contributions as follows.

- We revisit the evaluation of EE to support downstream applications that need to utilize an event instance as a whole. Specifically, we propose two new metrics to provide a more complete understanding of performance.

- We propose a new training paradigm for a typical end-to-end EE model, Doc2EDAG, to enable the flexible adaptation to new metrics with hard constraints.

- Our empirical studies show that under the *event-as-a-whole* scenarios, the traditional *role-averaged* evaluation tends to severely overestimate the performance. Moreover, the initial training scheme performs poorly on new metrics, while our RL-based training improves it significantly (about 10%).

2 Related Work

Since EE is a very sophisticated task that requires the unification of many sub-tasks (Ahn, 2006), including entity recognition, event detection, and argument extraction, plenty of previous research put considerable efforts to the modeling aspect.

Specifically, Nguyen and Grishman (2015); Liu et al. (2017); Chen et al. (2018); Wang et al. (2019); Liu et al. (2019) only considered event detection that is to detect trigger words and assign correct event types. Some advanced methods (Poon and Vanderwende, 2010; Riedel and McCallum, 2011; Li et al., 2013, 2014; Venugopal et al., 2014; Judea and Strube, 2016; Nguyen et al., 2016; Sha et al., 2018) tried to unify two sub-tasks, event detection and argument extraction, but all assumed that entity candidates were given in advance. A few studies attempted to fulfill all sub-tasks of EE jointly. Yang and Mitchell (2016) was the first work towards this goal but relied on handcrafted features. Later research (Nguyen and Nguyen, 2019) explored the joint modeling further by introducing neural networks but also retained many traditional lexical and syntactic features. Recently, Zheng et al. (2019a) formalized a new succinct task for EE without trigger words and proposed the first document-level end-to-end model, called Doc2EDAG. This novel model transformed the task of filling an event table into the generation of an EDAG and thus enabled the end-to-end modeling for EE.

With the rapid development of modeling techniques, labeled data gradually became the main bottleneck that prevented from putting EE into practice. Most of the previous research was based on ACE 2005[1], a benchmark dataset annotated by human experts. However, human annotation is both expensive and time-consuming. Recent research attempted to generate weakly labeled data by aligning event instances from knowledge bases to plain text and then assigning labels to matched samples. This strategy was originated from relation extraction (Mintz et al., 2009; Zheng et al., 2019b), but most existing EE models relied on trigger words to anchor an event mention. Accordingly, two types of research explorations emerged: one was to label trigger words with the help of extra linguistic resources (Chen et al., 2017) or predefined dictionaries (Yang et al., 2018), and the other was to remove the requirement of trigger words in modeling (Zeng et al., 2018; Liu et al., 2019; Zheng et al., 2019a). In this paper, we follow the no-trigger-words design because it can ease the labeling work of EE and thus generate large-scale data.

Different from all the related work, this paper focuses on the evaluation aspect and attempts to extend the scope of EE evaluation methods to better support the *event-as-a-whole* scenarios.

3 Preliminaries

In this section, we provide readers with necessary background to better understand our research.

3.1 Terminologies

We follow Yang and Mitchell (2016) to use a general "**entity**" notion that covers persons, dates, numbers, and so on for brevity. Next, let us recall the ground-truth event table in Figure 2 and clarify some widely used terminologies for EE. 1) An **event role**, corresponding to a column of an event table, is a basic semantic unit of an event type (e.g., "Role 1" is an event role). 2) An **event argument**, corresponding to an entry of an event table, refers to an entity that plays a specific event role (e.g., "E1" is an event argument). 3) An **event instance**, corresponding to a row of an event table, consists of a group of entities that jointly characterizes a specific incident (e.g., "[E1, E2, E4]" together forms an event instance).

3.2 Doc2EDAG

As discussed in the related work, Doc2EDAG enabled not only end-to-end modeling for EE but

---

[1] `https://www.ldc.upenn.edu/collaborations/past-projects/ace`

also simplified event labeling. Therefore, we adopt Doc2EDAG as the base end-to-end model and use its associated large-scale benchmark for validation.

Given a text document as the input, Doc2EDAG first extracts entities and encodes them with the document-level context. Then, for a triggered event type, Doc2EDAG generates an entity-based directed acyclic graph (EDAG) via a series of path-expanding sub-tasks. Each path-expanding sub-task is composed of a group of binary predictions (1: *expanding* or 0: *not*), where one prediction happens to one entity candidate.

The vanilla training of Doc2EDAG follows a given ground-truth EDAG and calculates corresponding losses for path-expanding sub-tasks. We refer to this kind of training as the maximum likelihood estimation (MLE) because its essential goal is to maximize the likelihood of ground-truth EDAGs. However, the vanilla MLE-based training cannot fit the newly proposed metrics with hard constraints.

4 New Evaluation Metrics

Similar to the initial *role-averaged* evaluation, the new evaluation starts from comparing a predicted event table with the ground-truth one. To be specific, they pick one predicted event instance and the most similar ground-truth one without replacement from corresponding event tables. The difference lies in the comparison of two picked event instances. Initially, the *role-averaged* evaluation collects evaluation statistics of TP, FP, and FN for each event role and averages them to calculate precision, recall, and F_1 scores for that event type. In contrast, the new evaluation considers an event instance as a whole and collects those statistics directly at the event level. Next, we illustrate the details of two new metrics on collecting TP, FP, and FN statistics when taking into consideration the *event-as-a-whole* requirement.

The NoFP Metric. An event instance that contains any FP argument belongs to an FP error at the event level. For an event instance that contains both FN arguments and TP arguments, we retain the statistics of FN and TP in proportion at the event level. For an event whose arguments are all correct, we count it as a TP event.

The NoFPFN Metric. We treat an event instance that contains either FP arguments or FN arguments as an FP error at the event level. Only for those event instances that are the same to the ground-truth ones, we treat them as TP events.

Note that the *NoFP* metric can be beneficial to risk-sensitive scenarios, such as finance, health, etc., where FP arguments of an event instance may cause disastrous effects. Moreover, the *NoFPFN* metric, also the most challenging one, can tell us how large the gap between the current progress and the perfect extractor is. In contrast, the initial *role-averaged* evaluation can only provide the approximate measures by averaging the performance of event role predictions, which only fit for the cases when downstream applications utilize arguments of an event instance independently.

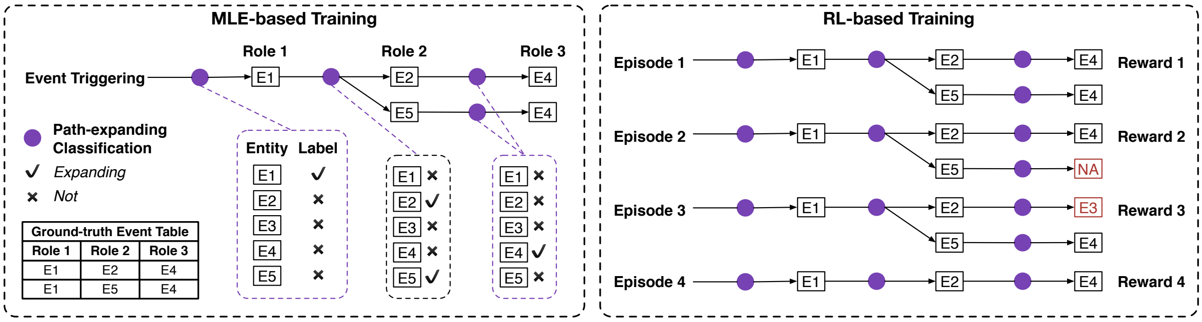
5 Optimizing New Metrics

Optimizing these new metrics is pretty challenging. First, these metrics are non-differentiable, so it is hard to specify corresponding training objectives. Besides, we can only calculate event-level metrics after obtaining predictions for all event roles, so the supervision for role-level predictions is inevitably delayed. Moreover, EDAG generation is an autoregressive procedure inherently, which suffers from the error-propagation problem.

To address these challenges, we develop an RL-based training paradigm for Doc2EDAG by viewing EDAG generation as a sequential decision-making process. In this way, we can explicitly optimize model parameters by a delayed reward, which can be specified by a non-differentiable metric. Moreover, the explorations during RL-based training also help to stabilize EDAG generation.

MDP. Instead of treating the EDAG generation as an autoregressive procedure, we regard it as a Markov decision process (MDP). First, we consider the event triggering as the beginning of this MDP, which is also the virtual starting node of the EDAG (Zheng et al., 2019a). Then, for a specific event role, which corresponds to one step of the MDP, we need to take specific actions for all encoded entities at all leaf nodes of the current EDAG. Next, the EDAG grows accordingly, and we move to the next event role. This iterative process continues until we reach the last role. By following specific evaluation metrics to compare the generated EDAG with the ground-truth one, we can obtain the final reward to guide the decision-making process from a global perspective.

State. In general, the state at each step is the part of EDAG before the current event role. In this



Role 1	Role 2	Role 3
E1	E2	E4
E1	E5	E4

Figure 3: An overview of the comparison between MLE-based training and RL-based training for Doc2EDAG, where all marks follow the meanings in Figure 1 and 2.

paper, to present a fair comparison with the vanilla Doc2EDAG with MLE-based training, we leverage the same method developed by Zheng et al. (2019a) to obtain state representations of the current EDAG. In this way, we can focus on the real impact of different supervision paradigms. For the step t, we denote its state as $\boldsymbol{s}_t$.

Action. At each step of the MDP, we need to take an action, *expanding* (1) or *not* (0), for each entity candidate at every leaf node of the current EDAG. We denote the action collection at step t as $\boldsymbol{a}_t$. Here the action concept is the same as the path-expanding prediction used in MLE-based training. Note that there are multiple actions to be made (one action per entity per expanding sub-task), which is a little bit similar to the setting of multi-agent RL (Buşoniu et al., 2010). While the difference is that our model unifies all these agents in a single model and enforces them to work collaboratively for a specific metric. Moreover, we need to face a growing number of actions during the expansion of an EDAG, which largely raises the difficulties of model training. Despite these challenges, we empirically demonstrate that the RL-based training can work pretty well with proper configurations.

Reward. For a specific evaluation metric, we utilize its rules to calculate the reward and use this reward to guide the optimization of model parameters. Moreover, there is no gap between training and inference because the model generates an EDAG by itself to get a reward during training, which includes the inference procedure.

Optimization. Given a document d and a triggered event type e with N_e event roles, we can take a series of actions to get an episode $\tau = (\boldsymbol{s}_1, \boldsymbol{a}_1, \boldsymbol{s}_2, \boldsymbol{a}_2, \cdots, \boldsymbol{s}_{N_e}, \boldsymbol{a}_{N_e})$ and calculate the final reward R_τ by comparing the generated EDAG with the ground truth. Then, we can write the overall loss function for the EDAG generation as

$$L_{edag} = -\mathbb{E}_{d,e}\left[\mathbb{E}_{\pi_\Theta(\tau)} R_\tau\right], \qquad (1)$$

where $\mathbb{E}_{d,e}$ is the expectation over training documents and their triggered event types, Θ denotes the model parameters, $\pi_\Theta(\tau) = \prod_{t=1}^{N_e} \pi_\Theta(\boldsymbol{a}_t|\boldsymbol{s}_t)$ estimates the probability of an episode, and $\pi_\Theta(\boldsymbol{a}_t|\boldsymbol{s}_t)$ corresponds to the policy at step t. We employ the REINFORCE algorithm (Williams, 1992) and the policy gradients (Sutton et al., 1999) to optimize the above objective. And we can write the gradient $\nabla_\Theta L_{edag}$ as

$$-\mathbb{E}_{d,e}\left[\mathbb{E}_{\pi_\Theta(\tau)}\left[\sum_{t=1}^{N_e} R_\tau \log \pi_\Theta(\boldsymbol{a}_t|\boldsymbol{s}_t)\right]\right]. \qquad (2)$$

Moreover, we also follow Zheng et al. (2019a) to obtain the final loss by summing L_{edag}, the loss of entity recognition L_{er}, and the loss of event triggering L_{et} as $L_{all} = \lambda_1 L_{er} + \lambda_2 L_{et} + \lambda_3 L_{edag}$, where λ_1, λ_2 and λ_3 are hyper-parameters.

Exploration. In our case, the complexity of generating an EDAG grows exponentially with the number of entities and path-expanding sub-tasks. To achieve efficient explorations under such a challenging scenario, we start from MLE-based training to get a relatively well-trained model and warm start RL-based training from it. After the warm start, we let the model sample actions according to the predicted path-expanding probability to achieve proper explorations.

Figure 3 depicts the comparison between MLE-based training and RL-based training, where we can observe two benefits of the latter one: 1) the model learns from the global supervision (reward), which can be specified by a specific metric; 2) the

Event	#Train	#Dev	#Test	#Total

model can explore diverse EDAG structures during training, which helps to stabilize the dynamic process of EDAG generation.

6 Experiments

In this section, we present extensive empirical studies to answer two questions: 1) how severe is the overestimation of the initial *role-averaged* evaluation under the *event-as-a-whole* requirement? 2) to what extent can RL-based training improve MLE-based training under new evaluation metrics? Subsequently, Section 6.2 answers the first question. Section 6.3, 6.4, and 6.5 together answer the second question.

6.1 Experimental Setup

Model. As Section 3.2 illustrates, Doc2EDAG owns the superiority of both providing end-to-end modeling and simplifying data labeling. Therefore, in this paper, we adopt Doc2EDAG as the base model to demonstrate the challenges of new evaluation settings and the benefits of the RL-based training paradigm. Moreover, we follow the open-source implementation[2] to reproduce MLE-based training.

Dataset. The ChFinAnn dataset (Zheng et al., 2019a) is the largest public dataset for EE at present, and it is also the initial benchmark for Doc2EDAG. Therefore, we employ it as the testbed to compare RL-based training with the initial MLE-based training. ChFinAnn dataset includes ten-years Chinese financial documents accompanied with corresponding event tables and contains five event types: *equity freeze* (EF), *equity repurchase* (ER), *equity underweight* (EU), *equity overweight* (EO), and *equity pledge* (EP). Table 1 summarizes this dataset.

Metric	Avg. P.	Avg. R.	Avg. F$_1$
Base*	-	-	76.3
Base	83.8	70.6	76.6
NoFP	60.4	52.4	56.1
Drop	-23.4	-18.2	-20.5
NoFPFN	37.5	34.8	36.1
Drop	-46.3	-35.8	-40.5

Table 2: We present the overall performance (Avg.) of the vanilla Doc2EDAG under different evaluation settings by averaging scores for each event type, where * indicates the copy of results in Zheng et al. (2019a),"Base" denotes the initial *role-averaged* evaluation, "NoFP" denotes the *NoFP* evaluation, "NoFPFN" denotes the *NoFPFN* evaluation, and "Drop" represents the difference between the line above it and the "Base" line.

Hyper-parameters. MLE-based training sets all hyper-parameters the same as those presented in Zheng et al. (2019a). As for RL-based training, we utilize the following settings. To enable efficient explorations, we first train Doc2EDAG by MLE for 30 epochs and then turn to RL for another 70 epochs, where the total number of training epochs is still 100. To alleviate the noises of policy gradients, we sample five independent episodes for each document in the training batch and adopt a relatively small learning rate of $1e^{-5}$. For all other hyper-parameters, we set them the same as those in MLE-based training. Moreover, for each training method, we utilize the development set to pick the best epoch for the target evaluation metric.

Evaluation. We consider three evaluation settings: 1) the *role-averaged* evaluation, which is the base setting that provides approximate measures by averaging the performance of event roles; 2) the *NoFP* evaluation, strictly penalizing incorrect event arguments; 3) the *NoFPFN* evaluation, explicitly penalizing both incorrect and incomplete event arguments. For all settings, we collect evaluation statistics of TP, FP, and FN as Section 4 describes to compute the precision (P.), recall (R.), and F$_1$ scores (in the percentage format).

6.2 The Overestimation Problem of the Role-averaged Evaluation

In this section, we conduct experiments to reveal the overestimation problem of the initial *role-averaged* evaluation under the *event-as-a-whole* scenario. Following the setups mentioned above,

Table 3: We evaluate the vanilla Doc2EDAG under different settings and report results for all event types, where all marks follow those in Table 2.

we reproduce a Doc2EDAG model with the initial MLE-based training. Then, we evaluate this model with different evaluation methods. Table 2 presents the overall comparison, and Table 3 records performance comparisons for each event type. We can observe that the performance results of our reproduced model roughly match those reported by Zheng et al. (2019a) under the base setting. However, there is a drastic drop in the performance scores under new metrics. On average, the F_1 score decreases 20.5 under the *NoFP* metric, and the F_1 decrement reaches 40.5 under the *NoFPFN* metric. The *role-averaged* metric does not consider the *event-as-a-whole* requirement and tends to produce overestimated performance that is too optimistic to fit the real situation. The vast performance degradation demonstrates that the overestimation problem can be quite severe.

Moreover, the degree of overestimation depends on the event type and varies irregularly. For example, as Table 3 shows, the model achieves similar F_1 scores for EF and EU events (71.9 vs. 70.0), but the performance drops under the *NoFP* evaluation are quite different (-24.0 vs. -15.7). The underlying reason is that the *role-averaged* evaluation only tells us the averaged performance of role predictions, which is an approximate measure. Therefore, in downstream applications that utilize an event instance as a whole, it is critical for them to utilize our newly designed metrics to be aware of the real performance.

6.3 The NoFP Evaluation

The *NoFP* evaluation considers an event instance as a whole and strictly penalizes FP entities. Under this evaluation setting, we compare the RL-based training that directly optimizes the specific metric with the initial MLE-based training that mimics path-expanding predictions of a ground-truth EDAG. Table 4 shows the overall performance comparisons, and Figure 4 presents performance improvements of RL-based training for all event types. We can observe that, on average, RL-based training improves the MLE-based one by 8.9% of F_1 scores, and similar improvements happen for all event types. These vast improvements demonstrate that considering the *NoFP* metric explicitly during training can bring remarkable benefits.

Model	Avg.		
	P.	**R.**	**F_1**
MLE	60.4	52.4	56.1
RL	66.2	56.7	61.1
Inc	+5.8	+4.3	+5.0

Table 4: The averaged (Avg.) performance of all event types under the *NoFP* evaluation, where “MLE” denotes Doc2EDAG with MLE-based training, “RL” denotes the model with RL-based training, and “Inc” represents the increment between “RL” and “MLE”.

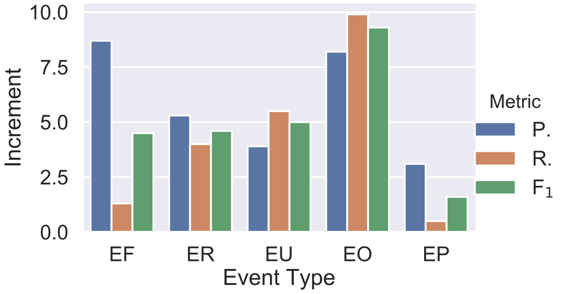

Figure 4: The performance increment between RL-based training and MLE-based training for all event types under the *NoFP* evaluation.

6.4 The NoFPFN Evaluation

We further consider the *NoFPFN* evaluation that penalizes not only FP entities but also FN entities. As Table 5 shows, RL-based training obtains similar improvements over MLE-based training on average. To be specific, the relative improvement in terms of the F_1 score reaches 11.3%. Since RL-

Model	**Avg.** **P.**	 **R.**	 **F_1**
MLE	37.5	34.8	36.1
RL	39.6	40.7	40.2
Inc	+2.1	+5.9	+4.1

Table 5: The averaged (Avg.) performance of all event types under the *NoFPFN* evaluation, where all abbreviations follow Table 4.

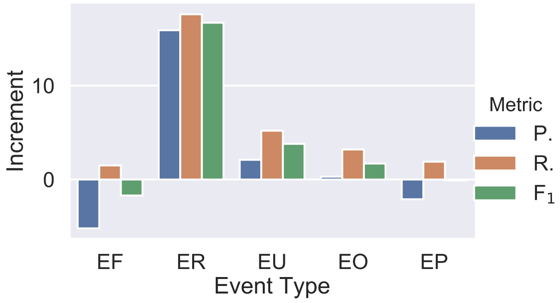

Figure 5: The performance increment between RL-based training and MLE-based training for all event types under the *NoFPFN* evaluation.

based training and MLE-based training share the same network architecture, we can clearly see the benefits of evaluation-aware learning.

Moreover, Figure 5 shows performance improvements of RL-based training for all event types. Interestingly, under the much challenging *NoFPFN* evaluation, we observe that the model automatically finds a trade-off between different event types. For example, the model sacrifices a little performance on EF (-1.7) and EP (-0.1) events but earns much more improvements on ER ($+16.7$), EU ($+3.8$), and EO ($+1.7$) events. Such an automatic trade-off is quite appealing because it is entirely data-driven and can adapt to different scenarios flexibly.

6.5 The Role-averaged Evaluation

In this subsection, we include performance comparisons under the initial setting, the *role-averaged* evaluation, where RL-based training follows the initial rule to calculate rewards. Table 6 shows the averaged comparison results. We can observe that MLE-based training achieves competitive performance compared with RL-based training. The underlying reason is that both MLE-based training and the *role-averaged* evaluation focus on improving the role-level predictions, so these two techniques are much consistent with each other. Nevertheless, RL-based training still obtains a small gain of the F_1 score ($+1.1$) because it can make a proper trade-off between the precision and the recall. Figure 6 presents performance improvements for all event types, and we also observe similar trade-offs. Therefore, we can conclude that RL-based training can achieve remarkable improvements under new metrics while still maintain competitive performance for the initial setting.

Model	**Avg.** **P.**	 **R.**	 **F_1**
MLE	83.8	70.6	76.6
RL	79.9	75.7	77.7
Inc	-3.9	+5.1	+1.1

Table 6: The averaged (Avg.) performance of all event types under the *role-averaged* evaluation, where all abbreviations follow Table 4.

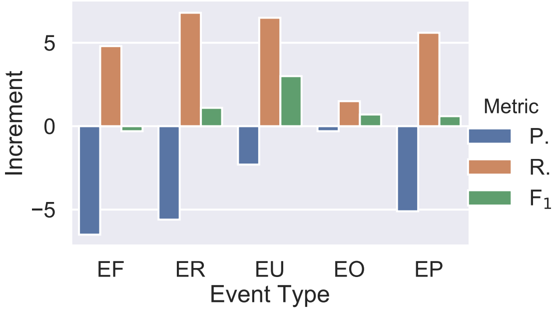

Figure 6: The performance increment between RL-based training and MLE-based training for all event types under the *role-averaged* evaluation.

7 Conclusion and Future Work

In conclusion, our new metrics provide a more complete understanding of performance than the *role-averaged* metric under the *event-as-a-whole* scenario. Moreover, our proposed RL-based training for Doc2EDAG can be a better choice than the MLE-based one when adapting the model to these new metrics. Extensive experiments demonstrate the necessity of new evaluation metrics and the superiority of the novel training scheme.

Given the necessity of employing new metrics, however, as Table 2 shows, the current performance is still far from satisfactory, even for RL-based training. Therefore, further improving EE under these new metrics calls for much more attention from the research community.

Abstract

Simultaneous speech-to-text translation is widely useful in many scenarios. The conventional cascaded approach uses a pipeline of streaming ASR followed by simultaneous MT, but suffers from error propagation and extra latency. To alleviate these issues, recent efforts attempt to directly translate the source speech into target text simultaneously, but this is much harder due to the combination of two separate tasks. We instead propose a new paradigm with the advantages of both cascaded and end-to-end approaches. The key idea is to use two separate, but synchronized, decoders on streaming ASR and direct speech-to-text translation (ST), respectively, and the intermediate results of ASR guide the decoding policy of (but is not fed as input to) ST. During training time, we use multitask learning to jointly learn these two tasks with a shared encoder. En-to-De and En-to-Es experiments on the MuST-C dataset demonstrate that our proposed technique achieves substantially better translation quality at similar levels of latency.

1 Introduction

Simultaneous speech-to-text translation incrementally translates source-language speech into target-language text, and is widely useful in many cross-lingual communication scenarios such as international travels and multinational conferences. The conventional approach to this problem is a cascaded one (Arivazhagan et al., 2020; Xiong et al., 2019; Zheng et al., 2020b), involving a pipeline of two steps. First, the streaming automatic speech recognition (ASR) module transcribes the input speech on the fly (Moritz et al., 2020; Wang et al., 2020), and then a simultaneous text-to-text translation module translates the partial transcription into target-language text (Oda et al., 2014; Dalvi et al., 2018; Ma et al., 2019; Zheng et al., 2019a,b, 2020a; Arivazhagan et al., 2019).

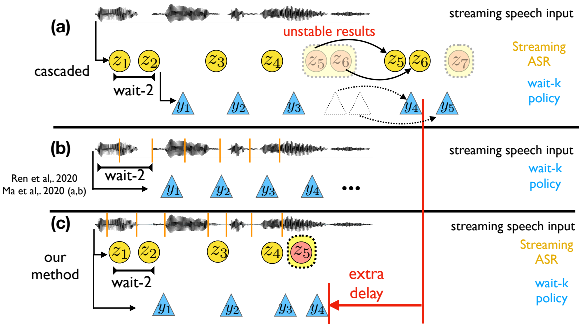

Figure 1: Comparison between (a) cascaded pipeline, (b) direct simultaneous ST, and (c) our ASR-assisted simultaneous ST. In (a), streaming ASR keeps revising some tail words for better accuracy, but causing extra delays to MT. Method (b) directly translates source speech without using ASR. Our work (c) uses the intermediate results of the streaming ASR module to guide the decoding policy of (but not feed as input to) the speech translation module. Extra delays between ASR and MT are reduced in direct translation systems (b–c).

However, the cascaded approach inevitably suffers from two limitations: (a) **error propagation**, where streaming ASR's mistakes confuse the translation module (which are trained on clean text), and this problem worsens with noisy environments and accented speech; and (b) **extra latency**, where the translation module has to wait until streaming ASR's output stabilizes, as ASR by default can repeatedly revise its output (see Fig. 1).

To overcome the above issues, some recent efforts (Ren et al., 2020; Ma et al., 2020b,a) attempt to directly translate the source speech into target text simultaneously by adapting text-based wait-k strategy (Ma et al., 2019). However, unlike simultaneous translation whose input is already segmented into words or subwords, in speech translation, the key challenge is to figure out the number of valid tokens within a given source speech segment in or-

---

August 1–6, 2021.

der to apply the wait-k policy. Ma et al. (2020b,a) simply assume a fixed number of words within a certain number of speech frames, which does not consider various aspects of speech such as different speech rate, duration, pauses and silences, all of which are common in realistic speech. Ren et al. (2020) design an extra Connectionist Temporal Classification (CTC)-based speech segmenter to detect the word boundaries in speech. However, the CTC-based segmenter inherits the same shortcoming of CTC, which only makes local predictions, thus limiting its segmentation accuracy. On the other hand, to alleviate the error propagation, Ren et al. (2020) employ several different knowledge distillation techniques to learn the attentions of ASR and MT jointly. These knowledge distillation techniques are complicated to train and it is an indirect solution for the error propagation problem.

We instead present a simple but effective solution (see Fig. 2) by employing two separate, but synchronized, decoders, one for streaming ASR and the other for End-to-End Speech-to-text Translation (E2E-ST). Our key idea is to use the intermediate results of streaming ASR to guide the decoding policy of, but not feed as input to, the E2E-ST decoder. We look at the beam of streaming ASR to decide the number of tokens within the given source speech segment. Then it is straightforward for the E2E-ST decoder to apply the wait-k policy and decide whether to commit a target word or to wait for more speech frames. During training time, we jointly train ASR and E2E-ST tasks with a shared speech encoder in a multi-task learning (MTL) fashion to further improve the translation accuracy. We also note that having streaming ASR as an auxiliary output is extremely useful in real application scenarios where the user often wants to see both the transcription and the translation. En-to-De and En-to-Es experiments on the MuST-C dataset demonstrate that our proposed technique achieves substantially better translation quality at similar level of latency.

2 Preliminaries

We formalize full-sentence tasks (ASR, MT and ST) using the sequence-to-sequence framework, and the streaming tasks (simultaneous MT and streaming ASR) using the test-time wait-k method.

Full-Sentence Tasks: ASR, NMT and ST The encoder first encodes the entire source input into a sequence of hidden states; in NMT, the input is a sequence of words, $\mathbf{x} = (x_1, x_2, ..., x_m)$, while in ASR and ST, we use $\mathbf{s}$ to denote the input speech frames. A decoder sequentially predicts target language tokens $\mathbf{y} = (y_1, y_2, ..., y_n)$ in NMT and ST or transcription $\mathbf{z}$ in ASR, conditioned on all encoder hidden states and previously committed tokens. For example, the NMT model and its parameters $\boldsymbol{\theta}^{\text{MT}}_{\text{full}}$ are defined as:

$$p_{\text{full}}(\mathbf{y} \mid \mathbf{x}; \boldsymbol{\theta}^{\text{MT}}_{\text{full}}) = \prod\nolimits_{t=1}^{|\mathbf{y}|} p(y_t \mid \mathbf{x}, \mathbf{y}_{<t}; \boldsymbol{\theta}^{\text{MT}}_{\text{full}})$$

$$\hat{\boldsymbol{\theta}}^{\text{MT}}_{\text{full}} = \mathop{\mathbf{argmax}}_{\boldsymbol{\theta}^{\text{MT}}_{\text{full}}} \prod_{(\mathbf{x},\mathbf{y}^*)\in D} p_{\text{full}}(\mathbf{y}^* \mid \mathbf{x}; \boldsymbol{\theta}^{\text{MT}}_{\text{full}})$$

Similarly, we can obtain the definitions for ASR ($p_{\text{full}}(\mathbf{z} \mid \mathbf{s}; \boldsymbol{\theta}^{\text{ASR}}_{\text{full}})$) and ST ($p_{\text{full}}(\mathbf{y} \mid \mathbf{s}; \boldsymbol{\theta}^{\text{ST}}_{\text{full}})$). Our model was learned from scratch in this work, but it can be improved with pre-training methods (Zheng et al., 2021; Chen et al., 2020).

Simultaneous MT and Streaming ASR In streaming decoding scenarios, we have to predict target tokens conditioned on the partial source input that is available. For example, the **test-time wait-k** method of Ma et al. (2019) predicts each target token y_t after reading source tokens $\mathbf{x}_{\le t+k}$ using a full-sentence NMT model:

$$\hat{y}_t = \mathop{\mathbf{argmax}}_{y_t} p_{\text{wait-}k}(y_t \mid \mathbf{x}_{\le t+k}, \hat{\mathbf{y}}_{<t}; \hat{\boldsymbol{\theta}}^{\text{MT}}_{\text{full}}) \tag{1}$$

Intuitively speaking, wait-k only commits a new target word on receiving each new source word after an initial k source words waiting. Similarly, in the case of streaming ASR, we could define $\hat{z}_t$ with growing speech chunks $\bar{\mathbf{s}}_i$ that are fed gradually.

3 Direct Simultaneous Translation with Synchronized Streaming ASR

In text-to-text simultaneous translation, the input stream is already segmented. However, when we deal with speech frames as source inputs, it is not easy to determine the number of valid tokens within certain speech segments. Therefore, to better guide the translation policy, it is essential to detect the number of valid tokens accurately within low latency. Different from the sophisticated design of speech segmenter in Ren et al. (2020), we propose a simple but effective method by using a synchronized streaming ASR and using its beam to determine the number of words within certain speech segments. Note that we only use streaming ASR for source word counting, but the translation decoder does not condition on any of ASR's output.

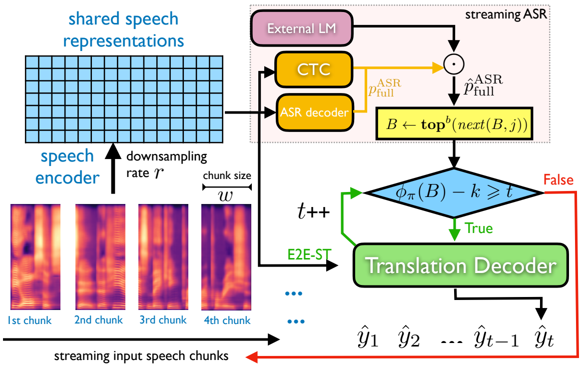

Figure 2: Decoding for synchronized streaming ASR and E2E-ST. Speech signals are fed into the encoder chunk by chunk. For each new-coming speech chunk, we look at the current streaming ASR beam (B) to decide the translation policy. See details in Algorithm 1.

3.1 Streaming ASR-Guided Simultaneous ST

As shown in Fig. 2, at inference time, the speech signals are fed into the ST encoder by a series of fixed-size chunks $\overline{\mathbf{s}}_{[1:i]} = [\overline{\mathbf{s}}_1, ..., \overline{\mathbf{s}}_i]$, where $w = |\overline{\mathbf{s}}_i|$ can be chosen from 32, 48 and 64 frames of spectrogram. As a result of the CNN encoder, there is down sampling rate r (e.g., we use $r = 4$), from spectrogram to encoder hidden states. For example, when we receive a chunk of 32 frames, the encoder will generate 8 more hidden states. In conventional streaming ASR, the number of steps of beam search is the same as the number of hidden states.

We denote B_j to be the beam at time step j, which is an ordered list of size of b, and it expands to the next beam B_{j+1} with the same size:

$$\begin{aligned} B_0 =& [\langle \text{<s>},\ \hat{p}_{\text{full}}^{\text{ASR}}(\text{<s>} \mid \overline{\mathbf{s}}_0; \boldsymbol{\theta})\rangle] \\ B_j =& \mathbf{top}^b(next(B_{j-1}, j)) \\ next(B, j) =& \{\langle \mathbf{z} \circ z_j,\ p \cdot \hat{p}_{\text{full}}^{\text{ASR}}(z_j \mid \overline{\mathbf{s}}_{\leq \tau(j)}, \mathbf{z}; \boldsymbol{\theta})\rangle \mid \\ & \langle \mathbf{z}, p\rangle \in B, z_j \in V\} \end{aligned}$$

where $\mathbf{top}^b(\cdot)$ returns the top b candidates, and $next(B, j)$ expands the candidates from the previous step to the next step. Each candidate is a pair $\langle \mathbf{z}, p\rangle$, where $\mathbf{z}$ is the current prefix and p is the accumulated probability from joint score between an external language model, CTC and ASR probabilities, $\hat{p}_{\text{full}}^{\text{ASR}}$. We denote the number of observable speech chunks at j step as $\tau(j) = \lceil j * r/w \rceil$. And vice versa, for each new speech chunk, ASR beam search will advance for w/r steps.

Note CTC often commits empty tokens ϵ due to empty speech frames, and the lengths of different hypotheses within beam of streaming ASR are quite different from each other. To take every hypothesis into consideration, we design two policies to decide the number of valid tokens.

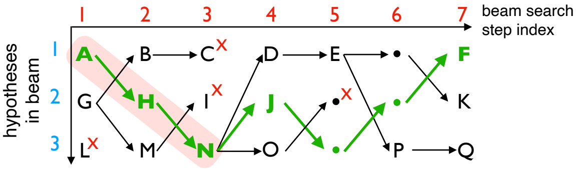

Figure 3: An example of streaming ASR beam search with beam size 3. LCP is shaded in red ($\phi_{\text{LCP}}(B_7) = 3$); SH is highlighted in bold ($\phi_{\text{SH}}(B_7) = 5$). We use • to represent empty outputs in some steps caused by CTC.

Algorithm 1 Streaming ASR-guided Simultaneous ST

```
Input: speech chunks $\overline{\mathbf{s}}_{[1:T]}$; $k$; $\phi_\pi(B_j)$; streaming decoding models: $p_{\text{full}}^{\text{ST}}$ and $\hat{p}_{\text{full}}^{\text{ASR}}$
Initialize: ASR and ST indices: $j = t = 0$; $B = B_0$
for $i = 1 \sim T$ do                                   ▷ feed speech chunks
    repeat $w/r$ steps                     ▷ do ASR beam search $w/r$ steps
        $B \leftarrow \mathbf{top}^b(next(B, j))$; $j$++         ▷ ASR beam search
    while $\phi_\pi(B) - k \geqslant t$ do                        ▷ new tokens?
        $\hat{y}_{t+1} \leftarrow p_{\text{wait-}k}^{\text{ST}}(y_{t+1} \mid \overline{\mathbf{s}}_{[1:i+1]}, \hat{\mathbf{y}}_{\leq t}; \boldsymbol{\theta}_{\text{full}}^{\text{ST}})$
        yield $\hat{y}_{t+1}$; $t$++            ▷ commit translation to user
```

- **Longest Common Prefix** (LCP) uses the length of longest shared prefix in the streaming ASR beam as the number of valid tokens within given speech. This is the most conservative strategy, which has similar latency to cascaded methods.
- **Shortest Hypothesis** (SH) uses the length of shortest hypothesis in the current streaming ASR beam as the number of valid tokens.

More formally, let $\phi_\pi(B)$ denote the number of valid tokens in the beam B under policy π:

$$\begin{aligned} \phi_{\text{LCP}}(B) &= \max\{i \mid \exists \mathbf{z}', s.t. \forall \langle \mathbf{z}, c\rangle \in B, \mathbf{z}_{\leq i} = \mathbf{z}'\} \\ \phi_{\text{SH}}(B) &= \min\{|\mathbf{z}| \mid \langle \mathbf{z}, c\rangle \in B\} \end{aligned}$$

For example in Fig. 3, $\phi_{\text{LCP}}(B_7) = 3$, $\phi_{\text{SH}}(B_7) = 5$. Also note that $\phi_{\text{LCP}}(B) \leq \phi_{\text{SH}}(B)$ for any beam B, and that both policies are *monotonic*, i.e. $\phi_\pi(B_j) \leq \phi_\pi(B_{j+1})$ for $\pi \in \{\text{LCP}, \text{SH}\}$ and all j.

Note we always feed the entire observable speech segments into ST for translation, and streaming ASR-generated transcription is not used for translation, so LCP might have similar latency with cascaded methods but the translation accuracy is much better because more information on the source side is revealed to the translation decoder.

As shown in Algorithm 1, during simultaneous ST, we monitor the value of $\phi_\pi(B_j)$ while speech

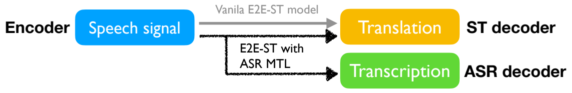

Figure 4: We use full-sentence MTL framework to jointly learn ASR and ST with a shared encoder.

chunks are gradually fed into system. When we have $\phi_\pi(B) - k \geqslant t$ where t is the number of translated tokens, the ST decoder will be triggered to generate one new token as follows:

$$\hat{y}_t = \mathop{\mathbf{argmax}}_{y_t} p_{\text{wait-}k}(y_t \mid \bar{\mathbf{s}}_{[1:\tau(j)]}, \hat{\mathbf{y}}_{<t}; \hat{\boldsymbol{\theta}}^{\text{ST}}_{\text{full}}) \quad (2)$$

3.2 Joint Training between ST and ASR

Different from existing simultaneous translation solutions from (Ren et al., 2020; Ma et al., 2020b,a), which make adaptations over vanilla E2E-ST architecture as shown in gray line of Fig. 4, we instead use simple MTL architecture which performs joint full-sentence training between ST and ASR:

$$\hat{\boldsymbol{\theta}}^{\text{ST}}_{\text{full}}, \hat{\boldsymbol{\theta}}^{\text{ASR}}_{\text{full}} = \mathop{\mathbf{argmax}}_{\boldsymbol{\theta}^{\text{ST}}_{\text{full}}, \boldsymbol{\theta}^{\text{ASR}}_{\text{full}}} \prod_{(\mathbf{s}, \mathbf{y}^*, \mathbf{z}^*) \in D} p^{\text{ST}}_{\text{full}}(\mathbf{y}^* \mid \mathbf{s}; \boldsymbol{\theta}^{\text{ST}}_{\text{full}}) \cdot p^{\text{ASR}}_{\text{full}}(\mathbf{z}^* \mid \mathbf{s}; \boldsymbol{\theta}^{\text{ASR}}_{\text{full}})$$

For ASR training, we use hybrid CTC/Attention framework (Watanabe et al., 2017). Note that we train ASR and ST MTL with full-sentence fashion for simplicity and training efficiency, and only perform wait-k decoding policy at inference time. Also, $\boldsymbol{\theta}^{\text{ST}}_{\text{full}}$ and $\boldsymbol{\theta}^{\text{ASR}}_{\text{full}}$ share the same speech encoder.

4 Experiments

We conduct experiments on English-to-German (En→De) and English-Spanish (En→Es) translation on MuST-C (Di Gangi et al., 2019). We employ Transformer (Vaswani et al., 2017) as the basic architecture and LSTM (Hochreiter and Schmidhuber, 1997) for LM. For streaming ASR decoding we use a beam size of 5. Translation decoding is greedy due to incremental commitment.

Raw audios are processed with Kaldi (Povey et al., 2011) to extract 80-dimensional log-Mel filterbanks stacked with 3-dimensional pitch features using a 10ms step size and a 25ms window size. Text is processed by SentencePiece (Kudo and Richardson, 2018) with a joint vocabulary size of 8K. We take Transformer (Vaswani et al., 2017) as our base architecture, which follows 2 layers of 2D convolution of size 3 with stride size of 2. The Transformer model has 12 encoder layers and 6 decoder layers. Each layer has 4 attention head with a size of 256. Our streaming ASR decoding method follows Moritz et al. (2020). We employ 10 frames look ahead for all experiments. For LM, we use 2 layers stacked LSTM (Hochreiter and Schmidhuber, 1997) with 1024-dimensional hidden states, and set the embedding size as 1024. LM are trained on English transcription from the corresponding language pair in MuST-C corpus. For the cascaded model, we train ASR and MT models on Must-C dataset respectively, and they have the same Transformer architecture of our ST model. Our experiments are run on 8 1080Ti GPUs. And the we report the case-sensitive detokenized BLEU.

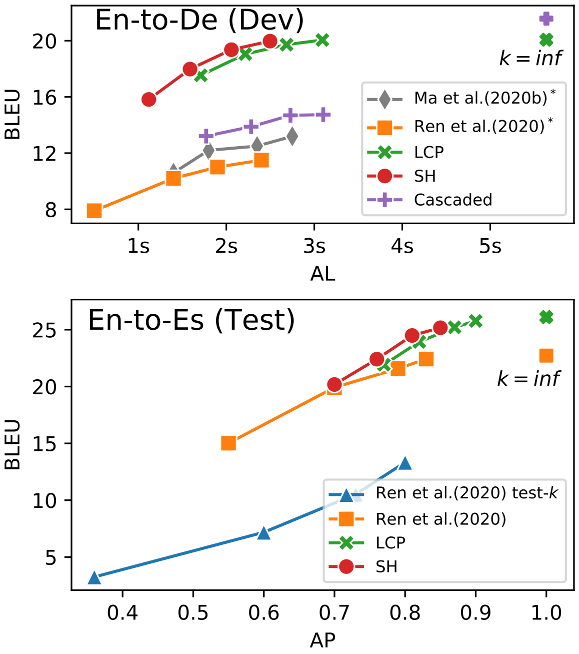

Figure 5: Translation quality v.s. latency. The dots on each curve represents different wait-k policy with k=1,3,5,7 from left to right respectively. Baseline* results are from Ma et al. (2020b). k=*inf* is full-sentence decoding for ASR and translation. test-k denotes testing time wait-k. We use a chunk size of 48.

Translation quality against latency In order to clearly compare with related works, we evaluate the latency with AL defined in Ma et al. (2020b) and AP defined in Ren et al. (2020). As shown in Fig. 5, for En→De, results are on the dev set to be consistent with Ma et al. (2020b). Compared with baseline models, our method achieves much better translation quality with similar latency. To validate the effectiveness of our method, we compare our method with Ren et al. (2020) on En→Es translation. Their method does not evaluate the

chunk index	1	2	3	4	5	6	end
Gold transcript	can I be	**honest**	*SIL*	I don 't **love**	**that question**	*SIL*	
Gold translation	Darf ich **ehrlich** sein ?			Ich **mag diese Frage** nicht .			
Streaming ASR	can I			be **on this** I don 't	**love that question**		
simul-MT wait-3				Kann ich **da** sein ? "	Ich **liebe**		**diese Frage** nicht .
SH wait-3				Kann ich **ehrlich** sein ? Ich **liebe**	**diese Frage**		nicht .
LCP wait-3				Kann ich **ehrlich** sein ? Ich			**liebe diese Frage** nicht .

Figure 6: An example from the dev set of En→De translation. In the cascaded approach (streaming ASR + simul-MT wait-3), the ASR error (*"on this"* for *"honest"*) is propagated to the MT module, causing the wrong translation (*"da"*). Our methods give accurate translations ("ehrlich") with better latency (esp. for the SH policy, the output of *"diese Frage"* is synchronous with hearing *"that question"*). *"SIL"* denotes silence in speech.

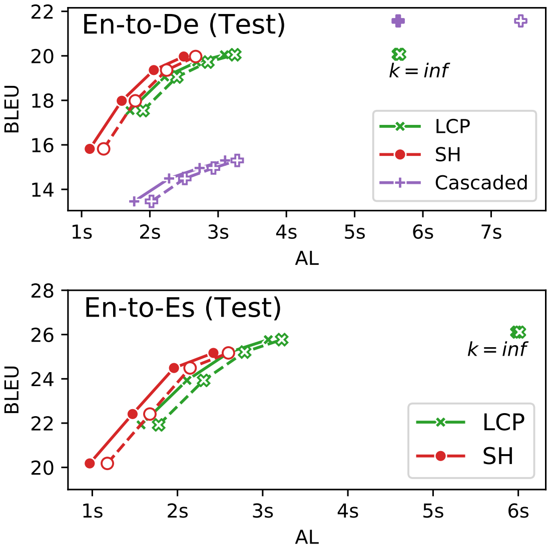

Figure 7: Translation quality against latency. Each curve represents decoding with wait-k policy, k=1,3,5,7 from left to right. The dashed lines and hollow markers indicate the latency considering the computational time. The chunk size is 48.

Model	En→De			En→Es		
	$w=32$	$w=48$	$w=64$	$w=32$	$w=48$	$w=64$

− *LM*	14.60	15.66	15.91	18.54	19.15	19.95
− *LM* & *AD*	13.76	14.82	15.26	17.42	18.06	19.32
SH	16.04	15.82	15.87	20.45	20.18	19.84
− *LM*	13.76	14.01	13.84	17.31	17.21	17.78
− *LM* & *AD*	10.44	11.25	11.65	13.61	14.27	14.62

Table 1: BLEU score of wait-1 decoding with different chunk sizes and ASR scoring functions. *AD* denotes ASR Decoder. *LM* denotes Language Model.

plausibility of the detected tokens, so it has a more aggressive decoding policy which results in lower latency. However, our method can still achieve better results with slightly lower latency. Besides that, our model is trained in full-sentence mode, and only decodes with wait-k at inference time, which is very efficient to train. Our test-time wait-k could achieve similar quality with their genuine wait-k (i.e., retrained) models which are very slow to train. When we compare with their test-time wait-k, our model significantly outperforms theirs.

We further evaluate our method on the test set of En→De and En→Es translation. As shown in Fig. 7, compared with the cascaded model, our model has notable successes in latency and translation quality. To verify the online usability of our model, we also show computational-aware latency. Because our chunk window is 480ms, and the latency caused by the computation is smaller than this window size, which means that we can finish decoding the previous speech chunk when the next speech chunk needs to be processed, so our model can be effectively used online.

Fig. 6 demonstrates that our method can effectively avoid the error propagation and obtain better latency compared to the cascaded model.

Effect of chunk size and joint decision Table 1 shows that the results are relatively stable with various chunk sizes. It can be flexible to balance the response frequency and computational ability. We explore the effectiveness of ASR joint scoring, and observe that the translation quality drops a lot without LM. Without LM and AD, our token recognition approach is similar to the speech segmentation in Ren et al. (2020), which implies that their model is hard to segment the source speech accurately, leading to unreliable translation decisions for ST.

5 Conclusion

We proposed a simple but effective ASR-assisted simultaneous E2E-ST framework. The streaming ASR module can guide (but not give direct input to) the wait-k policy for simultaneous translation. Our method improves ST accuracy with similar latency.

Abstract

Understanding linguistics and morphology of resource-scarce code-mixed texts remains a key challenge in text processing. Although word embedding comes in handy to support downstream tasks for low-resource languages, there are plenty of scopes in improving the quality of language representation particularly for code-mixed languages. In this paper, we propose HIT, a robust representation learning method for code-mixed texts. HIT is a hierarchical transformer-based framework that captures the semantic relationship among words and hierarchically learns the sentence-level semantics using a fused attention mechanism. HIT incorporates two attention modules, a multi-headed self-attention and an outer product attention module, and computes their weighted sum to obtain the attention weights. Our evaluation of HIT on one European (*Spanish*) and five Indic (*Hindi*, *Bengali*, *Tamil*, *Telugu*, and *Malayalam*) languages across four NLP tasks on eleven datasets suggests significant performance improvement against various state-of-the-art systems. We further show the adaptability of learned representation across tasks in a transfer learning setup (with and without fine-tuning).

1 Introduction

India is the second most populated country in the world, where ~ 1.36 billion people speak in over 200 different languages. Among them, the top five languages (*Hindi, Bengali, Telegu, Tamil,* and *Malayalam*) covers $\sim 93\%$of the entire population with more than 26% of them being bilingual (as per Wikipedia). Moreover, a significant proportion of them (Singh et al., 2018a) use code-mixed languages to express themselves in Online Social Networks (OSN).

Code-mixing (CM) is a linguistic phenomenon in which two or more languages are alternately used during conversation. One of the languages is usually English, while the other can be any regional language such as Hindi (Hindi + English → *Hinglish*), Bengali (Bengali + English → *Benglish*), Spanish (Spanish + English → *Spaniglish*), etc. Their presence on social media platforms and in day-to-day conversions among the people of a multi-lingual communities (such as Indians) is overwhelming. Despite the fact that a significant population is comfortable with code-mixed languages, the research involving them is fairly young. One of the prime reasons is the linguistic diversity, i.e., research on any language often fails to adapt for other distant languages, thus they need to be studied and researched separately. In recent years, many organizations have identified the challenges and have put in commendable efforts for the development of computational systems in regional monolingual or code-mixed setups.

Traditionally, the NLP community has studied the code-mixing phenomenon from a task-specific point of view. Recently, a few studies (Pratapa et al., 2018; Aguilar and Solorio, 2020) have started learning representations for code-mixed texts for semantic and syntactic tasks. While the former has showcased the importance of multi-lingual embeddings from CM text, the latter has made use of a hierarchical attention mechanism on top of positionally aware character bi-grams and tri-grams to learn robust word representations for CM text. Carrying over the same objective, in this paper, we introduce a novel **HI**erarchically attentive **T**ransformer (HIT) framework to effectively encode the syntactic and semantic features in embeddings space. At first, HIT learns sub-word level representations employing a fused attention mechanism (FAME) – an *outer-product* based attention mechanism (Le et al., 2020) fused with standard multi-headed self-attention (Vaswani et al., 2017). The intuition of sub-word level representation learning is supple-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4625–4639
August 1–6, 2021.

mented by the lexical variations of a word in code-mixed languages. The *character-level* HIT helps in representing phonetically similar word and their variations to a similar embedding space and extracts better representation for noisy texts. Subsequently, we apply HIT module at *word-level* to incorporate the semantics at the sentence-level. The output of HIT is a sequence of word representations, and can be fed to the architectures of any downstream NLP tasks. For the evaluation of HIT, we experiment on one classification (sentiment classification), one generative (MT), and two sequence-labelling (POS tagging and NER) tasks. In total, these tasks span to eleven datasets across six code-mixed languages – one European (*Spanish*) and five Indic (*Hindi*, *Bengali*, *Telugu*, *Tamil*, and *Malayalam*). Our empirical results show that representations learned by HIT are superior to existing multilingual and code-mixed representations, and report state-of-the-art performance across all tasks. Additionally, we observe encouraging adaptability of HIT in a transfer learning setup across tasks. The representations learned for a task is employed for learning other tasks w/ and w/o fine-tuning. HIT yields good performance in both setups for two code-mixed languages.

Main contributions: We summarize our contributions as follow:

- We propose a hierarchical attention transformer framework for learning word representations of code-mixed texts for six non-English languages.
- We propose a hybrid self-attention mechanism, FAME, to fuse the multi-headed self-attention and outer-product attention mechanisms in our transformer encoders.
- We show the effectiveness of HIT on eleven datasets across four NLP tasks and six languages.
- We observe good task-invariant performance of HIT in a transfer learning setup for two code-mixed languages.

Reproducibility: Source codes, datasets and other details to reproduce the results have been made public at `https://github.com/LCS2-IIITD/HIT-ACL2021-Codemixed-Representation`.

2 Related Work

Recent years have witnessed a few interesting work in the domain of code-mixed/switched representation learning. Seminal work was driven by bilingual embedding that employs cross-lingual transfer to develop NLP models for resource-scarce languages (Upadhyay et al., 2016; Akhtar et al., 2018; Ruder et al., 2019). Faruqui and Dyer (2014) introduced the BiCCA embedding using bilingual correlation, which performed well on syntactical tasks, but poorly on cross-lingual semantic tasks. Similarly, frameworks proposed by Hermann and Blunsom (2014) and Luong et al. (2015) depend on projecting the words of two languages into a single embedding space.

However, as demonstrated by Pratapa et al. (2018), bilingual embedding techniques are not ideal for CS text processing and should be replaced by multi-lingual embeddings learnt from CM data. The transformer-based Multilingual BERT (Devlin et al., 2019) embedding has been demonstrated (Pires et al., 2019) to possess impressive cross-lingual model transfer capabilities. Also, the XLM model (Conneau and Lample, 2019) has also shown the effects of cross-lingual training for low-resource and CM language tasks.

Another school of thought revolves around sub-word level representations, which can help to capture variations found in CM and transliterated text. Joshi et al. (2016) proposed a CNN-LSTM based model to learn the sub-word embeddings through 1-D convolutions of character inputs. They showed that it resulted in better sentiment classification performance for CM text. On top of this intuition, attention-based frameworks have also been proven to be successful in learning low-level representations. The HAN (Yang et al., 2016) model provides the intuition of hierarchical attention for document classification, which enables it to differentially attend to more and less important content, at the word and sentence levels. In another work, Aguilar and Solorio (2020) proposed CS-ELMo for code-mixed inputs with similar intuition. It utilizes the hierarchical attention mechanism on bi-gram and tri-gram levels to effectively encode the sub-word level representations, while adding positional awareness to it.

Our work builds on top of these two earlier works to push the robustness of code-mixed representations to higher levels. However, the main difference between existing studies and HIT is the incorporation of outer-product attention-based fused attention mechanism (FAME).

3 Proposed Methodology

In this section, we describe the architecture of HIT for learning effective representations in code-

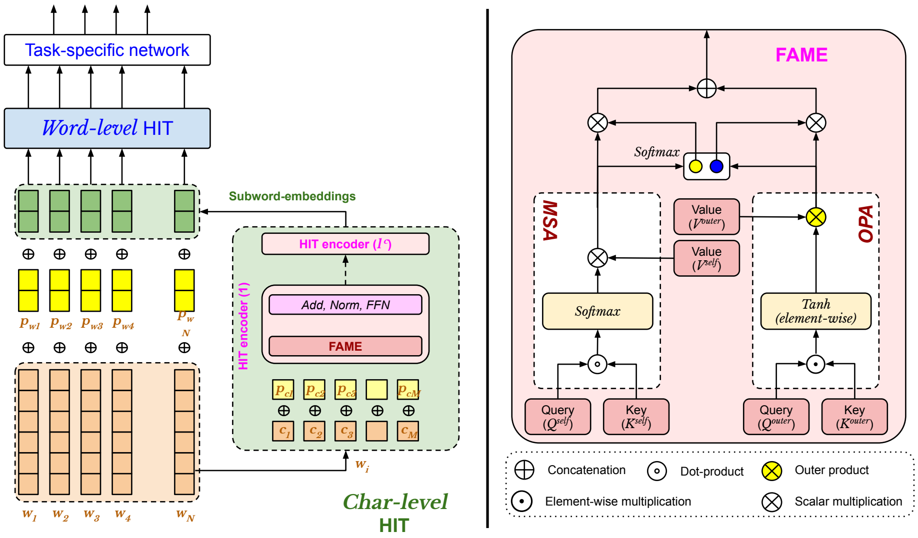

Figure 1: **Hi**erarchical **T**ransformer along with our novel **FAME** mechanism for attention computation.

mixed languages. The backbone of HIT is transformer (Vaswani et al., 2017) and Hierarchical Attention Network (HAN) (Yang et al., 2016). HIT takes a sequence of words (a code-mixed sentence) $S = \langle w_1, w_2, ..., w_N \rangle$ as input and processes each word w_i using a *character-level* HIT to obtain sub-word representation $S^{sb} = \langle sb_1, sb_2, ..., sb_N \rangle$. The *character-level* HIT is a transformer encoder, where instead of computing multi-headed self-attention only, we amalgamate it with an outer-product attention mechanism (Le et al., 2020) as well. The intuition of outer-product attention is to extract higher-order character-level relational similarities among inputs. To leverage both attention mechanisms, we compute their weighted sum using a softmax layer. Subsequently, we pass it through the typical *normalization* and *feed-forward* layers to obtain the encoder's output. A stacking of l_c encoders is used. In the next layer of the hierarchy, these sub-word representations are combined with positional and rudimentary embeddings of each word and forwarded to the *word-level* HIT's encoder. Finally, the output of *word-level* HIT is fed to the respective task-specific network. The hierarchical nature of HIT enables us to capture both *character-level* and *word-level* relational (syntactic and semantic) similarities. A high-level schema of HIT is shown in Figure 1.

3.1 Fused Attention Mechanism (FAME)

FAME extends the multi-headed self-attention (MSA) module of a standard transformer by including a novel outer-product attention (OPA) mechanism. Given an input x, we use three weight matrices, W_Q^{self}, W_K^{self}, and W_V^{self}, to project the input to *Query* (Q^{self}) , *Key* (K^{self}), and *Value* (V^{self}) representations for MSA, respectively. Similarly for OPA we use W_Q^{outer}, W_K^{outer}, and W_V^{outer} for the projecting x to Q^{outer}, K^{outer} and V^{outer}. Next, the two attention mechanisms are learnt in parallel, and a weighted sum is computed as its output. Formally, $H = \alpha_1 \cdot Z_{self} \oplus \alpha_2 \cdot Z_{outer}$, where Z_{self} and Z_{outer} respectively are the outputs of multi-headed self attention and outer-product attention modules, and α_1 and α_2 are the respective weights computed through a softmax function.

Multi-Headed Self Attention. The standard transformer self-attention module (Vaswani et al., 2017) computes a scaled dot-product between the *query* and *key* vectors prior to learn the attention weights for the *value* vector. We compute the output as follows:

$$\begin{aligned} Z_{self} &= softmax\left(\frac{Q^{self} \cdot K^{self^T}}{\sqrt{d^k}}\right) V^{self} \\ &= \sum_{i}^{N} softmax\left(\frac{q \cdot k_i}{\sqrt{d^k}}\right) v_i, \forall q \in Q^{self} \end{aligned}$$

where N is the sequence length, and d^k is the dimension of the *key* vector.

Outer-Product Attention. This is the second attention that we incorporate into FAME. Although the fundamental process of OPA (Le et al., 2020) is similar to the multi-headed self-attention computation, OPA differs in terms of different operators and the use of row-wise *tanh* activation instead of softmax. To compute the interaction between the query and key vectors, we use element-wise multiplication as opposed to the dot-product in MSA. Subsequently, an element-wise *tanh* is applied before computing the outer-product with the value vector. The intuition is to exploit fine-level associations between the *key*-scaled *query* and *value* representations in a code-mixed setup. Similar to the earlier case, we define OPA as:

$$Z_{outer} = \sum_{i}^{N} tanh\left(\frac{q \odot k_i}{\sqrt{d_k}}\right) \otimes v_i, \forall q \in Q^{outer}$$

where $\odot$ is the element-wise multiplication, and $\otimes$ is the outer-product.

3.2 Task-specific Layers

As we mention earlier, HIT can be adapted for various NLP tasks including sequence labelling, classification, or generative problems. In the current work, we evaluate HIT on part-of-speech (POS) tagging, named-entity recognition (NER), sentiment classification, and machine translation (MT). We mention their specific architectural details below.

For the sentiment classification, we apply a *GlobalAveragePooling* operation over the token embeddings to obtain the sentence embeddings. Additionally, we concatenate extracted statistical features along with the embeddings before feeding into the final classification layer. We use *tf-idf* (term frequency–inverse document frequency) vectors for $\{1, 2, 3\}$-grams of words and characters extracted from each text. We hypothesize that these statistical features contain sufficient information to get rid of any handcrafted features like the ones suggested by Bansal et al. (2020). Finally, a *softmax* activation function is used for the prediction. Similarly, for POS tagging and NER, the corresponding labels for each of the token's embedding is obtained through a softmax activated output. In case of MT, we use an encoder-decoder framework where both the encoder and the decoder are based on the HIT framework.

4 Experiments, Results, and Analyses

In this section, we furnish the details of chosen datasets, our experimental results, comparative study, and necessary analyses.

4.1 Datasets

We evaluate 11 publicly available datasets across 4 tasks in 6 code-mixed languages. For POS tagging, we employ Hindi, Telugu, Bengali, and Spanish, whereas, we evaluate Hindi and Spanish datasets for NER. Similarly, in sentiment classification, we incorporate Hindi, Tamil, Malayalam, and Spanish code-mixed sentences. Finally, for machine translation, we use a recently released Hindi-English code-mixed parallel corpus. A brief statistics of all datasets is presented in Table 1.

Tasks	**Lang**	**Train**		**Test**		**Total**	**#Labels**
		#Sent	**#Token**	**#Sent**	**#Token**		
POS	Hi*	1191	6575	148	2300	1489	14

Table 1: Dataset statistics. Star(*) signifies 90-10 ratio.

- **POS tagging:** We use the Hindi-English code-mixed POS dataset provided by Singh et al. (2018b). It was collected from Twitter and has 1489 sentences. Each token in the sentence is tagged with one of the 14 tags[1]. The Bengali and Telugu datasets are collected from ICON-2016 workshop[2]. The instances are the social-media messages, collected from Twitter, Facebook and WhatsApp, and have 1982 and 626 sentences in Telugu and Bengali, respectively. These two datasets follow Google universal tagset (Petrov et al., 2011) and contain 52 and 39 tags respectively. For Spanish, we use Linguistic Code-switching Evaluation (LinCE) POS dataset (AlGhamdi et al., 2016) consisting of more that $35k$ sentences with 14 tags.
- **Sentiment classification:** We explore the Hinglish sentiment classification dataset developed by Joshi et al. (2016). The dataset contains 3879 Facebook public posts comprises of 15% *negative*, 50% *neutral*, and 35% *positive* samples. We further consider two sentiment classification datasets for Dravidian languages *viz.* Tamil and Malayalam (Chakravarthi et al., 2020), containing 15744 and 6739 instances respectively with four sentiment labels – *positive*, *negative*, *neutral*, and *mixed feelings*. Additionally, we use SemEval-2020 (Patwa et al., 2020) dataset for Spanish code-mixed sentiment classification. It supports a classic 3-way sentiment classification.
- **Named-entity recognition:** For NER, we em-

Table 2: Performance of HIT on sentiment classification. Best scores are highlighted in bold.

ploy Hindi (Singh et al., 2018c) and Spanish (Aguilar et al., 2018) datasets with 2079 and 52781 sentences, respectively. In Hindi, the labels are *name*, *location*, and *organization*. The Spanish dataset has six additional labels – *event*, *group*, *product*, *time*, *title*, and *other* named entities.

• **Machine Translation:** We utilize a recently developed Hindi-English code-mixed parallel corpus for machine translation (Gupta et al., 2020) comprising more than $200k$ sentence pair. For experiments, we transliterate all Devanagari Hindi text.

4.2 Baselines

POS tagging, NER & sentiment classification: ▷ **BiLSTM** (Hochreiter and Schmidhuber, 1997): It is a weak baseline with two conventional BiLSTM layers. For POS and NER, we additionally incorporate a CRF layer for the final classification. ▷ **HAN** (Yang et al., 2016): We adapt the Hierarchical Attention Network (HAN) for our purpose. The subword embedding is computed at the first level of attention network followed by a word-level attention at the second level. Recently, Bansal et al. (2020) also adopted HAN for code-mixed classification. ▷ **ML-BERT** (Devlin et al., 2019): We fine-tune multilingual BERT (Devlin, 2019). ▷ **CS-ELMo** (Aguilar and Solorio, 2020): It is one of state-of-the-arts on code-mixed languages. It uses pre-trained ELMo (Peters et al., 2018) to transfer knowledge from English to code-mixed languages. ▷ **Subword-LSTM** (Joshi et al., 2016): It is a hybrid CNN-LSTM model. A 1D convolution operation is applied for the subword representation. Subsquently, the convoluted features are max-pooled and fed to an LSTM. Since this system disregards word boundaries in a sentence, we use it for *sentiment classification only*.

Machine translation: For machine translation, we evaluate HIT against **GFF-Pointer** (Gupta et al., 2020), a gated feature fusion (GFF) based approach to amalgamate the XLM and syntactic features during encoding and a Pointer generator for decoding. Furthermore, we also incorporate three other baselines for comparison – **Seq2Seq** (Sutskever et al., 2014), **Attentive-Seq2Seq** (Bahdanau et al., 2014) and **Pointer Generator** (See et al., 2017).

4.3 Experimental Setup

For each experiment, we use a $dropout = 0.1$ in both transformer block and the task specific layers. Categorical cross-entropy loss with Adam ($\eta = 0.001, \beta_1 = 0.9, \beta_2 = 0.999$) optimizer (Kingma and Ba, 2014) is employed in all experiments. We train our models for maximum 500 epochs with an early-stopping criteria having $patience = 50$. We additionally use a learning rate scheduler to reduce learning rate to 70% at plateaus with a patience of 20 epochs. All models are trained with *batch-size*$= 32$.

4.4 Experimental Results

We compute precision, recall, F1-score for POS, NER, and sentiment classification, whereas, BLEU, METEOR, and ROUGE scores are reported for the machine translation task.

Sentiment classification: As shown in Table 2, HIT obtains best F1-scores across all languages. For Hindi, three baselines (BiLSTM, ML-BERT, and CS-ELMo) obtain the best F1-score of 0.909, where HIT yields a small improvement with 0.915 F1-score. In comparison, we observe an improvement of 1.4% for Tamil, where HIT and the best baseline (CS-ELMo) report 0.473 and 0.459 F1-scores, respectively. We observe the same pattern for Malayalam and Spanish as well – in both cases, HIT obtains improvements of 0.9% and 2.0%, respectively. For Malayalam, HIT reports 0.651 F1-score, whereas CS-ELMo reports 0.642 F1-score. In case of Spanish, HAN turns out to be the best baseline with 0.440 F1-score. Com-

Table 5: Performance of HIT encoder-decoder on En-Hi Translation (**B**: BLEU, **R**: Rouge-L and **M**: METEOR). † Values are taken from Gupta et al. (2020).

paratively, HIT achieves 0.460 F1-score. The last two rows of Table 2 report ablation results – a) excluding outer-product attention (Atn^{outer}) from HIT; and b) excluding sub-word embeddings (*character-level* HIT). In all cases, the absence of *sub-word* embeddings yields negative effect on the performance; hence, suggesting the effectiveness of *character-level* HIT in the architecture. On the other hand, omitting outer-product attention declines F1-scores in 3 out of 4 cases – we observe a margin improvement of 0.04 points for Malayalam. In summary, HIT attains state-of-the-art performance across all four datasets, whereas, the best baseline (CS-ELMo) reports 1.2% lower scores on average.

POS tagging: Table 3 shows the comparative results for POS tagging in Hindi, Telugu, Bengali, and Spanish. Similar to sentiment classification, we observe that HIT attains best F1-scores across three datasets (0.625% better on average). It achieves 0.919, 0.762, 0.853, and 0.825 F1-scores for Hindi, Telugu, Bengali, and Spanish, respectively. In comparison, CS-ELMo yields best F1-scores among all the baselines across three datasets *viz.* Hindi (0.910), Telugu (0.775), and Bengali (0.847). For Spanish, ML-BERT obtains the best baseline F1-score of 0.802. From ablation, we observe the negative effect on performance by removing either the outer-product attention or *character-level* HIT for the majority of the cases.

NER: The performance of HIT for NER is also in-line with the previous two tasks, as show in Table 4. As mentioned earlier, we evaluate HIT for Hindi and Spanish datasets. In both cases, we observe $\geq 1\%$ improvement in F1-score, in comparison with the best baseline (CS-ELMo).

In all three tasks, CS-ELMo is arguably the most consistent baseline. Together with the state-of-the-art performance of HIT, we regard the good performance to the subword-level contextual modelling – both systems use contextual representational models (ELMo and Transformer) to encode the syntactic and semantic features. Moreover, the FAME module in HIT assists in improving the performance even further.

Machine Translation: Finally, Table 5 reports the results for the English to Hindi (En-Hi) machine translation task. For comparison, we also report BLEU, METEOR, and ROUGE-L scores for four baseline systems – Seq2Seq (Sutskever et al., 2014), Attentive-Se2Seq (Bahdanau et al., 2014), Pointer Generator (See et al., 2017), and GFF-Pointer (Gupta et al., 2020). For all three metrics, HIT reports significant improvement (1-9 points) over the state-of-the-art and other baselines. GFF-Pointer obtains 21.55 BLEU score, while the other baselines yield BLEU scores in the range $[15 - 17]$. In comparison, HIT obtain 28.22 BLEU, *an extremely convincing result.* Similarly, HIT reports 51.52 ROUGE and 29.59 METEOR scores, respectively.

Source Tasks		Fine-tune	Target Tasks: PoS	Target Tasks: NER	Target Tasks: Sentiment
	PoS	w/o	0.919	0.702	**0.890**

(b) NER

Table 8: Error Analysis on Hindi code-mixed dataset.

4.5 Effects of Transfer Learning across Tasks

One of the core objectives of representation learning is that the learned representation should be task-invariant – the representations learned for one task should also be (near) effective for other tasks. The intuition is that the syntactic and semantic features captured for a language should be independent of the tasks, and if it does not comply, the representation can be attributed to capture the task-specific feature, instead of linguistic features. To this end, we perform transfer learning experiments with (w/) and without (w/o) fine-tuning. Since we have only one dataset for Tamil, Telugu, Bengali, and Malayalam, we choose Hindi and Spanish code-mixed datasets (POS, NER, and sentiment classification) for the study. Table 6 reports results for both code-mixed languages. For each case, we learn HIT's representation on one (source) task and subsequently utilize the representation for the other two tasks (targets). Moreover, we repeat each experiment with and without fine-tuning HIT.

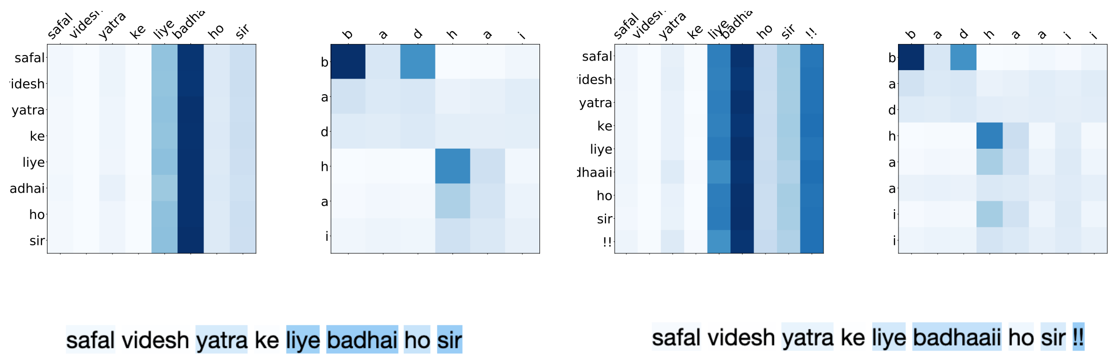
For Hindi code-mixed, we do not observe the positive effect of transfer learning for NER. It could be because of the limited lexical variations of named-entities in other datasets. However, we obtain the best F1-score (0.936) for POS tagging in a transfer learning setup with sentiment classification. Similarly, for the sentiment classification as target, we observe performance improvements with both POS and NER as source tasks. In Spanish, we also observe increment in F1-scores for all three tasks. We attribute these improvements to the availability of more number of sentences for HIT to leverage the linguistic features in both Hindi and Spanish.

4.6 Error Analysis

In this section, we analyze the performance of HIT both quantitatively and qualitatively. At first, we report the confusion matrices[3] for Hindi NER and sentiment classification in Table 7. In both cases, we observe the *true-positives* to be significant for all labels. Furthermore, we also observe the *false-positives* to be extremely low (except for '*B-Org*'

---

[3] Confusion matrices and more error cases for other tasks are presented in the appendix.



(a) Original input.

(b) Perturbed input.

Figure 2: Interpretation of Hindi code-mixed sentiment prediction (a) Grad-CAM (Selvaraju et al., 2019) analysis of original text; (b) Grad-CAM of perturbed text (*'badhaaii'*); For both case, the *word-level* and *char-level* attention plots are shown.The impact of the word *'badhai'* on the overall prediction is shown through gradients and attention heatmaps. The representation learning of phonetically similar word (e.g., *'badhaaii'*) is also noticeable in the perturbed case. It signifies that HIT is flexible to the spelling variations, a common feature in code-mixed environment.

in NER) for majority of the cases – suggesting very good precision in general. The major contribution in error is due to the *neutral* and *other* classes in sentiment and NER, respectively. In sentiment analysis, 10% of the *positive* and *negative* labels each were mis-classified as *neutral*. Similarly in NER, we observe that the *organization* entities (*B-Org & I-Org*) and *other* classes confuse with each other in a significant number of samples. It may be due to the under-represented ($\sim$ 13%) *organization* entities in the dataset.

We also perform qualitative error analysis of HIT and CS-ELMo. Table 8 reports the results for the NER and sentiment classification tasks[3]. For the first example in sentiment classification, HIT accurately predicts the sentiment labels as *positive*; however in comparison, CS-ELMo mis-classifies it as *neutral*. For the second example, both HIT and CS-ELMo wrongly predict the sentiment as *neutral*. One possible reason could be the presence of the negatively-inclined word *chodo* (*leave*) in the sentence. For NER, the sentence has two entities (one *person* and one *organization*). While HIT correctly identifies '*dhan dhan satguru*' as person, it could not recognize '*msg*' as organization. On the other hand, CS-ELMo correctly identifies both.

Furthermore, we take the first example of sentiment analysis (from Table 8) to get the insight of HIT. It is not hard to understand that the most positive vibe is attributed by the phrase '*badhai ho sir*' (*congratulations sir*). To validate our hypothesis, we use a gradient based interpretation technique, Grad-CAM (Selvaraju et al., 2019), which uses gradients of neural networks to show the effect of neurons on the final output. Due to hierarchical and modular nature of HIT, we are able to extract the intermediate word level representations learnt by the *character-level* HIT and compute the gradient of loss of the actual class considering these representations. The magnitude of gradient shows the impact of each word on the final output. Figure 2a shows the word-level and character-level gradient maps for the original input. We can observe that HIT attends to the most important component in both cases. For *word-level*, it highlights the positive phrase '*liye badhai*' (*congratulations on*). Moreover, character-level HIT attends to the two syllables '*b*' and '*dh*' in the word '*badhai*' (*congratulation*). It suggests that both the *word-level* and *character-level* components are capable of extracting important features from inputs. Furthermore, to check the robustness, we investigate HIT on a perturbed input. In the previous example, we tweak the spelling of the most important word '*badhai*' to '*badha$\underline{a}\underline{i}$i*' (an out-of-vocabulary word considering the dataset). Figure 2b shows similar patterns in the perturbed input case as well. It signifies that HIT identifies the phonetic similarity of the two words and is flexible to the spelling variants, a common feature in code-mixed environment.

4.7 HIT's Performance on Monolingual Data

In this section, we outline the performance of HIT for monolingual and low-resource settings. We consider the sentiment classification dataset curated by Akhtar et al. (2016), containing 5417 transliterated

Model	Hi Sentiment			Magahi POS		
	Pr.	Re.	F1	Pr.	Re.	F1
BiLSTM	0.619	0.533	0.554	0.594	0.804	0.626
HAN	0.602	0.528	0.551	0.729	0.857	0.649
ML-BERT	0.604	0.556	0.576	0.757	0.867	0.708
CS-ELMO	0.593	0.520	0.542	0.771	0.884	0.759
HIT	**0.641**	**0.629**	**0.635**	**0.783**	**0.913**	**0.775**

Table 9: Performance of HIT on monolingual tasks. Best scores are highlighted in bold.

Tasks	Model	# Params(M)	Train Time(s/ep)
Sentiment	CS-ELMo	2.9	18
	HAN	2.7	14
	BiLSTM	2.8	12
	ML-BERT	179.2	172
	HIT	2.7	13
POS	CS-ELMo	2.4	4
	HAN	1.4	3
	BiLSTM-CRF	1.5	2
	ML-BERT	177.9	114
	HIT	1.4	2

Table 10: Parameters and Runtime: Number of trainable parameters and training runtime (second/epoch) for the Hi-En PoS and sentiment classification tasks.

Hindi reviews with 4 sentiment labels - *positive*, *negative*, *neutral*, and *conflict*. We also utilize a Magahi POS dataset (Kumar et al., 2012), annotated with 33 tags from the BIS-tagset [4]. We report the performance of HIT and other baselines on these two datasets in Table 9. For the Hindi sentiment classification task, we observe that HIT yields an F1-score of 0.635, which is better than CS-ELMo and ML-BERT by 9.3% and 5.9%. Also, for Magahi POS, HIT reports the best F1-score of 0.775 – increaments of $+2.1\%$ and $+9.5\%$ over CS-ELMo and ML-BERT, respectively. These results suggest that HIT is capable of handling monolingual and low-resource texts in an efficient manner.

4.8 Learnable Parameters and Power Usage

We conduct all our experiments on 1 Tesla T4 GPU. In Table 10, we report the total trainable parameters for HIT and other baselines. We observe that HIT requires a comparable number of parameters. For instance, in the Hindi-English sentiment analysis task (sequence classification), HIT has a total ~$2.7M$ trainable parameters, while other baselines such as, CS-ELMo, HAN, Subword-LSTM, and BiLSTM require ~$2.9M$, ~$2.7M$, ~$2.1M$, and ~$2.8M$ parameters, respectively. ML-BERT has a whopping ~$179.2M$ parameters. Similarly, in Hindi-English POS tagging, the number of parameters for HIT is comparable (or even lesser) – HIT: ~$1.4M$, CS-ELMo: ~$2.4M$, HAN: ~$1.4M$, BiLSTM-CRF: ~$1.5M$, ML-BERT: ~$177.9M$. We observed similar distribution for other tasks/languages as well.

We further note that HIT is significantly more efficient than the current SOTA models as it takes 13 s/epoch to train which is significantly lower than CS-ELMo (18 s/epoch), HAN (14 s/epoch), and ML-BERT (172 s/epoch), while it takes a bit more time compared to BiLSTM (12 s/epoch) and Subword-LSTM (7 s/epoch). We also computed the amount of power consumption for training HIT for a maximum 500 epochs. Following the guidelines of Strubell et al. (2019), we estimate a total power consumption of 0.383 kWh and equivalent CO2 emission of 0.365 pounds.

5 Conclusion

In this work, we present HIT – a hierarchical transformer-based framework for learning robust code-mixed representations. HIT contains a novel fused attention mechanism, which calculates a weighted sum of the multi-headed self attention and outer-product attention, and is capable of capturing relevant information at a more granular level. We experimented with eleven code-mixed datasets for POS, NER, sentiment classification, and MT tasks across six languages. We observed that HIT successfully outperforms existing SOTA systems. We also demonstrate the task-invariant nature of the representations learned by HIT via a transfer learning setup, signifying it's effectiveness in learning linguistic features of CM text rather than task-specific features. Finally, we qualitatively show that HIT successfully embeds semantically and phonetically similar words of a code-mixed language.

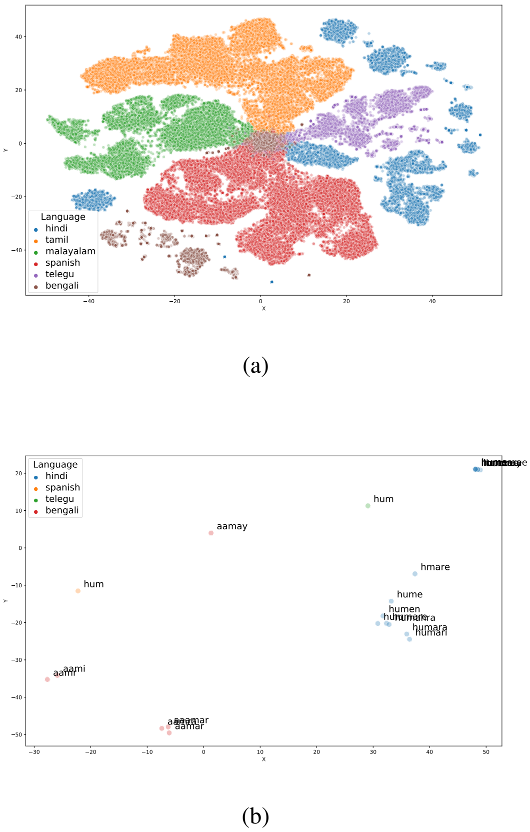
A Appendix

A.1 Semantic Understanding of Languages

In this section, we study the semantic relationships between different Indic languages. We calculate the proportion of common words in Table 11 between different language pairs to understand the multilingualism in India. We observe that Bengali code-mixed texts have the highest proportion of English words 32% as compared to other languages. Moreover, 50% of all Bengali words are also present in the Hindi CM texts, although 58% of those words are English. We observe that users using Hindi CM texts use very few words taken from other languages. On the other hand, a significant proportion of Bengali and Telugu CM words are common in other languages, although, majority of them are English. The two Dravidian languages, Tamil and Malayalam, show a very distinctive behavior. They share very little linguistic similarity with other Indic languages. On the other hand, 10% of all Tamil words are used in Malayalam and 17% of all Malayalam words are used in Tamil. Moreover, this sharing is not driven by English, as, only 27% of these words are English, which is the lowest proportion among all other language pairs. Being originate from a similar root and having a phonetic resemblance makes Tamil and Malayalam *sister languages*[5]. Similar observations are also made from the word representation lens. We use t-SNE (Van der Maaten and Hinton, 2008) plots to embed HIT's representations onto a 2-D space for interpretability (Fig 3). Although, the embeddings are well clustered based on the languages, we can easily figure out the semantically similar words across languages embedded onto a similar space. Furthermore, Fig 3(b) shows that pronouns (e.g., '*aap*') in Tamil, Telegu and Hindi are embedded onto a similar space with Bengali words *'aamar'*, '*aamay*'. Although each of these representations are learned on separate models on separate datasets, the robustness of the underlying hierarchical representation enables our model to capture cross-lingual semantics from noisy code-mixed texts. We can attribute these observations to the relatedness of Indic languages on a socio-cultural basis.

A.2 Datasets

We report all available POS tags in Table 12.



(a)

(b)

Figure 3: t-SNE visualization (a) of all words; (b) of selected pronouns. Overlapping clusters show how semantically similar words from different languages are embedded onto a similar space.

A.3 Confusion Matrices and Error Analysis

We report the confusion matrices to show the label-wise performance for the sentiment classification, PoS tagging and NER in Tables 5, 4, and 6, respectively.

We similarly perform qualitative analysis on the MT task where our model shows superior performance as compared to the baselines. In example 1 of Table 13 (d), HIT translates the English text '*'Licencing and import policies were liberalise"* to *"Licencing aur policies liberal the* ।*"*. Although this prediction has very low BLEU score when evaluated against the target, this example shows an interesting observation. The overall translation is a contextually meaningful sentence in Hindi. Further HIT translates the phrase *'were liberalise'* to *'liberal the'*. In Hindi, *'the'* represents past tense. Another interesting observation is the ability of HIT to copy texts from source to predicted text. Even without having an explicit copying mechanism (See et al., 2017), HIT is able to understand

Abstract

The paradigm of data programming, which uses weak supervision in the form of rules/labelling functions, and semi-supervised learning, which augments small amounts of labelled data with a large unlabelled dataset, have shown great promise in several text classification scenarios. In this work, we argue that by not using any labelled data, data programming based approaches can yield sub-optimal performances, particularly when the labelling functions are noisy. The first contribution of this work is an introduction of a framework, SPEAR which is a semi-supervised data programming paradigm that learns a *joint model* that effectively uses the rules/labelling functions along with semi-supervised loss functions on the feature space. Next, we also study SPEAR-SS which additionally does subset selection on top of the joint semi-supervised data programming objective and *selects* a set of examples that can be used as the labelled set by SPEAR. The goal of SPEAR-SS is to ensure that the labelled data can *complement* the labelling functions, thereby benefiting from both data-programming as well as appropriately selected data for human labelling. We demonstrate that by effectively combining semi-supervision, data-programming, and subset selection paradigms, we significantly outperform the current state-of-the-art on seven publicly available datasets. [1]

1 Introduction

Modern machine learning techniques rely on large amounts of labelled training data for text classification tasks such as spam detection, (movie) genre classification, sequence labelling, *etc*. Supervised learning approaches have utilised such large amounts of labelled data and, this has resulted in huge successes in the last decade. However, the acquisition of labelled data, in most cases, entails a painstaking process requiring months of human effort. Several techniques such as active learning, distant supervision, crowd-consensus learning, and semi-supervised learning have been proposed to reduce the *annotation cost* (Settles et al., 2008). However, clean annotated labels continue to be critical for reliable results (Bach et al., 2019; Goh et al., 2018).

Recently, Ratner et al. (2016) proposed a paradigm on data-programming in which several Labelling Functions (LF) written by humans are used to weakly associate labels with the instances. In data programming, users encode the weak supervision in the form of labelling functions. On the other hand, traditional semi-supervised learning methods combine a small amount of labelled data with large unlabelled data (Kingma et al., 2014). In this paper, we leverage semi-supervision in the feature space for more effective data programming using labelling functions.

1.1 Motivating Example

We illustrate the LFs on one of the seven tasks on which we experiment with, *viz.*, identifying spam/no-spam comments in the YouTube reviews. For some applications, writing LFs is often as simple as using keyword lookups or a regex expression. In this specific case, the users construct heuristic patterns as LFs for classifying spam/not-spam comments. Each LF takes a comment as an input and provides a binary label as the output; +1 indicates that the comment is spam, -1 indicates that the comment is not spam, and 0 indicates that the LF is unable to assert anything for the comment (referred to as an *abstain*). Table 1 presents a few example LFs for spam and non-spam classification.

In isolation, a particular LF may neither be always correct nor complete. Furthermore, the LFs

Id	**Description**
LF1	If `http` or `https` in comment text, then return +1 otherwise ABSTAIN (return 0)
LF2	If length of comment is less than 5 words, then return -1 otherwise ABSTAIN (return 0).(Non spam comments are often short)
LF3	If comment contains `my channel` or `my video`, then return +1 otherwise ABSTAIN (return 0).

Table 1: Three LFs based on keyword lookups or regex expression for the *YouTube* spam classification task

Training data		LF outputs		Features	
id	Label	LF1(+1)	LF2(-1)	F1	F2
S_1	+1	1	0	1	0
S_2	-1	0	1	0	1
S_3	-1	0	0	0	1
S_4	+1	1	1	1	0
Test data					
S_5	-1	0	1	0	1
S_6	+1	0	0	1	0

Table 2: Example illustrating the insufficiency of using data programming using only LFs.

may also produce conflicting labels. In the past, generative models such as Snorkel (Ratner et al., 2016) and CAGE (Chatterjee et al., 2020) have been proposed for consensus on the noisy and conflicting labels assigned by the discrete LFs to determine the probability of the correct labels. Labels thus obtained could be used for training any supervised model/classifier and evaluated on a test set. We will next highlight a challenge in doing data programming using only LFs that we attempt to address. For each of the following sentences $S_1 \ldots S_6$ that can constitute *an observed set of training instances*, we state the value of the true label (± 1). While the candidates in S_1 and S_4 are instances of a spam comment, the ones in S_2 and S_3 are not. In fact, these examples constitute one of the canonical cases that we discovered during the analysis of our approach in Section 4.4.

1. $\langle \boldsymbol{S_1}, +1 \rangle$: Please help me go to college guys! Thanks from the bottom of my heart. https://www.indiegogo.com/projects/
2. $\langle \boldsymbol{S_2}, -1 \rangle$: I love this song
3. $\langle \boldsymbol{S_3}, -1 \rangle$: This song is very good... but the video makes no sense...
4. $\langle \boldsymbol{S_4}, +1 \rangle$: https://www.facebook.com/teeLaLaLa

Further, let us say we have a completely *unseen set of test instances*, S_5 and S_6, whose labels we would also like to predict effectively:

5. $\langle \boldsymbol{S_5}, -1 \rangle$: This song is prehistoric
6. $\langle \boldsymbol{S_6}, +1 \rangle$: Watch Maroon 5's latest ... www.youtube.com/watch?v=TQ046FuAu00

In Table 2, we present the outputs of the LFs as well as some n-gram features F1 ('.com') and F2 ('This song') on the observed training examples S_1, S_2, S_3 and S_4 as well as on the unseen test examples S_5 and S_6. For S_1, the correct consensus can easily be performed to output the true label +1, since LF1 (designed for class +1) gets triggered, whereas LF2 (designed for class -1) is not triggered. Similarly, for S_2, LF2 gets triggered whereas LF1 is not, making it possible to easily perform the correct consensus. Hence, we have treated S_1 and S_2 as unlabelled, indicating that we could learn a model based on LFs alone without supervision if all we observed were these two examples and the outputs of LF1 and LF2. However, the correct consensus on S_3 and S_4 is challenging since both LF1 and LF2 either fire or do not. While the (n-gram based) features F1 and F2 appear to be informative and could potentially complement LF1 and LF2, we can easily see that correlating feature values with LF outputs is tricky in a completely unsupervised setup. To address this issue, we ask the following questions:

(A) What if we are provided access to the true labels of a small subset of instances - in this case, only S_3 and S_4? Could the (i) correlation of features values (*eg.* F1 and F2) with labels (*eg.* +1 and -1 respectively), modelled via a small set of labelled instances (*eg.* S_3 and S_4), in conjunction with (ii) the correlation of feature values (*eg.* F1 and F2) with LFs (*eg.* LF1 and LF2) modelled via a potentially larger set of unlabelled instances (*eg.* S_1, S_2), help improved prediction of labels for hitherto unseen test instances S_5 and S_6?

(B) Can we precisely determine the subset of the unlabelled data that, when labelling would help us train a model (in conjunction with the labelling functions) that is most effective on the test set? In other words, instead of randomly choosing the labelled dataset for doing semi-supervised learning (part A), can we intelligently select the labelled subset? In the above example, choosing the labelled set as S_3, S_4 would be much more useful than choosing the labelled set as S_1, S_2.

As a solution to (A), in Section 3.3, we present a new formulation, SPEAR, in which the parameters over features and LFs are jointly trained in a semi-supervised manner. SPEAR expands as **S**emi-su**P**ervis**E**d d**A**ta p**R**ogramming. As for (B), we present a subset selection recipe, SPEAR-SS (in

Section 3.4), that recommends the sub-set of the data (*e.g.* S_3 and S_4), which, after labelling, would most benefit the joint learning framework.

1.2 Our Contributions

We summarise our main contributions as follows: To address (A), we present SPEAR (*c.f.*, Section 3.3), which is a novel paradigm for jointly learning the parameters over features and labelling functions in a semi-supervised manner. We jointly learn a parameterized graphical model and a classifier model to learn our overall objective. To address (B), we present SPEAR-SS (*c.f.*, Section 3.4), which is a subset selection approach to *select* the set of examples which can be used as the labelled set by SPEAR. We show, in particular, that through a principled data selection approach, we can achieve significantly higher accuracies than just randomly selecting the seed labelled set for semi-supervised learning with labelling functions. Moreover, we also show that the automatically selected subset performs comparably or even better than the hand-picked subset by humans in the work reported by Awasthi et al. (2020), further emphasising the benefit of subset selection for semi-supervised data programming. Our framework is agnostic to the underlying network architecture and can be applied using different underlying techniques without a change in the meta-approach. Finally, we evaluate our model on seven publicly available datasets from domains such as spam detection, record classification, and genre prediction and demonstrate significant improvement over state-of-the-art techniques. We also draw insights from experiments in synthetic settings (presented in the appendix).

2 Related Work

Data Programming and Unsupervised Learning: Snorkel (Ratner et al., 2016) has been proposed as a generative model to determine correct label probability using consensus on the noisy and conflicting labels assigned by the discrete LFs. Chatterjee et al. (2020) proposed a graphical model, CAGE, that uses continuous-valued LFs with scores obtained using soft match techniques such as cosine similarity of word vectors, TF-IDF score, distance among entity pairs, *etc*. Owing to its generative model, Snorkel is highly sensitive to initialisation and hyper-parameters. On the other hand, the CAGE model employs user-controlled quality guides that incorporate labeller intuition into the model. However, these models completely disregard feature information that could provide additional information to learn the (graphical) model. These models try to learn a combined model for the labelling functions in an unsupervised manner. However, in practical scenarios, some labelled data is always available (or could be made available by labelling a few instances); hence, a completely unsupervised approach might not be the best solution. In this work, we augment these data programming approaches by designing a semi-supervised model that incorporates feature information and LFs to learn the parameters jointly. Hu et al. (2016) proposed a student-teacher model that transfers rule information by assigning linear weight to each rule based on an agreement objective. The model we propose in this paper jointly learns parameters over features and rules in a semi-supervised manner rather than just weighing their outputs and can therefore be more expressive.

Other works such as Jawanpuria et al. (2011); Dembczyński et al. (2008) discovers simple and conjuctive rules from input features and assign weight to each rules for better generalization. Nagesh et al. (2012) induces rules from query language to build NER extractor while Kulkarni et al. (2018) uses active learning to derive consensus among labelers to label data.

Semi-Supervised Data Programming: The only work which, to our knowledge, combines rules with supervised learning in a joint framework is the work by Awasthi et al. (2020). They leverage both rules and labelled data by associating each rule with exemplars of correct firings (*i.e.*, instantiations) of that rule. Their joint training algorithms denoise over-generalized rules and train a classification model. Our approach differs from their work in two ways: a) we do not have information of rule exemplars - thus our labelled examples need not have any correspondence to any of the LFs (and may instead complement the LFs as illustrated in Table 2) and b) we employ a semi-supervised framework combined with graphical model for consensus amongst the LFs to train our model. We also study how to automatically select the seed set of labelled data, rather than having a human provide this seed set, as was done in (Awasthi et al., 2020).

Data Subset Selection: Finally, another approach that has been gaining a lot of attention recently is data subset selection. The specific application of data subset selection depends on the goal at hand. Data subset selection techniques have been used to reduce end to end training time (Mirzasoleiman et al., 2019; Kaushal et al., 2019; Killamsetty et al., 2021) and to select unlabelled points in an active learning manner to label (Wei et al., 2015; Sener and Savarese, 2017) or for topic summarization (Bairi et al., 2015). In this paper, we present a framework (SPEAR-SS) of data subset selection for *selecting* a subset of unlabelled examples for obtaining labels complementary to the labelling functions.

3 Methodology

3.1 Problem Description

Let $\mathcal{X}$ and $\mathcal{Y} \in \{1...K\}$ be the feature space and label space, respectively. We also have access to m labelling functions (LF) λ_1 to λ_m. As mentioned in Section 1.1, each LF λ_j is designed to record some class; let us denote[2] by $k_j \in \{1...K\}$, the class associated with λ_j. The dataset consists of 2 components, *viz.*,

1. $\mathcal{L} = \{(\mathbf{x}_1, y_1, \mathbf{l}_1), (\mathbf{x}_2, y_2, \mathbf{l}_2), \ldots, (\mathbf{x}_N, y_N, \mathbf{l}_N)\}$, which denotes the labelled dataset and

2. $\mathcal{U} = \{(\mathbf{x}_{N+1}, \mathbf{l}_{N+1}), (\mathbf{x}_{N+2}, \mathbf{l}_{N+2}), \ldots, (\mathbf{x}_M, \mathbf{l}_M)\}$, which denotes the unlabelled dataset wherein $\mathbf{x}_i \in \mathcal{X}$, $y_i \in \mathcal{Y}$.

Here, the vector $\mathbf{l}_i = (l_{i1}, l_{i2}, \ldots, l_{im})$ denotes the firings of all the LFs on instance $\mathbf{x}_i$. Each l_{ij} can be either 1 or 0. $l_{ij} = 1$ indicates that the LF λ_j has fired on the instance i and 0 indicates it has not. All the labelling functions are discrete; hence, no continuous scores are associated with them.

3.2 Classification and Labelling Function Models

SPEAR has a feature-based classification model $f_\phi(\mathbf{x})$ which takes the features as input and predicts the class label. Examples of $f_\phi(\mathbf{x})$ we consider in this paper are logistic regression and neural network models. The output of this model is $P^f_\phi(y|\mathbf{x})$, *i.e.*, the probability of the classes given the input features. This model can be a simple classification model such as a logistic regression model or a simple neural network model.

Notation	Description
f_ϕ	The feature-based Model
P^f_ϕ	The label probabilities as per the feature-based model f_ϕ
P_θ	The label probabilities as per the LF-based Graphical Model
L_{CE}	Cross Entropy Loss: $L_{CE}\left(P^f_\phi(y\|\mathbf{x}), \tilde{y}\right) = -\log\left(P^f_\phi(y = \tilde{y}\|\mathbf{x})\right)$
H	Entropy function : $H(P^f_\phi(y\|\mathbf{x})) = -\sum_{\hat{y}} P^f_\phi(y = \hat{y}\|\mathbf{x}) \log P^f_\phi(y = \hat{y}\|\mathbf{x})$
g	Label Prediction from the LF-based graphical model
LL_s	Supervised negative log likelihood
LL_u	Unsupervised negative log likelihood summed over labels
KL	KL Divergence between two probability models
R	Quality Guide based loss

Table 3: Summary of notation used.

We also use an LF-based graphical model $P_\theta(\mathbf{l}_i, y)$ which, as specified in equation (1) for an example $\mathbf{x}_i$, is a generative model on the LF outputs and class label y.

$$P_\theta(\mathbf{l}_i, y) = \frac{1}{Z_\theta} \prod_{j=1}^{m} \psi_\theta(l_{ij}, y) \tag{1}$$

$$\psi_\theta(l_{ij}, y) = \begin{cases} \exp(\theta_{jy}) & \text{if } l_{ij} \neq 0 \\ 1 & \text{otherwise.} \end{cases} \tag{2}$$

There are K parameters $\theta_{j1}, \theta_{j2} ... \theta_{jK}$ for each LF λ_j, where K is the number of classes. The model makes the simple assumption that each LF λ_j independently acts on an instance $\mathbf{x}_i$ to produce outputs $l_{i1}, l_{1i} ... l_{im}$. The potentials ψ_θ invoked in equation (1) are defined in equation (2). Z_θ is the normalization factor. We propose a joint learning algorithm with semi-supervision to employ both features and LF predictions in an end-to-end manner.

3.3 Joint Learning in SPEAR

We first specify the objective of SPEAR and thereafter explain each of its components in greater detail:

$$\begin{aligned}
\min_{\theta,\phi} & \sum_{i \in \mathcal{L}} L_{CE}\left(P^f_\phi(y|\mathbf{x}_i), y_i\right) + \sum_{i \in \mathcal{U}} H\left(P^f_\phi(y|\mathbf{x}_i)\right) \\
& + \sum_{i \in \mathcal{U}} L_{CE}\left(P^f_\phi(y|\mathbf{x}_i), g(\mathbf{l}_i)\right) + LL_s(\theta|\mathcal{L}) \\
& + LL_u(\theta|\mathcal{U}) + \sum_{i \in \mathcal{U} \cup \mathcal{L}} KL\left(P^f_\phi(y|\mathbf{x}_i), P_\theta(y|\mathbf{l}_i)\right) \\
& + R(\theta|\{q_j\})
\end{aligned} \tag{3}$$

Before we proceed further, we refer the reader to Table 3 in which we summarise the notation built so far as well as the notation that we will soon be introducing.

First Component (L1): The first component (L1) of the loss $L_{CE}\left(P^f_\phi(y|\mathbf{x}_i), y_i\right) = -\log\left(P^f_\phi(y = y_i|\mathbf{x}_i)\right)$ is the standard cross-entropy loss on the labelled dataset $\mathcal{L}$ for the model P^f_ϕ.

Second Component (L2): The second component L2 is the semi-supervised loss on the unlabelled data $\mathcal{U}$. In our framework, we can use any

---

[2] We use the association of LF λ_j with some class k_j only in the quality guide component (QG) of the loss in eqn. 3

unsupervised loss function. However, for this paper, we use the Entropy minimisation (Grandvalet and Bengio, 2005) approach. Thus, our second component $H\left(P_\phi^f(y|\mathbf{x}_i)\right)$ is the entropy of the predictions on the unlabelled dataset. It acts as a form of semi-supervision by trying to increase the confidence of the predictions made by the model on the unlabelled dataset.

Third Component (L3): The third component $L_{CE}\left(P_\phi^f(y|\mathbf{x}_i), g(\mathbf{l}_i)\right)$ is the cross-entropy of the classification model using the hypothesised labels from CAGE (Chatterjee et al., 2020) on $\mathcal{U}$. Given that $\mathbf{l}_i$ is the output vector of all labelling functions for any $\mathbf{x}_i \in \mathcal{U}$, we specify the predicted label for $\mathbf{x}_i$ using the LF-based graphical model $P_\theta(\mathbf{l}_i, y)$ from eqn. (1) as: $g(\mathbf{l}_i) = \text{argmax}_y P_\theta(\mathbf{l}_i, y)$.

Fourth Component (L4): The fourth component $LL_s(\theta|\mathcal{L})$ is the (supervised) negative log likelihood loss on the labelled dataset $\mathcal{L}$ as per eqn. (3):

$$LL_s(\theta|\mathcal{L}) = -\sum_{i=1}^{N} \log P_\theta(\mathbf{l}_i, y_i)$$

Fifth Component (L5): The fifth component $LL_u(\theta|\mathcal{U})$ is the negative log likelihood loss for the unlabelled dataset $\mathcal{U}$ as per eqn. (3). Since the true label information is not available, the probabilities need to be summed over y: $LL_u(\theta|\mathcal{U}) = -\sum_{i=N+1}^{M} \log \sum_{y \in \mathcal{Y}} P_\theta(\mathbf{l}_i, y)$

Sixth Component (L6): The sixth component $KL(P_\phi^f(y|\mathbf{x}_i), P_\theta(y|\mathbf{l}_i))$ is the Kullback-Leibler (KL) divergence between the predictions of both the models, *viz.*, feature-based model f_ϕ and the LF-based graphical model P_θ summed over every example $\mathbf{x}_i \in \mathcal{U} \cup \mathcal{L}$. Through this term, we try and make the models agree in their predictions over the union of the labelled and unlabelled datasets.

Quality Guides (QG): As the last component in our objective, we use quality guides $R(\theta|\{q_j\})$ on LFs, which have been shown in (Chatterjee et al., 2020) to stabilise the unsupervised likelihood training while using labelling functions. Let q_j be the fraction of cases where λ_j correctly triggered, and let q_j^t be the user's belief on the fraction of examples $\mathbf{x}_i$ where y_i and l_{ij} agree. If the user's beliefs were not available, we consider the precision of the LFs on the validation set as the user's beliefs. Except for the SMS dataset, we take the precision of the LFs on the validation set as the quality guides. If $P_\theta(y_i = k_j|l_{ij} = 1)$ is the model-based precision over the LFs, the quality guide based loss can be expressed as $R(\theta|\{q_j^t\}) = \sum_j q_j^t \log P_\theta(y_i = k_j|l_{ij} = 1) + (1-q_j^t)\log(1-P_\theta(y_i = k_j|l_{ij} = 1))$. Throughout the paper, we consider QG always in conjunction with Loss **L5**.

In summary, the first three components (L1, L2 and L3) invoke losses on the supervised model f_ϕ. While L1 compares the output f_ϕ against the ground truth in the labelled set $\mathcal{L}$, L2 and L3 operate on the unlabelled data $\mathcal{U}$ by minimizing the entropy of f_ϕ (L2) and by calibrating the f_ϕ output against the noisy predictions $g(\mathbf{l}_i)$ of the graphical model $P_\theta(\mathbf{l}_i, y)$ for each $\mathbf{x}_i \in \mathcal{U}$ (L3). The next two components L4 and L5 focus on maximizing the likelihood of the parameters θ of $P_\theta(\mathbf{l}_i, y)$ over labelled $\mathbf{x}_i \in \mathcal{L}$ and unlabelled $\mathbf{x}_i \in \mathcal{U}$ datasets respectively. Finally, in L6, we compare the probabilistic outputs from the supervised model f_ϕ against those from the graphical model $P_\theta(\mathbf{l}, y)$ through a KL divergence based loss. We use the ADAM (stochastic gradient descent) optimizer to train the non-convex loss objective.

Previous data programming approaches (Bach et al., 2019; Chatterjee et al., 2020) adopt a cascaded approach in which they first optimise a variant of L5 to learn the θ parameters associated with the LFs and thereafter use the noisily generated labels using $g(\mathbf{l})$ to learn the supervised model f_ϕ using a variant of L3. In contrast, our approach learns the LF's θ parameters and the model's ϕ parameters jointly in the context of the unlabelled data $\mathcal{U}$.

We present synthetic experiments to illustrate the effect of SPEAR for data programming and semi-supervision in a controlled setting in which (i) the overlap between classes in the data is controlled and (ii) the labelling functions are accurate. The details of the synthetic experiments are provided in the appendix.

3.4 SPEAR-SS: Subset Selection with SPEAR

Suppose we are given an unlabelled data set $\mathcal{U}$ and a limited budget for data labelling because of the costs involved in it. It is essential for us to choose the data points that need to be labelled properly. We explore two strategies for selecting a subset of data points from the unlabelled set. We then obtain the labels for this subset, and run SPEAR on the combination of this labelled and unlabelled set. The two approaches given are intended to maximise diversity of the selected subset in the feature space. We complement both the approaches with Entropy Filtering (also described below).

Unsupervised Facility Location: In this approach, given an unlabelled data-set $\mathcal{U}$, we want to select a subset $\mathcal{S}$ such that the selected subset has maximum diversity with respect to the features. Inherently, we are trying to maximise the information gained by a machine learning model when trained on the subset selected. The objective function for unsupervised facility location is $f_{\text{unsup}}(\mathcal{S}) = \sum_{i \in \mathcal{U}} \max_{j \in \mathcal{S}} \sigma_{ij}$ where σ_{ij} denotes the similarity score (in the feature space $\mathcal{X}$) between data instance $\mathbf{x}_i$ in unlabelled set $\mathcal{U}$ and data instance $\mathbf{x}_j$ in selected subset data $\mathcal{S}$. We employ a lazy greedy strategy to select the subset. In conjunction with Entropy Filtering described below,we call this technique *Unsupervised Subset Selection*.

Supervised Facility Location: The objective function for Supervised Facility Location (Wei et al., 2015) is $f_{\text{sup}}(\mathcal{S}) = \sum_{y \in \mathcal{Y}} \sum_{i \in \mathcal{U}_y} \max_{j \in \mathcal{S} \cap \mathcal{U}_y} \sigma_{ij}$. Here we assume that $\mathcal{U}_y \subseteq \mathcal{U}$ is the subset of data points with hypothesised label y. Simply put, $\mathcal{U}_y$ forms a partition of $\mathcal{U}$ based on the hypothesized labels obtained by performing unsupervised learning with labelling functions. In conjunction with Entropy Filtering, we call this technique *Supervised Subset Selection*.

Entropy Filtering: We also do a filtering based on entropy. In particular, we sort the examples based on maximum entropy and select fB number of data points[3], where B is the data selection budget (which was set to the size of the labelled set $|\mathcal{L}|$ in all our experiments). On the filtered dataset, we perform the subset selection, using either the supervised or unsupervised facility location as described above. Below, we describe the optimisation algorithm for subset selection.

Optimisation Algorithms and Submodularity: Both $f_{\text{unsup}}(\mathcal{S})$ and $f_{\text{sup}}(\mathcal{S})$ are submodular functions. We select a subset $\mathcal{S}$ of the filtered unlabelled data, by maximising these functions under a cardinality budget k (*i.e.*, a labelling budget). For cardinality constrained maximisation, a simple greedy algorithm provides a near-optimal solution (Nemhauser et al., 1978). Starting with $\mathcal{S}^0 = \emptyset$, we sequentially update

$$\mathcal{S}^{t+1} = \mathcal{S}^t \cup \underset{j \in \mathcal{U} \setminus \mathcal{S}^t}{\operatorname{argmax}} f(j|\mathcal{S}^t) \tag{4}$$

where $f(j|\mathcal{S}) = f(\mathcal{S} \cup j) - f(\mathcal{S})$ is the gain of adding element j to set $\mathcal{S}$. We iteratively execute the greedy step (4) until $t = k$ and $|\mathcal{S}^t| = k$. It is easy to see that the complexity of the greedy algorithm is $O(nkT_f)$, where T_f is the complexity of evaluating the gain $f(j|\mathcal{S})$ for the supervised and unsupervised facility location functions. We then significantly optimize this simple greedy algorithm via a lazy greedy algorithm (Minoux, 1978) via memoization and precompute statistics (Iyer and Bilmes, 2019).

Dataset	$\lvert\mathcal{L}\rvert$	$\lvert\mathcal{U}\rvert$	#Rules/LFs	Precision	%Cover	|Test|
MIT-R	1842	64888	15	80.7	14	14256
YouTube	100	1586	10	78.6	87	250
SMS	69	4502	73	97.3	40	500
Census	83	10000	83	84.1	100	16281
Ionosphere	73	98	64	65	100	106
Audit	162	218	52	87.5	100	233
IMDB	284	852	25	80	58.1	500

Table 4: Statistics of datasets and their rules/LFs. Precision refers to micro precision of rules. %Cover is the fraction of instances in $\mathcal{U}$ covered by at least one LF. Size of Validation set is equal to $|\mathcal{L}|$.

4 Experiments

In this section, we (1) evaluate our joint learning against state-of-the-art approaches and (2) demonstrate the importance of subset selection over random subset selection. We present evaluations on seven datasets on tasks such as text classification, record classification and sequence labelling.

4.1 Datasets

We adopt the same experimental setting as in Awasthi et al. (2020) for the dataset split and the labelling functions. However (for the sake of fairness), we set the validation data size to be equal to the size of the labelled data-set unlike Awasthi et al. (2020) in which the size of the validation set was assumed to be much larger.

We use the following datasets: **(1) YouTube**: A spam classification on YouTube comments; **(2) SMS Spam Classification (Almeida et al., 2011)**, which is a binary spam classification dataset containing 5574 documents; **(3) MIT-R (Liu et al., 2013)**, is a sequence labelling task on each token with following labels: *Amenity, Prices, Cuisine, Dish, Location, Hours, Others*; **(4) IMDB**, which is a plot summary based movie genre binary classification dataset, and the LFs (and the labelled set) are obtained from the approach followed by Varma and Ré (2018); **(5) Census** (Dua and Graff, 2017), **(6) Ionosphere**, and **(7) Audit**, which are all UCI datasets. The task in the Census is to predict whether a person earns more than $50K or not.

---

[3] In our experiments, we set $f = 5$

Ionosphere is radar binary classification task given a list of 32 features. The task in the Audit is to classify suspicious firms based on the present and historical risk factors.

Statistics pertaining to these datasets are presented in Table 4. Since we compare performances against models that adopt different terminology, we refer to rules and labelling functions interchangeably. For fairness, we restrict the size of the validation set and keep it equal to the size $|\mathcal{L}|$ of the labelled set. For all experiments involving comparison with previous approaches, we used code and hyperparameters from (Awasthi et al., 2020) but with our smaller-sized validation set. Note that we mostly outperform them even with their larger-sized validation set as can be seen in Table 5. More details on training and validation set size are given in the appendix.

4.2 Baselines

In Table 5, we compare SPEAR and SPEAR-SS against other following standard methods on seven datasets.

Only-$\mathcal{L}$: We train the classifier $P_\theta(y|\mathbf{x})$ only on the labelled data $\mathcal{L}$ using loss component L1. As explained earlier, following (Awasthi et al., 2020), we observe that a 2-layered neural network trained with the small amount of labelled data is capable of achieving competitive accuracy. We choose this method as a baseline and report gains over it.

$\mathcal{L} + \mathcal{U}_{maj}$: We train the baseline classifier $P_\theta(y|x)$ on the labelled data $\mathcal{L}$ along with $\mathcal{U}_{maj}$ where labels on the $\mathcal{U}$ instances are obtained by majority voting on the rules/LFs. The training loss is obtained by weighing instances labelled by rules as $\min_\theta \sum_{(\mathbf{x}_i,\mathbf{l}_i)\in\mathcal{L}} - \log P_\theta(\mathbf{l}_i|\mathbf{x}_i) + \gamma \sum_{(\mathbf{x}_i,y_i)\in\mathcal{L}} - \log P_\theta(y_i|\mathbf{x}_i)$.

Learning to Reweight (L2R) (Ren et al., 2018): This method trains the classifier by an online training algorithm that assigns importance to examples based on the gradient direction.

$\mathcal{L}$+$\mathcal{U}_{Snorkel}$ (Ratner et al., 2016): Snorkel's generative model that models class probabilities based on discrete LFs for consensus on the noisy and conflicting labels.

Posterior Regularization (PR) (Hu et al., 2016): This is a method for joint learning of a rule and feature network in a teacher-student setup.

Imply Loss (Awasthi et al., 2020): This approach uses additional information in the form of labelled rule exemplars and trains with denoised rule-label loss. Since it uses information in addition to what we assume, Imply Loss can be considered as a skyline for our proposed approaches.

4.3 Results with SPEAR

SPEAR uses the 'best' combination of the loss components L1, L2, L3, L4, L5, L6. To determine the 'best' combination, we perform a grid search over various combinations of losses using validation accuracy/f1-score as the criteria for selecting the most appropriate loss combination. Imply Loss uses a larger-sized validation set to tune their models. In our experiments, we maintained a validation set size equal to the size of the labelled data. In Table 5, we observe that SPEAR performs significantly better than all other approaches on all but the MIT-R data-set. Please note that all results are based on the same hand-picked labelled data subset as was chosen in prior work (Awasthi et al., 2020; Varma and Ré, 2018), except for Audit and Ionosphere. Even though we do not have rule-exemplar information in our model, SPEAR achieves better gains than even ImplyLoss. Recall that the use of ImplyLoss can be viewed as a skyline approach owing to the additional exemplar information that associates labelling functions with specific labelled examples. The slightly lower performance of the 'best' SPEAR on the MIT-R data-set can be partially explained by the fact that there are no LFs corresponding to the '0' class label, owing to which our graphical model is not trained for all classes. However, as we will show in the next section, by suitably determining a subset of the data-set that can be labelled (using the facility location representation function), we achieve improved performance even on the MIT-R data-set (see Table 5). Also, note that in Table 5, we present results on two versions of Audit, one in which both the train and test set are balanced, and the other where the labelled training set is imbalanced. In the imbalanced case (where the number of positives are only 10%), we were unable to successfully run the ImplyLoss and Posterior-Reg models (and hence the '-'), despite communication with the authors. We see that SPEAR and similarly, SPEAR-SS (discussed below) significantly outperform the baselines by almost 40% in the imbalanced case. In the balanced case, the gains are similar to what we observe on the other datasets.

Methods	Datasets							
	YouTube [Accuracy]	SMS [F1]	MIT-R [F1]	IMDB [F1]	Census [Accuracy]	Ionosphere [F1]	Audit (Imb) [F1]	Audit (Bal) [F1]

SPEAR-SS (Random Subset Selection)	+3.5	+1.8	-2.9	+4.0	-5.2	+4.7	+41.7	+2.0
SPEAR-SS (Unsupervised Subset Selection)	+3.9	+1.9	+2.6	-0.6	+2.5	+4.8	+43.5	+3.3
SPEAR-SS (Supervised Subset Selection)	**+4.2**	+3.2	+**2.9**	**+6.3**	+2.5	+5.1	**+44.5**	+3.5

Table 5: Performance of SPEAR and SPEAR-SS for three subset selection schemes on seven data-sets. All numbers reported are gains over the baseline method (Only-$\mathcal{L}$). All results are averaged over 5 runs. Numbers in brackets '()' represent standard deviation of the original score. Handpicked instances refers to instances selected from the dataset for designing LFs. These instances are taken directly from (Awasthi et al., 2020) to ensure fair comparison.

4.4 Results with SPEAR-SS

Recall that all results discussed so far (including those for SPEAR) on the Youtube, SMS, MIT-R, IMDB and Census datasets were based on the same 'hand-picked' labelled data subset as in prior work (Awasthi et al., 2020; Varma and Ré, 2018). In the case of Audit and Ionosphere, the labelled subset was randomly picked. In Table 5, we summarise the results obtained by employing supervised and unsupervised subset selection schemes for picking the labelled data-set and present comparisons against results obtained using (i) 'hand-picked' labelled data-sets, and (ii) random selection of the labelled set. In each case, the size of the subset is the same, which we set to be the size of the hand-picked labelled set. Our data selection schemes are applied to the 'best' SPEAR model obtained across various loss components. We observe that the best-performing model for the supervised and unsupervised data selection tends to outperform the best model based on random selection. Secondly, we observe that between the supervised and unsupervised data selection approaches, the supervised one tends to perform the best, which means that using the hypothesised labels does help. Thirdly, we observe that YouTube, MIT-R, IMDB and Audit using the selected subset outperform prior work that employ hand picked data-set, whereas, in the case of SMS, Census and Ionosphere, we come close. Finally, our approach is more stable than other approaches as the standard deviation of SPEAR is low for 5 different runs across all the datasets.

As an illustration, the examples such as S_3 and S_4 referred to in Section 1.1 were precisely obtained through supervised subset selection in SPEAR-SS, to form part of the labelled dataset. As previously observed in Table 2, S_3 and S_4 *complement* (via n-grams features such as F1 and F2) the effect of the labelling functions LF1 and LF2 on the unlabelled examples such as S_1 and S_2, when included in the labelled set. Further detailed results with subset selection, *etc.* can be found in the appendix. In general, we observe that when the subset of instances selected for labelling is *complementary* to the labelling functions (as in our case), the performance is higher than when the labelled examples (exemplars) are inspired by labelling functions themselves as done in the work by Awasthi et al. (2020).

4.5 Significance Test

We employ the Wilcoxon signed-rank test (Wilcoxon, 1992) to determine whether there is a significant difference between SPEAR and Imply Loss (current state-of-the-art). Our null hypothesis is that there is not significant difference between SPEAR and Imply loss. For $n = 7$ instances, we observe that the one-tailed hypothesis is significant at $p < .05$, so we reject the null hypothesis. Clearly, SPEAR significantly outperforms Imply loss and, therefore, all previous baselines.

Similarly, we perform the significance test to assess the difference between SPEAR-SS and Imply Loss. As expected, the one-tailed hypothesis is significant at $p < 0.05$, which implies that our SPEAR-SS approach significantly outperforms Imply Loss, and thus all other approaches.

5 Conclusion

We study how data programming can benefit from labelled data by learning a model (SPEAR) that

Methods	Datasets			
	YouTube [Accuracy]	SMS [F1]	MIT-R [F1]	Census [Accuracy]
ImplyLoss (Awasthi et al., 2020)	94.1	93.2	74.3	81.1
SPEAR (Handpicked)	+0.3	**+0.2**	-0.9	**+0.9**
SPEAR-SS (Supervised Subset Selection)	**+0.8**	0.0	**+1.7**	-0.3

Table 6: Comparison of SPEAR and SPEAR-SS against ImplyLoss on subset of datasets from Table 5 for which ImplyLoss used a much larger validation set than $|\mathcal{L}|$. JL uses a validation set sizes equal to $|\mathcal{L}|$.

jointly optimises the consensus obtained from labelling functions in an unsupervised manner, along with semi-supervised loss functions designed in the feature space. We empirically assess the performance of the different components of our joint loss function. As another contribution, we also study some subset selection approaches to guide the selection of the labelled subset of examples. We present the performance of our models and present insights on both synthetic and real datasets. While outperforming previous approaches, our approach is often better than an exemplar-based (skyline) approach that uses the additional information of the association of rules with specific labelled examples.

A Illustration of SPEAR on a synthetic setting

Through a synthetic example, we illustrate the effectiveness of our formulation of combining semi-supervised learning with labelling functions (*i.e.*, combined Losses 1-6) to achieve superior performance. Consider a 3-class classification problem with overlap in the feature space as depicted in Figure 1. The classes are A, B and C. Though we illustrate the synthetic setting in 2 dimensions, in reality, we performed similar experiments in three dimensions (and results were similar). We randomly pick 5 points from each class $i \in \{a, b, c\}$, and corresponding to each such point (x_i, y_i) we create a labelling function based on its coordinates:

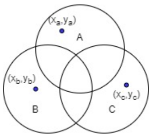

Figure 1: Synthetic data

- LF_a: Consider the point (x_a, y_a). The corresponding LF will be: if $y \geq y_a$ return 1 (i.e. classify as class A) else return 0 (abstain).

- LF_b: Similarly for (x_b, y_b) the LF will return 1 if $x \leq x_b$ and else will return 0.

- LF_c: The LF corresponding to (x_c, y_c) will return 1 if $x \geq x_c$ and else will return 0.

These seemingly 15 weak labelling functions (5 for each class) actually aid in classification when the labelled example set is extremely small and the classifier is unable to get a good estimate of the class boundaries. This can be observed in Table 7 wherein we report the F1 score on a held out test dataset for models obtained by training on the different loss components. The results are reported in the case of three dimensions, wherein each circle was obtained as a 3-dimensional gaussian. The means for the three classes A, B and C were respectively, $(0, 0, 0)$, $(0, 1, 0)$ and $(0, 0, 1)$

and the variance for each class was set to $(1, 1, 1)$. The training and test sets had 1000 examples each, with roughly equal number of samples randomly generated from each class (gaussian). In the first experiment (result in the first row of Table 7), the training was performed on the L1 loss by treating the entire data-set of 1000 examples as labelled. In all the other experiments only 1% (10 examples with almost uniform distribution across the 3 classes) of the training set was considered to be labelled and the remaining (990 examples) were treated as unlabelled.

Loss component used for training	F1 Score
L1 (on entire dataset as labelled)	0.584
L1 (1% labelled)	0.349
L1 (1% labelled) +L2	0.352
L1 (1% labelled)+L2+L3+L4 (1% labelled)+L5+L6	**0.440**
L4 (1% labelled)+L5	0.28

Table 7: F1 scores on test data in the synthetic setting

We make the following important observations with respect to Table 7: (1) **Skyline:** When the entire training data is treated as labelled and loss function L1 is minimized, we obtain a skyline model with F1 score of 0.584. (2) With just 1% labelled data on L1, we achieve 0.349 F1 score (using only the labelled data). (3) We obtain an F1 score of 0.28 using the labelling functions on the unlabelled data (for L5) in conjunction with the 1% labelled data (for L4). (4) When the 1% labelled data (for L1) and the remaining observed unlabelled data (for L2) are used to train the semi-supervised model using L1+L2, an F1 score of 0.352 is obtained. (5) However, by jointly learning on all the loss components, we observe an F1 score of 0.44. This is far better than the numbers obtained using only (semi)-supervised learning and those obtained using only the labelling functions. Understandably, this number is lower than the skyline of 0.584 mentioned on the first row of Table 7.

B Network Architecture

To train our model on the supervised data L, we use a neural network architecture having two hidden layers with ReLU activation. We chose our classification network to be the same as (Awasthi et al., 2020). In the case of MIT-R and SMS, the classification network contain 512 units in each hidden layer whereas the classification network for Census has 256 units in its hidden layers. For the YouTube dataset, we used a simple logistic regression as a classifier network, again as followed in (Awasthi et al., 2020). The features as well as the labelling functions for each dataset are also directly obtained from Snorkel (Ratner et al., 2016) and (Awasthi et al., 2020). Please note that all experiments (barring those on subset selection) are based on the same hand-picked labelled data subset as was chosen in (Awasthi et al., 2020).

Datasets	lr (f network)	lr (g network)	Batch Size
SMS	0.0001	0.01	256
MIT-R	0.0003	0.001	512
Census	0.0003	0.001	256
Youtube	0.0003	0.001	32
Ionosphere	0.003	0.01	32
Audit	0.0003	0.01	32
IMDB	0.0003	0.01	32

Table 8: Hyper parameter details for the different datasets

In each experiment, we train our model for 100 epochs and early stopping was performed based on the validation set. We use Adam optimizer with the dropout probability set to 0.8. The learning rate for f and g network are set to 0.0003 and 0.001 respectively for YouTube, Census and MIT-R datasets. For SMS dataset, learning rate is set to 0.0001 and 0.01 for f and g network. For Ionosphere dataset, learning rate for f is set to 0.003. For each experiment, the numbers are obtained by averaging over five runs, each with a different random initialisation. The model with the best performance on the validation set was chosen for evaluation on the test set. As mentioned previously, the experimental setup in (Awasthi et al., 2020) surprisingly employed a large validation set. For fairness, we restrict the size of the validation set and keep it equal to the size of the labelled set. For all experiments involving comparison with previous approaches, we used code and hyperparameters from (Awasthi et al., 2020) but with our smaller sized validation set.

Following (Awasthi et al., 2020), we used binary-F1 as an evaluation measure for the SMS, macro-F1 for MIT-R datasets, and accuracy for the YouTube and Census datasets.

C Optimisation Algorithms and Submodularity: Lazy Greedy and Memoization

Both $f_{\text{unsup}}(X)$ and $f_{\text{sup}}(X)$ are submodular functions, and for data selection, we select a subset

Loss Combination	Datasets				
	YouTube (Accuracy)	SMS (F1)	MIT-R (F1)	IMDB (F1)	Census (Accuracy)
L1+L2+L3+L4	94.6	93.1	72.5	73.6	82.0
L1+L2+L4+L6	92.0	91.9	69.7	73.3	81.3
L1+L3+L4+L6	94.4	93.2	29.8	74.4	81.0
L1+L2+L3+L4+L6	94.4	92.3	29.5	64.4	80.9
L1+L3+L4+L5+L6	**94.6**	**93.4**	**73.2**	**77.1**	**82.0**
L1+L2+L3+L4+L5+L6	94.5	93.0	72.8	76.9	81.9

Table 9: Performance on the test data, of various loss combinations from our objective function in equation (3). For each dataset, the numbers in **bold** refer to the 'best' performing combination, determined based on performance on the validation data-set. In general, we observe that all the loss components (barring L2) contribute to the best model. Note that all combinations includes QG (Component 7).

X of the unlabelled data, which maximises these functions under a cardinality budget (i.e. a labelling budget). For cardinality constrained maximisation, a simple greedy algorithm provides a near optimal solution (Nemhauser et al., 1978). Starting with $X^0 = \emptyset$, we sequentially update $X^{t+1} = X^t \cup \text{argmax}_{j \in V \setminus X^t} f(j|X^t)$, where $f(j|X) = f(X \cup j) - f(X)$ is the gain of adding element j to set X. We run this till $t = k$ and $|X^t| = k$, where k is the budget constraint. It is easy to see that the complexity of the greedy algorithm is $O(nkT_f)$ where T_f is the complexity of evaluating the gain $f(j|X)$ for the supervised and unsupervised facility location functions. This simple greedy algorithm can be significantly optimized via a lazy greedy algorithm (Minoux, 1978). The idea is that instead of recomputing $f(j|X^t), \forall j \notin^t$, we maintain a priority queue of sorted gains $\rho(j), \forall j \in V$. Initially $\rho(j)$ is set to $f(j), \forall j \in V$. The algorithm selects an element $j \notin X^t$, if $\rho(j) \geq f(j|X^t)$, we add j to X^t (thanks to submodularity). If $\rho(j) \leq f(j|X^t)$, we update $\rho(j)$ to $f(j|X^t)$ and re-sort the priority queue. The complexity of this algorithm is roughly $O(kn_R T_f)$, where n_R is the average number of re-sorts in each iteration. Note that $n_R \leq n$, while in practice, it is a constant thus offering almost a factor n speedup compared to the simple greedy algorithm. One of the parameters in the lazy greedy algorithms is T_f, which involves evaluating $f(X \cup j) - f(X)$. One option is to do a naïve implementation of computing $f(X \cup j)$ and then $f(X)$ and take the difference. However, due to the greedy nature of algorithms, we can use memoization and maintain a precompute statistics $p_f(X)$ at a set X, using which the gain can be evaluated much more efficiently (Iyer and Bilmes, 2019). At every iteration, we evaluate $f(j|X)$ using $p_f(X)$, which we call $f(j|X, p_f)$. We then update $p_f(X \cup j)$ after adding element j to X. Both the supervised and unsupervised facility location functions admit precompute statistics thereby enabling further speedups.

D Role of different components in the loss function

Given that our loss function has seven components (including the quality guides), a natural question is 'how do we choose among the different components for joint learning (JL)?' Another question we attempt to answer is 'whether all the components are necessary for JL?' For our final model (*i.e.*, the results presented in Tables 6 and 7 of the main paper), we attempt to choose the best performing JL combination of the 7 loss components, *viz.* L1, L2, L3, L4, L5, L6. To choose the 'best' JL combination, we evaluate the performance on the validation set of the different JL combinations. Since we generally observe considerably weaker performance by selecting lesser than 3 loss terms, we restrict ourselves to 3 or more loss terms in our search. We report performance on the test data, of various JL combinations from our objective function for each of the four data-sets. For each data-set, the numbers in **bold** refer to the 'best' performing JL combination, determined based on performance on the validation data-set.

The observations on the results are as follows. Firstly, we observe that all the loss components (barring L2 for three datasets) contribute to the best model. Furthermore, we observe that the best JL combination (picked on the basis of the validation set) either achieves the best performance or close to best among the different JL combinations as measured on the test dataset. Secondly, we observe that QGs do not cause significant improvement in the performance during training.

Fingerprinting Fine-tuned Language Models in the Wild*

Nirav Diwan[1], Tanmoy Chakravorty[1], and Zubair Shafiq[2]

Abstract

There are concerns that the ability of language models (LMs) to generate high quality synthetic text can be misused to launch spam, disinformation, or propaganda. Therefore, the research community is actively working on developing approaches to detect whether a given text is organic or synthetic. While this is a useful first step, it is important to be able to further fingerprint the author LM to attribute its origin. Prior work on fingerprinting LMs is limited to attributing synthetic text generated by a handful (usually < 10) of pre-trained LMs. However, LMs such as GPT2 are commonly fine-tuned in a myriad of ways (e.g., on a domain-specific text corpus) before being used to generate synthetic text. It is challenging to fingerprinting fine-tuned LMs because the universe of fine-tuned LMs is much larger in realistic scenarios. To address this challenge, we study the problem of large-scale fingerprinting of fine-tuned LMs in the wild. Using a real-world dataset of synthetic text generated by 108 different fine-tuned LMs, we conduct comprehensive experiments to demonstrate the limitations of existing fingerprinting approaches. Our results show that fine-tuning itself is the most effective in attributing the synthetic text generated by fine-tuned LMs.

1 Introduction

Background & motivation. State-of-the-art language models (LMs) can now generate long, coherent, and grammatically valid synthetic text (Devlin et al., 2019; Radford et al., 2018, 2019; Brown et al., 2020). On one hand, the ability to generate high quality synthetic text offers a fast and inexpensive alternative to otherwise labor-intensive useful applications such as summarization and chat bots (Yoo and Jeong, 2020; Yu et al., 2020; Wang et al., 2019; Liu and Lapata, 2019). On the other hand, such high quality synthetic text can also be misused by bad actors to launch spam, disinformation, or propaganda. For example, LMs such as Grover (Zellers et al., 2019) are shown to be capable of generating full-blown news articles, from just brief headlines, which are more believable than equivalent human written news articles. In fact, prior work has shown that humans cannot distinguish between organic (i.e., human written) and synthetic (i.e., generated by LM) text (Ippolito et al., 2020; Jawahar et al., 2020; Munir et al., 2021). Thus, this ability to generate high quality synthetic text can further be misused for social impersonation and phishing attacks because users can be easily misled about the authorship of the text.

Problem statement. To mitigate the potential misuse of LMs, the research community has started developing new text attribution techniques. However, as shown in Figure 1, the attribution of synthetic text is a multistage problem. The first step is to distinguish between organic and synthetic text (P1). Prior work has used the LM's output word probability distribution to detect synthetic text (Ippolito et al., 2020; Gehrmann et al., 2019; Zellers et al., 2019). However, there are several publicly available pre-trained LMs that might be used to generate synthetic text. Thus, the second step is to detect the pre-trained LM used to generate synthetic text (P2). Prior approaches showed promising results by attempting to fingerprint the LM based on its distinct semantic embeddings (Pan et al., 2020; Uchendu et al., 2020). However, pre-trained LMs such as GPT2 (Radford et al., 2019) are commonly fine-tuned before being used to generate synthetic text. Thus, the third step is to detect the fine-tuned LM used to generate synthetic text (P3). To the best of our knowledge,

prior work lacks approaches to effectively fingerprint fine-tuned LMs.

Technical challenges. It is particularly challenging to fingerprint fine-tuned LMs simply because of the sheer number of possible fine-tuned variants. More specifically, a pre-trained LM can be fine-tuned in a myriad of ways (e.g., separately on different domain-specific text corpora), resulting in a large number of classes. Another challenge to fingerprint fine-tuned LMs is that we cannot make assumptions about the nature of fine-tuning (e.g., parameters, training data) or generation (e.g., prompts). Prior work on fingerprinting pre-trained LMs is limited to evaluation on a small number of classes ($<$ 10 classes) and on synthetic text that is artificially generated using set prompts.

Proposed approach. To fingerprint synthetic text generated by fine-tuned LMs, we utilize the RoBERTa model (Liu et al., 2019) and attach a CNN-based classifier on top. We fine-tune the RoBERTa model for the downstream task of sentence classification using a synthetic text corpus. The fine-tuned model is used to extract embeddings as features that are then fed to the CNN classifier. We show that the fine-tuned RoBERTa model is able to capture the topic-specific distinguishing patterns of the synthetic text. Upon visualizing the generated features, the samples form closely-condensed distinguishable clusters based on the topic of the organic corpus the LMs have been fine-tuned upon. Therefore, we conclude that fine-tuning itself significantly helps fingerprinting a fine-tuned LM. Note that our fingerprinting approach does not assume access to the text corpus used for LM fine-tuning. We only assume access to arbitrary synthetic text generated by fine-tuned LMs.

Dataset. We gather a real-world dataset of synthetic text generated by fine-tuned LMs in the wild. More specifically, we extract synthetic text from the subreddit r/SubSimulatorGPT2. Each of the 108 users on r/SubSimulatorGPT2 is a GPT2 LM that is fine-tuned on 500k posts and comments from a particular subreddit (e.g., r/askmen, r/askreddit,r/askwomen). It is noteworthy that users on r/SubSimulatorGPT2 organically interact with each other using the synthetic text in the preceding comment/reply as their prompt.

Evaluation. We evaluate our models using a suite of evaluation metrics. We also adapt confidence-based heuristics, such as the gap statistic. Our best model is accurate for a large number of classes, across a variety of evaluation metrics, showing impressive results for the largest setting of 108 classes. While it obtains around 46% precision and 43% recall, its top-10 accuracy is about 70%. In other words, the correct class is one of the top-10 predictions in about 70% of the cases. If we give the model the option to not make a classification decision, via confidence estimation, it doubles the precision of the top classification from 46% to around 87% with a decrease of recall from 43% to 27%.

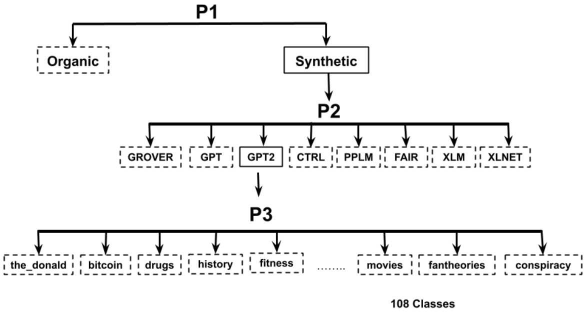

Figure 1: Attribution of text formulated as a series of three problems: P1, P2, and P3.

We summarize our key contributions as follows:

1. **Problem formulation.** To the best of our knowledge, we are the first to explore the problem of attribution of synthetic text generated by fine-tuned LMs (P3). We are also the first to investigate synthetic text attribution for a large number of classes on a real-world dataset. We also show that P3 is a much more challenging problem as compared to P1 and P2.
2. **Comprehensive model.** We design and implement a comprehensive set of different feature extraction techniques. We use them on a variety of machine learning and deep learning pipelines to build detection models.
3. **Rigorous evaluation.** We conduct rigorous evaluation on a real-world dataset of synthetic text generated by fine-tuned LMs. We use several evaluation metrics such as top-k accuracy and precision-recall tradeoff to compare different detection models. We also provide insights into the performance of different feature sets and classification algorithms.

Paper Organization: The rest of the paper is organized as follows. Section 2 contextuailzes our work with respect to prior literature. We analyze the real-world dataset of synthetic text generated by fine-tuned LMs in Section 3. Section 4 describes different feature sets and classification algorithms for fingerprinting fine-tuned LMs. Section 5 presents the results of our experimental evaluation before concluding in Section 6.

2 Related Work

Figure 1 illustrates three different problem formulations for attribution of synthetic text generated by LMs. The first line of research (**P1**) aims to distinguish between organic (by humans) and synthetic (by LMs) text. Given synthetic text, the second line of research (**P2**) further aims to attribute the synthetic text generated by pre-trained LMs such as BERT and GPT. Finally, in this paper, we further aim to (**P3**) attribute the synthetic text generated by fine-tuned LMs. Here, we first discuss prior work on **P1** and **P2** and then highlight the importance and unique challenges of **P3**.

P1: As the quality of synthetic text generated by LMs has improved, the problem of distinguishing between organic and synthetic text has garnered a lot of attention. Gehrmann et al. (2019) aimed to distinguish between synthetic text generated by GPT2 and Heliograf versus organic text by books, magazines, and newspapers. They showed that humans had a hard time classifying between organic and synthetic. Their proposed GLTR model, which uses probability and ranks of words as predicted by pre-trained LMs as features, was able to achieve 87% AUC. Zellers et al. (2019) developed Grover, a LM to generate fake news. They also showed that humans had a hard time distinguishing between organic and synthetic text generated by Grover. A classifier based on Grover achieved near perfect accuracy and significantly outperformed other classifiers based on pre-trained LMs. Ippolito et al. (2020) presented an interesting trade-off between distinguishability of organic and synthetic text. They showed that synthetic text optimized to fool humans is actually much easily detected by automated classification approaches. They generated synthetic text from pre-trained GPT2 using different sampling strategies and parameters, and used different classifiers such as GLTR that use pre-trained LMs and a purpose-built fine-tuned BERT based classifier. They showed that their fine-tuned BERT based classifier was able to significantly outperform other approaches as well as humans.

P2: Given synthetic text, recent work has further attempted to attribute authorship of synthetic text generated by pre-trained LMs. Uchendu et al. (2020) fingerprinted pre-trained LMs by attributing synthetic text to its author LM. They conducted exhaustive experiments using conventional authorship attribution models (Kim, 2014; Zhang et al., 2015; Cho et al., 2014) for eight pre-trained LMs – GPT (Radford et al., 2018), GPT2 (Radford et al., 2019) , GROVER (Zellers et al., 2019), FAIR (Ng et al., 2019), CTRL (Keskar et al., 2019), XLM (Conneau and Lample, 2019), XLNET (Yang et al., 2019), and PPLM (Dathathri et al., 2020). They showed that derived linguistic features when used with simple classifiers (Random Forest, SVM) perform the best. Pan et al. (2020) prepared a corpus of organic text and queried each of the five LMs – BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), GPT, GPT2 and XLNET, to generate pre-trained embeddings. Then, they trained a multilayer perceptron using the embeddings and obtained perfect accuracy in fingerprinting the pre-trained LM. Munir et al. (2021) used stylometric features as well as static and dynamic embeddings using ML classifiers to attribute synthetic text generated by four pre-trained LMs – GPT, GPT2, XLNet, and BART (Lewis et al., 2020). They obtained near perfect accuracy in fingerprinting pre-trained LMs on a purpose-built dataset of synthetic text.

P3: In this paper, we further attempt to attribute authorship of synthetic text generated by fine-tuned LMs. This problem is relevant in the real-world because malicious actors typically fine-tune a pre-trained LM for domain adaption (e.g., to generate fake news articles vs. food reviews) (Zellers et al., 2019). There are two main novel aspects of **P3** that make it more challenging than **P1** and **P2**. *First*, LMs can be fine-tuned in numerous different ways. More specifically, an attacker can use various datasets to fine-tune a pre-trained LM and further set the fine-tuning parameters and epochs in many different ways. Therefore, the size of the universe of fine-tuned LMs is expected to be quite large in **P3**. In **P1**, the problem is a simple binary classification problem (organic vs. synthetic). Similarly, in **P2**, the problem has still limited number classes because only a handful of pre-trained LMs are publicly available (e.g., GPT, GPT2, etc.). For instance, Munir et al. (2021), Pan et al. (2020), and Uchendu et al. (2020) respectively considered a universe of four, five, and eight pre-trained LMs. In contrast, in this paper, we consider 108 fine-tuned LMs. *Second*, prior work mostly considered attributing authorship of synthetic text generated in a controlled setting. For example, synthetic text is often generated by providing a topical prompt (Uchendu et al., 2020). As another example, the attribution classifier often assumes some information about the training data (Zellers et al., 2019). In contrast, here we consider the problem of attributing synthetic text in an uncontrolled setting assuming no control or knowledge about training or generation phases of fine-tuning LM.

3 Dataset

Prior work on detection and attribution of synthetic text has relied on artificial purpose-built datasets in a controlled environment. We overcome this issue by gathering a real-world dataset of synthetic text by different GPT2 bots on the r/SubSimulatorGPT2. Note that r/SubSimulatorGPT2 is independently designed and operated by its moderators. Each user on the r/SubSimulatorGPT2 subreddit is a GPT2 small (345 MB) bot that is fine-tuned on 500k posts and comments from a particular subreddit (e.g., r/askmen, r/askreddit, r/askwomen). The bots generate posts on r/SubSimulatorGPT2, starting off with the main post followed by comments (and replies) from other bots. The bots also interact with each other by using the synthetic text in the preceding comment/reply as their prompt. In total, the subreddit contains 401,214 comments posted between June 2019 and January 2020 by 108 fine-tuned GPT2 LMs (or class). The complete details of various design choices are described here: `https://www.reddit.com/r/SubSimulatorGPT2Meta/`

Table 1 lists some representative examples of the synthetic text generated by three different fine-tuned GPT2 LMs on our dataset. We note that the synthetic text is fairly coherent and also captures the unique vocabulary and style of the subreddit used for fine-tuning. For example, the excerpt from r/conspiracy reads like a conspiracy discussion, the excerpt from r/confession mentions a suggestive reply to the main post, and the excerpt for r/wallstreetbets uses the specialised finance terms like “puts”.

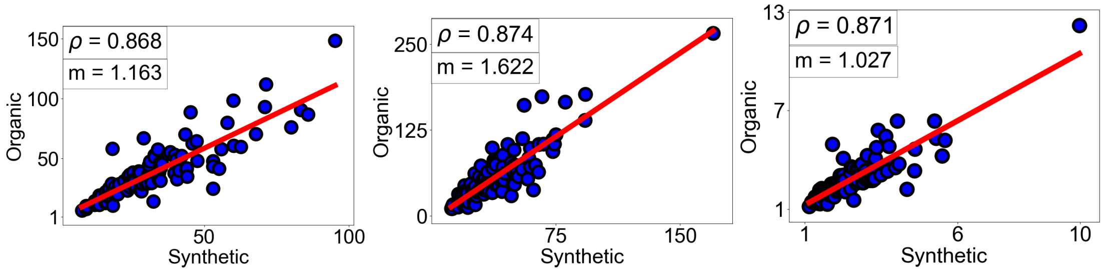
Next, we quantitatively compare and contrast synthetic and organic texts corresponding to different subreddits. To this end, we collect organic text from the corresponding subreddits. Specifically, we randomly sample 1,000 comments from each subreddit class of synthetic and organic text. We contrast basic lexical characteristics, vocabulary, and readability of synthetic and organic text.

Subreddit	Synthetic text excerpt
r/conspiracy	I’m sure the elite have been working to control what they do, but I don’t think they have the resources or manpower to control something as massive as the global economy.
r/confession	You need to tell her how you feel! She needs to know how you feel so that you can work out how to make the right decision. You can tell her how much you hate being a coward and how you’d never be able to live up to your promise.
r/wallstreetbets	There’s a huge amount of volatility right now that I don’t know how well my eyes can handle. I’m not going to buy any puts for the next week.

Table 1: Excerpts of synthetic text generated by GPT2 LMs fine-tuned on different subreddits.

Lexical. First, we contrast the following basic lexical features: average/standard deviation of number of words/sentences per comment. We also measure the Pearson correlation coefficient (ρ) between pairs of synthetic and organic texts in Figures 2a to 2d. We note a high correlation ($\rho > 0.83$) across all lexical features. Thus, we conclude that there is a strong dependency between the lexical characteristics of the synthetic and organic text. This finding indicates that *synthetic text generated by fine-tuned GPT2 models indeed captures the lexical characteristics of the corresponding organic text used for fine-tuning*.

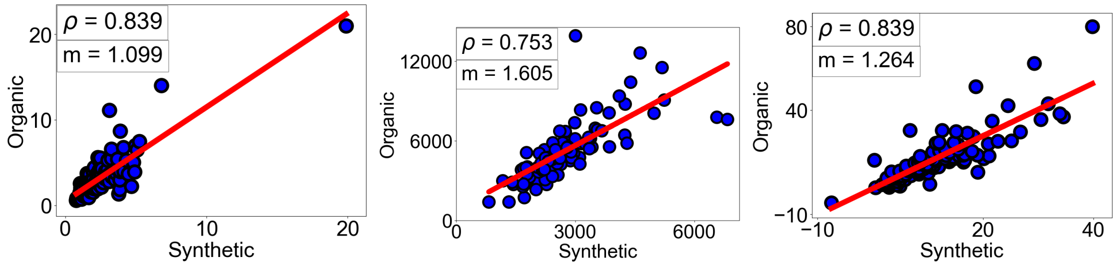
Vocabulary. Second, we compare the vocabularies of synthetic and organic text of each class. We do some basic pre-processing: lower-case, tokenize, and lemmatize all words, remove all punctuation and emojis, and replace hyperlinks and numbers with standard tags. Figure 2e compares the vocabulary size of synthetic and organic text. While organic text seems to have a large vocabulary than synthetic text, we note a strong correlation ($\rho = 0.76$) between their vocabulary sizes. We further compute Jaccard similarity to measure pair-wise vocabulary overlap between different synthetic and organic texts. Figure 3 visualizes the similarity matrices between all pairs classes – synthetic-synthetic, organic-organic, and synthetic-organic. It is noteworthy that the left



(a) Average #Words

(b) SD Words

(c) Average #Sentences



(d) SD Sentences

(e) Vocabulary Size

(f) KF Readability

Figure 2: A class-wise comparison of organic and synthetic text indicating strong correspondence in terms of: (a) average number of words; (b) standard deviation of number of words; (c) average number of sentences; (d) standard deviation of number of sentences; (e) vocabulary size; and (f) Kincaid-Flescher readability. ρ is the Pearson correlation coefficient and m is the slope of the linear fit.

diagonal represents much higher overlap between corresponding pairs of synthetic and organic text classes, even across synthetic-organic text classes. This finding indicates that the *fine-tuned GPT2 models indeed pick up the vocabulary from the organic text in the corresponding subreddit*. It is also noteworthy that the average vocabulary overlap among synthetic text classes in Figure 3a is much higher than that among organic text classes as shown in Figure 3b. This indicates that *synthetic text vocabulary combines information from both pre-training and fine-tuning* – the text corpus used to pre-train the base GPT2 model as well as the text corpus from the particular subreddit used to fine-tune it.

Readability. Finally, we compare the readability of the synthetic and organic text. Figure 2f compares the Kincaid-Flescher readability score (Kincaid et al., 1975) of synthetic and organic text. We note that the average readability of synthetic text (16.8) is less than that of organic text (11.5). This observation corroborates the findings in recent prior work (Uchendu et al., 2020). Similar to lexical and vocabulary analysis, we note a strong correlation ($\rho = 0.84$) between the readability of synthetic and organic text.

Additionally, using the organic text as reference, we measure the quality of the synthetic text using well-known metrics – METEOR (Banerjee and Lavie, 2005) and BLEU (Papineni et al., 2002). We observe that the synthetic text achieves high average scores across all the metrics. We include the results in the appendix.

Overall, we have two key takeaways: (1) synthetic text is *coherent* although with lower overall readability than organic text; (2) synthetic text captures the *characteristics of the organic text used to fine-tune it*.

4 Methods

Fingerprinting fine-tuned LMs needs to operate under the following realistic assumptions. (i) Fingerprinting methods cannot assume any knowledge about the nature of the LM, fine-tuning (e.g., parameters, layers) or generation (e.g., prompt). (ii) They also cannot assume any access to the organic text used for LM fine-tuning. (iii) Since a LM can be fine-tuned in a myriad of ways, these methods need to consider a large number of classes. (iv) These methods are assumed to have access to a limited sample of synthetic text generated by each of the potential fine-tuned LMs.

4.1 Pre-processing

We lower cased the comments and replaced all hyperlinks with a standard tag [*LINK*]. Next, we to-

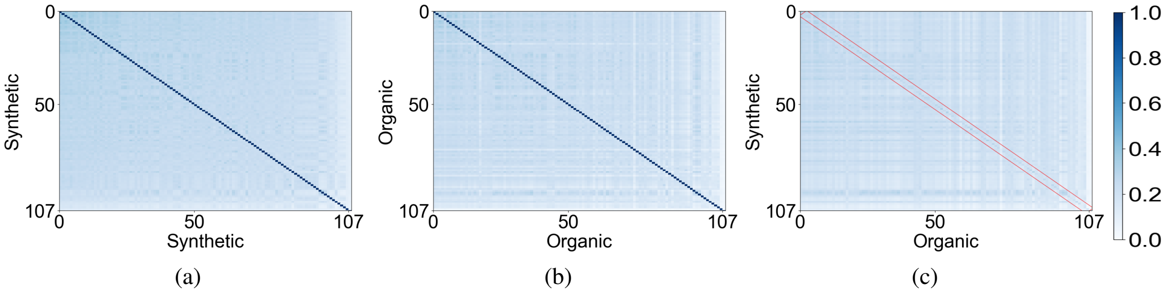


Figure 3: Pair-wise vocabulary overlap between classes of (a) synthetic text, (b) organic text, and (c) cross-comparison of organic and synthetic text. The higher intensity in (a) indicates more vocabulary overlap between classes of (a) synthetic text as compared to (b) organic text. The dark diagonal (highlighted in red box) in (c) indicates significant vocabulary overlap between the synthetic and organic text from the same subreddit.

kenized the comments. Any comment with 5 or fewer tokens was removed. The maximum number of tokens in a comment is limited to 75. In case a comment is larger, only the first 75 tokens in a comment are taken into consideration. This is consistent for all the models we experimented with. The limit was decided based on the limit of the size of the GPU (11GB) used for fine-tuning GPT2 and RoBERTa models.

4.2 Features

We consider several different feature extraction architectures to encode the synthetic text into representation vectors. As we discuss later, these representation vectors are then fed to classifiers.

Writeprints: Writeprints feature set has been widely used for authorship attribution (Iqbal et al., 2008; Pearl and Steyvers, 2012; Abbasi and Chen, 2006). We extract a total of 220 features that include *lexical* (e.g., total number of words, total number of characters, average number of characters per word, digits percentage, upper case characters percentage), *syntactic* (e.g., frequencies of function words, POS tags unigram, bigrams, trigrams), *content-based* (e.g., bag of words, bigrams/trigrams) and *idiosyncratic* (e.g., misspellings percentage) features.

GLTR: Gehrmann et al. (2019) used pre-trained LMs to extract word likelihood features – word ranks and probabilities. We follow the original approach to average the word probabilities of the text based on pre-trained BERT and GPT2. We also bin the word ranks into 10 unequal ranges. The bins are: [1], [2-5], [6-10], [11-25], [26-50], [51-100], [101-250], [251-500], [501-1000], [> 1000].

Glove: Glove embeddings (Pennington et al., 2014) have been commonly used in large-scale authorship attribution (Ruder et al., 2016). We follow (Kim, 2014; Zhang et al., 2015) to create a representation vector of the size (max # tokens × 100, where max # tokens is set to 75) using Glove.

Pre-trained LMs (GPT2 and RoBERTa): We also extract the embeddings for each comment using the pre-trained GPT2/RoBERTa model. Similar to Nils and Gurevych (2019); Feng et al. (2020); Zhu and de Melo (2020), we take the [CLS] token representation from the last layer to extract the embeddings of size 1×768. The final embeddings are then scaled between the values of [-3, 3] using min-max normalization.

Fine-tuned (FT) LMs (GPT2 and RoBERTa): We add a softmax classification layer to the pre-trained GPT2/RoBERTa model. Then, we fine-tune the LM for the task of sentence classification using the synthetic text in the training dataset. We again extract the embeddings (size = 1×768) by taking the [CLS] token representation from the second last layer. The final embeddings are then scaled between the values of [-3, 3] using min-max normalization.

4.3 Classifiers

Shallow classifiers: We use a probabilistic classifier – Gaussian Naive Bayes (GNB), an ensemble decision classifier – Random Forest (RF), and a feed-forward multilayer perceptron (MLP) across all of the feature representations.

CNN classifier: We experiment with a *stacked* CNN model where convolution layers with different kernel sizes are stacked before the embedding layer (Kim, 2014). In this architecture, we attach two stacked convolution 1D layer, followed by a batch normalisation layer and a max pooling layer.

Architecture	Classifier	Macro		Top-k	
		Prec	Recall	5	10
GLTR	GNB	5.5	4.4	12.9	20.9
	RF	7.8	6.6	12.6	19.0
	MLP	3.6	6.3	15.6	23.7
Writeprints	GNB	8.2	5.8	14.1	21.4
	RF	10.2	8.4	14.9	21.8
	MLP	16.9	14.7	30.8	42.1
GloVE	GNB	19.2	9.3	21.9	31.2
	RF	20.5	16.9	27.1	36.2
	MLP	29.7	27.2	44.4	54.1
	CNN	31.1	26.7	44.2	53.5
GPT2	GNB	24.8	12.4	27.8	37.7
	RF	10.5	7.8	15.8	27.1
	MLP	44.9	29.0	47.5	56.9
	CNN	30.9	28.7	49.1	59.1
RoBERTa	GNB	39.2	15.8	30.8	41.0
	RF	11.1	8.4	16.6	25.8
	MLP	44.0	34.8	54.8	62.5
	CNN	33.5	32.0	53.1	63.0
FT-GPT2	GNB	40.1	37.0	56.9	66.0
	RF	27.6	22.8	34.8	45.2
	MLP	40.2	36.4	55.7	64.0
	CNN	44.6	42.1	60.9	68.9
FT-RoBERTa	GNB	**47.7**	41.5	57.9	64.9
	RF	42.0	36.8	46.9	53.2
	MLP	42.8	41.5	58.2	65.3
	CNN	46.0	**43.6**	**62.0**	**69.7**

Table 2: Performance of multi-class classifiers based on macro Precision (Prec), Recall and top-k accuracy ($k = 5, 10$) for the largest setting of 108 classes.

The output is then fed to two dense layers, the latter of which is a softmax layer.

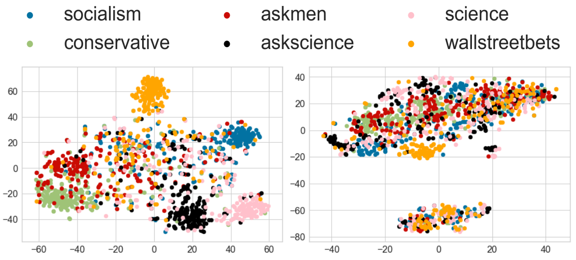
In addition, we also experiment with other shallow classifiers (SVM, Decision Tree) and two more types of feature generators (fine-tuned GLTR, trainable word embeddings). We report additional results, observations and the hyperparameters for all the models in the appendix.

5 Evaluation

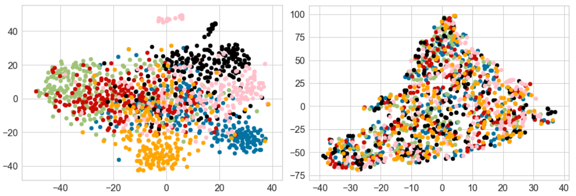
We conduct experiments to evaluate these methods using the real-world Reddit dataset as described in Section 3. Our training, validation, and test sets consist of 800, 100 and 200 synthetic comments respectively from each of the 108 subreddit classes. In total, our training, validation and test sets comprise 86k, 11k and 22k comments respectively. For evaluation, we use macro precision and recall. We also measure top-k accuracy based on the confidence score to assess the accuracy of the classifiers in k ($k = 5, 10$) guesses for 108 classes.

5.1 Results

Table 2 lists the results of different feature representations and classifiers. Overall, classifiers based on fine-tuned LM embeddings perform the best, with RoBERTa slightly outperforming GPT2. Fine-tuned embeddings are successfully able to capture the domain of the organic text the LM is fine-tuned on. To provide further insights into our best performing feature representations, we visualize the feature embeddings of pre-trained and fine-tuned RoBERTa and GPT2. Figure 4 plots the 2D projection of synthetic text (using t-SNE) generated by different LMs that are fine-tuned on various subreddits. Fine-tuned embeddings form more cohesive and separated clusters than pre-trained embeddings. Thus, we conclude that fine-tuning these embeddings is beneficial in attributing synthetic text generated by different fine-tuned LMs. Note that certain clusters are more cohesive and better separated than others. For example, the most distinct cluster is observed for r/wallstreetbets in Figures 4a and 4c for fine-tuned embeddings. However, it is not quite distinct in Figures 4b and 4d for pre-trained embeddings. We also note that some clusters with high topical similarity (e.g., r/science and r/askscience) are closer to each other. On the other hand, some clusters with likely lower topical similarity (e.g., r/socialism and r/conservative) are far apart.



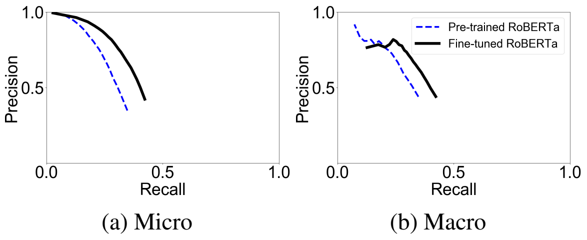
(a) Fine-tuned RoBERTa (b) Pre-trained RoBERTa



(c) Fine-tuned GPT2 (d) Pre-trained GPT2

Figure 4: Visualisation of fine-tuned (a,c) and pre-trained embeddings (b,d) of specific classes. Closely condensed clusters specific to the domain of the organic text form in the fine-tuned embeddings.

Despite combining word probabilities from both BERT and GPT2, GLTR is ineffective. We find that synthetic texts generated from different fine-tuned models have similar word probabilities because perhaps they are more impacted by the pre-training process rather than the subsequent fine-tuning. This shows that the classifier that performs well for distinguishing between organic and synthetic text (P1) does not work well



(a) Micro (b) Macro

Figure 5: (a) Micro and (b) Macro *precision-recall trade-off* by varying the gap statistic threshold. The comparison with *all baselines* is included in the appendix.

for distinguishing between synthetic text by different fine-tuned LMs (P3). Writeprints feature set provides some improvement but is still ineffective. Our finding corroborates Manjavacas et al. (2017), who reported that linguistic and stylistic features as used in Writeprints are not effective in distinguishing between synthetic text. GloVE again offers some improvement over Writeprints but its performance remains significantly worse than that of our best performing method.

Overall, fine-tuned RoBERTa embeddings with CNN performs the best with 46.0% precision and 43.6% recall. In about 44% of the cases, this classifier can correctly fingerprint fine-tuned LM amongst 108 classes; in about 70% of cases the correct prediction is one of the top-10 guesses. It is noteworthy that Random Forest which performed exceedingly well in prior work on fingerprinting pre-trianed LMs (Uchendu et al., 2020), does not perform well for fingerprinting fine-tuned LMs. Surprisingly, a relatively simple classifier like GNB achieves comparable precision and recall for our top guess. However, CNN outperforms GNB by a small margin, achieving the best top-10 accuracy of 69.7% for FT-RoBERTa.

5.2 Discussion

Next, we analyze the performance of our best performing RoBERTa feature representation and classifier (CNN) under different conditions.[1]

Precision-Recall trade-off. We evaluate the precision-recall trade-off by imposing a threshold on the confidence of our prediction. To this end, we use the *gap statistic*, defined as the difference between the probability of the highest and second highest prediction (Narayanan et al., 2012). If the gap statistic is lower than our threshold, the classifier chooses to not make a prediction for the test sample. This invariably has an impact on precision and recall. Typically, the precision of the classifier increases, since it can more accurately predict the correct class for the samples it has a high confidence in. Due to certain samples not being predicted for, recall is expected to decrease. Note that since the classifier may make different number of predictions across classes, micro and macro precision/recall could be different.

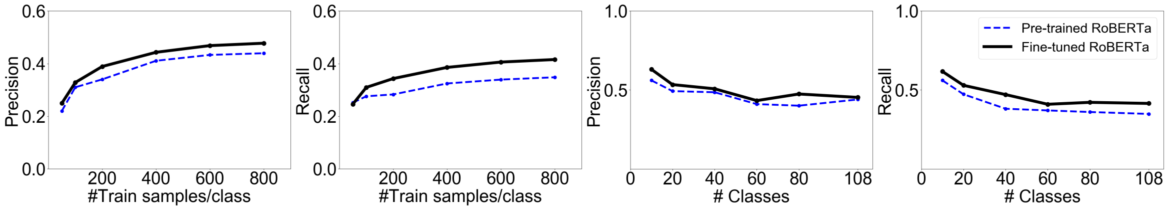
Figures 9a and 9b respectively plot the micro and macro precision/recall as we vary the gap statistic. Overall, the classifier using FT-RoBERTa embeddings achieves a better precision-recall trade-off compared to using standard RoBERTa embeddings. As expected, precision improves at the expense of recall for larger values of gap statistic. Micro precision increases 46% to over 87% with a reduction in the micro recall from 43% to 27%. Similarly, despite potential class imbalance, macro precision increases 46% to over 81% with a reduction in the micro recall from 43% to 26%. Thus, we conclude that the confidence of our best performing fingerprinting method can be tuned to achieve very high precision with some compromise on recall.

Impact of number of training samples. Next, we evaluate the impact on the performance of our best models by varying training size from 50 to 800 samples per class. As we vary the training data, we keep the same test set, i.e., 200 samples from each class. Figures 8a and 8b, respectively show that precision and recall of FT-RoBERTa plateau at around 400 samples per class. Despite at twice the training data, using training 800 samples per class has similar precision/recall as compared to using 400 training samples per class. We conclude that having more training samples of synthetic text may not always lead to a significant improvement in fingerprinting performance.

Impact of number of classes. We further vary the number of classes from 10 to 108 and report the performance of our best models. Figures 8c and 8d show that for a 10-class problem, FT-RoBERTa + CNN achieves 63.0% precision and 61.7% recall. As expected, both precision and recall decrease as the number of classes increases. For 108 classes, the same classifier achieves 46.0% precision and 43.6% recall. This indicates that fingerprinting a fine-tuned LM is highly challenging when the universe of potential fine-tuned LMs is larger.

---

[1] Other baseline results are reported in the appendix.



(a) (b) (c) (d)

Figure 6: Comparison between the performances of pre-trained and fine-tuned RoBERTa by varying different parameters. (a) Precision and (b) Recall with the varying training size. (c) Precision and (c) Recall with the varying number of classes. Overall, fine-tuned RoBERTa outperforms pre-trained RoBERTa. The comparison with *all baselines* is included in the appendix.

6 Conclusion

In this paper, we studied the problem of attribution of synthetic text generated by fine-tuned LMs. We designed a comprehensive set of feature extraction techniques and applied them on a number of different machine learning and deep learning pipelines. The results showed that the best performing approach used fine-tuned RoBERTa embeddings with CNN classifier. Our findings present opportunities for future work on fingerprinting LMs in even more challenging open-world scenarios, where the list of potential LMs might be incomplete or synthetic text is not available to train attribution classifiers.

Ethics and Broader Impact

Any biases found in the gathered dataset are unintentional, and we do not intend to do harm anyone. We would also like to acknowledge that the use of large-scale transformer models requires non-trivial compute resources (GPUs/TPUs) that contributes to global warming (Strubell et al., 2019). However, we did not train the models from scratch and simply fine-tuned them for our work.

A Appendix

A.1 Implementation, Infrastructure, Software

We run all experiments on a 24-core machine with two Intel(R) Xeon(R) Silver 4116 CPU@2.10GHz CPU's and 512 GB RAM. Additionally, the server has a GeForce RTX 2080 Ti (11 GB) GPU card. We use huggingface, pytorch (1.4.0) and Tensorflow (v.1.23.0) to implement and evaluate all deep learning models in the paper. For classical ML, we utilize scikit-learn (v.0.23.1). All implementations are done using Python language (v.3.7).

A.2 Hyper-parameters

Fine-tuned RoBERTa + CNN: We attach 2 CNN convolutional 1D of kernel sizes 2 and 3 layers back to back. The stride for both the layers is 1. The number of output filters for each of the two convolutional layers is 16. We then attach a batch normalization layer of size 16. This is followed by a max pooling layer of size 2 with stride 1. We fine-tuned the model for 15 epochs and monitored the validation loss. If the validation loss did not improve for 5 consecutive epochs, we stopped the fine-tuning.

Fine-tuned RoBERTa + Dense: We used RoBERTaForSequenceClassification wrapper from the huggingface module, which attaches a softmax layer on top of pre-trained RoBERTa model. We extracted the embeddings of the second to last layer of size 1x768. For all of our models, we used a *AdamW* optimizer with a learning rate of 0.00005. We used batch size of 48 and only picked the first 75 tokens of each token. We did not use any padding.

For the soft classifiers, using the fine-tuned RoBERTa embeddings, we obtained the best results with the following parameters -

SVM: C = 0.1, cachesize=200, classweight = None, coef0 = 0.0, degree=3, gamma='scale', kernel='linear', tol=0.001

MLP: activation='relu', alpha=0.01,epsilon=1e-08, hiddenlayersizes = 64, learningrate='adaptive', learningrateinit=0.0001

RF - criterion='entropy', maxdepth=None, maxfeatures='auto', maxleafnodes=None, minsamplesleaf = 1

DT - criterion = 'entropy', maxdepth = None, maxfeatures = None, maxleafnodes=None, minsamplesleaf = 1

GNB - Default sklearn parameters performed the best

A.3 Running Time

All fine-tuned models took a maximum of 8 minutes per epoch. For the soft classifiers, MLP and SVM took the maximum time. Due to the large size of the dataset and the large embedding space, SVM took about 6 hours to train. MLP took an average of 3 hours. Rest of the classifiers took less than an hour for training.

A.4 Additional Results

A.4.1 Additional Dataset Analysis

Besides the analaysis in the dataset section of the main text, we used 4 metrics - METEOR, BLEU, GLEU and CHRF for measuring the coherency of the synthetic text, using the organic text as reference. Using 1000 comments from each class of synthetic and organic text, we obtained high class-wise average scores on all metrics - METEOR (0.31), BLEU (0.58), GLEU (0.63) and CHRF (0.51). This provides further evidence that synthetic text is coherent and readable when compared to its organic counterpart. In figure 7 , we illustrate the scores for each individual class, sorted by increasing CHRF scores.

A.4.2 Feature extraction

Besides the feature extraction methods we mentioned in the Methods section of the main text, we also experimented with two more methods:

1. **Fine-tuned GLTR:** Using the training set, we fine-tuned separate BERT and GPT2 models for each class for the task of mask completion. All models were then used for extracting GLTR word likelihood features for the complete training and test sets. Subsequently, the training representations were then fed to a sequential neural classi-

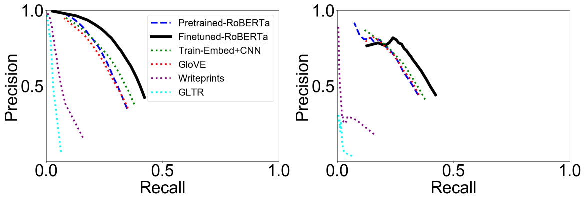
Figure 8: A comparison between the performances of various embeddings by varying problem parameters. (a) Precision and (b) Recall with the varying training set size. (a) Precision and (b) Recall with the varying number of classes. Overall, fine-tuned RoBERTa outperforms all the baselines.



(a) Micro (b) Macro

Figure 9: (a) Micro and (b) Macro *precision-recall trade-off* by varying the gap statistic threshold.

Base Architecture	**Classifier**	**Macro**		**Top - 5**	**Top - 10**
		Precision	**Recall**		
Writeprints	DT	6.9	6.6	6.6	6.6
	SVM	19.3	16.3	33.2	44.8
GLTR	DT	5.7	5.5	5.57	5.58
	SVM	7.3	7.0	10	13.1
RoBERTa	DT	6.3	5.3	6.3	6.3
	SVM	8.3	6.9	7.8	8.9
Trainable-Word	MLP	20.4	18.9	34.3	44.3
	CNN	28.6	27.0	44.0	53.1
FT RoBERTa	Dense	44.0	42.3	60.8	68.9
	DT	29.5	28.7	28.7	28.7
	SVM	42.7	41.1	58.3	65.6

Table 3: Results of Decision Tree (DT) and SVM with the embeddings. We also include the results of the trainable word embeddings model.

fier like Bi-LSTM. The intuition was that word likelihoods extracted using the class's fine-tuned GLTR model would be high for synthetic text generated for the class's language model. For example, a r/wallstreetbets fine-tuned GLTR feature extractor would extract higher word likelihoods, as compared to other GLTR models, from a synthetic comment generated by the language model fine-tuned on r/wallstreetbets. However, for an extremely small setting of 5 classes, we only obtained a precision and recall of around 33% each. Due to the (a) expensive cost of fine-tuning 108 BERT and GPT2 models, (b) expensive cost of extracting GLTR features for a dataset of 100k examples, (c) extremely poor results of the approach on a small setting, we did not continue with experimenting the model in a larger setting.

2. **Trainable word embeddings** - We tokenized and represented each comment using an allocated set of integers based on the vocabulary of the training set. Then, similar to the GloVE feature extraction, we passed the representation into a trainable word embedding layer, followed by MLP or CNN. The results for these were slightly worse than that for the GloVE features. We report the results in Table 3.

Additionally, for all the feature representations mentioned in the main text, we tested SVM and decision tree. Overall, they were outperformed by the other classifiers with one notable exception. For Writeprints features, SVM showed the best results of precision and recall of 19.3% and 13.3% respectively. We report the results in Table 3.

A.5 Other baselines

Precision-recall trade-off. For the precision-recall trade-off in the results section of the main text, we presented a comparison with additional baselines in Figure 9. Fine-tuned RoBERTa performs the best among all methods for both micro and macro precision-recall trade-offs. They are followed in a decreasing order by the pre-trained RoBERTa embeddings, the trainable word embeddings, the GloVE word embeddings, Writeprints, and GLTR respectively.

Training set size and classes. We report the comparison with all other baselines for the varying training size and the number of classes in Figure 8. Similar to the precision-recall trade-off, the fine-tuned RoBERTa embeddings perform the best, followed by pre-trained RoBERTa embeddings, GloVE word embeddings, trainable word embeddings, Writeprints, and GLTR.

Analyzing Code Embeddings for Coding Clinical Narratives

Abstract

Medical professionals review clinical narratives to assign medical codes as per the International Classification of Diseases (ICD) for billing and care management. This manual process is inefficient and error-prone as it involves a nuanced one-to-many mapping. Recent works on automated ICD coding learn mappings between low-dimensional representations of the reports and the codes. While they propose novel neural networks for encoding varied types of information about the codes, it is unclear as to what information in the medical codes is helpful for performance improvement and why. Here, we compare different ways to represent, or embed, the codes based on their textual, structural and statistical characteristics, using a single deep learning baseline model in quantitative evaluations on discharge reports from the MIMIC-III Intensive Care Unit database. We also qualitatively analyse the nature of the cases that benefit most from the code embeddings and demonstrate that code embeddings are important for predicting ambiguous and oblique codes.

1 Introduction

Free-text clinical narratives contain the majority of information pertaining to patient state, disease progression and care management. Following a patient encounter, the text reports from the visit are codified by representing the key diagnoses and procedures according to the International Classification of Diseases (ICD) system (Medicode (Firm), 1996). The resulting ICD codes are used for a variety of diagnostic, billing, epidemiology and research purposes (Bach and First, 2018; Feder et al., 2018; Alsentzer et al., 2019).

The process of ICD coding, i.e., mapping clinical text reports to ICD codes, is challenging. It involves processing diverse domain-specific text with large vocabulary and significant irrelevant content to make a nuanced choice of a small set of codes from a high-dimensional taxonomy of 15,000 ICD codes. Hence, manual ICD coding tends to be time-intensive, costly, and error-prone (Lang, 2007; Shi et al., 2017; Xie and Xing, 2018), and there is great interest in automated ICD coding methods.

Previous works on automated ICD coding have employed conventional rule-based or machine learning methods (Larkey and Croft, 1996; Farkas and Szarvas, 2008; Perotte et al., 2014). Recently, deep learning methods (Baumel et al., 2017; Xie and Xing, 2018; Nie et al., 2018; Mullenbach et al., 2018; Vu et al., 2020; Cao et al., 2020; Teng et al., 2020; Yuan et al., 2020) have achieved leading-edge performance. Of these, the best performing deep learning approaches typically employ attention mechanisms to use representations of the ICD codes to guide the model's predictions. However, the specific representations of the ICD codes used vary from code textual descriptions (Mullenbach et al., 2018) and code hierarchy (Vu et al., 2020; Cao et al., 2020) to code co-occurrences (Cao et al., 2020) and graph of medical entities associated with codes (Teng et al., 2020; Yuan et al., 2020). Yet, it is unclear which ICD code representation is most effective, what types of cases would benefit from these representations, and why.

Addressing these gaps requires comparing different code embeddings within one united framework. We introduce a simple attention mechanism to leverage varied statistical, textual, structural representations of ICD codes and enhance a predefined baseline clinical notes classifier. We use discharge reports within the benchmark MIMIC-III Intensive Care Unit database (Johnson et al., 2016) for comparative evaluation, and perform extensive experiments to characterize effects of dif-

August 1–6, 2021.

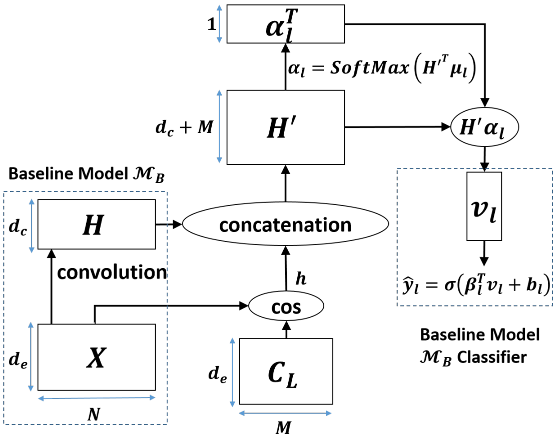

Figure 1: Proposed model architecture

ferent code embeddings on prediction performance. Quantitative results show that our proposed attention mechanism (a) enables 7-9% micro-F-1 boost over the baseline classifier, and (b) performs at least as accurately as more advanced two-level attention, hyperbolic embedding or graph convolutional network approaches. We further perform qualitative analyses and show that our attention network enables large improvements when the coding task is more ambiguous or nuanced. Our approach and findings offer practical means to enhance performance in nuanced text classification tasks.

2 Methods

The task entails mapping a given free-text discharge report to a set of ICD codes. This is a multi-label text classification problem. We propose an approach for learning varied textual, structural and statistical representations of the ICD codes (i.e., code embeddings), and employing them to enhance performance of a given baseline model.

2.1 Attention to Code Embeddings

Figure 1 illustrates the architecture. We start with a given baseline model $\mathcal{M}_B$ based on a convolutional layer. $\mathcal{M}_B$ takes word embeddings $X \in \mathbb{R}^{d_e \times N}$ of words in a given report as input and learns to generate their hidden representation $H \in \mathbb{R}^{d_c \times N}$, where N is the length of input medical narratives after padding, d_e is the input embedding size, and d_c is the number of filters. We propose code embeddings $C_L \in \mathbb{R}^{d_e \times M}$ as an auxiliary for $\mathcal{M}_B$, where M is the number of ICD codes. We compute the cosine similarity between X and C_L, and denote the result as h. We then compute per-label attention weights α_l as follows:

$$\alpha_l = \mathrm{SoftMax}(\begin{bmatrix} H \\ h \end{bmatrix}^{\mathrm{T}} \mu_l), \qquad (1)$$

where [ ] indicates concatenation (denoted as H') and $\mu_l \in \mathbb{R}^{d_c+M}$ is a vector parameter for label l. Weights α_l denote attention from the note representation to the code representation for label l and can be used to enhance performance of $\mathcal{M}_B$ (e.g., as shown in Figure 1). Then we apply the attention weights α_l to H' to get the final representation v_l of an input report corresponding to label l. We also adopt the same classifier as $\mathcal{M}_B$, which uses a linear layer and a sigmoid transformation, as illustrated in the right dotted box, where β_l and b_l are the weight and bias of the classification layer for label l, respectively. $\hat{y}_l$ is the binary classification probability that X belongs to l.

We set both the word embeddings for text input and the code embeddings for ICD codes as non-trainable to give the best performance. Our proposed method introduces only a small number of learnable parameters for labels.

2.2 Code Embeddings

Each ICD code has a unique identifier and a text description and is structurally situated in a tree hierarchy. Further, based on the reports labelled with any given ICD code, we can obtain sample statistics of the code usage. We propose to learn embeddings or representations that capture the above textual, structural, and statistical characteristics of ICD codes, as described below.

Textual code embeddings are obtained by either (a) averaging word vectors (Mikolov et al., 2013) of the words in the description of a code (denoted as CE-w2v) or (b) learning the contextual representation of the code description with BERT (Devlin et al., 2019) (denoted as CE-BERT). For CE-w2v, we use gensim[1] to train the word vectors with discharge reports. For CE-BERT, we use Keras BERT[2] uncased large model to get contextualized word representations, apply max pooling to all the word representations and then add a linear layer for dimension reduction to get code representations with 100 dimensions. This is integrated end-to-end into our model.

Structural code representations leverage the

---

[2] `https://github.com/CyberZHG/keras-bert`

ICD tree hierarchy. We capture the parent-child and sibling relations in triples (e.g., (401, *ParentOf*, 401.1) or (401.1, *SiblingOf*, 401.9). We then feed the triples into a knowledge graph embedding approach such as TransR (Lin et al., 2015) (denoted by CE-TransR).

Statistical code representations are learned from the sample statistics between ICD codes and the discharge reports from the training dataset. We designate the embedding of code l as the weighted average of word vectors, as follows:

$$C_l = \frac{1}{N} \sum_{i=1}^{N} v_{w_i} \sum_{d \in docs(l)} tf(w_i, d), \qquad (2)$$

where the weight of a word vector v_{w_i} is proportional to the sum of term frequencies of the word in the notes that are labelled with the code l; N indicates the size of the dataset vocabulary; docs(l) refers to the set of notes associated with code l; and tf(w_i, d) is the function that returns the term frequency of the word w_i in document d. We apply smoothing with increasing all word counts by one, and denote resulting embeddings as CE-Stat.

3 Experiments

We follow the recent state-of-the-art (SOTA) ICD coding studies and perform experiments on the benchmark Medical Information Mart for Intensive Care-III (MIMIC-III) dataset (Johnson et al., 2016). Specifically, we implement our proposed code embeddings (denoted as CE-xxx) atop the popular CAML baseline (Mullenbach et al., 2018). Note that our approach is amenable to any baseline of choice.

Data: Like previous works (Mullenbach et al., 2018; Vu et al., 2020), we focus on multi-label classification task of mapping the discharge reports in the MIMIC-III dataset to ICD codes. Preprocessing details are listed in Appendix A.1. The resultant preprocessed dataset, termed as FULL, has over 52,700 discharge reports associated with subsets of over 8,929 ICD codes (unlike the 8,921 ICD codes reported in prior works). We evaluated our approach on the FULL dataset.

As our focus was to understand what information in ICD codes enables performance improvement, we also investigated whether and to what extent the choice of a code subset affects performance. Therefore, we created new subsets of MIMIC-III (termed sub-datasets) for further evaluation. Specifically, we selected the top *k* frequent ICD codes in the FULL MIMIC-III dataset and collated the subset of discharge reports tagged with at least one of the top *k* frequent codes. We term the sub-datasets as Top-k for k=20, 50, 100 and 300.

Finally, we also evaluated our approach on the more widely used subselection of top-50 codes (termed as Top-50$^+$) (Shi et al., 2017). We note that the Top-50$^+$ dataset is much smaller than the other Top-k and FULL datasets because it excludes reports without associated diagnosis descriptions. The detailed breakdown of the dataset sizes and splits are showed in Appendix A.2.

Evaluations: We evaluate performance against two baseline models (i.e., $\mathcal{M}_B$): (a) CAML which uses a per-label attention mechanism within a convolutional neural network (CNN) classifier and (b) DR-CAML which uses code embeddings to constrain the learned model parameters of CAML (Mullenbach et al., 2018). We provide all parameters and model tuning details of the proposed method in Appendix A.3. We follow prior works and report micro-F1 to evaluate model performance, and showcase detailed comparisons for other common metrics. For each experiment, we report averages from 3 independent runs.

Comparative Results on Top-k Sub-Datasets: Table 1 shows the performance of our CE approach compared with baselines on the 5 MIMIC-III sub-datasets. Our CE approach (any embedding type) outperforms the baselines in all the Top-k sub-datasets. We observe that CE-w2v, CE-BERT and CE-TransR lead to slightly better performance than CE-Stat. CE also obtains comparable results on the FULL dataset compared to the baselines. As prior works did not focus on understanding the relation between information in the codes and model performance, there are no reported results on our Top-20, Top-50, Top-100, and Top-300 datasets. Thus, we only compared with baselines in Table 1.

We highlight that our experiments on the FULL dataset were limited by the memory size of the GPUs used. To address this, we reduced batch size of our method (from 128 to 16) and also applied a linear layer to reduce the number of dimensions (M) from the number of FULL codes to 50. Consequently, for the FULL dataset, our CE approach does not improve over baselines and SOTA. However, as our results indicate ability to consistently improve over baselines for different datasets, we posit that increasing batch size and allowing attention to focus on all the FULL codes would enable

Data size	Top-20	Top-50	Top-100	Top-300	FULL†

our approach to perform comparably with SOTA.

Comparisons with SOTA on Top-50^+: As the Top-50^+ benchmark is the common dataset evaluated in all SOTA works, we tabulate the results of our proposed approach on the Top-50^+ dataset in relation to previously published SOTA results in Table 2. We observe that our approach outperforms all previous methods in terms of macro-/micro-averaged F1 and AUC, except for Vu et al. (2020) (Vu et al., 2020). The performance of Vu et al. (2020) (Vu et al., 2020) is slightly higher than ours, as they use a model based on bidirectional long short-term memory (Bi-LSTM) (Hochreiter and Schmidhuber, 1997) with a similar but more complex attention mechanism. While we also ran experiments with Bi-LSTMs, we found that they tend to be computationally intensive and often did not converge, and thus focused on the more practical CNNs. We further tried to combine code embeddings of different kinds (e.g. CE-w2v + CE-TransR) to see if there is any synergistic effect, but found that no such combination led to performance improvement. We report results of the combination experiments on Top-50^+ in Appendix A.4.

4 Qualitative Analysis

To dissect gains of the code representations, we performed qualitative analyses on the Top-50^+ test results.

Data Selection: For each CE embedding, we computed the per-code micro-F1 gains over baseline CAML, summed the gains across all the CE embeddings, and rank-ordered the ICD codes by total micro-F1 gain. Next, we selected the 10 codes with the highest gains over baseline (CE $\gg$ baseline) and also the 10 codes with the least gains over baseline (CE $\approx$ baseline). For the first selection (those with the highest gains over baseline), our 4 CE methods typically improve over the baseline. For the second selection of the 10 lowest gain codes, CE is almost always as good as the baseline in these cases. Specifically, out of all discharge summaries for the second selection, the baseline outperforms all 4 CE methods in only 0.2% of cases and 2 out of 4 CE methods in only 1.2% of cases. Hence, we term this second selection as "CE $\approx$ baseline". For qualitative review, we randomly sampled 5 cases corresponding to each of these 20 codes from the Top-50^+ testset and obtained 100 cases.

Review Procedure: All qualitative analyses were performed independently by two clinical reviewers. After analysis, the two reviewers discussed to arrive at consensus. First, for each of the 20 codes selected, reviewers considered the ICD coding guidelines and assessed whether they fall into medical, procedural, or surgical categories. Next, for each of the 100 cases selected, reviewers read the discharge reports and marked out reports that did not have any viable information relating to the code assignment for exclusion from further analysis. Second, for reports deemed viable, the

Explicit & Oblique	2	6
Explicit	10	15

Figure 2: Results of Qualitative Analysis

reviewers assessed whether the reports explicitly delineated the codes (e.g., word-to-word match with code description or synonymous mentions) or contained information that more obliquely relates to the codes (e.g., mentions which might lead a domain expert with specialized knowledge to indirectly infer the code). Third, reviewers further indicated whether the mentions were sparse (1-2 circumscribed mentions) or not (several mentions or extensive sections relating to the code). Finally, reviewers marked out whether the reports had diverse expressions linking to the codes.

Qualitative Analysis Results: Figure 2 details the results. Comparing the code characteristics, we observe that codes where CE gains more tend to (a) have descriptions that include "unspecified" or "not elsewhere classified" and (b) fall into the medical category. In contrast, codes where CE does not gain much tend to be more procedural or surgical in nature. Next, comparing characteristics of the mappings between the notes and the codes, we observe that cases where CE gains more tend to have more oblique mentions; while cases where CE does not gain much tend to have more explicit mentions. This suggests that code embeddings may provide more gains in cases where the discharge reports more obliquely correspond to the code. We detail more in Appendix A.5 and A.6 by providing excerpts from 2 exemplar cases and also showing that CE enables strong Micro-F1 gains on the oblique codes (codes with descriptions including "unspecified" or "not elsewhere classified") of the FULL dataset.

We found that the numbers of cases with sparse mentions were similar for the cases where CE gained more vs. less over baseline. That said, the reviewers did observe that codes such as "Tobacco use disorder" were largely associated with sparse mentions and these kinds of cases were more likely to be accurately predicted with CE than with the baseline. We also note that the cases corresponding to higher gains for CE tended to have more diversity in expression.

5 Conclusions and Future Work

We proposed and characterized methods to leverage representations that capture statistical, textual, and structural properties of medical codes for clinical report coding. We implemented the proposed method on a simple but efficient baseline system and demonstrated substantial performance improvements in micro-F1. Additionally, we performed qualitative evaluation studies to show that our method is more useful in cases when the code prediction task is more ambiguous or nuanced. Future work will experiment with more general datasets and enhancements of the attention network to further improve performance.

A Appendix

A.1 Data Preprocessing

We preprocess discharge reports following CAML. By retaining a maximum of 2,500 words for each summary, we obtain a vocabulary of about 52,000 words. We found there is a minor parsing error in CAML data preprocessing. When CAML read diagnosis and procedure codes from MIMIC III PROCEDURES_ICD.csv and DIAGNOSES_ICD.csv using Python function pandas.read_csv(), the data type of codes used is numpy.int64. In fact, the data type should be str. We correct this error by indicating the data type. For full codes, the number of common codes contained in our produced codes and CAML codes is 8706. For top-50 codes, only one code is different.

A.2 Dataset Splits and Details

Data size	Top-20	Top-50	Top-100	Top-300	FULL	Top-50^+
Train	42,590	44,804	46,458	47,285	47,724	8,067
Dev.	1,471	1,574	1,600	1,622	1,632	1,574
Test	3,054	3,242	3,291	3,352	3,373	1,730

Table 3: Data splits details

Table 3 shows the number of discharge summaries contained in the training, development and test data for all the top-k, full and Top-50^+ data. We can see through sub-selection, Top-50^+ is much smaller than the other data.

A.3 Parameters and Model Tuning

Our code embeddings introduce extra training parameters due to the changes in attention structure. For a Top-k dataset, $2k^2$ more parameters are added. For small k, this number is negligible. For greater k, such as the FULL dataset, we add one fully-connected layer after h to reduce the first k in $2k^2$ to a fixed number, so that the number of the introduced parameters is smaller than the number of original parameters of CAML.

We also tuned the batch size and learning rate to enhance performance. For top-20/50/100/300 data, we use a fixed batch size of 128 in all our models. For Top-50^+ and FULL, we use a fixed batch size of 16 in all our models. Due to the expensive GPU memory cost in cosine matrix computation and the large number of added feature maps, we add a linear layer to reduce the size of cosine matrix. For all datasets, we set learning rate to 0.001. For CAML based methods, we use the settings from (Mullenbach et al., 2018).

A.4 Detailed Evaluation on Top-50^+

We report deeper analyses on the Top-50^+ benchmark in Table 4. We first assess whether CE improves performance over CAML by adding more features to the representation of a discharge report. Specifically, we add 50 filters (thus enhancing number of features) to those used in CAML and DR-CAML, and denote the revised models as CAML_add and DR-CAML_add. We observe that the additional filters offer limited improvements in comparison with the CE approach (any embedding). This suggests that our CE approach may not just be adding more features to improve performance. Next we assess if combining the different CE embeddings would enable even better performance. We experiment with several combinations of our different code embeddings: (a) CE+WT combining CE-w2v and CE-TransR, (b) CE+WTS combining CE-w2v, CE-TransR and CE-Stat, and (c) CE+BTS combining CE-BERT, CE-TransR and CE-Stat. We observe that the combinations of CE embeddings do not improve the performance much over individual CE embeddings. This suggests that dot product of discharge summary representation with concatenation of multiple code representations may not have synergistic effects.

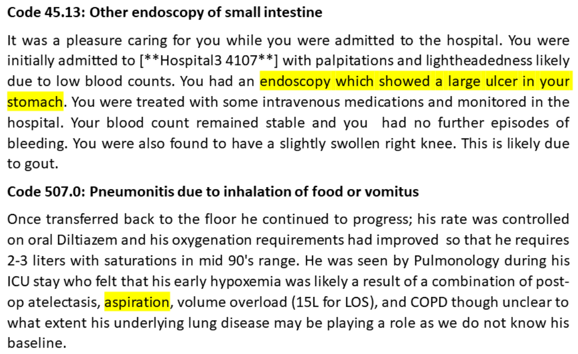
We look into the oblique codes in the testing data of FULL. We select the codes of which the code descriptions containing keywords from [“unspecified”, “not elsewhere classified”, “other”]. Table 5



Code 45.13: Other endoscopy of small intestine

It was a pleasure caring for you while you were admitted to the hospital. You were initially admitted to [**Hospital3 4107**] with palpitations and lightheadedness likely due to low blood counts. You had an endoscopy which showed a large ulcer in your stomach. You were treated with some intravenous medications and monitored in the hospital. Your blood count remained stable and you had no further episodes of bleeding. You were also found to have a slightly swollen right knee. This is likely due to gout.

Code 507.0: Pneumonitis due to inhalation of food or vomitus

Once transferred back to the floor he continued to progress; his rate was controlled on oral Diltiazem and his oxygenation requirements had improved so that he requires 2-3 liters with saturations in mid 90's range. He was seen by Pulmonology during his ICU stay who felt that his early hypoxemia was likely a result of a combination of post-op atelectasis, aspiration, volume overload (15L for LOS), and COPD though unclear to what extent his underlying lung disease may be playing a role as we do not know his baseline.

Figure 3: Illustrations of Oblique Coding Cases

shows the Micro-F1 scores of our code embedding methods compared with the baseline methods. From the table, we can see our methods perform better on the oblique codes, especially CE-w2v.

A.6 Case Illustrations

To provide richer insight on the qualitative analysis, we provide two case illustrations, shown in Figure 3. In both cases, the indicated ground truth codes were missed by the baseline but predicted correctly by our CE approach. In the first case (i.e., code 45.13), there are synonym mentions of "EGD" in the Major Surgical Procedure, Images, and Brief Hospital Course subsections of the report. However, indirect phrases on the type of endoscopy performed in the Discharge Instructions imply that this is specifically a case of upper gastrointestinal endoscopy, which leads to the said code assignment. In the second case (i.e., code 507.0), there are no explicit mentions of pneumonitis with vomitus anywhere in the discharge report. However, there is only one oblique mention of "aspiration" without the word pneumonia or its equivalent. As this code is also often termed as "aspiration pneumonia" in medical parlance, the oblique mention ties down the link between the report and the said code assignment.

Automatic Construction of Sememe Knowledge Bases via Dictionaries

Abstract

A sememe is defined as the minimum semantic unit in linguistics. Sememe knowledge bases (SKBs), which comprise words annotated with sememes, enable sememes to be applied to natural language processing. So far a large body of research has showcased the unique advantages and effectiveness of SKBs in various tasks. However, most languages have no SKBs, and manual construction of SKBs is time-consuming and labor-intensive. To tackle this challenge, we propose a simple and fully automatic method of building an SKB via an existing dictionary. We use this method to build an English SKB and a French SKB, and conduct comprehensive evaluations from both intrinsic and extrinsic perspectives. Experimental results demonstrate that the automatically built English SKB is even superior to HowNet, the most widely used SKB that takes decades to build manually. And both the English and French SKBs can bring obvious performance enhancement in multiple downstream tasks. All the code and data of this paper (except the copyrighted dictionaries) can be obtained at `https://github.com/thunlp/DictSKB`.

1 Introduction

A word is the smallest linguistic element that can be used on its own with a particular meaning, but not the smallest semantic unit (O'Grady et al., 1997). The meaning of a word can be divided into smaller components. In linguistics, a *sememe* is defined as the minimum semantic unit of human languages (Bloomfield, 1926). Some linguists believe that meanings of all words can be expressed by a limited set of predefined sememes (Goddard and Wierzbicka, 1994). For example, the basic meaning of "boy" can be expressed by the compositions of `human`, `male` and `child`, while the meaning of "girl" can be expressed by `human`, `female` and `child`, where `human`, `male`, `female` and `child` are predefined sememes. It is even deemed that this sememe-based semantic system as well as the sememe set is universal among different languages, in which case sememes are also named *universal semantic primitives* (Wierzbicka, 1996).

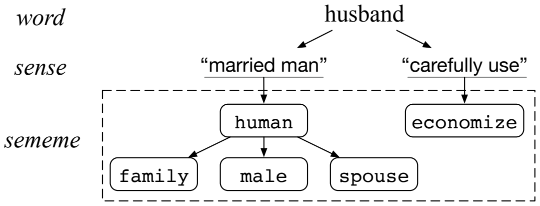

Figure 1: Sememe annotations of the word "husband" in HowNet.

Sememes are implicit in words and cannot be directly used in natural language processing (NLP). Dong and Dong (2006) make a seminal contribution and put the sememe-based semantic system into practice. They define a set of about $2,000$ sememes and use them to annotate senses of over $100,000$ Chinese and English words, whereupon a sememe knowledge base (SKB) named HowNet is built up. Figure 1 illustrates an example of how words are annotated with sememes in HowNet.

As a sememe-based lexical knowledge base, HowNet is very different from most other lexical knowledge bases like WordNet (Miller, 1998), which extensionally explain meanings of words by word-level relations, e.g., hyponym and meronym. In contrast, HowNet provides intensional definitions using infra-word sememes. This distinctness brings special advantages to HowNet. First, the sememe-to-word semantic compositionality endows HowNet with particular suitability for integration into neural networks (Qi et al., 2019a; Li et al., 2019). The sememes of a word can be re-

garded as semantic labels and easily incorporated into the neural processing unit of the word, e.g., a cell of RNN (Qin et al., 2020). Second, the nature that a limited set of sememes are used to express meanings of unlimited words makes HowNet very useful in low-data regimes, e.g., improving embeddings of rare words (Sun and Chen, 2016; Niu et al., 2017), where sememes serve as a bridge between high-frequency and rare words. Thus far a large body of research has demonstrated the usefulness of HowNet in various NLP tasks (Qi et al., 2020b).

HowNet is distinctive and valuable, but it covers only two languages. Most languages have no SKBs like HowNet, which deprives NLP in those languages of benefit from sememes. An obvious solution to this problem is to build an SKB for each language manually, but it is not realistic because it would be unimaginably time-consuming and labor-intensive.[1] To address the challenge, previous studies try to extend HowNet to other languages by automatically predicting sememes for words in those languages (Qi et al., 2018, 2020a). However, existing methods are not effective enough, and manual effort is necessary to ensure the correctness of their sememe prediction results.

In this paper, we explore a fully automatic way to build an SKB for a language via dictionaries with a *controlled defining vocabulary*. A dictionary, especially a learner's dictionary, usually uses a well-chosen list of words to construct all its definitions, and the word list is named controlled defining vocabulary (CDV) (Atkins and Rundell, 2008). A CDV is composed of high-frequency words that not only cover the vast majority of texts but also form a semantic basis so as to express meanings of all other words (Nation and Waring, 2004). To some extent, words in a CDV can fit the definition of sememes (Wierzbicka, 1996). This discovery inspires us to utilize a dictionary to build an SKB by regarding the words in its CDV as sememes.

We design a quite simple and quick process for automatically building SKBs based on dictionaries. First, a sememe set is constructed based on the CDV of a dictionary by removing words that are not suitable as sememes (e.g., stop words), then sememes of words are extracted from corresponding definitions, and finally an SKB composed of words annotated with sememes is established. We adopt the process to build an English SKB and a French SKB and conduct both intrinsic and extrinsic evaluations. In intrinsic evaluation, we find that both the SKBs possess high sememe annotation consistency, and the English SKB performs even better than the English part of HowNet. In extrinsic evaluation, we apply the dictionary-based SKBs to several sememe-incorporated models originally designed for HowNet and carry out experiments on different downstream tasks. Experimental results show that incorporating the SKBs can bring consistent performance enhancement, and the English SKB-incorporated models even outperform HowNet-incorporated models. These results demonstrate the usefulness and effectiveness of the dictionary-based SKBs as well as the feasibility of building SKBs via dictionaries.

To conclude, our contributions are threefold: (1) discovering the similarity between sememes and words in the controlled defining vocabulary, which is the first time as far as we know; (2) proposing to automatically build an SKB via a dictionary, which can be achieved by a simple and quick process; and (3) building an English SKB and a French SKB based on dictionaries and demonstrating their effectiveness in multiple downstream tasks.

2 Related Work

2.1 HowNet and Its Applications

Since HowNet was published (Dong and Dong, 2003), it has attracted considerable attention of NLP researchers. In the era of statistical NLP, it plays a very important role in various NLP tasks including word similarity computation (Liu and Li, 2002), word sense disambiguation (Zhang et al., 2005; Duan et al., 2007), text classification (Sun et al., 2007), sentiment analysis (Zhu et al., 2006; Fu et al., 2013), etc.

When deep learning becomes the mainstream approach of NLP, the usefulness of HowNet is also proved in diverse tasks including word representation learning (Sun and Chen, 2016; Niu et al., 2017), language modeling (Gu et al., 2018), semantic composition (Qi et al., 2019a), sequence modeling (Qin et al., 2020), reverse dictionary (Zhang et al., 2020), word sense disambiguation (Hou et al., 2020), textual adversarial attacking (Zang et al., 2020) and backdoor attacking (Qi et al., 2021).

2.2 Expansion of HowNet

To tackle the challenge that many new words are not contained in HowNet, Xie et al. (2017) present

---

[1] The construction of HowNet takes several linguistic experts more than two decades.

the task of lexical sememe prediction, aiming to expand HowNet by automatically predicting sememes for new words. They propose two simple and effective sememe prediction methods inspired by recommendation system. Jin et al. (2018) further incorporate Chinese characters into sememe prediction and achieve higher performance when predicting sememes for Chinese words.

Another research line focuses on extending HowNet to other languages. Qi et al. (2018) propose the task of cross-lingual lexical sememe prediction, aiming to extend HowNet to a new language by predicting sememes for words in that language. Qi et al. (2020a) present a more efficient way to extend HowNet to other languages, i.e., building a multilingual SKB based on BabelNet (Navigli and Ponzetto, 2012). BabelNet is composed of multilingual synsets that contain synonyms in many languages. Words (synonyms) in a synset have the same meaning and hence the same sememes. Therefore, they propose to predict sememes for the multilingual synsets, by which all the words in synsets will obtain predicted sememes at the same time.

Limited by the accuracy of sememe prediction, manual examination is necessary if we want to put the above HowNet expansion methods into service. In contrast, our proposed dictionary-based SKB construction method is completely automatic and can build a usable SKB very quickly.

2.3 Applications of Dictionaries

Dictionaries are handy and high-quality resources for NLP research. A main application of dictionaries is word sense disambiguation, where dictionaries play the role of sense inventory, and their definitions provide abundant semantic information for each sense (Lesk, 1986; Luo et al., 2018a,b; Kumar et al., 2019; Huang et al., 2019; Du et al., 2019; Blevins and Zettlemoyer, 2020). The semantic information in dictionary definitions is also used to improve word representation learning (Tissier et al., 2017; Bahdanau et al., 2017; Bosc and Vincent, 2018; Scheepers et al., 2018). In addition, dictionary definitions are also utilized in reverse dictionary (Hill et al., 2016; Pilehvar, 2019; Zhang et al., 2020), knowledge graph embedding (Zhong et al., 2015; Xie et al., 2016), reading comprehension (Long et al., 2017), etc. As far as we know, this paper is the first work to utilize dictionaries to build SKBs.

3 Building an SKB via a Dictionary

In this section, we detail the process of building an SKB via a dictionary. We take the building process of an English SKB based on *Longman Dictionary of Contemporary English* (LDOCE) (Bullon, 2006), a highly influential English learner's dictionary, as an example, and the building method can be readily generalized to other languages or dictionaries.[2]

3.1 Constructing the Sememe Set

We first construct the sememe set from the CDV of LDOCE by removing some words. LDOCE uses an approximately $2,000$-word CDV named Longman Defining Vocabulary (Bullock, 2011), which is developed from General Service List (West, 1953), a famous high-frequency word list for English learners. The CDV includes some stop words such as "that" and "to", which bear insignificant meanings and are not suitable as sememes. Thus, we filter them out according to the stop word list of NLTK (Loper and Bird, 2002). But negators like "not" are retained because they are critical to the meanings of words. In addition, according to previous work (Xie et al., 2017; Qin et al., 2020), sememes that are annotated to too many or too few words are usually uninformative and ineffective to downstream applications. Therefore, we count the frequencies of words in the CDV occurring in all definitions and empirically remove the most frequent 1% and the infrequent 10%. So far we have obtained the sememe set that is composed of $2,046$ sememes.

3.2 Extracting Sememes from Definitions

Next, we extract sememes for each sense of each word from its definition. We take the word "beautiful" as a running example to illustrate the process of sememe extraction, as shown in Figure 2.

"beautiful" has two senses in LDOCE, and both of them are adjective. For each sense, we first use NLTK to normalize its definition including tokenization and lemmatization. For example, the definition of its first sense is normalized into a sequence of tokens: {"someone", "or", "something", "that", "be", "beautiful", "be", "extremely", "attractive", "to", "look", "at"}. Then we remove the tokens that are not in the sememe set. In the above example, "someone", "something", "or", "that", "be", "to" and "at" are removed. So far we obtain the sememes

---

[2] The building process and evaluation results of the French SKB are given in Appendix A and B.

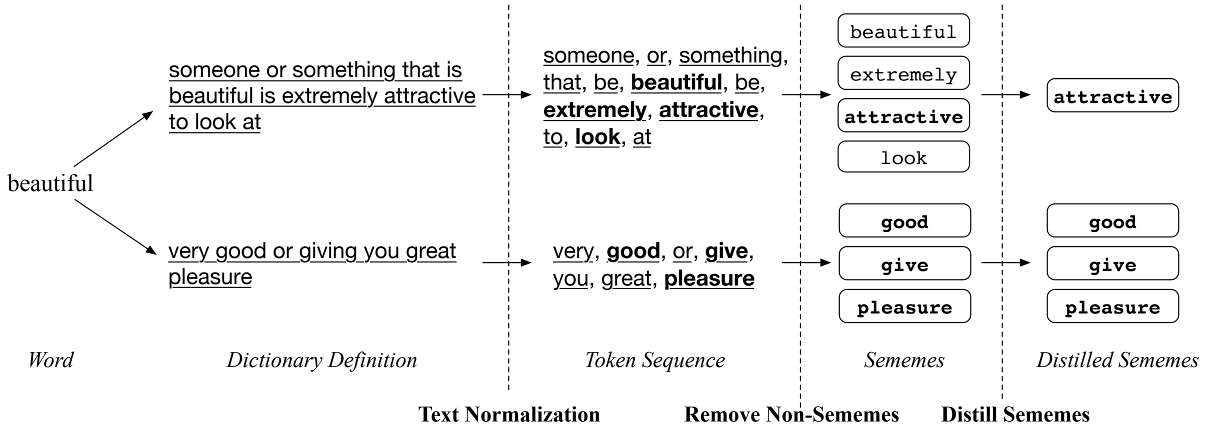

Figure 2: The process of extracting sememes from dictionary definitions for the word "beautiful".

SKB	#Word/Phrase	#Sense	#Sememe	#AvgSem
HowNet	50,879	111,519	2,187	2.26
EDSKB	70,218	105,160	2,046	6.03
EDSKB*	70,218	105,160	1,682[3]	2.04

Table 1: Statistics of EDSKB, its distilled version EDSKB* and the English part of HowNet.[4] #AvgSem denotes the average sememe number per sense.

of the first sense of "beautiful": {`beautiful`, `extremely`, `attractive`, `look`}. In a similar way, we can obtain the sememes of its second sense: {`good`, `give`, `pleasure`}.

By repeating this process on all the words of LDOCE, we obtain an English SKB that we name EDSKB. Its statistics are shown in Table 1.

3.3 Distilling Sememes of Senses

By comparison with HowNet, we find that the sememe set of EDSKB is smaller (EDSKB $2,046$ vs. HowNet $2,187$), but its average sememe number per sense is much larger (EDSKB 6.03 vs. HowNet 2.26), which means the sememes of EDSKB are utilized more fully and effectively. Moreover, annotating a sense with more sememes can explain the sense more accurately and finely. Nevertheless, it would also increase the distinguishability between different senses/words, which has an adverse effect on some downstream tasks. For example, word-level textual adversarial attacking conducts word substitution to generate adversarial examples, in which fewer substitute words usually lead to lower attack success rates (Wang et al., 2019; Zang et al., 2020). In a sememe-based word substitution strategy (Zang et al., 2020), more sememes per sense mean fewer substitute words that share the same sememes can be found, which will decrease the final adversarial attack success rate. To address this problem, we intend to craft an extra distilled version of EDSKB by distilling its sememes of senses.

To this end, we need to determine the importance of each sememe of a sense, and remove the relatively unimportant sememes. Here we resort to dependency parsing (Kubler et al., 2009). Dependency parsing is used to analyze syntactic structures of a sentence by identifying the word that another word is "dependent" on, e.g., the adjective is dependent on the noun in an adjective-noun phrase. We believe that the words with more dependents are more important in a definition. Hence, we define the importance score of a sememe for a sense as the number of the dependents of its original word in the definition.

Then, we empirically remove the sememes whose importance scores are below the highest importance score minus t for the senses having m or more sememes. Here t and m are two hyperparameters and are tuned to 1 and 4 respectively, based on the performance on the validation sets of downstream tasks, especially adversarial attacking. For example, for the first sense of "beautiful", by using AllenNLP (Gardner et al., 2018) to conduct dependency parsing on its definition, we obtain the numbers of dependents of all the words in the definition. Correspondingly, we get the importance scores of the four sememes {`beautiful`, `extremely`, `attractive`, `look`}, which are 2, 0, 6 and 0 respectively. The highest impor-

---

[3] Notice that its sememe set shrinks because some sememes are not annotated to any senses anymore.

[4] The data of HowNet are obtained from OpenHowNet (Qi et al., 2019b).

tance score is 6 and thus the sememes whose importance scores are less than 5 are removed, i.e., `beautiful`, `extremely` and `look`. Finally, the remaining sememe of the first sense of "beautiful" is {`attractive`}. As for the second sense, it has only 3 sememes and all of them are retained (the sememe number threshold for sememe reduction is $m = 4$). Therefore, its final sememes after reduction are still {`good`, `give`, `pleasure`}.

By repeating the above process on all the words, we obtain a distilled version of EDSKB (signified by EDSKB*), whose average sememe number per sense is comparable with HowNet (2.04 vs. 2.26). Its detailed statistics are also shown in Table 1.

Later experiments (on both English and French) show that the full version outperforms the distilled version in some downstream tasks while not in others. In practice, we can build both full and distilled versions and conduct experiments to see which one is better in a specific task. It is affordable to build and evaluate two versions.

4 Intrinsic Evaluation

In this section, we conduct an intrinsic evaluation to assess the sememe annotation consistency of EDSKB. Sememe annotation consistency measures how compatible the sememe annotations for different words/senses are, e.g., whether two synonyms are annotated with exactly the same sememes. The sememe annotation consistency of an SKB not only reflects its intrinsic quality but also has impact on its effectiveness in downstream tasks.

We evaluate both full and distilled versions of EDSKB, and the English part of HowNet for comparison. We adopt a sememe consistency assessment method named CCSA (Liu et al., 2020), which is designed for HowNet originally but can be used for any SKB. This method is motivated by the idea that semantically close senses should have similar sememes, which conforms to the linguistic definition of sememes. It actually implements a sememe prediction process that predicts sememes for a small proportion of senses according to the sememe annotations of the other senses. The sememe prediction method it adopts is based on collaborative filtering (Xie et al., 2017), and tends to predict the sememes that are annotated to semantically close senses to the target sense. Therefore, higher sememe prediction performance means the semantically close senses are annotated with more similar sememes, and the sememe annotations are more consistent. Correspondingly, the sememe annotation consistency of an SKB is measured by two sememe prediction evaluation metrics, namely mean average precision (MAP) and F1 score.

SKB	MAP	F1
HowNet	0.93	0.91
EDSKB	0.88	0.86
EDSKB*	**0.95**	0.91

Table 2: Sememe annotation consistency results. The **boldfaced** results show statistically significant improvement over the best results from baselines with $p<0.1$ given by t-test, and the underlined results represent having no significant difference.[5]

Table 2 lists the evaluation results of sememe annotation consistency. We can see that the distilled version of EDSKB has overall higher consistency than HowNet, and the full version of EDSKB yields lower consistency results. It is not strange because CCSA is based on sememe prediction and according to previous work (Qi et al., 2020a), senses with more sememes usually have lower prediction performance. Since the full version of EDSKB has much more sememes per sense than HowNet, it is actually not fair to compare their consistency using CCSA. The distilled version of EDSKB has a similar average sememe number as HowNet, and its superior results can demonstrate the great consistency of the dictionary-based SKB.

5 Extrinsic Evaluation

In this section, we conduct extrinsic evaluations to assess the effectiveness of EDSKB in downstream tasks. We pick three representative sememe-incorporated neural network models that are used for language modeling, sequence modeling and textual adversarial attacking tasks, respectively. All of them are originally designed for HowNet and have demonstrated efficacy on their respective tasks.

5.1 Language Modeling

In this subsection, we try to apply EDSKB to the task of language modeling. We use SDLM (Gu et al., 2018), a sememe incorporation method for language models, to incorporate EDSKB into two representative language models based on recurrent neural networks (RNNs).

Language modeling is aimed at predicting the next word given previous context (Bengio et al.,

---

[5] The same is true for the following tables.

2003). Language models based on RNNs, especially LSTMs (Hochreiter and Schmidhuber, 1997), are very popular, which use RNNs to encode the previous text into a vector and then feed the vector to a classifier to predict the next word. SDLM reforms the prediction process. Instead of directly predicting the next word, SDLM predicts sememes first, then senses and finally the next word.

Base Models We use two representative LSTM-based language models as the base models into which EDSKB is incorporated by SDLM.

- **Tied LSTM** (Zaremba et al., 2014), which enhances a vanilla two-layer LSTM language model by introducing dropout and weight tying. We use its large version whose word embedding and hidden vector sizes are $1,500$.
- **AWD-LSTM** (Merity et al., 2018), which adopts several regularization and optimization strategies including DropConnect (Wan et al., 2013) and non-monotonically triggered average stochastic gradient descent, and is a very strong baseline language model. Its hidden vector size is $1,150$ and word embedding size is 400.

Baseline Methods In addition to the two original base models, we additionally use SDLM to incorporate HowNet into the base models as baseline methods.

Datasets We choose two benchmark language modeling datasets for evaluation, namely Penn Treebank (PTB) (Marcus et al., 1993) and WikiText-2 (Merity et al., 2017). PTB consists of news stories from the Wall Street Journal. The numbers of tokens in its training, validation and test sets are $887,521$, $70,390$ and $78,669$, respectively. WikiText-2 is made up of Wikipedia articles, and it has $2,088,628$, $217,646$ and $245,569$ tokens in its training, validation and test sets.

Experimental Settings In our experiments, we use the official implementation of SDLM and its default hyper-parameters as well as training methods. The evaluation metric is perplexity. The lower perplexity a language model computes, the better the language model is.

Experimental Results Table 3 lists the perplexity results on the two datasets. We observe that the models incorporated with EDSKB, especially the full version, consistently outperform the two base models without sememe incorporation and even the HowNet-incorporated models. These results demonstrate the effectiveness of EDSKB in language modeling.

Dataset	PTB		WikiText-2	
Model	Valid	Test	Valid	Test
Tied LSTM	63.92	63.98	53.10	51.41
+HowNet	58.93	58.95	48.83	47.28
+EDSKB	**58.81**	**58.82**	**43.38**	**42.15**
+EDSKB*	60.17	60.15	45.18	42.59
AWD-LSTM	58.89	59.24	45.29	44.13
+HowNet	58.95	58.92	46.84	45.29
+EDSKB	**56.94**	**57.13**	**42.44**	**41.25**
+EDSKB*	58.63	58.59	43.85	43.95

Table 3: Perplexity results of different language models on the validation and test sets of PTB and WikiTex-2.

5.2 Sequence Modeling

In this subsection, we incorporate EDSKB into RNNs to improve their sequence modeling ability by SememeCell (Qin et al., 2020), a sememe incorporation method for enhancing RNNs.

SememeCell uses a special RNN cell to encode sememes of a word into a latent vector and transmits it to the corresponding RNN cell of the word, aiming to inject the semantic information of sememes into RNNs. It has demonstrated its effectiveness in improving the sequence modeling ability of RNNs in multiple downstream tasks, including natural language inference, sentiment analysis and paraphrase detection (Qin et al., 2020).

Base Models Following Qin et al. (2020), we choose two most representative RNNs, namely LSTM, GRU (Cho et al., 2014), and their bidirectional versions (BiLSTM and BiGRU) as the base models, into which sememes are incorporated by SememeCell.

Baseline Methods In addition to the vanilla and HowNet-incorporated RNNs, we also design another two baseline methods.

- **+Pseudo**. RNNs incorporated with either EDSKB or HowNet have a little more parameters than vanilla RNNs. To eliminate the possible effect brought by more parameters, we build a pseudo-SKB named Pseudo. Specifically, for each sense in EDSKB, we substitute its sememes with the same number of meaningless labels. The labels are randomly sampled from a label set with the same size as the sememe set of ED-

SKB. We use SememeCell to incorporate this pseudo-SKB into the two base models as baselines, which have exactly the same numbers of parameters as EDSKB-incorporated models.

- **+Definition**. EDSKB is obtained from dictionary definitions by the transformation from a sequence of words (definition) into several discrete semantic labels (sememes). We intend to compare the EDSKB-incorporated models and models incorporated with the complete dictionary definitions. Since SememeCell only takes a vector (i.e., the sum of sememe embeddings) as input, we can leverage it to incorporate definitions into RNNs by encoding definitions into vectors with a sentence encoder. Specifically, we choose the powerful pre-trained language model BERT (Devlin et al., 2019) as the sentence encoder and use the hidden vector of the `[CLS]` token as the definition embedding. The definition-incorporated RNN models are also baselines.

Downstream Tasks and Datasets RNNs are basic sequence encoders and can be used in many downstream NLP tasks. Following Qin et al. (2020), we choose two representative tasks to evaluate the sentence modeling ability of EDSKB-incorporated RNNs.

- Natural language inference (NLI), which is aimed at determining whether a natural language hypothesis can be inferred from a premise. It is a typical sentence pair classification task. We use the SNLI dataset (Bowman et al., 2015) for evaluation. SNLI contains about $570,000$ English premise-hypothesis pairs, and each pair is manually labeled one of three relation labels, namely "entailment", "contradiction" and "neutral".
- Sentiment analysis, which aims to recognize the sentiment orientation of a sentence and is a typical single sentence classification task. Following Qin et al. (2020), we use the CR dataset (Hu and Liu, 2004) for evaluation. It contains about $8,000$ product reviews and each review is labeled with "positive" or "negative".

Experimental Settings We use the official implementation of SememeCell (Qin et al., 2020) and the default hyper-parameter settings and training methods, where the embedding size (for both word and sememe embeddings) is 300 and hidden size is $2,048$. In the baseline method +Definition, to keep the definition vector size comparable with sememe embedding size, we choose the medium version of BERT, which has 512-dimensional hidden vectors and 8 layers.[6] As for evaluation metrics, we use accuracy for both NLI and sentiment analysis.

Dataset	Method	LSTM	GRU	BiLSTM	BiGRU
SNLI	vanilla	80.66	82.00	81.30	81.61
	+Pseudo	81.28	80.90	81.91	82.07
	+HowNet	81.87	82.90	82.55	83.15
	+Definition	81.62	82.80	81.10	83.22
	+EDSKB	**82.32**	**83.18**	82.54	**83.55**
	+EDSKB*	81.78	82.10	82.11	82.35
CR	vanilla	74.17	76.37	77.62	78.76
	+Pseudo	73.96	75.44	76.16	78.20
	+HowNet	76.47	78.57	77.66	76.25
	+Definition	76.29	78.20	77.19	77.77
	+EDSKB	**77.51**	**79.68**	**78.95**	**78.88**
	+EDSKB*	75.09	77.54	76.90	78.18

Table 4: Accuracy results of different models on the test sets of SNLI and CR.

Experimental Results Table 4 shows the evaluation results on the test sets of SNLI and CR. We can see that RNNs incorporated with dictionary-based SKB, especially the full version (+EDSKB), yield overall better results than vanilla RNNs, which proves that the dictionary-based SKB can improve the sequence modeling ability of RNNs. Furthermore, the +EDSKB models outperform +Pseudo models that have the same number of parameters, +Definition models that have the same semantic information source, and +HowNet models that incorporate another SKB. These results demonstrate the superiority of discrete sememes over definitions, and the advantage of dictionary-based SKB over HowNet in enhancing RNNs. +Pseudo performs slightly better than vanilla in some cases, which is probably because +Pseudo utilizes the random meaningless labels as noises. The addition of noise has been proven a regularization method for mitigating overfitting and improving performance in neural networks (Bishop, 1995).

5.3 Textual Adversarial Attacking

In this subsection, we investigate the effectiveness of EDSKB in textual adversarial attacking.

Adversarial attacking has attracted considerable research attention recently, mainly because it can reveal the vulnerability of neural network models and help improve their robustness and interpretability (Xu et al., 2020). Adversarial attacks use *ad-*

---

[6] `https://github.com/google-research/bert`

versarial examples (Szegedy et al., 2014), which are maliciously crafted by perturbing the original model input, to fool the victim model. In textual adversarial attacking, word-level attack methods, mainly based on word substitution, are a kind of popular attack method and have demonstrated overall better attack performance (Wang et al., 2019).

Zang et al. (2020) decompose the process of word-level attacks into two steps: (1) determining the substitute set for each word in the original input via a word substitution strategy, e.g., synonym-based and word embedding-based substitution strategies; and (2) searching the combinations of each original word's substitutes for adversarial examples that can successfully fool the victim model.

They also propose an adversarial attack approach that employs a sememe-based word substitution strategy and achieves strong attack performance. The sememe-based word substitution strategy essentially regards a word w_1 as the substitute of another word w_2, if one sense of w_1 has the same sememes as one sense of w_2, according to an SKB. We use this approach to conduct textual adversarial attacks and measure the attack performance.

Baseline Methods In addition to the original sememe-based attack approach that uses HowNet as the SKB, we choose some other baseline methods for comparison. Notice that all these baseline methods use the same approach to search for adversarial examples (the aforementioned step 2) and differ in word substitution strategies (step 1) only.

- **+Synonym**, the attack method that uses synonym-based word substitution strategy. Following previous work (Ren et al., 2019), we use WordNet as the thesaurus and the words in a synset can be regarded as substitutes of each other.
- **+Definition**, the attack method that uses a definition-based word substitution strategy. Inspired by word embedding-based word substitution, we encode the definition of each sense of words into a vector and define the similarity between two words as the cosine similarity between their closest definition vectors. Then, a certain number of words that are most similar to the target word are regarded as its substitutes. Specifically, we still use the medium-size BERT to encode definitions into 512-dimensional vectors. And the number of substitutes of each word is the same as that in the sememe-based substitution strategy.

Victim	Attack Method	ASR	%M	%IGE	PPL
BiLSTM	+Synonym	79.0	10.45	7.59	593.09
	+Definition	90.0	8.76	7.56	518.71
	+HowNet	93.6	9.02	2.57	**468.92**
	+EDSKB	26.5	8.27	3.77	538.46
	+EDSKB*	**94.0**	8.29	**1.27**	507.34
BERT	+Synonym	81.3	9.22	8.00	576.82
	+Definition	86.3	8.03	7.18	538.00
	+HowNet	91.2	8.25	2.08	503.06
	+EDSKB	29.7	8.10	3.36	**485.00**
	+EDSKB*	**93.3**	**7.66**	**1.07**	544.51

Table 5: Adversarial attack results of different word substitution strategies. ASR is short for attack success rate. %M, %IGE and PPL denote word modification rate, increase rate of grammatical errors and perplexity, respectively.

In this task, the +Pseudo baseline in the previous section cannot work because it would regard random words as substitutes of the target word.

Victim Models and Datasets Following Zang et al. (2020), we choose BiLSTM and BERT, specifically $\text{BERT}_{\text{BASE}}$ as the victim models we intend to attack. The evaluation task is sentiment analysis and the evaluation dataset is SST-2 (Socher et al., 2013). SST-2 comprises about $10,000$ sentences in movie reviews and each sentence is labeled with "positive" or "negative". The accuracy results of BiLSTM and BERT on the test set of SST-2 are 83.75 and 90.28.

Experimental Settings We use the official implementation of the sememe-based attack approach (Zang et al., 2020) and the default hyper-parameter settings.

Evaluation Metrics Following Zang et al. (2020), we use attack success rate to measure the effectiveness of an attack method and three metrics to assess the quality of its adversarial examples. The three metrics are (1) word modification rate, the percentage of words in the original input that are perturbed; (2) increase rate of grammatical errors in adversarial examples compared with original input, where LanguageTool grammar checker is used; and (3) perplexity given by GPT-2 (Radford et al., 2019) that is used to measure the fluency of adversarial examples. The lower the three metrics are, the better the quality of adversarial examples is.

Experimental Results According to Table 5, we find that the attack method based on EDSKB*

Word	SKB	Sememes
screenwriter	HowNet	`human`, `occupation`, `entertainment`, `compile`, `shows`
	EDSKB	`someone`, `write`, `play`, `film`, `television`
	EDSKB*	`write`, `play`, `film`, `television`
tweet	HowNet	`InstitutePlace`, `ProperName`, `produce`, `software`, `LookFor`, `document`, `information`, `internet`
	EDSKB	Sense 1: `bird`, `make`, `high`, `small`, `short`, `sound` Sense 2: `service`, `message`, `network`, `short`, `send`, `use`, `social`
	EDSKB*	Sense 1: `bird`, `sound` Sense 2: `message`, `send`, `use`, `network`

Table 6: Two cases of sememe annotations in HowNet, EDSKB and EDSKB*.

not only achieves the highest attack success rates but also generates adversarial examples with overall higher quality. These results show that the dictionary-based SKB EDSKB* can better capture the semantic relations between words and find appropriate substitutes for adversarial attacks. Attack success rates of the EDSKB-based method are extremely low. It is because EDSKB has too many sememes per sense, which causes the found substitutes to be very few (EDSKB 1.6, EDSKB* 12.6 and HowNet 15.3 on average), according to the sememe-based word substitution strategy that requires substitutes to have the same sememes.

6 Case Study on Sememe Annotations

In this section, we give two cases of sememe annotations in EDSKB and EDSKB* as well as HowNet in Table 6.

The first case is the word "screenwriter". In HowNet, this word has only one sense that is annotated by five sememes, as listed in the second row of Table 6. As for EDSKB and EDSKB*, according to *Longman Dictionary of Contemporary English* (LDOCE), this word also has only one sense whose definition is "someone who writes plays for film or television". EDSKB provides five sememes and one (`someone`) is filtered out in EDSKB*. By comparison, we can find that sememes in EDSKB and EDSKB* can represent the meaning of the word more specifically, e.g, `write` and `play`, while sememes in HowNet seem to express a more general meaning.

The second case is about the word "tweet". HowNet only annotates one sense for this word, i.e., "to send a message on Twitter". As for EDSKB and EDSKB*, since LDOCE contains the basic meaning of this word, i.e., "to make the short high sound of a small bird", the sememes including `bird` and `sound` are extracted to express this meaning. In addition, for the shared sense, sememes in EDSKB and EDSKB* are more succinct than those in HowNet, e.g., `message` in EDSKB/EDSKB* can better describe the core meaning of "tweet" than `document` and `information` in HowNet.

From the two cases, we can see the advantage of the dictionary-based SKBs over HowNet in terms of sememe annotations. We hope that the dictionary-based SKBs can be used to perfect HowNet by supplying more senses and annotating more suitable sememes.

7 Conclusion and Future Work

In this paper, we propose to utilize a dictionary to build an SKB for the first time, which can be implemented by a simple, quick and fully automatic process. We try utilizing existing dictionaries to build an English SKB and a French SKB, and demonstrate their effectiveness on multiple NLP tasks. Extensive experimental results prove the reliability and practicality of our idea about dictionary-based SKB construction.

It is worth mentioning that although EDSKB delivers better empirical results than HowNet, HowNet has its unique advantages including better interpretability and multilinguality. In the future, therefore, we will systematically compare the sememe annotations in EDSKB and HowNet and try to use EDSKB to improve and expand HowNet. Besides, the hierarchical structures of sememes in HowNet are neglected in this paper. We will also explore to extract sememes with hierarchy from dictionary definitions.

Acknowledgements

This work is supported by the National Key Research and Development Program of China (Grant No. 2020AAA0106502 and No. 2020AAA0106501) and Beijing Academy of Artificial Intelligence (BAAI). We also thank all the anonymous reviewers for their valuable comments and suggestions.

Ethical Considerations

In this paper, we use two copyrighted dictionaries, namely Longman Dictionary of Contemporary English and Le Petit Robert French Dictionary. We extract data from the electronic versions of the two dictionaries we bought for the research purpose only. We will not release the dictionary data. In addition, the datasets we use in downstream tasks are all open and free (actually also widely used).

The task we tackle is sememe knowledge base construction, which is not a practical application and is only related to NLP research. Therefore, the datasets we build and the models we use would not be misused by common people.

In addition, since we do not use very large models, the required energy in this work is very limited. Finally, we use no demographic or identity characteristics.

A Building Process of a French SKB

In this section, we describe the building process of a dictionary-based French SKB that we call FDSKB. We choose Le Petit Robert French Dictionary 2016 edition (Robert et al., 2015), a very popular French dictionary, as the base dictionary.

Constructing the Sememe Set We first construct a sememe set from the defining vocabulary of the dictionary. Similar to EDSKB, we remove the most frequent and infrequent words that appear in definitions as well as some stop words, and obtain a sememe set comprising $2,919$ sememes (defining words).

Extracting Sememes from Definitions We use Stanza (Qi et al., 2020c) to tokenize and lemmatize the definitions of all words in the dictionary and extract the sememes of each sense of each word according to the sememe set. So far, we have obtained the full version of FDSKB, whose statistics are shown in Table 7.

Distilling Sememes of Senses We adopt a similar way to EDSKB to distill the sememes of senses. Specifically, we use Stanza to conduct dependency parsing for every definition and obtain the importance score of each sememe. Then we empirically remove the unimportant sememes according to the experimental results of downstream tasks. In this way, we obtain the distilled version of FDSKB (FDSKB*), whose statistics are also in Table 7.

B Evaluation of FDSKB

In this section, similar to EDSKB, we conduct both intrinsic and extrinsic evaluations for FDSKB and FDSKB*. Notice that since HowNet covers only English and Chinese, there are no available HowNet-based baseline methods for French.

SKB	#Word/Phrase	#Sense	#Sememe	#AvgSem
FDSKB	55,836	113,722	2,919	4.32
FDSKB*	55,836	113,722	2,919	1.97

Table 7: Statistics of FDSKB and its distilled version FDSKB*. #AvgSem denotes the average sememe number per sense.

Dataset	French News		FR-Wikipedia	
Model	Valid	Test	Valid	Test
Tied LSTM	17.02	18.35	17.23	15.75
+FDSKB	15.72	16.85	17.14	15.60
+FDSKB*	15.70	16.89	**16.50**	**15.15**
AWD-LSTM	18.41	19.71	16.76	15.30
+FDSKB	15.41	16.47	**15.45**	15.72
+FDSKB*	**14.03**	**15.14**	15.90	**14.10**

Table 8: Perplexity results on the validation and test sets of French News and FR-Wikipedia. The **boldfaced** results show statistically significant improvement over the best results from baselines with p<0.1 given by t-test, and the underlined results represent having no significant difference.[7]

B.1 Intrinsic Evaluation

We still use CCSA (Liu et al., 2020) to measure the sememe annotation consistency. The MAP and F1 score for FDSKB are 83.47 and 80.51 respectively, and those for FDSKB* are 90.03 and 90.01 respectively. These results are comparable to those of EDSKB and can prove good sememe annotation consistency of FDSKB. Besides, similar to EDSKB, the distilled version FDSKB* delivers better sememe annotation consistency than FDSKB because it has fewer sememes per sense.

B.2 Extrinsic Evaluation

We conduct extrinsic evaluation for FDSKB and FDSKB* on three tasks including language modeling, natural language inference (NLI) and text classification.

Language Modeling

Similar to EDSKB, we use SDLM (Gu et al., 2018) to incorporate FDSKB into Tied LSTM (Zaremba et al., 2014) and AWD-LSTM (Merity et al., 2018). The experimental settings are the same as those in English experiments.

We choose two evaluation datasets: (1) **French News**[8], which comprises French news articles from

---

[8] `https://webhose.io/free-datasets/french-news-articles/`

Dataset	Method	LSTM	GRU	BiLSTM	BiGRU
XNLI	vanilla	61.14	60.88	61.56	61.36
	+Pseudo	60.96	61.46	61.10	61.12
	+Definition	61.64	61.10	61.80	61.86
	+FDSKB	62.38	61.54	**62.52**	61.44
	+FDSKB*	**62.52**	**61.74**	62.16	**62.06**
MARC	vanilla	79.98	79.16	80.35	80.64
	+Pseudo	80.35	79.38	79.16	80.53
	+Definition	81.10	79.39	80.65	80.80
	+FDSKB	81.39	80.58	80.65	**82.14**
	+FDSKB*	**81.43**	**81.10**	**80.98**	81.84

Table 9: Accuracy results of different models on the test sets of XNLI and MARC.

popular news sites. It has 2,131,774 / 358,972 / 370,059 tokens in its training / validation / test sets. (2) **FR-Wikipedia**[9], which is composed of French Wikipedia articles. The token numbers in its training / validation / test sets are 3,252,094 / 520,333 / 517,669.

The experimental results are given in Table 8. We observe that both FDSKB and FDSKB* bring decreases of perplexity, which demonstrates the effectiveness of the French dictionary-based SKB in language modeling and the practicality of our dictionary-based SKB building method. Notice that since the perplexity results of original Tied LSTM and AWD-LSTM on the two French datasets are quite good, the enhancement brought by FDSKB is comparatively less than that in English.

NLI and Text Classification

Similar to EDSKB, we use SememeCell (Qin et al., 2020) to incorporate FDSKB into RNNs and measure the improvement of sequence modeling ability on the tasks of NLI and text classification.

The base models are still LSTM, GRU, BiLSTM and BiGRU. And the baseline methods are also +Pseudo and +Definition. Here we use FlauBERT (Le et al., 2020), a French pre-trained language model, to encode definitions into 768-dimensional vectors. The other experimental settings are the same as English.

As for evaluation datasets, we use XNLI (Conneau et al., 2018) and MARC (Keung et al., 2020) respectively. XNLI is a cross-lingual NLI dataset in 15 languages. It is based on another NLI dataset MNLI (Williams et al., 2018) and constructs its training set by machine translation, which has 361,469 sentence pairs. It has 2,500 and 5,000 sentence pairs in the validation and test sets which are manually translated from English. MARC (Multilingual Amazon Reviews Corpus) is a large corpus of Amazon reviews in 6 languages. We use its French part for product category classification. It has 40,000 / 1,323 / 1,345 reviews in its training / validation / test sets.

Table 9 shows the accuracy results on the test sets of XNLI and MARC. The results are basically consistent with the experimental results in English datasets. The incorporation of the dictionary-based SKB can improve the performance of RNN models on the two different tasks, which reflects that the SKB has enhanced the sequence modeling ability of RNNs. Moreover, the results also demonstrate the usefulness and effectiveness of our dictionary-based SKB and its building method.

C Experiment Running Environment

For all the experiments, we use a server whose major configurations are as follows: (1) CPU: Intel(R) Xeon(R) E5-2680 v4 @ 2.40GHz, 56 cores; (2) RAM: 125GB; (3) GPU: 8 Nvidia RTX2080 GPUs, 12GB memory. The operation system is Ubuntu 18.04.2 LTS (GNU/Linux 4.15.0-108-generic x86_64). We use PyTorch[10] v1.5.0 and Python v3.6.9 as the programming framework for the experiments on neural network models.

Abstract

Multi-hop reasoning is an effective and explainable approach to predicting missing facts in Knowledge Graphs (KGs). It usually adopts the Reinforcement Learning (RL) framework and searches over the KG to find an evidential path. However, due to the large exploration space, the RL-based model struggles with the serious sparse reward problem and needs to make a lot of trials. Moreover, its exploration can be biased towards spurious paths that coincidentally lead to correct answers. To solve both problems, we propose a simple but effective RL-based method called RARL (Rule-Aware RL). It injects high quality symbolic rules into the model's reasoning process and employs partially random beam search, which can not only increase the probability of paths getting rewards, but also alleviate the impact of spurious paths. Experimental results show that it outperforms existing multi-hop methods in terms of Hit@1 and MRR.

1 Introduction

Knowledge Graphs (KGs), which store facts as triples in the form of (*subject entity*, *relation*, *object entity*), benefit various NLP applications (Lan and Jiang, 2020; Wang et al., 2019b; He et al., 2017). However, existing KGs face with serious incompleteness despite of their large scales. Therefore, KG completion, which aims to reason missing facts based on existing triples, has been an important research area.

The past decade has witnessed the rise of embedding-based reasoning methods on KGs (Bordes et al., 2013; Yang et al., 2014; Balažević et al., 2019). However, due to their black-box nature, these methods cannot provide interpretations for a specific prediction (Ji et al., 2020; Sadeghian et al., 2019). Recently, there has been growing interest in using multi-hop reasoning to improve the interpretability (Gardner et al., 2013; Rocktäschel and Riedel, 2017). This approach usually adopts Reinforcement Learning (RL) to find a reasoning path (Xiong et al., 2017; Das et al., 2018; Hildebrandt et al., 2020). Starting from the query entity, the RL-based model sequentially selects an outgoing edge and transits to a new entity until it arrives at the target.

However, due to the complexity of the KG, the number of paths grows exponentially when the reasoning hop increases. Most of paths cannot arrive at correct answers, and cannot receive a none-zero reward, which is also called the "sparse reward problem" (Nair et al., 2018). Moreover, since golden paths are not available in the training process, the RL-based model may coincidentally reach the target via a meaningless path (i.e. spurious paths). Take the query (*Captain America, director, ?*) as an instance. Although the path (*Captain America, country, US, lives in*$^{-1}$, *Peter Farrelly*), can arrive at the target. It is semantically inconsistent with the query relation *director* and is an accidental success. One trouble is that the RL-based model relies heavily on rewards and reinforces the past actions receiving high rewards regardless of their path quality. In addition, in large scale KGs, there are more spurious paths than correct ones (Lin et al., 2018). It is more easier for the model to discover spurious ones first other than the true and meaningful ones. If the model finds spurious ones first, these spurious paths will lead to a biased exploration and induce negative influence to the reasoning process (Guu et al., 2017; Lin et al., 2018).

Lin et al. (2018) uses shaped rewards calculated by pre-trained embedding-based models and an action dropout mechanism to solve the above two challenges, respectively. However, its performance largely depends on the embedding-based model used. In addition, embedding-based model increases the opacity of the reasoning process. Motivated by this, we focus on the action selection

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4687–4692
August 1–6, 2021.

strategy and propose RARL (Rule Aware RL), a simple but effective model to solve the above two challenges. RARL introduces high quality rules as prior information about actions and explores K paths in one episode. It selects actions from three parts: actions matching rules, actions with high scores, and actions randomly sampled. The former two parts can increase the probability of reasoning paths arriving at targets. The later one allows the model to explore a more diverse path set and thus avoids the model adhering to the past actions receiving high rewards, which can naturally mitigate the impact of spurious paths.

We evaluate RARL on three benchmark datasets, and experimental results show the effectiveness of RARL when compared with existing multi-hop methods.

2 Preliminaries

Let $\mathcal{E}$ be the set of entities and $\mathcal{R}$ be the set of relations, a knowledge graph can be represented as $\mathcal{G} = \{(e_s, r, e_t)\} \subseteq \mathcal{E} \times \mathcal{R} \times \mathcal{E}$. In this paper, we focus on the standard link prediction task. Given a query of the form $(e_s, r_q, ?)$, the reasoning model is expected to predict the correct answer e_t after traversing over the graph.

2.1 The RL-based Knowledge Reasoning Framework

Following (Das et al., 2018), when given a query $(e_s, r_q, ?)$, the RL-based model can be viewed as an agent, which interacts with the KG environment and aims to find a reasoning path $p = (e_s, r_1, e_1, ...)$ to explicitly show how to conduct reasoning. The parameters of the policy defines a policy. At each time t, the agent selects an action a_t, i.e. an outgoing edge of the current position e_t, to expand the path using a policy. Here, we define $A_t = \{(r', e') | (e_t, r', e') \in \mathcal{G}\}$ as the possible actions at time t. The model first uses a Long Short-Term Memory network (LSTM) to encode the path history into a vector $\mathbf{h}_t$. Then, the policy network π_θ (a two-layer feed-forward network) calculates a distribution over all possible actions in A_t.

$$\pi_\theta(a_t|e_t) = \sigma(\mathbf{A}_t(W_2 ReLU(W_1[\mathbf{h}_t;\mathbf{e}_t;\mathbf{r_q}]))), \quad (1)$$

where $\mathbf{e}_t \in \mathbb{R}^d$ and $\mathbf{r_q} \in \mathbb{R}^d$ are embeddings of e_t and r_q, respectively. $\mathbf{A}_t \in \mathbb{R}^{|A_t| \times 2d}$ is the stack of all actions embeddings in A_t and σ denotes the softmax operator. After this, the next edge is selected via an ϵ-greedy action selection strategy.

A binary reward $R(p)$ is observed after the maximum time step T: $R(p) = 1$ if the path ends at the correct answer and 0 otherwise.

The objective of the model is to maximize the expected reward:

$$J(\theta) = \sum_{(e_s, r_q, e_t) \in \mathcal{G}} \sum_{\hat{z} \in P(e_s, r_q)} R(\hat{z}) \pi_\theta(\hat{z}|e_s, r_q), \quad (2)$$

where $P(e_s, r_q)$ is the set of all reasoning paths related to the given query $(e_s, r_q, ?)$. The optimization is then performed by using REINFORCE algorithm (Williams, 1992).

2.2 Beam Search

In the RL context, Beam Search (BS) (Sutskever et al., 2014) stores top-K scoring partially constructed paths at each time step, where K is known as the beam size. At each time t, BS extends itself via the following process. Let us denote the paths set held by BS at the end of time t as $B_t = \{p_{[1:t]}, ..., p_{[K:t]}\}$. For each path $p = (e_s, r_1, ..., e_t) \in B_t$, we first generate its candidate paths $cand(p)$,

$$\begin{aligned} cand(p) &= cond(e_s, r_1, ..., e_t) \\ &= \{(e_s, r_1, ..., e_t, r', e') | (e_t, r', e') \in \mathcal{G}\}. \end{aligned} \quad (3)$$

Each candidate path $p \in cand(p)$ is associated with a score $s(p)$ calculated by the policy network. Here, $s(p) = \pi_\theta((r', e')|e_t)$. Further, we take the union of these candidate paths $\mathcal{B}_t = \bigcup_{p \in B_t} cand(p)$. A new beam B_{t+1} is generated by picking the K top-most elements in $\mathcal{B}_t$.

3 The RARL Model

As illustrated in Figure 1, the RARL model consists of two parts: the KG environment and the agent. By interacting with the environment, the agent employs a beam search based action selection strategy and picks K actions to extend the beam in one episode. The action selection strategy selects actions from three parts: actions matching rules, actions with high scores, and actions randomly sampled. After the maximum time step, the agent will receive binary rewards.

3.1 Rule Based Action Selection

In a typical KG, when the path length increases, finding a non-zero reward is exponentially more difficult. Learning from such sparse rewards requires lots of effective exploration. However, in the beginning, due to the randomly initialized parameters,

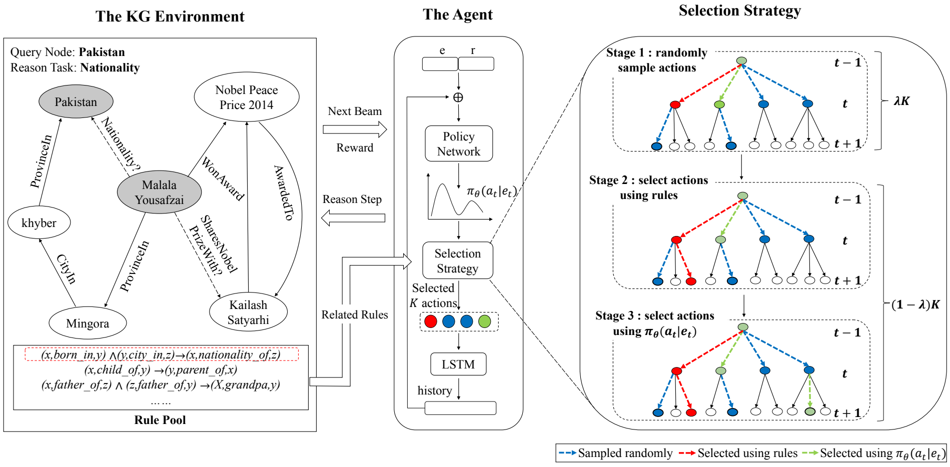

Figure 1: The reasoning process of RARL. Left: The KG environment. The dashed edges are part of queries and the solid edges are observed facts. Middle: The structure of the agent. By interacting with the environment, it picks K actions to extend the beam in one episode. Right: An illustration of the action selection strategy at time t. It first randomly samples λK actions and then selects the remaining $(1-\lambda)K$ actions using rules and probabilities.

the model chooses actions randomly and can hardly arrive at targets. This makes the sparse reward problem even worse (Xiong et al., 2017; Hare, 2019). Considering that rules precisely characterize a mapping from query relations to semantic composition paths (Zhang et al., 2019), RARL utilizes rules as prior information about actions to increase the probability of paths receiving rewards, which can also help to facilitate effective exploration.

The rules mined from KGs are in the form of $head \leftarrow body$, where the head is an atom $r(a, b)$ and the body is in the format of: $r(x_0, x_1) \wedge \ldots \wedge r(x_n, x_{n+1})$. Note that $r(x_i, x_j)$ is equivalent to the fact triple (x_i, r, x_j).

Given the query relation r_q, RARL first selects rules R_{r_q} whose heads are identical to r_q from the rule pool. At each time step t, it maintains a beam B_t of K paths. For each path $p = \{e_s, r_1, e_1, ..., r_t, e_t\} \in B_t$, RARL expands its candidate paths based on the outgoing edges of e_t. Next, for all candidate paths in $\mathcal{B}_t$, only those in which relation sequence can match related rules from left to right are selected. For instance, suppose R_{r_q} contains only one rule $r_q \leftarrow r_1 \wedge r_2$, given two candidate paths $(e_s, r_1, e_1, r_2, e_2)$, $(e_s, r_2, e_3, r_3, e_4)$, only the relation sequence in the former path can successfully matches the rule. As a result, the former one will be selected to generate B_{t+1}. If the number of candidate paths matching rules excesses the beam size, RARL selects top-K paths from these paths matching rules according to their scores calculated by the policy network. If not, remaining paths not matching rules are selected as a compliment. To make a balance between actions generated by free exploration and actions matching rules, RARL randomly masks some related rules to shrink the number of paths matching rules.

3.2 Partially Random Beam Search

To ease the impact of spurious paths, we try to prevent the RL-based model from the obsession of spurious paths and induce diversity during BS. Inspired by (Guu et al., 2017), we introduces partially randomness to standard BS, to fight against the impact of spurious paths.

Like regular beam search, at time t, RARL computes the set of all candidate paths $\mathcal{B}_t$ and sorts them by their scores computed by the policy network π_θ. Instead of selecting K highest-scoring candidate paths, RARL randomly chooses λK candidate paths from $\mathcal{B}_t$ and remaining paths are chosen according to their scores. In this way, low-scoring paths discarded in standard BS can also have the chance to be explored. Besides, the randomness can avoid the model sticking to the paths getting rewards. In the experiment, RARL selects paths with replacement when available actions smaller than λK.

3.3 The Overall Selection Strategy

RARL selects candidate actions by three stages: (1) Randomly sample λK actions based on the current position; (2) Select actions matching the

related rules based on the history; (3) Select actions in descending order of scores. If the number of actions matching rules from the second stage excesses $(1-\lambda)K$, then RARL selects the top $(1-\lambda)K$ actions according to their scores. If not, it continue to select actions via the third stage. The total size of actions selected from the last two parts are $(1-\lambda)K$.

4 Experiments

4.1 Experimental Setup

Datasets and Rules We adopt three datasets to evaluate the performance of RARL for link prediction: UMLS (Kok and Domingos, 2007), WN18RR (Dettmers et al., 2017), and FB15K-237 (Toutanova et al., 2015). For FB15k-237, 20 relations in the film field are selected. Following (Niu et al., 2020), We use AIME+ (Galárraga et al., 2015) to automatically extract rules, and we limit the maximum length of rules to 2.

Table 2 lists the statistics of rules with various confidence thresholds mined from these three datasets.

Model	Various Confidence Thresholds				
	0.5	0.6	0.7	0.8	0.9
UMLS	2,154	1,678	1,159	561	170
WN18RR	5	4	3	3	3
FB15K-237	2,044	1,621	1,255	912	565

Table 2: Statistics of rules mined on the three datasets.

Hyperparameters We set the dimensions of entity and relation embeddings within (50, 200). A three-layer LSTM is used as the path encoder and its hidden dimension is set in (100, 200). The λ is set as 0.9, 0.4 and 0.7 for UMLS, WN18RR and FB15K-237, respectively, according to the average degree of nodes and the average number of relation rules on each dataset.

4.2 Link Prediction Results

Table 1 summarizes the experimental results of our proposed approach and the baselines. As shown in Table 1, RARL achieves competitive results over multi-hop reasoning methods. On FB15K-237, RARL outperforms all baselines in terms of Hit@1, Hits@10, and MRR. On WN18RR and UMLS, the RARL achieves the best results in terms of Hit@1 and MRR. The Hit@1 results emphasize the superiority of our approach in high-precision link prediction and confirm the effectiveness of high quality rules. We also notice that the emebedding-based methods perform better on UMLS and FB15K-237 compared with multi-hop reasoning methods. One reason is that the multi-hop reasoning methods are more sensitive to the sparsity and incompleteness of graphs compared with embedding-based methods. It is hard for them to find evidential paths reaching targets via strictly searching in the KG. While the embedding-based methods(Lin et al., 2018; Fu et al., 2019) map entities and relations into a unified semantic space to capture inner connections, which relaxes this restriction.

4.3 Ablation Study

We perform an ablation study to look deep into the framework of RARL. We deactivate the validity of rule information, random mechanism from RARL. The MRR results are summarized in Table 3. It can be observed that removing each reasoning component of RARL results in a significant performance drop on UMLS and WN18RR. On FB15K-237, removing rule information seems like to be no influence. As a result, we further conduct an analysis experiment using w/o rule setting and found lower results on the testing set. This performance gap may be caused by the difference of data distribution between the testing set and the validation set.

Besides, our ablation study shows that removing partial randomness has a greater negative impact on reasoning performance. This suggests that increasing the exploration diversity to get more valid path patterns is important in training stage.

	UMLS	WN18RR	FB15K-237
RARL w/o Rule	.813	.448	.551
RARL w/o Random	.792	.438	.501
RARL	.872	.455	.551

Table 3: Ablation study of the proposed method.

5 Conclusions

In this paper, we introduced RARL, a new RL-based method for knowledge graph reasoning. RARL makes use of high-quality symbolic rules and partical random beam search jointly and efficiently fights against the sparse reward and spurious path problems. Experimental results demonstrate that RARL achieves better performance compared with existing multi-hop methods in terms of both Hit@1 and MRR.

Abstract

Contemporary works on abstractive text summarization have focused primarily on high-resource languages like English, mostly due to the limited availability of datasets for low/mid-resource ones. In this work, we present XL-Sum, a comprehensive and diverse dataset comprising 1 million professionally annotated article-summary pairs from BBC, extracted using a set of carefully designed heuristics. The dataset covers 44 languages ranging from low to high-resource, for many of which no public dataset is currently available. XL-Sum is highly abstractive, concise, and of high quality, as indicated by human and intrinsic evaluation. We fine-tune mT5, a state-of-the-art pretrained multilingual model, with XL-Sum and experiment on multilingual and low-resource summarization tasks. XL-Sum induces competitive results compared to the ones obtained using similar monolingual datasets: we show higher than 11 ROUGE-2 scores on 10 languages we benchmark on, with some of them exceeding 15, as obtained by multilingual training. Additionally, training on low-resource languages individually also provides competitive performance. To the best of our knowledge, XL-Sum is the largest abstractive summarization dataset in terms of the number of samples collected from a single source and the number of languages covered. We are releasing our dataset and models to encourage future research on multilingual abstractive summarization. The resources can be found at `https://github.com/csebuetnlp/xl-sum`.

Input Article: Yahoo's patents suggest users could weigh the type of ads against the sizes of discount before purchase. It says in two US patent applications that ads for digital book readers have been "less than optimal" to date. [...] "Greater levels of advertising, which may be more valuable to an advertiser and potentially more distracting to an e-book reader, may warrant higher discounts," it states. [...] It adds that the more willing the customer is to see the ads, the greater the potential discount. [...] At present, several Amazon and Kobo e-book readers offer full-screen adverts when the device is switched off and show smaller ads on their menu screens. [...] Yahoo does not currently provide ads to these devices, and a move into the area could boost its shrinking revenues.

Summary: Yahoo has signalled it is investigating e-book adverts as a way to stimulate its earnings.

Table 1: A sample article-summary pair from the XL-Sum dataset. To highlight the abstractiveness of the summary, we underline the novel words and phrases that do not appear in the article text. Also, portions of the article relevant to the summary have been color-coded. As we can see, these portions are concisely paraphrased in the summary, unlike extractive methods.

1 Introduction

Automatic text summarization (Nenkova and McKeown, 2011) is a fundamental problem in natural language processing. Given an input text (typically a long document or article), the goal is to generate a smaller, concise piece of text that conveys the key information of the input text. There are two main approaches to automatic text summarization: *extractive* and *abstractive*. Extractive methods crop out one or more segments from the input text and concatenate them to produce a summary. These methods were dominant in the early era of summarization, but they suffer from some limitations, including weak coherence between sentences, inability to simplify complex and long sentences, and unintended repetition (See et al., 2017; Widyassari et al., 2020).

---

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4693–4703
August 1–6, 2021.

Abstractive summarization, on the other hand, generates summaries that may contain words and phrases not present in the input text (e.g., via paraphrasing), and may arguably relate more to human-generated summaries (Hsu et al., 2018). Although abstractive summaries can be more coherent and concise than extractive summaries (Cohn and Lapata, 2008), generating them is more challenging due to the nature of this task. Limited availability of good datasets conducive to abstractive methods has made it even more difficult. For these reasons, extractive models had been performing better than abstractive ones historically. However, the success of sequence-to-sequence (seq2seq) models (Cho et al., 2014; Sutskever et al., 2014) over the last decade and the recent advances in Transformer-based models (Vaswani et al., 2017; Devlin et al., 2019) have rejuvenated abstractive text summarization (Rush et al., 2015; See et al., 2017; Zhang et al., 2020), which had previously received much less attention in comparison to extractive approaches (Nenkova and McKeown, 2012). Still, the scarcity of good datasets, especially for low-resource languages, remains a roadblock.

Typical seq2seq models are heavily data-driven, i.e., a large number of article-summary pairs are required to train them effectively. As a result, abstractive summarization has centered around the English language, as most large abstractive summarization datasets (Hermann et al., 2015; Grusky et al., 2018; Narayan et al., 2018) are available in English only. Though there have been some recent efforts for curating multilingual abstractive summarization datasets (Giannakopoulos et al., 2015; Cao et al., 2020; Scialom et al., 2020), they are limited in terms of the number of languages covered, the number of training samples, or both.

In this work, we introduce **XL-Sum**, a large-scale abstractive summarization dataset of news articles crawled from the British Broadcasting Corporation (BBC)[1] website. Using a custom crawler, we collect 1 million professionally annotated article-summary pairs covering 44 languages. Originating from a single source, these samples exhibit similar summarization strategies across all languages, making them ideal for the multilingual summarization task. XL-Sum introduces the first publicly available summarization dataset and benchmarks for many languages (e.g., Bengali, Swahili). Thus, this dataset potentially enables and facilitates research on low-resource languages, bringing technological advances to communities of these languages that have been traditionally under-served.

We achieve higher than 11 ROUGE-2 score on the 10 languages we benchmark on multilingual summarization, even exceeding 15 ROUGE-2 score (16.58 being the state-of-the-art for English, obtained by Zhang et al. (2020) on XSum (Narayan et al., 2018), a similar dataset) on many of them. In addition, we also conduct experiments on low-resource summarization task and show competitive results, indicating that the dataset can be used even for the low-resource languages individually.

In summary, we make the following main contributions in this paper:

- We release XL-Sum, a dataset containing 1 million article-summary pairs in 44 languages, being the first publicly available abstractive summarization dataset for many of them.
- We create a data curation tool that can automatically crawl and extract article-summary pairs from BBC, using which the dataset can be made even larger over time.
- We are the first to perform multilingual summarization on a diverse set of languages, achieving strong baselines on all languages tested.

We are releasing the dataset, curation tool, and summarization model checkpoints. We believe that our efforts in this work will encourage the community to push the boundaries of abstractive text summarization beyond the English language, especially for low and mid-resource languages.

2 The XL-Sum Dataset

In this section, we present details of the XL-Sum dataset together with the curation process. Table 2 shows the article-summary statistics for all languages in the XL-Sum dataset.

2.1 Content Source

BBC publishes news in 43 languages[2] ranging from low-resource languages such as Bengali and

Table 2: Languages covered by the XL-Sum dataset, and the number of samples for each language. Here, a sample denotes an article-summary pair. If we consider languages with less than 15,000 training samples to be low-resource, then more than two-thirds of the constituent languages in XL-Sum fall into this category.

---

[a] West African Pidgin English

Swahili to high-resource ones including English and Russian. Among the 43 languages, Serbian is a special case that is published in both Cyrillic, the official script, and Latin, the colloquial script. We treat them as different languages in this work, totaling to a coverage of 44 languages.

2.2 Content Search

As BBC does not provide any archive or RSS feed on their website, we designed a crawler to recursively crawl pages starting from the homepage by visiting different article links present in each page visited. We were able to take advantage of the fact that all BBC sites have somewhat similar structures, and were able to scrape articles from all sites. We discarded pages with no textual contents (mostly pages consisting of multimedia contents) before further processing.

2.3 Article-Summary Extraction

The process of automatically collecting summaries of articles differs across different datasets. For example, the CNN/DM dataset (Hermann et al., 2015) merged bullet point highlights provided with the articles as reference summaries, whereas the XSum dataset (Narayan et al., 2018) used the first line of the article as the summary and the rest of the article as the input.

Our method of collecting summaries was made easier by the consistent editorial style of the BBC articles we crawled. BBC typically provides a summary of a whole article in the form of a bold paragraph containing one or two sentences at the beginning of each article. These summaries are written professionally by the authors of the articles in order to convey its main story within one small paragraph. This is in contrast to the headline which serves to draw the attention of viewers into reading the article. (We show an example article-summary pair from BBC English in Table 1.) We designed a number of heuristics to make the extraction effective by carefully examining the HTML structures of the crawled pages:

1. The desired summary must be present within the beginning two paragraphs of an article.
2. The summary paragraph must have some portion of texts in bold format.
3. The summary paragraph may contain some hyperlinks that may not be bold. The proportion of bold texts and hyperlinked texts to the total length of the paragraph in consideration must be at least 95%.
4. All texts except the summary and the headline must be included in the input text (including image captions).
5. The input text must be at least twice as large as the summary.

Any sample that did not conform to these heuristics were discarded. Our strategy of automatic annotation of summaries resembles XSum to some extent, but we found the first line to contain meta-information in many articles (e.g., author information, date of last modification). As such, we used the bold paragraphs as the summaries instead.

3 Human Evaluation of XL-Sum

Despite being written by professionals, evaluating the quality of the XL-Sum dataset is crucial to ensure that it can be valuable and used by a wider community for abstractive summarization. For this, we thoroughly conducted human evaluations on a subset of the dataset.

We hired professional annotators[3] to assess the quality of the top-10 languages according to the number of speakers worldwide.[4] It is worth noting that not all of these 10 languages are high-resource (e.g., Bengali is a low-resource language despite being one of the most widely spoken).

Each evaluator was asked to assess the quality of a random subset of the dataset (around 250 article-summary pairs) by answering the following questions with 'Yes'/'No':

Property A: Does the summary convey what the article is about?

Property B: If the answer to property `A` is 'Yes', does the summary contain any information that is inconsistent with the article?

Property C: If the answer to property `A` is 'Yes', does the summary contain any information that cannot be inferred from the article?

The motivation for designing these properties stemmed from recent progress on the quality estimation of neural language generation (NLG) models. Belinkov and Bisk (2018) showed that NLG models are vulnerable to noisy and low-quality training samples, hence, it is essential to validate the quality of the summary through Property `A`. Ensuring factual consistency and faithfulness (Wang et al., 2020; Maynez et al., 2020) of the generated summaries is also a key consideration for neural abstractive summarization since neural models have been shown to generate hallucinated texts (See et al., 2017). Property `B` checks for consistency between the article and the summary; while Property `C` assesses the hallucination implicitly by limiting the knowledge domain to the input article and identifying additional information present in the summary.

Language/Dataset	A	B	C
CNN/DM	98.33	1.22	24.57
XSum	92.00	0.00	71.74
English	99.66	0.00	37.37
Chinese	93.49	0.00	29.56
Hindi	90.91	0.00	31.42
Spanish	84.71	0.00	42.93
French	99.20	0.00	26.72
Arabic	98.34	0.00	25.31
Bengali	91.14	0.00	26.85
Russian	95.65	0.00	38.64
Portuguese	88.31	0.47	38.50
Indonesian	97.59	0.41	27.57

Table 3: Quality of XL-Sum (along with CNN/DM and XSum) assessed by human evaluators. In most of the cases, the evaluators agree that the summaries convey the main idea (Property A), and do not conflict with the input text (Property B). However, the summaries may contain some additional information (Property C), since the editors writing the summaries may use their common sense and additional domain knowledge not present in the article.

It is desirable that property `A` would have a high percentage of 'Yes', while both property `B` and `C` would have a low percentage. However, the third property can be a bit ambiguous, since some pieces of information may not be directly present in the input article, but a professional with background knowledge and understanding of the article topic may infer them inherently. Since text summarization is posed as a closed-domain task, we asked the annotators to label accordingly, i.e., not making use of any additional information outside the article. We provided them with some sample annotations in English to aid them during annotation. The percentages of 'Yes' for the three properties are shown in Table 3.[5] We also showed human evaluation of CNN/DM and XSum for contrast. Each article-summary pair was labeled by

---

[3] Each evaluator had at least an undergraduate degree and had native or bilingual proficiency in the languages they were assigned to. Bilingual proficiency was determined by professional language tests for the corresponding language.

[4] `https://w.wiki/Pss`

[5] We measured inter-annotator agreement using Cohen's kappa coefficient. Most scores were within the 0.7-0.9 range, showing high agreement between the evaluators

two separate evaluators, and we considered each pair to exhibit property `A` if both agreed upon it and property `B` and `C` if at least one of them did.

We can see from Table 3 (Property `A`) that most languages showed a high percentage of good summaries in the upper nineties, while some had a slightly lower percentage (i.e., Spanish and Portuguese). We were informed by the annotators that the negative summaries were mostly extracted from opinion pieces and blog posts, the bold paragraphs of which did not convey the main story of the articles.

Almost none of the summaries contained any conflicting information (Property `B`), while about one-third on average had information that was not directly inferrable (Property `C`). Interestingly, more than 75% of the latter had missing information such as first names, designations, or elaborations of acronyms. For example, a summary had the phrase 'President-elect Joe Biden' while its corresponding article had no presence of the first name 'Joe'. Another article had NHS elaborated in the summary, which was absent in the article. In general. the types of extra information carried in the summaries were more or less the same across all languages. CNN/DM and XSum exhibit extra information in the summaries as well, implying this phenomenon is common in abstractive text summarization datasets.

The presence of extra information in the summaries is understandable, since professional experts writing these summaries not only use the information present in the article text, but also incorporate their knowledge and understanding of the outside world. But for a closed-domain summarization model or a layman to the topic, inferring this information is not so straightforward, which makes the automatic abstractive summarization task more challenging. This phenomenon may explain why language models fine-tuned on pretrained checkpoints (Raffel et al., 2020; Qi et al., 2020; Zhang et al., 2020) are achieving state-of-the-art results in abstractive summarization, as they are able to make use of outside information gained from the high volume of texts they were pretrained with. Additionally, it would be interesting to investigate whether the recent trend of incorporating real-world knowledge and commonsense reasoning (Tandon et al., 2018; Deng et al., 2020) into language models could improve text summarization performance.

4 Intrinsic Evaluation of XL-Sum

Although the human evaluations provided good insights into the quality of the summaries, there are several other aspects of the summaries that are often infeasible or impractical to judge by human evaluators. With the above backdrop, several works (Narayan et al., 2018; Grusky et al., 2018; Bommasani and Cardie, 2020) have proposed many automatic metrics to quantify important features of abstractive summaries (e.g., novel words, abstractivity, compression, and redundancy).

Novel n-gram ratio: Narayan et al. (2018) proposed the percentage of n-grams in the summary that do not occur in the input article as a means of measuring abstractiveness.

Abstractivity: Grusky et al. (2018) introduced *fragments*, which greedily match text spans between the article and the summary, and Bommasani and Cardie (2020) generalized it to introduce *abstractivity* to measure absractiveness.

Compression: Bommasani and Cardie (2020) proposed *compression* as a metric to quantify conciseness. Compression is measured by

$$\textbf{CMP}(A, S) = 1 - \frac{|S|}{|A|} \tag{1}$$

where $|A|$ and $|S|$ denote the length of the article and the summary, respectively. We measured length in terms of number of tokens.

Redundancy: Although Bommasani and Cardie (2020) proposed a metric to measure *redundancy*, it is only applicable to multi-sentence summaries, which is not the case for most examples in XL-Sum. Thus, we propose a new redundancy metric by calculating the number of repetitive n-grams in the summary text.

Let $\{g_1, g_2, \cdots, g_m\}$ be the unique n-grams occurring in a summary S, and let $\{f_1, f_2, \cdots, f_m\}$ be their respective frequencies. Then the total number of repeated n-grams are $\sum_{i=1}^{m}(f_i - 1)$. We define redundancy as the ratio of redundant n-grams and the total number of n-grams in S:

$$\begin{aligned}\textbf{RED}(S) &= \frac{\sum_{i=1}^{m}(f_i - 1)}{\sum_{i=1}^{m} f_i} \\ &= 1 - \frac{m}{|S| - n + 1}\end{aligned} \tag{2}$$

It is preferred of a good summary to have a high novel n-gram ratio, abstractivity, and compression; while having a low redundancy score.

Language /Dataset	**Percentage of novel n-grams ↑**				**ABS ↑**	**CMP ↑**	**RED (n=1) ↓**	**RED (n=2) ↓**
	n = 1	**n = 2**	**n = 3**	**n = 4**				
CNN/DM	13.20	52.77	72.22	81.40	38.75	90.90	13.73	1.10
XSum	35.76	83.45	95.50	98.49	75.70	90.40	5.83	0.16
English	32.22	80.99	94.57	98.06	71.74	92.97	6.56	0.20
Chinese	36.13	79.23	91.14	94.58	70.23	92.95	7.37	0.50
Hindi	29.55	74.77	90.87	96.29	64.63	93.00	9.91	0.16
Spanish	32.63	76.29	91.96	96.57	66.60	92.49	11.45	.0.57
French	35.41	74.72	88.39	93.24	65.29	88.34	8.34	0.44
Arabic	49.88	84.56	94.79	98.10	76.72	90.62	3.93	0.18
Bengali	38.81	81.10	92.10	95.89	72.76	94.74	2.93	0.25
Russian	49.27	85.89	95.57	98.34	78.39	91.25	4.34	0.16
Portuguese	30.28	77.11	92.23	96.71	66.80	94.47	10.22	0.34
Indonesian	33.54	76.87	91.73	96.53	66.68	91.62	3.94	0.23

Table 4: Intrinsic evaluation of our XL-Sum dataset compared to CNN/Daily Mail and XSum. All values are reported in percentage for easier comparison. We use ↑ to indicate "higher is better" and ↓ for the reverse. Both of XL-Sum and XSum are highly abstractive, concise, and shows comparable quality, although the XSum dataset contains only English samples. For both XL-Sum and XSum, percentages of novel n-grams (n = 1, 2, 3, 4) are significantly higher than CNN/DM. High abstractiveness (ABS) scores of XL-Sum and XSum also bolster this finding. Additionally, low redundancy (RED) and high compression (CMP) values indicate that XL-Sum and XSum are more concise than CNN/DM.

We show these metrics in Table 4 (for redundancy, we report values for $n = 1, 2$). We also show these metrics for the CNN/DM and XSum datasets.

The results indicate that the XL-Sum dataset is highly abstractive—about one-third of the tokens, and more than 75% of the bigrams in the summaries are novel, and the abstractiveness score is also high (more than 65% for most of the languages). Additionally, XL-Sum is very concise (the summary is less than one-tenth of the input article for most of the languages), and contains minimal redundancy (less than 10% for the majority). The quality of XSum is comparable, however, it is limited to only one language (i.e., English). On the other hand, the CNN/Daily Mail dataset is significantly behind XL-Sum and XSum as indicated by most of the metrics mentioned above.

5 Experiments and Benchmarks

In previous sections, we have discussed the quality of XL-Sum. In addition, it is imperative to see how state-of-the-art models perform when trained on this dataset. Moreover, for many languages (e.g., Bengali, Swahili), currently, there is no publicly available dataset and benchmarks for abstractive text summarization to the best of our knowledge. In this section, we train summarization models with the XL-Sum dataset and provide several baselines and benchmark results.

Fine-tuning Transformer-based (Vaswani et al., 2017) seq2seq models initialized with pretrained weights from self-supervised training (Raffel et al., 2020; Liu and Lapata, 2019; Rothe et al., 2020; Qi et al., 2020; Zhang et al., 2020) has been shown to achieve state-of-the-art performance on many abstractive text summarization datasets. There are many multilingual pretrained checkpoints available through the Hugging Face Transformers Library (Wolf et al., 2020). Among them, we chose to use the mT5 model (Xue et al., 2021), a multilingual language model pretrained on a large dataset of 101 languages.

We performed summarization experiments in two settings: (i) multilingual, and (ii) low-resource. For performance reporting, for each language, we randomly sampled 500 pairs for its development set and 500 pairs for its test set, while using the rest of the pairs for training. We tokenized our training samples using the 250k wordpiece (Wu et al., 2016) vocabulary provided with the mT5 checkpoint. Due to computational constraints, we used the base model (600M parameters) and had to truncate the inputs to 512 tokens and the outputs to 64 tokens. We used the ROUGE-1, ROUGE-2 and ROUGE-L (Lin, 2004) scores for automatic evaluation. For inference, we used beam search with beam size 4 and length penalty of $\alpha = 0.6$ (Wu et al., 2016).

5.1 Multilingual Summarization

Multilingual training is performed by training a single model with training samples from multiple languages. It has been previously used in several NLP tasks including neural machine translation (Arivazhagan et al., 2019) and language model pretraining (Conneau and Lample, 2019). However, multilingual training in the context of abstractive summarization has not been a major focus of the community. As such, the aim of this experiment is to demonstrate that a single model can perform well on summarizing texts in different languages, and that sister languages with morphological similarity can take advantage of positive transfer from each other which is not possible in monolingual settings.

For this experiment, we followed a similar training strategy as Conneau and Lample (2019): we sampled each batch from a single language containing 256 samples and used a smoothing factor (α) of 0.5 so that batches of low-resource languages would be sampled at a higher rate, increasing their frequency during training.

We fine-tuned the mT5 model for 35k steps on a distributed cluster of 8 Nvidia Tesla P100 GPUs for 4 days. We used the Adafactor optimizer (Shazeer and Stern, 2018) with a linear warmup of 5,000 steps and 'inverse square root' learning rate schedule. We show the ROUGE scores achieved by the model on the top-10 languages in Table 5.

Language	R-1	R-2	R-L
English	36.99	15.18	29.64
Chinese	36.89	15.23	30.52
Hindi	34.51	13.55	28.23
Spanish	30.93	12.14	23.76
French	34.47	15.94	27.53
Arabic	33.23	13.74	27.84
Bengali	28.32	11.43	24.23
Russian	31.10	13.47	25.54
Portuguese	31.06	11.62	23.39
Indonesian	36.17	16.70	30.50

Table 5: ROUGE scores for multilingual summarization achieved by the mT5 model when fine-tuned on the XL-Sum training set.

As we can see from the table, the multilingual model achieved higher than 11 ROUGE-2 scores on all languages. Some of these languages (e.g., Bengali) are low-resource, but the model still obtained competitive results comparable to high and mid-resource languages. Also, we are the first to report the abstractive summarization benchmark for a number of languages, including Bengali.

The mT5-base model achieves a R2-score of 15.18 on the English language. In comparison, the state-of-the-art PEGASUS$_{\text{BASE}}$ model (Zhang et al., 2020) obtained an R-2 score of 16.58 trained on the XSum English dataset, which is similar to XL-Sum in nature. This result suggests that the performance is comparable to the state-of-the-art English summarization. The R-2 scores for other languages are also similar to English, indicating that our dataset can help to effectively generate automatic summaries for all languages tested, including those low-resource ones.

5.2 Low-Resource Summarization

We have shown the effectiveness of the multilingual training strategy in summarizing articles for a wide set of languages with a single model. However, training the model is compute-heavy and it may not be realistic in many scenarios. For the dataset to be termed as versatile, models trained on individual languages should be able to perform competitively with the multilingual model. To confirm this is indeed the case, we performed training on five low-resource languages from Table 2 (Amharic, Azerbaijani, Bengali, Japanese, Swahili) in a compute-efficient setup. We fine-tuned mT5 on each language separately for 6-10 epochs (since the total training samples were limited, we had to be careful to prevent overfitting) on a single-GPU (Nvidia RTX 2080Ti) machine. For these experiments, we used a batch size of 32 and trained with a slanted learning rate schedule (Howard and Ruder, 2018). We show the ROUGE scores of each model in Table 6. We use the results from the multilingual models as baseline.

Language	Low-resource R-1/R-2/R-L	Multilingual R-1/R-2/R-L
Amharic	15.33/5.12/13.85	**17.49/6.34/15.76**
Azerbaijani	16.79/6.94/15.36	**19.29/8.20/17.62**
Bengali	25.33/9.50/22.02	**28.32/11.43/24.02**
Japanese	44.55/21.35/34.43	**47.17/23.34/36.20**
Swahili	34.29/15.97/28.21	**38.18/18.16/30.98**

Table 6: Performance of mT5 model fine-tuned on a low-resource training setup vs multi-lingual setup as mentioned in the previous section.

As evident by the results from Table 6, the multilingual model outperformed all the models trained on a single language. This is expected since similar languages can have positive transfer between them (Conneau et al., 2020) when trained together. However, the low-resource models do not trail by a large margin, in all cases the difference is not more than 2 for R-2 scores. This is a good indication that models fine-tuned on such a low amount of samples can still generalize to produce results competitive to multilingual models.

The case for Amharic, Azerbaijani and Japanese call for a discussion on their performance. The first two had comparatively low scores, while the last one (Japanese) had considerably higher scores compared to the other languages. Amharic and Azerbaijani had approximately 4k and 6k training samples respectively, which we conjecture is the primary reason behind their underperformance. Moreover, we did not find any reliable stemmer to preprocess the generated summaries before computing ROUGE, which may also hurt the scores. On the other hand, Japanese texts are not word-segmented and the words need to be separated before calculating ROUGE. We used Fugashi (McCann, 2020), and possibly due to its aggressive segmentation, the scores turned out to be higher than other languages. Similar high results have also been reported while measuring BLEU (Papineni et al., 2002) scores for machine translation evaluation in Japanese (Kudo, 2018).

Results in Table 6 show that although these languages are low-resource, the scores of the two setups are close, indicating our dataset can also be useful when used with a constrained computation capability. This is likely to contribute towards advances in low-resource text summarization, enabling fairness and access to the underserved communities.

6 Related Works

Rush et al. (2015); Nallapati et al. (2016) pioneered neural abstractive summarization, using recurrent attentional seq2seq models (Bahdanau et al., 2015). See et al. (2017) introduced Pointer-Generator networks for abstractive summarization, which can learn to copy words from the input text, in addition to generating new texts with the decoder. Gehring et al. (2017) proposed convolutional seq2seq models and applied it to perform abstractive summarization. Narayan et al. (2018) extended the work by integrating topic embeddings with the model.

Pretrained language models have recently been successfully applied to abstractive summarization. Liu and Lapata (2019) initialized the encoder and Rothe et al. (2020) initialized both the encoder and the decoder of a seq2seq model with the pretrained BERT (Devlin et al., 2019) weights and fine-tuned the models for abstractive summarization. Raffel et al. (2020); Qi et al. (2020) used fully pre-trained seq2seq models, while Zhang et al. (2020) introduced a summarization-specific pretraining objective to achieve state-of-the-art results on multiple datasets.

Most works on abstractive summarization have so far focused on English, in large part due to a lack of benchmark datasets for other languages. Giannakopoulos et al. (2015) introduced MultiLing 2015, a summarization dataset spanning 40 languages. However, MultiLing 2015 is limited in size, with the training set having only 10k samples in total. Cao et al. (2020); Scialom et al. (2020) introduced two new datasets for multilingual summarization, but both were limited to less than 10 languages. Moreover, samples for different languages were collected from different sources, making them exposed to different types of summarization strategies, which raises questions on the uniformity of the summaries.

7 Conclusion and Future Works

In this paper, we present XL-Sum, a large-scale, high-quality multilingual text summarization dataset, containing 1 million samples across 44 languages collected from a single source, BBC. For many of the languages, XL-Sum provides the first publicly available abstractive summarization dataset and benchmarks. We also make the dataset curation tool available for the researchers, which will help to grow the dataset over time. Thorough human and intrinsic evaluations indicate that the summaries in our dataset are highly abstractive and concise while conveying the main idea with little to no conflict with the input article. Additionally, we demonstrate that multilingual training can help towards better summarization, most likely due to the positive transfer between sister languages with morphological similarity. Moreover, XL-Sum is also useful in a low-resource and compute-efficient setting.

In future, we will investigate the use of our dataset for other summarization tasks (e.g., cross-lingual summarization Zhu et al., 2019).

We hope the XL-Sum dataset will be helpful for the research community, especially for the researchers working to ensure fair access to technological advances to under-served communities with low-resource languages.

Use of Formal Ethical Reviews in NLP Literature: Historical Trends and Current Practices

Abstract

Ethical aspects of research in language technologies have received much attention recently. It is a standard practice to get a study involving human subjects reviewed and approved by a professional ethics committee/board of the institution. How commonly do we see mention of ethical approvals in NLP research? What types of research or aspects of studies are usually subject to such reviews? With the rising concerns and discourse around the ethics of NLP, do we also observe a rise in formal ethical reviews of NLP studies? And, if so, would this imply that there is a heightened awareness of ethical issues that was previously lacking? We aim to address these questions by conducting a detailed quantitative and qualitative analysis of the ACL Anthology, as well as comparing the trends in our field to those of other related disciplines, such as cognitive science, machine learning, data mining, and systems.

1 Introduction

With the rapid advances in the field of Natural Language Processing (NLP), language technologies are getting woven into the daily fabric of our lives and the society. Since “language is a portal of emotions, a proxy of human behavior, and a strong signal of individual characteristics” (Hovy and Spruit, 2016), large-scale deployment of language technology has potential risks that require early detection and mitigation. Naturally, there have been several discussions about the potential harms and ethical issues concerning NLP (Hovy and Spruit, 2016; Conway and O’Connor, 2016). They have mostly revolved around building or deploying systems in sensitive areas such as hate speech (Sap et al., 2019), social media (Benton et al., 2017), clinical NLP and mental health (Šuster et al., 2017; Mikal et al., 2016) and use of sensitive or personal information (Larson, 2017). While building NLP systems, there are also ethical risks associated with involvement of human subjects through user studies or data collection activities (Shmueli et al., 2021).

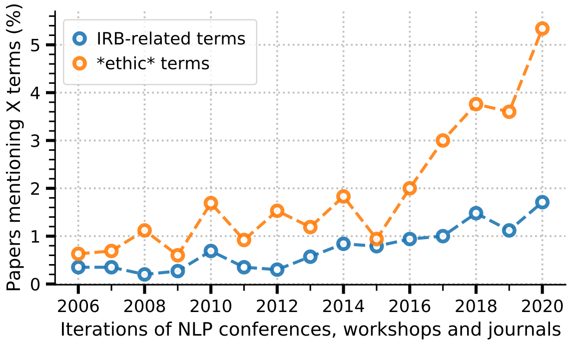

Figure 1: Percentage(%) of papers mentioning IRB-related and *ethic* terms in NLP conferences, journals, and workshops from 2006 to 2020.

The awareness of the dangers of the existing and new NLP applications has led to the curation of several ethical guidelines and frameworks. Undergirded by lessons from the past, these guidelines and frameworks help researchers consider and contextualize critical ethical concerns. Most of the ethical issues in NLP are rooted in the data being used for research. Couillault et al. (2014) is one of the first works to explore the ethics of data collection and evaluation in NLP. Several other works have proposed best practices for dealing with ethical implications of NLP research and deployment (Prabhumoye et al., 2019; Leidner and Plachouras, 2017; Bender and Friedman, 2018; Schnoebelen, 2017). There is now an increased awareness around this topic with a number of workshops and tutorials on ethics at NLP conferences (Tsvetkov et al., 2018; Hovy et al., 2017; Alfano et al., 2018). Such discussions have resulted in a number of reforms at NLP conferences. NLP conferences now have new track called *Ethics in NLP*. Furthermore, several ML and NLP conferences such as **NeurIPS** 2020,

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4704–4710
August 1–6, 2021.

NAACL 2021 and **ACL** 2021[1] now recommend the inclusion of broader impact statement in their papers, which allows for authors to introspect and be mindful of the ethical implications their research poses.

Although an NLP researcher might be individually committed towards ethical research practices, they may not have the expertise in ethical and legal issues to gauge the potential risks of a technology or a dataset that they are building. The practice of getting the research/study approved by an ethical review board (aka Institutional Review Board or IRB)[2] instituted by the organization is thus critical in early defusal of the potential harms. The two primary functions of IRB are (i) to protect the rights and welfare of human research subjects, and (ii) to support and facilitate the conduct of valuable research (Bankert and Amdur, 2006; Klitzman, 2012; Byerly, 2009). Traditionally, IRB has been a long-standing norm in biomedical research due to its overt exposure to human subjects. However, with computing research pervading human lives, IRBs have started covering computing research as well (Buchanan and Ess, 2009; Vitak et al., 2017). With regards to NLP, most of the data collection and annotation processes as well as user studies come under the purview of these boards. These are particularly necessary if they cover sensitive topics such as mental health or hate speech which can affect the human subjects involved in data collection or the users of the system.

How frequently do NLP researchers take IRB approvals for their studies? What aspects of NLP research or which topics of study are typically considered for IRB approvals? What are the historical and current trends, and what can we say about the awareness of the NLP research community around ethical issues? In this paper, we try to answer these questions through a quantitative and qualitative analysis of papers from the ACL anthology that seek IRB approvals. According to our findings, IRB approvals were almost non-existent in the NLP literature until 2006, but there has been a steady increase since 2016. We also study the distribution of IRB approvals by country and industry/academia affiliation, as well as compare the recent trends in NLP conferences to that of various prominent conferences ranging from machine learning and data mining to human-computer interaction and systems. One of the key findings of this study is that IRB permission was mostly sought for either data collection or annotation studies, but hardly ever for data re-purposing or system design/deployment - a void that we think the NLP community should be conscious about.

2 Method

To determine the trends of IRB approvals in NLP research, we resort to searching for IRB- and ethics-related terms in research papers. We obtain the papers (PDFs) for major NLP conferences, journals and workshops [**ACL**, **COLING**, **EACL** **EMNLP**, **LREC**, **NAACL**, **CL**, **TACL**, and **WS**] from the ACL Anthology (curated by Joshi et al. (2020)). For a comparative analysis, we also collect papers from other related conferences [**CogSci**, **InterSpeech**, **NeurIPS**, **CVPR**, **ICWSM**, **CHI**, **COMPASS**] for the years 2019 and 2020, during which there was considerably more discussion around ethics of computing research.

In order to retrieve papers that seek IRB approvals, we search for the following keywords which cover the phrases used for IRB in countries that are frequently represented at these conferences: review board, ethics board, ethics panel, ethics committee, consent form, and IRB.[3] To further compare and calibrate, we also search for papers that contain the wildcard string *ethic*, which brings up a broader set of papers that may discuss ethical repercussions of their work, even if any approval is not explicitly sought or mentioned. To assist with a robust search over this textual data, we use the Allen AI SPIKE interface[4] (Taub Tabib et al., 2020; Shlain et al., 2020) and use pdfgrep[5] to cross-check our results.

IRB-related term search yielded 210 papers from the ACL anthology (till 2019), which were then manually checked for precision and annotated for *aspects* (see Figure 3) and *topics* (e.g., hate speech, social media, mental health, etc.) of the research for which IRB permission was sought. Through our manual curation, we found that 94.17% of these papers actually took the approval for their research study thus showing that our search is precise in capturing the terms.

---

[1] `https://2021.aclweb.org/ethics/Ethics-FAQ/`

[2] In this paper, we use IRB as a generic term to refer to such review boards which are known by slightly different terms in different geographies.

[3] Collectively referred to as IRB-related terms from hereon.

[4] URL when accessed: `https://spike.staging.apps.allenai.org/datasets/acl/search`

[5] Command-line tool: `https://pdfgrep.org/`

The remaining papers were mostly ethical frameworks and recommendations (e.g., Hovy and Spruit (2016); Bender and Friedman (2018)) which merely mentioned the need for seeking IRB approvals in NLP research.

3 Findings

3.1 How many papers seek IRB approvals?

	06	07	08	09	10	11	12	13	14	15	16	17	18	19	20
ACL	0.0	0.0	0.0	0.9	0.4	0.0	0.0	0.0	0.0	0.3	0.3	0.7	1.0	0.5	1.7
EMNLP	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.5	0.4	0.0	0.0	0.6	0.5	0.6	1.1
NAACL	0.0	0.0		0.0	0.0		0.0	0.0		0.0	1.1		1.2	1.4	
EACL	0.0			0.0			0.0		0.0			0.0			
AACL															1.1
COLING	0.0		0.0		0.0		0.0		0.0		0.0		1.2		0.8
LREC	0.8		0.3		1.1		0.6		1.1		0.8		2.1		2.9
CL	0.0	2.4	0.0	0.0	0.0	2.1	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0
TACL								0.0	0.0	0.0	2.6	0.0	2.1	0.0	1.9
WS	0.3	0.5	0.2	0.2	0.8	0.4	0.3	0.9	1.3	1.3	1.6	1.4	1.8	1.5	1.8

Figure 2: The percentage (%) of papers in NLP conferences, journals and workshops over the past 15 years that mention <u>IRB-related</u> terms. The intensity of color is proportional to the % values. The boxes with a gray hatch reflect the years when that particular conference was not held.

Figure 2 shows the percentage(%) of papers in each NLP conference iteration that mention IRB-related terms. It is immediately obvious that for almost all the conferences only a minuscule number of papers mention IRB approvals. However, it is heartening to see that the number of mentions is increasing in recent years. **LREC** and **WS** particularly stand out among the other conferences for having at least some mentions of IRB approvals in every iteration. For **LREC**, it is understandable, since the theme of the conference revolves around data and resource generation. In the case of **WS**, IRB mentions are consistently increasing over the years. We observed that this is mostly due to the diverse nature of workshops some of which are on resource generation (Popescu-Belis et al., 2019) or cover sensitive topics (Niederhoffer et al., 2019; Yannakoudakis et al., 2019). Journals such as **CL** and **TACL** have very few papers in each iteration, so even one IRB mention appears to be a lot. It should be noted that there is a possibility that a research study has obtained IRB approval but has not disclosed it in their paper. However, based on the authors' experience (and anecdotes from personal conversations), it is highly unlikely that anyone who has been through the IRB approval process will fail to mention it.

3.2 What kinds of research seek IRB approvals?

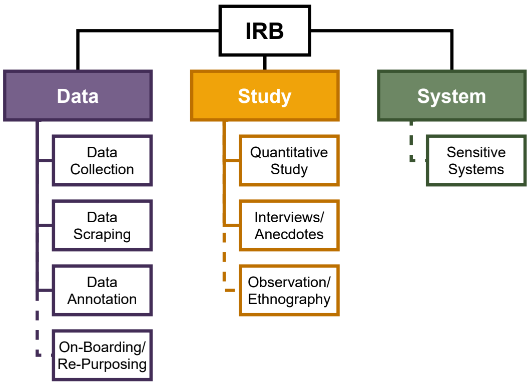

Figure 3: Different *aspects* of research for which IRB approvals were sought in the papers that we manually analyzed.

We manually go through each of the 58 NLP papers (which excludes **WS**) to derive the *aspects* and understand the context in which IRB approvals are sought and build a taxonomy of the broad topics covered (Figure 3). We see that most of them (24 papers; 41.3%) take IRB approvals for collection of data which can often involve human subjects directly. It is followed by the annotation of data with 20 papers (34%) taking IRB approvals. A meager 7 papers (12%) in our set take IRB approvals for scraping data which is the automatic collection of data from web pages or social media posts without explicit consent from the users. We see that only one paper takes IRB approval for re-purposing and further annotation of data (Rogers et al., 2018). One of the core concerns of GDPR is the usage of personal data collected by media platforms for a purpose different than what the user consented to and hence such re-purposing of data should ideally undergo IRB approvals. 12 papers (20%) take approvals for conducting user studies of both qualitative (survey, interview) and quantitative nature (semantic edits). Interestingly, we see that only one paper has taken IRB approval for the whole system owing to its sensitive nature (Cao et al., 2018).

We also look at the nature (or *topics*) of the work for which the IRB approvals are taken. We observe that 48.4% of papers that mention IRB have sensitive topics (such as mental health, hate speech, clinical/medical NLP), 20.3% of the papers are for collection of eye movement, EEG and audio/video recordings of human subjects, and rest of them are generic data collection or user study. To further understand the trends, we look at certain tracks of **ACL** 2020 which deal with sensitive topics or

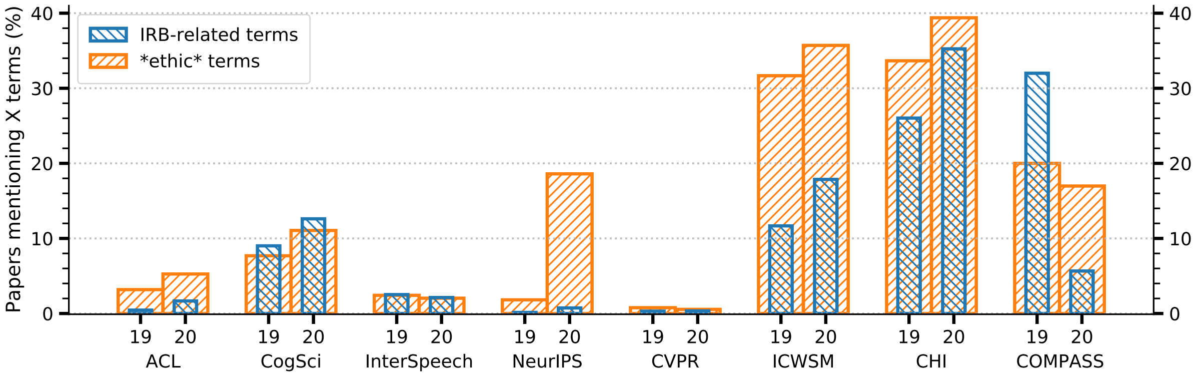

Figure 4: Percentage(%) of papers mentioning IRB-related and *ethic* terms in related conferences.

data collection. We notice that only 1/42 *Resource and Evaluation* papers and 3/24 *Computation Social Science* papers have taken IRB approvals. It is worth noting that 29/210 papers we have annotated only used an informed consent form without explicitly mentioning whether an ethical review board was involved in the process.

3.3 What is the distribution of IRB approvals by country and industry/academia?

	Total Papers	**Percent Papers**
Countries		
USA	47/5368	0.88%
Canada	5/358	1.40%
Germany	5/850	0.59%
UK	5/1088	0.46%
Netherlands	3/226	1.33%
Sweden	2/100	2.00%
South Korea	2/151	1.32%
China	2/2350	0.09%
Affiliation Types		
University	52/7730	0.67%

Table 1: Distribution of % IRB-related term mentions among countries and different types of affiliations for NLP conferences (excluding **LREC** and **WS**) from 2012 to 2020. [6]

Table 1 shows the distribution of papers which mention IRB approvals along two dimensions: countries and types of institutions. As can be observed, most of the listed countries are WEIRD[7] societies. When it comes to the type of institution, we find that universities account for the vast majority of papers seeking IRB approvals, followed by joint collaborations. This trend can be counter-intuitive as an industry is more likely to be regulated and accountable for the ethical and legal concerns of their work. One possibility is that industries perhaps do not engage in external data collection/annotation work or conduct user studies as much as academic institutions do. Alternatively, it is possible that the data collection/annotation process is a completely independent pipeline that is not specific to the research paper in which it is used and thus is not reported.

3.4 How do the IRB trends in NLP research compare with those in related fields?

We look at the following conferences for our analysis: **CogSci** in cognitive science, **InterSpeech** in speech processing, **NeurIPS** in machine learning, **CVPR** in computer vision, **ICWSM** in social media mining, **CHI** in human-computer interaction, and **COMPASS** in computing systems deployment. We specifically analyze these conferences for 2019 and 2020 iterations as there have been significant changes made in the conferences during this period in terms of reporting the ethical ramifications of their research. Figure 4 shows the % of papers mentioning *ethic* and IRB-related terms for each conference iteration. We calculate for *ethic* to understand how aware and concerned each field/conference is towards the ethical implications of the research they conduct.

It is not surprising that IRB mentions for **CHI** are so high ($\sim 35\%$) given that more than 65% percent of CHI papers include at least one user study (Koeman, 2020). **ICWSM** works with datasets and systems related to web and social media analytics and hence would need to undergo IRB approvals. This is apparent in the relatively high number of IRB

---

[7] Western, Educated, Industrialized, Rich and Democratic

mentions in both 2019 and 2020. Unlike the other conferences we choose for our analysis, **CogSci** is a non-computing conference. Linguistics work is frequently found in **CogSci**, which often makes use of human subjects. We observe that it has the most consistent representation of both *ethic* and IRB-related term mentions among the years. As previously discussed, one of the concerns is that sensitive systems are seldom taking IRB approvals. On the contrary, we notice that **COMPASS**, a conference largely focused on deploying computing systems, is prevalent in taking IRB approvals. **InterSpeech** and **CVPR** have significantly fewer papers with IRB mentions ($< 0.35\%$ and $< 2.5\%$, respectively) and the trends have hardly changed over the years, despite the fact that they conduct research with speech, multimodal, and vision data that may have been collected from human subjects. Among these, there is a ray of hope for **ACL** which is showing a significant positive trend in both *ethic* and IRB mentions without any external reinforcement, thanks to the increasing awareness in the field. **NeurIPS**, on the other hand, has seen a meteoric rise in their *ethic* mentions, which, on manual inspection reveals, is due to their mandatory inclusion of broader impact statements. There has also been a slight increase in their IRB mentions, which could be attributed to this, indicating that broader impact statements might help researchers be more cautious when proposing their research to the larger community. This quantitative testimony from **NeurIPS** shows that **ACL** and other *CL conferences are moving in the right direction with their inclusion of stringent ethics reviews for their papers.

4 Way Forward

In this paper, we conduct a survey of IRB approvals in NLP research. The two key observations we make are as follows. First, very few papers ($< 0.8\%$ of all papers published) since 2006 have sought an IRB approval; though we do observe a rise in numbers ($< 1.3\%$ of all papers published) since 2016. This is much smaller compared to the numbers we observe for other conferences such as **CogSci**, **CHI**, **ICWSM** or **COMPASS**. Second, the majority of the IRB approvals were obtained for data collection or annotation that directly involved users, with only a few studies seeking approvals for data scraping or re-purposing. Such approvals are even more scarce for sensitive systems where we seldom see any paper taking IRB approvals solely for the system. The number of papers creating new datasets is expected to be greater than 1% of all NLP papers[8]; the number of papers that re-purpose an existing dataset is expected to be even greater than this. Therefore, clearly not all papers creating datasets, and almost no paper re-purposing datasets take approvals from IRB. As such, re-purposing data collected from human subjects without their explicit consent on how the data will be re-used is potentially dangerous and may even have legal repercussions. Furthermore, with the exception of a couple of papers, to date, there is no practice or trend of taking IRB approval for designing, developing, and deploying systems. This is in stark contrast to the practice in other related fields/conferences such as **COMPASS**. Much of the harm caused by a system could actually come from its design or style of training or deployment, rather than the underlying datasets.

We see that the broad impact statements have helped conferences such as **NeurIPS** which were traditionally oblivious to ethical issues (Nanayakkara et al., 2021). We believe that, in a similar way, the impact statements introduced in **NAACL**[9] and **ACL** 2021, with specific clauses for seeking IRB, will be highly beneficial in limiting the aforementioned potential risks by increasing the awareness amongst researchers of broader ethical repercussions of their research. It will be interesting to conduct a similar study a few years down the line and contrast with the findings of the current study.

Acknowledgements

We thank Prof. Emily M. Bender (UW) for providing useful insights and inspiration at the early stages of this work. We also thank Dr. Mary L. Gray and Ms. Anu Kannepalli (Microsoft) for their many insightful inputs, Prof. Yoav Goldberg (Allen AI) for setting up the SPIKE instance for us, and Prof. Katharina Reinecke (UW) and Dr. Prasanta Bhattacharya (A*STAR) for the broad discussions around IRBs. We also thank anonymous reviewers from ACL and NLP4PI workshop for their thoughtful suggestions and feedback.

---

[8] As a crude statistics, consider the fact that the number of accepted papers in the *Resource and Evaluation* track in **ACL** 2020 was 5.4%, whereas only 1.7% of all the papers in that year sought for IRB approvals.

Abstract

Mistranslated numbers have the potential to cause serious effects, such as financial loss or medical misinformation. In this work we develop comprehensive assessments of the robustness of neural machine translation systems to numerical text via behavioural testing. We explore a variety of numerical translation capabilities a system is expected to exhibit and design effective test examples to expose system underperformance. We find that numerical mistranslation is a general issue: major commercial systems and state-of-the-art research models fail on many of our test examples, for high- and low-resource languages. Our tests reveal novel errors that have not previously been reported in NMT systems, to the best of our knowledge. Lastly, we discuss strategies to mitigate numerical mistranslation.

1 Introduction

Just as neural machine translation (NMT) systems have achieved tremendous benchmark results, they have been proven brittle when faced with irregular inputs such as noisy text (Belinkov and Bisk, 2018; Michel and Neubig, 2018) or adversarial inputs (Cheng et al., 2020). Among such errors, mistranslation of *numerical text* constitutes a crucial but under-explored category that may have profound implications. For example, in the medical domain, mistranslating the number of confirmed cases of a contagious disease like COVID-19 may exacerbate public health misinformation. Numerical errors made in financial document translation, *e.g.*, an extra or omitted digit or decimal point, could lead to significant monetary loss. Surprisingly, we find that numerical mistranslation is a general issue faced by state-of-the-art NMT systems, including commercial and research systems, with evidence present across contexts: for both high and low resource languages, and for both close and distant languages.

Type	**Input**	**Output**
Separators	The distance is 557,601.101 meters.	**[De]**: Die Entfernung beträgt 557.601.101 Meter.
Numerals	The total weight is two hundred and two kg.	**[Zh]**: 总重量为220公斤。
Digits	The R0 of the disease is 3.28.	**[Ne]**: रोगको R0 28.२28 हो।
Units	There were 100.01 million cases worldwide.	**[Zh]**: 全世界有1.001 亿病例。(100.1 million)

Table 1: Numerical errors discovered by our method when behavioural testing two popular commercial translation systems using their public APIs.

De facto standard metrics such as BLEU (Papineni et al., 2002) may fail to flag a numerical translation error, which only contributes a very minor penalty, as it is typically a single-token mistranslation. To facilitate the discovery of numerical errors made by NMT systems, we propose a black-box test method[1] for assessing and debugging the numerical translation of NMT systems in a systematic manner. Our method extends the `CheckList` behavioural testing framework (Ribeiro et al., 2020) by designing automatic test cases to assess a suite of fundamental capabilities a system should exhibit in translating numbers.

Our tests on state-of-the-art NMT systems expose novel error types that have evaded close examination (Table 1). These error types greatly extend the *number* category (`NUM`) of the *catastrophic errors* (Specia et al., 2020) of NMT systems with richer error types. Finally, the abuse of these errors constitute vectors of attack: error-prone numerical tokens injected into monolingual data may

Capability	Examples
Integers	There were 914 confirmed cases of COVID-19 reported yesterday.
Decimals	The reproduction number of COVID-19 is between 3.28 and 5.70.
Numerals	The total amount of transfer is fifty-two dollars and seven cents.
Separators	123,456.12 (En) → 123.456,12 (De)

Table 2: Tested capabilities of NMT systems in translating common types of numerical text.

corrupt *back-translation-based* training, as the resulting back-translated sentences are very likely to contain the desired errors.

2 Method

We follow Ribeiro et al. (2020)'s `CheckList` in designing our evaluation suite for NMT systems: we present several basic *capabilities* an NMT system should be expected to exhibit in translating common everyday numerical text; we then generate *test examples* specific to each capability to benchmark performance and find bugs in NMT systems.

2.1 Capabilities of Translating Numbers

We explore four capabilities (see Table 2), demonstrating expected translation ability of a system on common types of numerical text. Concretely, the *Integers* and *Decimals* represent basic capabilities; they can be manifested by testing on sequences of digits with variable lengths (*e.g.*, 100 vs. 10000) or decimals with the decimal mark placed at varying locations (1.001 vs. 10.01). We find that the tested NMT systems are more likely to malfunction when translating larger integers and decimals with longer fractional parts. The *Numerals* capability pertains to whether a system is able to translate numbers that are presented as words. The *Separators* capability checks if a model can deal with numbers containing decimal or thousands separators.[2] Systems that fail to manifest one or more of these capabilities may produce wrong numbers that can be inconspicuous to users and become a ready, exploitable source of misinformation.

2.2 Test Examples

To efficiently test the identified capabilities across multiple systems on distinct language pairs, we generate desired test examples using templates. For example, to test the *Numerals* capability, we use a template sentence such as "CNBC reported there were at least `[NUM]` cases worldwide.", where "`[NUM]`" is a number with the format "`ddd.ddn`", consisting of multiple digits and a numeral (*e.g.*, 100.01 million).

We experiment with formats of various lengths and decimal-point positions. We fill a format with random digits and numerals, and explore 25 different formats across all capabilities. This allows us to generate a diversity of numbers at scale, akin to fuzzing a program with random inputs to uncover bugs. We also note that all the numbers created for a format can be seen as a set of "adversarial" examples, as they are small perturbations of each other. Details about the test examples for each capability and the testing process can be found in Supplementary material.

3 Evaluation

Before presenting experimental results and discussion of our test framework, we first detail our evaluation setup.

Language pairs. We test both high-resource (HR) and low-resource (LR) scenarios. For HR, we consider two language pairs: English-German and English-Chinese, and for LR, we focus on English-Tamil and English-Nepali. We test both translation directions for each pair.

SOTA systems. We conduct behavioural testing against two popular commercial translation systems (denoted by **A** and **B**). As research systems, we use pre-trained models that were shown to perform well in WMT competitions (denoted by **R**), specifically, fairseq's transformer for English-German (Ng et al., 2019), English-Tamil (Chen et al., 2020), and English-Chinese/Nepali (Fomicheva et al., 2020).

The evaluation metric. For each capability we curate a list of test examples (sentences containing numbers), which are taken from various sources, including existing corpora or manually crafted (details in Supplementary material). To these sentences we remove the number component, and replace it with a number based on the specific capa-

---

[2] While *Decimals* and *Separators* may have overlapping instances (*e.g.*, the decimal mark), their specific formats in our testing are different (Table 2), which leads us to find non-overlapping error types: most *Decimals* errors involve translating numbers into wrong digits, whereas *Separators* errors pertain to mistranslation in localisation usage (*e.g.*, German and English use different decimal and thousand separators).

bility being tested. This test collection is then input to a translation system, and we report the *Pass Rate* (PR), the fraction of inputs where the system translates the numerical component perfectly.[3]

3.1 Testing Performance

Table 3 shows the results of testing the three SOTA systems across the HR/LR language pairs.

Among the four capabilities, *Numerals* turns out to be the most challenging across the systems tested, with the average $\overline{\text{PR}}$ of 70.8%. This is probably because, compared to other forms, numbers are less frequently written as words, resulting in insufficient examples available for training. At the other extreme, *Integers*, which tests on pure digits, is the easiest capability, as expected. Despite this, it is not a 'solved problem', given all systems report imperfect $\text{PR} < 100$ on at least one language.

Across the systems, the research system **R** ($\overline{\text{PR}}$: 77.8%) underperforms the two commercial ones ($\overline{\text{PR}}_A$: 80.6%, $\overline{\text{PR}}_B$: 90.4%). This is largely caused by the fact that the research system fails markedly on the En→Ne direction.

Per language, the results are similar in both translation directions, implying that numerical translation is a symmetric problem. Note that the results on LR are not always worse than that on HR (PRs on En-Ta are surprisingly the highest of all). This suggests that the size of training data is not the sole factor for high-quality numerical translation.

3.2 Error Analysis

We present analysis of novel types of mistranslations discovered from testing.

Decimal/thousands separators. We find that the decimal/thousands separators are prone to be mistranslated in localisation scenarios, when conventions differ between the languages (*e.g.*, "," and "." are the thousands and decimal separators in English while they are swapped in German). A common type of error is that a separator remains the same after translation (Table 4, row 1). This is probably due to the lack of sufficient training data to learn the translation of the separators in the target language.

Cardinal numerals. Cardinal numerals are commonly used in commercial and financial contexts. For example, the *financial characters* (*e.g.*, "壹" meaning one) are typical in Chinese financial documents. However, we find that the tested translation systems perform fairly poorly in translating cardinal numerals (Table 4, row 2). Common errors include mistranslation or under-translation of the unit words (*e.g.*, hundred) or the number words (*e.g.*, "陆拾"). Most often, the errors appear to be caused by the unique unit words used in different languages (*e.g.*, "万" in Chinese equals to 10 thousand), where a system needs to "compute" the correct amount for translation.

Digits. The pure digit translation (10→10) is expected to be easy, since a system may opt to copy the entire number as the translation. However, we find that the digit translation between English and low-resource languages can be far from satisfactory. An example is the translation between English and Nepali (Table 4, row 3). One reason for this result is that Nepali has its own numerals for digits (*e.g.*, १ denotes 1). As a result, a system would try to convert a digit into a Nepali digit (instead of keeping it unchanged) when translating numbers, which is difficult given limited training resources (Guzmán et al., 2019). Another common issue in digit translation is handling repeats of the same digit. A system is prone to omit or add one or more digits in the translation.

Units. This error often occurs when translating numbers accompanied by units of measurements (*e.g.*, 10 meters), especially when the target unit is unique to the language, *e.g.*, "角" in Chinese means "10 cents". In such cases (Table 4, last row), the system may need to learn the implicit conversion rules and then use them to "calculate" the correct numbers with the target unit of measurement. For example, when translating "10.01 million" into "1001 万" in Chinese, the system has to convert "10.01" into "1001" and then use the correct unit "万". An error may occur if the system fails either or both stages of this process (*i.e.*, mistranslating the numbers and/or units).

4 Potential Mitigation Strategies

Finally, we discuss several strategies that may mitigate the above errors discovered by our method[4].

---

[3] We count a Pass if the output matches the ground truth number, allowing for the use of digits (Arabic or local scripts) or numerals. For this purpose we use `num2words` (`https://pypi.org/project/num2words/`), `cn2an` (`https://github.com/Ailln/Cn2An.jl`), and locally developed scripts (for Ne and Ta).

[4] We leave validation of these strategies to future work.

Lang	Integers			Decimals			Numerals			Separators			Avg

Table 4: Examples of four major types of errors discovered by our tests on three SOTA NMT systems.

Separate treatment of numbers. Although NMT models have been shown capable of performing basic arithmetic or bracket matching (Suzgun et al., 2019), this paper demonstrates that handling the various forms of numerical text in reality is still challenging. It may be worth separating numerical translation out into an individual process, as in Statistical MT (Koehn, 2009), that identifies numbers in the input, applies specific translation rules to them, and incorporates the translation into the output (Tu et al., 2012).

Data augmentation. Training with more quality data leads to better translation quality (Barrault et al., 2020). In our testing, we observe a large proportion of errors (*e.g.*, financial characters, units) stemming from mistranslation of specific numerals that are unique or used less frequently (*e.g.*,

"角", decimetres) in a language. Such errors could potentially be reduced if more *numeral-specific* instances were added to training.

Tailoring BPE segmentation. The Byte Pair Encoding (BPE) has been used by most leading NMT systems. However, long sequences of digits or numbers with separators (*e.g.*, ",", ".") are often split into varying sized fragments by BPE. This would render learning more difficult, as the system has to account for the dependency between the partitions. To circumvent this, one may wish to segment numbers differently, *e.g.*, to encode all numbers as character sequences, or as meaningful groupings of components (*e.g.*, segment into groups of 3 digits when processing English.)

Sanity checks. It is helpful to post-check whether all numbers in a translation are correct by comparing them to the inputs. This could be automated in the same way as we measure the Pass Rate (§3), and once again drawing parallels to software testing, could be fully automated via continuous integration of NMT systems.

5 Conclusion

In this paper, we propose an evaluation method to systematically assess four fundamental capabilities of NMT systems in translation numbers by virtue of a variety of test cases. Our tests reveal novel types of errors that are general across multiple SOTA translation systems for both high and low resource languages. We hope that our study will help improve numerical translation quality and reduce misinformation caused by numerical mistranslation.

Impact Statement

This work aims to improve the performance of NMT systems. The impact of poor numerical translation may go beyond poor user experience, potentially leading to financial loss, medical misinformation, and even a vector for poisoning NMT systems. This paper's behavioural testing could be used by an attacker to uncover flaws in a commercial NMT system. However, as in attack research in the security community, responsible highlighting of such flaws serves the purpose of improving systems: knowledge of systemic flaws in numerical translations helps vendors improve their systems to mitigate these effects in the first place, while concerted attackers are likely to discover vulnerabilities independently.

A Appendix

A.1 Testing Process

Our behaviour testing proceeds in four steps.

1) Test template selection: we select English sentences from quality real corpora TICO-19 (Anastasopoulos et al., 2020) and WikiMatrix (Schwenk et al., 2019). TICO-19 contains documents about COVID-19 (*e.g.*, scientific articles, conversations, Wikipedia entries) between English and 36 languages. WikiMatrix consists of parallel sentences extracted from Wikipedia articles in 85 languages. We randomly select five sentences with each containing numbers for the evaluation of each capability. We make each sentence a template by replacing the contained number with the placeholder "`[NUM]`".

2) Template filling-in: we fill the templates with randomly generated numbers in the digital format (*e.g.*, 1230000). Then, we convert the digital number into desired formats for testing (*e.g.*, 1,230,000 for a separator or 1.234 million for a numeral).

3) Translation: To test a system, we use it to translate all the test examples across all capabilities, and collate the translation results.

4) Evaluation: Finally, we check the correctness of the number translation by comparing the number to that in the input. We account for various forms of the number (*e.g.*, for the number 5, we also consider 5.0 and five as correct translations) so as to reduce the false positives. We also manually examine the incorrect translations to ensure they are not false positives.

A.2 Create (Transfer) Test Cases to a New Domain

Our testing framework facilitates constructing test instances for new domains in the following steps:

1. Obtain a large corpus of text that contains numbers (*e.g.*,CommonCrawl);
2. Check if there is a number in the output translation;
3. If so, then test if the output number is the correct "translation" for the number in the source sentence;
4. Use instances that pass this test as templates for switching in our different numbers.

Capability	Template	Count	Remarks
Integers e.g., 5	1. As of March 28, 2020, a total of [NUM] laboratory-confirmed COVID-19 cases (Figure) were reported to CDC. 2. Case report forms were submitted to CDC for [NUM] cases. 3. UNESCO estimates [NUM] learners are potentially at risk (pre-primary to upper-secondary education). 4. There have been [NUM] confirmed cases of COVID19 to date. 5. CNBC reported there were at least [NUM] cases worldwide.	50	Ranging from 1 to 10 digits
Decimals e.g., 7.14	1. An average of [NUM] people is infected every day due to this disease 2. The distance between Sydney to Washington is [NUM] miles 3. The genome size of the coronavirus is approximately [NUM] 4. At this point, Rosberg was about [NUM] seconds behind his teammate. 5. The reproduction number of this disease is between [NUM] and [NUM].	40	Ranging from 1 to 4 decimal position
Numerals e.g., five hundred	1. The total amount of remittance is [NUM]. 2. Case report forms were submitted to CDC for [NUM] cases. 3. As of 8 April 2020, approximately [NUM] learners have been affected due to school closures in response to COVID-19. 4. As of December 2019, [NUM] cases of MERS-CoV infection had been confirmed by laboratory tests 5. They then planned an ambitious open-air concert in Tokyo, with a stage costing [NUM] dollars US.	40	{hundred, thousand, million, trillion}
Separators e.g., 12,230	1. An average of [NUM] people is infected every day due to this disease 2. The distance between Sydney to Washington is [NUM] miles 3. The genome size of the coronavirus is approximately [NUM] 4. They then planned an ambitious open-air concert in Tokyo, with a stage costing [NUM] dollars US. 5. As of December 2019, [NUM] cases of MERS-CoV infection had been confirmed by laboratory tests	35	Ranging from 4 to 10 digits

Abstract

The adoption of natural language generation (NLG) models can leave individuals vulnerable to the generation of harmful information memorized by the models, such as conspiracy theories. While previous studies examine conspiracy theories in the context of social media, they have not evaluated their presence in the new space of generative language models. In this work, we investigate the capability of language models to generate conspiracy theory text. Specifically, we aim to answer: can we test pretrained generative language models for the memorization and elicitation of conspiracy theories without access to the model's training data? We highlight the difficulties of this task and discuss it in the context of memorization, generalization, and hallucination. Utilizing a new dataset consisting of conspiracy theory topics and machine-generated conspiracy theories helps us discover that many conspiracy theories are deeply rooted in the pretrained language models. Our experiments demonstrate a relationship between model parameters such as size and temperature and their propensity to generate conspiracy theory text. These results indicate the need for a more thorough review of NLG applications before release and an in-depth discussion of the drawbacks of memorization in generative language models.

1 Introduction

Recent advances in natural language processing technologies have opened a new space for individuals to digest information. One of these rapidly developing technologies is neural natural language generation. These models, made up of millions, or even billions (Brown et al., 2020), of parameters, train on large-scale datasets. While attempts are made to ensure that only "safe" data is utilized for training these models, several studies have shown the prevalence of biases produced by these pretrained generation models (Sheng et al., 2019; Groenwold et al., 2020; Solaiman et al., 2019). Of equally alarming concern are the memorization and subsequent generation of factually incorrect data. Conspiracy theories are one particular type of this data that can be especially damaging.

While it is not new for researchers to learn that a model may memorize data (Radhakrishnan et al., 2019), we argue that the growing usage of machine learning models in society warrants targeted investigation to deter potential harms from problematic data. In this paper, we address the upsides and pitfalls of memorization in generative language models and its relationship with conspiracy theories. We further describe the difficulty of detecting this memorization for the categories of memorization, generalization, and hallucination. Previous studies investigating memorization of text generation models have done so with access to the model's training data (Carlini et al., 2019, 2020). As models are not always published with their training datasets, we set out to examine the difficult task of eliciting memorized conspiracy theories from a pretrained NLG model through various model settings **without access to the model's training data**.

We focus our study on the pre-trained GPT-2 language model (Radford et al., 2019). We investigate this model's propensity to generate conspiratorial text, analyze relationships between model settings and conspiracy theory generation, and determine how these settings affect the linguistic aspect of generations. To do so, we create a new conspiracy theory dataset consisting of conspiracy theory topics and machine-generated conspiracy theories.

Our contributions include:

- We propose the topic of conspiracy theory memorization in pretrained generative language models and outline the harms and benefits of different types of generations in these

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4718–4729
August 1–6, 2021. ©2021 Association for Computational Linguistics

models.

- We analyze pretrained language models for the inclusion of conspiracy theories without access to the model's training data.
- We evaluate the linguistic differences for generated conspiracy theories across different model settings.
- We create a new dataset consisting of conspiracy theory topics from Wikipedia and machine-generated conspiracy theory statements from GPT-2.

2 Spread of Conspiracy Theories

2.1 Dangers of conspiracy theories

A conspiracy theory is the belief, contrary to a more probable explanation, that the true account for an event or situation is concealed from the public (Goertzel, 1994). A variety of conspiracy theories ranging from the science-related moon landing hoax (Bizony, 2009) to the racist and pernicious Holocaust denialism[1] are widely known throughout the world. However, even as existing conspiracy theories continue circulating, new conspiracy theories are consistently spreading. This is especially concerning given that half of Americans believe at least one conspiracy theory (Oliver and Wood, 2014).

Widespread belief in conspiracy theories can be highly detrimental to society, driving prejudice (Douglas et al., 2019), inciting violence[2], and reducing science acceptance (van der Linden, 2015; Lewandowsky et al., 2013). Science denial has real-world consequences, such as resistance to measures for the reduction of carbon footprints (Douglas and Sutton, 2015) and outbreaks of preventable illnesses due to reduced vaccination rates (Goertzel, 2010). Further effects of conspiracy theory exposure can reach the political space and reduce citizens' likelihood of voting in elections due to feelings of powerlessness towards the government (Jolley and Douglas, 2014b).

At the time of writing, the COVID-19 pandemic is at its worst. Though COVID-19 vaccines have received approval and started distribution, new conspiracy theories surrounding the COVID-19 vaccine may hinder society in its road to recovery. Discussions of a link between vaccinations and autism have been circulating for years (Jolley and Douglas, 2014a; Kata, 2010). However, with the extreme interest throughout the world surrounding the COVID-19 pandemic, new vaccination rumors are arising, such as the vaccine causing DNA alteration and claims of the pandemic acting as a cover plan to implant trackable microchips[3]. The belief in these theories can prevent herd immunity through the lack of vaccinations[4] [5].

2.2 NLG spreading conspiracy theories

As NLG models are being utilized for various tasks such as chatbots and recommendations systems (Gatt and Krahmer, 2018), cases arise in which these conspiracy theories and other biases can propagate unintentionally (Bender et al., 2021). We present one such scenario in which an NLG model has memorized some conspiracy theories and is being used for story generation (Fan et al., 2018). An unaware individual may utilize this application and, given a prompt about the Holocaust, may receive a generated story discussing Holocaust denial. The user, now having been exposed to a new conspiracy theory, may choose to ignore this generated text at this stage. However, a potential negative outcome is that the user may become interested in this story and search the statements online out of curiosity. This can lead the user down the "rabbit hole" of conspiracy theories online (O'Callaghan et al., 2015) and alter their original assumptions towards believing this conspiracy theory.

2.3 Why are conspiracy theories difficult to detect?

Recent years have seen the emergence of several new tasks addressing fairness and safety within natural language processing in topics such as gender bias and hate speech detection. Although detection and mitigation of other biases and harmful content have been thoroughly studied, that pertaining to conspiracy theories is increasingly difficult due to its inconsistent linguistic nature.

Many existing tasks can utilize specific keyword lists such as Hatebase[6] for detection in addition to

[5] https://www.who.int/news-room/q-a-detail/herd-immunity-lockdowns-and-covid-19

[6] https://hatebase.org/

current techniques (Sun et al., 2019). However, conspiracy theory detection is an increasingly complex problem and cannot be approached in the same way as the previous topics. Conspiracy theories have no unified vocabulary or keyword list that can differentiate them from standard text. Previous studies of conspiracy theories have exhibited their tendency to lean towards issues of hierarchy and abuses of power (Klein et al., 2019). We argue this is not specific enough to define features for their detection. Often, specific keywords and tropes become typical of conspiracy theories regarding a specific topic, such as 9/11 and "false-flag" (Knight, 2008). However, as the number of topics surrounding conspiracy theories grows, it becomes infeasible to create and maintain these topic-specific vocabularies. To add to this difficulty, while humans can typically detect other types of biases, they cannot easily distinguish conspiracy theories from truthful text by merely reading the statement. Doing so typically requires knowledge of the topic itself or a more in-depth look into the theory narrative through network analysis[7]. To this end, the best way to stop the spread of conspiracy theories is not in late-stage detection but early intervention.

2.4 How can NLG models be misused?

While the generation of conspiracy theories may be an accidental outcome by NLG models, the possibility still exists that adversaries will intentionally utilize these language models to spread these theories and cause harm. In one such case, propagandists may utilize NLG models to reduce their workload when spreading influence (McGuffie and Newhouse, 2020). By merely providing topic-specific prompts, they can utilize these models to easily and efficiently produce a variety of conspiratorial text for online communities regarding the topics. As a result, these communities will appear to be larger than their actual size and provide the appearance that belief in the issue is high. This may provide real-life members with a sense of belonging and subsequently reinforce belief in the theories or even recruit new members (Douglas et al., 2017).

3 Memorization vs. Generalization vs. Hallucination

The memorization of data in the context of machine learning models has been highlighted in research for many years now. Related work has researched the types of information models memorize (Feldman and Zhang, 2020), how to increase generalization (Chatterjee, 2018), and the ability to extract information from these models (Carlini et al., 2020). While memorization is typically discussed in the space of memorization vs. generalization, we believe this can be broken down even further. In the context of conspiracy theories, we establish three types of generations:

- Memorized: generated conspiracy theories with exact matches existing within the training data.
- Generalized: generations that do not have exact matches in the data but produce text that follows the same ideas as those in the training data.
- Hallucinated: generations about topics that are neither factually correct nor follow any of the existing conspiracy theories surrounding the topic.

Studies on memorization tend to focus on either memorization vs. generalization or memorization vs. hallucination (Nie et al., 2019). In the latter case, it is easy to see how the term "memorization" can apply to the first two categories. Ideally, in an NLG model, we would hope for generations to be generalized since direct memorization can have the downsides of generating sensitive information (Carlini et al., 2019). There are also cases when hallucinations are ideal, such as in the realm of creative story-telling. Should we be able to distinguish among these categories, we could gain deeper insight into what and how these models learn during training. However, we acknowledge that classifying generations based on these categories is a difficult problem and believe this should be a task for future research in memorization.

Our focus in this paper is to evaluate 1) whether a model has memorized conspiracy theories during training and 2) the propensity for the model to generate this information among different model settings (as opposed to generating other memorized or hallucinated information about a topic). Evaluating memorization within a model can be done in two settings: with training data as a reference or without training data. Previous studies have evaluated memorization within machine learning models by utilizing the model's training dataset. However,

---

[7] https://theconversation.com/an-ai-tool-can-distinguish-between-a-conspiracy-theory-and-a-true-conspiracy-it-comes-down-to-how-easily-the-story-falls-apart-146282

the reality is that many models nowadays are not published alongside their training data (Kannan et al., 2016). In this case, the evaluation becomes increasingly difficult, as there is nothing to match a model's output to. In order to simulate a real-world environment, we analyze the second setting of investigating memorization without access to training data and instead treat the model as a black box when evaluating its outputs. Due to the difficulty of distinguishing among the three categories of memorization, generalization, and hallucination, we follow previous work and refer to both memorized and generalized generations as memorized samples for the rest of the paper.

4 When is memorization a good thing?

While we focus most of this paper on the downsides of memorization in natural language generation models, it is still important to address the benefits. There are several situations in which memorized information may be utilized, such as in dialogue generation (Gu et al., 2016). When used in the chatbot setting, a model may be asked questions on real-world knowledge. Assuming the model has learned correct factual information, this memorization can prove useful. Furthermore, conspiracy theories are a part of language and culture. It is not inherently bad that a model is aware of the existence or concept of conspiracy theories, particularly in cases where models may be deployed as an intervention in response to human-written conspiratorial text. This only becomes harmful when the model cannot recognize text as a conspiracy theory and generates text from the viewpoint of the conspiracy being true. Though memorization may aid in the described cases, the downside of the learned conspiracy theories (as factual statements) and other information such as societal biases can outweigh these benefits.

5 Data Collection

While conspiracy theory data may appear in misinformation datasets labeled as "Fake News" with other misinformation types, there are few existing datasets with conspiracy theory labeled text. Previous conspiracy theory studies contain datasets that are either small in size (Oliver and Wood, 2014), contain non-English data (Bessi et al., 2015), or pertain to events occurring after the release of GPT-2 (Ahmed et al., 2020; Uscinski et al., 2020). Therefore, we create a dataset exclusively dedicated to conspiracy theories [8]. We obtain our data for our analysis from two different sources: Wikipedia and GPT-2. We show samples from each of our datasets in Table 1.

	Conspiracy Theory
Wikipedia	The **Holocaust** is a lie, and the Jews are not the victims of the Nazis.
GPT-2	The US government is secretly running a secret program to create a super-soldier that can kill and escape from any prison.

Table 1: Samples from the Wikipedia dataset consisting of Wikipedia topics and General dataset of GPT-2 generated conspiracy theories without topic prompts. The Wikipedia topic is highlighted in bold and is used as a topic-prompt for text generation in GPT-2.

5.1 Wikipedia

We first aim to create a set of conspiracy theory topics. To gather this data, we utilize Wikipedia's category page feature. Each item listed in a category page is linked to a corresponding Wikipedia page. We obtain the page headers in the conspiracy theory category page and the following page headers in the Wikipedia conspiracy theory category tree. This process allows us to extract 257 Wikipedia pages regarding conspiracy topics. We further refine this dataset of conspiracy topics through the use of Amazon Mechanical Turk (Buhrmester et al., 2016). Ten workers are assigned to each Wikipedia conspiracy topic, and each worker is asked whether they have heard of a conspiracy theory related to the topic. We remove any topic from our dataset with fewer than six votes to focus our study on the well-known conspiracy theory topics that a model would be more likely to be prompted with. Our final dataset consists of the following seventeen conspiracy theory topics: Death of Marilyn Monroe, Men in black, Sandy Hook school shooting, UFO's, Satanic ritual abuse, Climate change, Area 51, 9/11, Vast right-wing conspiracy, Global warming, Shadow government, Holocaust, Flat Earth, Illuminati, Pearl Harbor, Moon landing, and John F. Kennedy assassination. We refer to this as the Wikipedia dataset for the remainder of the paper.

---

[8] https://github.com/sharonlevy/Conspiracy-Theory-Memorization

5.2 GPT-2

We create a second dataset consisting of machine-generated conspiracy theories. To do this, we elicit the conspiracy theories directly from GPT-2 Large with the HuggingFace transformers library (Wolf et al., 2020). We prompt GPT-2 with "The conspiracy theory is that" at varying temperature levels (0.4, 0.7, 1). We obtain 5000 theories at each temperature level and post-process the text by removing the original prompt and keeping only the first sentence. For the remainder of the paper, we refer to this dataset as the General dataset.

6 Generation of Conspiracy Theories

An intriguing question in the scope of conspiracy theory generation is: what can trigger a language model to generate conspiracy theories? We begin by investigating the effects of model parameters and decoding strategies on the generation of conspiracies when prompted with a topic. Of these, we study model temperature and model size.

We use our Wikipedia dataset to create a generic prompt as input to GPT-2, such as "The Holocaust is". In order to remove any trigger such as "Flat Earth is", we modify some of our topic titles during prompt creation to make a more neutral prompt. In the case of "Flat Earth", our prompt is "The Earth is", so that the model is not intentionally triggered to produce Flat Earth conspiracy text. We perform this action for the rest of our topics as well. For each prompt, we employ the model to create twenty generations with a token length of fifty.

When evaluating the generated text, we evaluate whether or not the text affirms the conspiracy theory. In this sense, we count "The Earth is flat" as affirming the conspiracy theory and "The Earth is flat is a conspiracy theory" as not affirming the theory. As such, we evaluate whether the model presents the theory as factual belief as opposed to whether it has knowledge of the theory.

To determine whether or not the generation affirms a known conspiracy theory, we utilize Amazon Mechanical Turk. Worker pay and instructions are detailed in Appendix A. We provide each worker with a reference passage describing known conspiracy theories for each topic and ask whether or not the generation affirms or aligns with the reference text. We make sure to state that the reference text contains several conspiracy theories about the topic at the top of each HIT. In this case, if a worker is exposed to new text, they are clearly informed that the text is a conspiracy theory. Should a worker encounter these theories in the future, they may even benefit from the task since they are now armed with the knowledge that these statements are in fact conspiracy theories. Seven workers are assigned to each generated sequence. If the text is voted as a conspiracy, it receives a point; otherwise, it is subtracted a point. We then retrieve those generations with two or more points (indicating a general consensus) and manually evaluate this subset of generations for another round of verification.

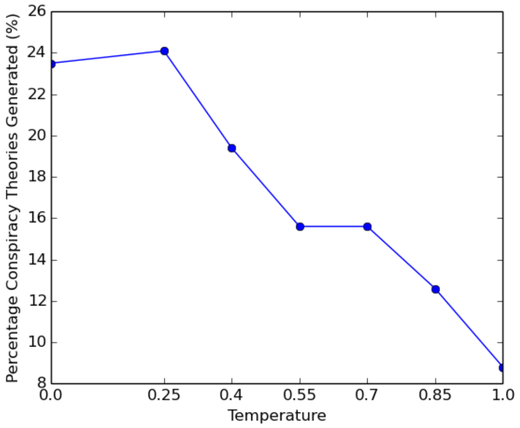

Figure 1: Percentage of conspiracy theories generated by GPT-2 Large at varying temperatures when prompted on 17 different conspiracy theory topics. Each topic is used to generate 20 sequences for a total of 340 generations.

6.1 Temperature

We first evaluate GPT-2 Large at temperature settings ranging from 0.25 to 1 with sampling, where 1 is the default setting for the model, and with greedy decoding on the Wikipedia dataset prompts. This decoding strategy changes the model's probability distribution for predicting the next word in the sequence. A lower temperature will increase the likelihood of high probability words and decrease the likelihood of low probability words. At each temperature level, we compute the percentage of generated text marked as conspiracy theories out of the total number of generations. We share our results in Figure 1.

It can be seen that as the temperature decreases, the model follows a general trend of generating more conspiracy theories. There is an exception when temperature $\rightarrow$ 0, which translates to simple greedy decoding. In this case, the proportion of conspiracy theories decreases slightly, indicating

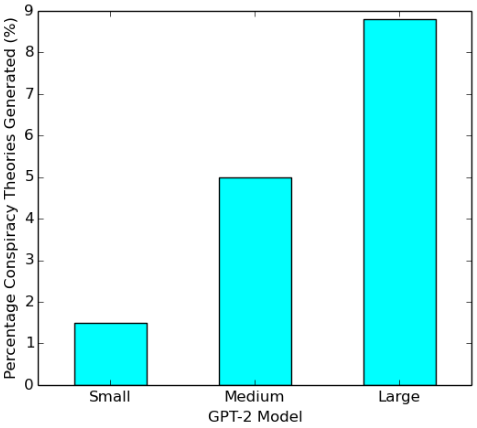

Figure 2: Percentage of conspiracy theories generated by GPT-2 models of size small, medium, and large when prompted on 17 different conspiracy theory topics. Each topic is used to generate 20 sequences for a total of 340 generations.

that while the model may memorize some theories, other information for specific topics is also memorized and have a higher likelihood of being generated. However, the general result curve shows that existing conspiracy theories are deeply rooted in the model during training for many topics. Given these findings, we believe it is best to add randomization to the decoding procedure, at the risk of quality and coherency, instead of greedy search in order to minimize the risk of generating deeply memorized conspiracy theories.

Decreasing the model's temperature allows us to evaluate which topics this deep memorization may be true for, as not every conspiracy topic may be ingrained in the model. We assess which topics the model increases its number of conspiracy theory generations for at a lower temperature. When parsing the previous results for each topic across the different temperature settings, we find this increase in conspiracy theory generations and, therefore, the prominent memorization of conspiracy theories for the topics of UFO's, 9/11, Holocaust, Flat Earth, Illuminati, and Moon landing.

6.2 Model size

Next, we aim to test a language model's size for its capability to memorize and generate conspiracy theories. Again, we utilize the Wikipedia dataset prompts for generations. We prompt three model sizes with our topics: GPT-2 Small (117M parameters), GPT-2 Medium (345M parameters), and GPT-2 Large (762M parameters). We keep a fixed temperature across the models and set it at the default value of 1. We use the same evaluation technique described above and compute the proportion of generations marked as conspiracy theories out of the total number of generations. These results are shown in Figure 2.

While nearly 10% of GPT-2 Large's generations are classified as conspiracy theories, GPT-2 Medium reduces this number by almost 50%. The GPT-2 Small model's conspiracy theory generations are substantially lower than this at a little over 1%. We can deduce that reducing model size vastly lowers a model's capacity to retain and memorize information after training, even if that information is profoundly prominent within the training data. Not only is this beneficial for mitigating the generation of conspiracy theories, but it can also allow the model to generalize better to other information for topic-specific prompts.

7 Towards Automated Evaluation

As we have shown that varying temperature and model size can individually lead to further elicitation and memorization of conspiracy theories, we now investigate the effects of varying the two together. In our previous experiments, we utilize Mechanical Turk to identify conspiracy theories among the generated text. However, we understand that human evaluation is not feasible for detecting conspiracy theories on a large scale. Instead, we desire to advance towards a more automated evaluation of memorization. As such, we investigate whether we can define a relationship between the memorization of conspiracy theories and perplexity across the different model parameters.

Following previous studies on fact-checking (Chakrabarty et al., 2018; Wang and McKeown, 2010) and model memorization (Carlini et al., 2020), we evaluate model generations against Google search results. This time, we utilize our General dataset, made up of conspiracy theories generated with the generic prompt "The conspiracy theory is that". We query Google with a generated conspiracy theory at each temperature setting and compare this theory to the first page of results. We did not manually use Google search for our generated text and instead created a script to automate this and scrape the text from the first page of results. We provided the minimum amount of information needed for making each search request so that this does not include search history and the

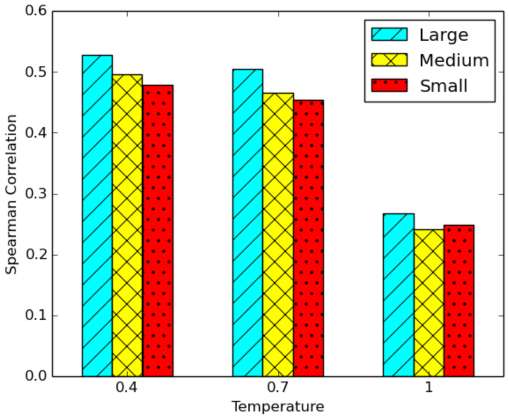

Figure 3: Spearman correlation of model perplexity vs. Google search BLEU score for GPT-2 generated conspiracy theories across varying temperature settings. Each generated theory is evaluated against the first page of Google search results with the BLEU metric.

more specific location information or cookies.

The temperature values of 0.4, 0.7, and 1 are used as lower temperature values start to produce many duplicate generations and lead to small sample sizes for this evaluation. We obtain the text snippet under each search result and evaluate this against the conspiracy theory with the BLEU metric (Papineni et al., 2002). The BLEU metric is utilized since many search results do not contain complete sentences and are instead highlighted phrases from the text related to the query and concatenated by ellipses. The perplexity score for a conspiracy theory is then calculated for each model size. The resulting BLEU and perplexity scores are ranked with the highest BLEU and lowest perplexity scores first. We use Spearman's ranking correlation (Hogg et al., 2005) to determine the resulting alignment between the two. These results are shown in Figure 3.

We find a strong relationship between a generated conspiracy theory's perplexity and its appearance in Google search results. This correlation becomes much weaker when the temperature is set to 1, indicating that the default setting's increased randomness may produce more hallucinated generations. However, given these results, we believe this can open the door towards the creation of more automated memorization evaluation techniques. Though our samples are generated through GPT-2 Large, we further test this alignment on the small and medium model sizes. We find that the relationship between Google search results and perplexity decreases as model size decreases for the smaller temperature settings, further confirming that model size does affect memorization.

	Temperature			
Classifier	0.4	0.7	1.0	p-val
dBERT	-0.974	-0.942	-0.887	0.110
VADER	-0.556	-0.527	-0.486	<0.001
TextBlob	-0.112	-0.033	0.017	<0.001
Average	-0.547	-0.500	-0.452	

Table 2: Comparison of average sentiment scores across GPT-2 Large generated conspiracy theories with the DistilBERT (dBERT), VADER, and TextBlob sentiment classifiers along with the Wilcoxon rank-sum p-values for generation pairs of temperature 0.4 and 1. The conspiracy theories are generated at the temperature values of 0.4, 0.7, and 1.0 and sentiment scores range from -1 to 1.

8 Linguistic Analysis

While our previous analysis aims to define a relationship between model parameters and the generation of conspiracy theories, we are also interested in evaluating whether these generations have any interesting linguistic properties. As such, we choose to test the question, are there any linguistic differences among the generated conspiracy theories across different model settings? We proceed by examining two linguistic aspects of our texts: sentiment and diversity.

8.1 Sentiment

When analyzing sentiment, we evaluate our General dataset of generated conspiracy theories at its three temperature levels. We are interested in answering the question: how will the model's temperature affect the sentiment of its generations that are not prompted by real-world stimulus? To proceed, we utilize three sentiment classifiers: DistilBERT (Sanh et al., 2019), VADER (Gilbert and Hutto, 2014), and TextBlob[9]. For DistilBERT we convert the output range of [0,1] to [-1,1] to match the other two classifier ranges. The average sentiment scores are displayed in Table 2 along with the Wilcoxon rank-sum p-values for each classifier output between temperature settings 0.4 and 1. The results show that decreasing the model's temperature triggers it to generate increasingly negative conspiracy theories. Although we do not achieve

---

	Temperature		
Size	0.4	0.7	1.0
Small	0.372	0.227	0.084
Medium	0.397	0.231	0.094
Large	0.421	0.255	0.120
p-value	<0.001	<0.001	<0.001

Table 3: Comparison of average BERTScore values across Wikipedia topic-prompted GPT-2 generations for varying model sizes and temperatures. Generations for each size-temperature pair are evaluated against other generations for their specific topic. Wilcoxon rank-sum p-values for the large-small model pairs at each temperature are listed at the bottom.

similar sentiment scores across the different classifiers, they all exhibit the same downward trend among score and temperature values. Additionally, classifier-temperature value pairs produce negative sentiment scores in all but one case. This follows previous work indicating that conspiracy theories and one's belief in them are emotional rather than analytical and are linked to negative emotions (van Prooijen and Douglas, 2018).

8.2 Diversity

Next, we analyze linguistic diversity across model sizes and model temperature. Utilizing the Wikipedia dataset, we compute the BERTScore (Zhang* et al., 2020) for each generation in reference to the other generations for each topic. This metric is used to measure the variance and contextual diversity across the different model generations for a specific conspiracy topic (Zhu et al., 2020). We do this across temperature values of 0.4, 0.7, and 1 and the different model sizes. These temperature values are utilized as lower temperature values start to produce duplicate generations. The average F1 scores for each setting pair is calculated and shown in Table 3 along with the corresponding p-values from a Wilcoxon rank-sum test for the large-small pairs at each temperature.

We find that as the temperature decreases, the similarity across generations for each topic increases. This is not surprising, as the outputs become less random at lower temperatures, and the model tends to output more memorized information. When comparing the scores among the different model sizes, the largest model contains the largest values, decreasing with the model size. We can infer that an increase in model size leads to more memorization, which allows the model to generate more contextually aligned outputs for specific topics instead of the diverse sets of outputs in smaller model sizes.

9 Moving Forward

Throughout this paper, we have discussed the risks and benefits of memorization in NLG models and have focused on the dangers of conspiracy theory generation. As we relayed in Section 2.3, conspiracy theory detection is a challenging problem due to its fuzzy linguistic vocabulary. We believe it is crucial to intervene earlier to mitigate these risks rather than detect them after the model's generation. While reducing memorization of harmful data in models is still an open problem, we discuss various methods to help accomplish this and encourage future research in the area: 1) preventing detrimental data from being introduced into the training set, 2) ensuring the dataset contains a much larger proportion of factually correct data for conspiracy theory topics than the conspiracy theories themselves, and 3) reducing model size.

The first solution prevents researchers from relying on these models to filter out harmful noise in large-scale datasets. Current models, such as GPT-2, attempt to filter out offensive and sexually explicit content from their datasets during creation[10]. We argue that this is not enough, as shown in the results of our analysis above. One way to proceed is to ensure that data is only collected from reliable sources instead of scraping the internet for large amounts of information. However, we also recognize that this is a tedious task and requires intensive scrutiny when collecting data. As such, the downsides to following this method may lead to smaller datasets and models with lower quality generations. In addition, this requires the additional consideration of deciding what data is "good" and what data can be harmful. In the space of conspiracy theories, the creation of a database regarding circulated conspiracy theories and debunking them seems like an appropriate direction to go.

While not completely eliminating the possibility of conspiracy theory generation, the second method aims to decrease their likelihood during generation. To accomplish this, researchers can supplement their existing dataset with a second dataset consisting of factually correct samples sur-

---

[10] https://github.com/openai/gpt-2/blob/master/modelcard.md

rounding conspiracy theory topics. This aims to oversample truthful data for training. While our study is confined to well-known conspiracy theories, the approach we discuss should be performed for all conspiracy-related topics and thus requires the additional task of identifying these subjects.

As our experiments in Section 6 have shown, model temperature and size profoundly affect the memorization and generation of conspiracy theories in NLG models. Since a user may set temperature, this setting cannot help prevent the generation of harmful data. However, modifying model size can. Though recent years have seen an increase in model size due to better performance on downstream tasks and the resulting generation of more coherent text (Solaiman et al., 2019), it comes at the cost of memorization. Therefore, researchers must strive to find a balance between memorization and fluency. When compromising model size, this mitigation strategy may also be complemented by oversampling factual data as specified above for further intervention.

10 Conclusion

In this paper, we highlight the issue of conspiracy theory memorization and generation in pretrained generative language models. We show that the root of the problem stems from the memorization of these theories by NLG models and discuss the dangers that may follow this. This paper further investigates the detection of conspiracy theory memorization in these models in a real-world scenario where one does not have access to the training data. To do so, we create a conspiracy theory dataset consisting of conspiracy theory topics and machine-generated text. Our experiments show that reducing a model's temperature and increasing its size allows us to elicit more conspiracy theories, indicating their memorization without verification against the ground-truth dataset. We hope our findings encourage researchers to take additional steps in testing language models for the generation of harmful content before release. Further, we hope our discussion on memorization can lead to further research in the area and advance the study of conspiracy theories in NLP.

Ethical Considerations

In this paper, we explore the topic of conspiracy theories in natural language generation. We acknowledge that in order to build a coherent and robust language model, a large-scale dataset must be used. As such, it is difficult to obtain data of this size that is 100% free of offensive or harmful samples. However, to improve and further progress research in natural language processing, considerations of disadvantages such as the memorization and subsequent generation of conspiracy theories must be taken into account.

In the previous sections of the paper, we feature how researchers can evaluate language models for the memorization and generation of conspiracy theory text. While we showcase methods for analyzing the generation of this harmful content, we acknowledge some potential risks: 1) adversaries may adjust their methods for hiding harmful content in language models so that it is not easily extracted or generated through our evaluation methods, and 2) attackers may use the methods discussed and leverage other language models to extract conspiracy text or amplify their generation in natural language applications. However, we believe bringing light to the issue of conspiracy theory memorization in NLG models is essential for research to progress in the direction of safe and fair natural language processing and will enable future research to utilize these studies in model interpretability.

While it may be possible for attackers to extract conspiracy theories from language models through more advanced techniques, we attempt to study how the ordinary user may fall prey to this type of information in a standard way. With language models becoming increasingly integrated into everyday natural language processing applications, the risks of unintentionally generating and spreading conspiracy theories rises. Our work can help researchers and engineers of language models thoroughly test these models for the generation of harmful conspiracy theory text using our analysis. We also hope to show researchers that even seemingly "clean" datasets may not diminish harmful noise from data and instead reflect or even amplify it after training.

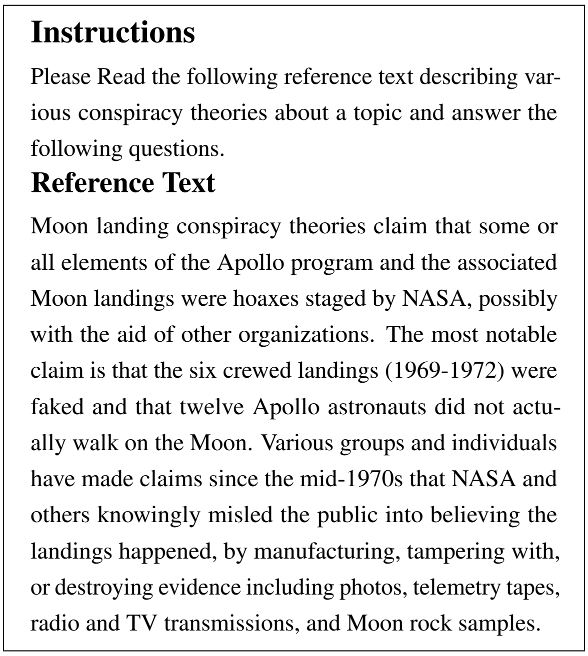
A Appendix

A.1 Mechanical Turk Experiments

Our conspiracy theory affirmation task was grouped into batches of 5 statements per topic and workers were compensated at 22¢ per batch. For the conspiracy topic task, we provided a topic, e.g. Holocaust, and ask the worker to click “yes” if they have heard of a conspiracy theory related to the topic. This simple task was paid at 2¢ per topic. The first task required workers to be located in the United States while the second task had no location restriction. For both tasks, the time it takes to read directions and answer the questions enabled workers to earn roughly $9/hour. This is currently well above the average worker compensation on Mechanical Turk of $2-5/hour (Hara et al., 2018; Hitlin, 2016) which states only 4% of workers earn more than the U.S. federal minimum wage of $7.25/hour. The second task, which contains no location restriction, may have workers from countries with a lower minimum wage. In Figures 4 and 5 we provide screenshots of an example of our conspiracy theory affirm task, including the topic reference text and worker instructions.



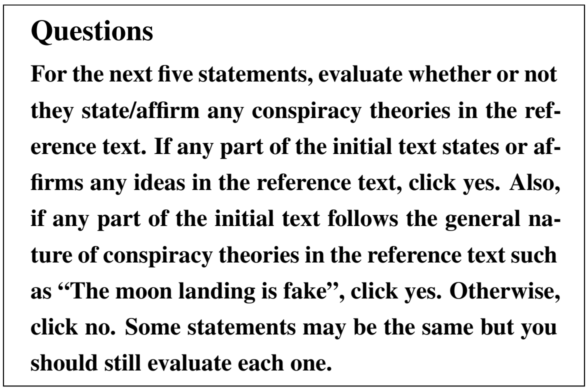
Instructions

Please Read the following reference text describing various conspiracy theories about a topic and answer the following questions.

Reference Text

Moon landing conspiracy theories claim that some or all elements of the Apollo program and the associated Moon landings were hoaxes staged by NASA, possibly with the aid of other organizations. The most notable claim is that the six crewed landings (1969-1972) were faked and that twelve Apollo astronauts did not actually walk on the Moon. Various groups and individuals have made claims since the mid-1970s that NASA and others knowingly misled the public into believing the landings happened, by manufacturing, tampering with, or destroying evidence including photos, telemetry tapes, radio and TV transmissions, and Moon rock samples.

Figure 4: Mechanical Turk conspiracy theory affirmation reference text.



Questions

For the next five statements, evaluate whether or not they state/affirm any conspiracy theories in the reference text. If any part of the initial text states or affirms any ideas in the reference text, click yes. Also, if any part of the initial text follows the general nature of conspiracy theories in the reference text such as “The moon landing is fake”, click yes. Otherwise, click no. Some statements may be the same but you should still evaluate each one.

Figure 5: Mechanical Turk conspiracy theory affirmation instructions.

A Text-Centered Shared-Private Framework via Cross-Modal Prediction for Multimodal Sentiment Analysis

Abstract

Multimodal fusion is a core problem for multimodal sentiment analysis. Previous works usually treat all three modal features equally and implicitly explore the interactions between different modalities. In this paper, we break this kind of methods in two ways. Firstly, we observe that textual modality plays the most important role in multimodal sentiment analysis, and this can be seen from the previous works. Secondly, we observe that comparing to the textual modality, the other two kinds of non-textual modalities (visual and acoustic) can provide two kinds of semantics, shared and private semantics. The shared semantics from the other two modalities can obviously enhance the textual semantics and make the sentiment analysis model more robust, and the private semantics can be complementary to the textual semantics and meanwhile provide different views to improve the performance of sentiment analysis together with the shared semantics. Motivated by these two observations, we propose a text-centered shared-private framework (TCSP) for multimodal fusion, which consists of the cross-modal prediction and sentiment regression parts. Experiments on the MOSEI and MOSI datasets demonstrate the effectiveness of our shared-private framework, which outperforms all baselines. Furthermore, our approach provides a new way to utilize the unlabeled data for multimodal sentiment analysis.

1 Introduction

Multimodal sentiment analysis is an emerging research field, which aims to understand people's sentiment using not only textual but also non-textual (visual, acoustic) data. This task has attracted increasing attention from the community recently, as people have realized that non-textual clues are helpful for detecting sentiment and the huge demands for the identification of opinions and sentiment in the video.

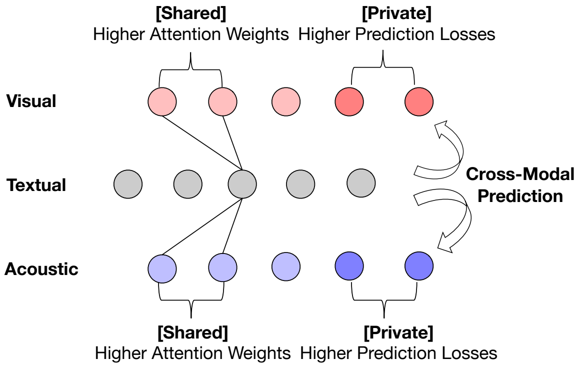

Figure 1: Distinguishing the shared and private features via cross-modal prediction.

Comparing to the traditional textual sentiment analysis(Liu, 2012), previous work demonstrates that the other non-textual data can improve the final performance (Chen et al., 2017; Zadeh et al., 2018b; Sun et al., 2020). There are two reasons. The first reason is that the three modalities can convey some common semantics. In this case, these non-textual common semantics do not provide additional information beyond textual data, but the repetitive information from them can strengthen the final performance. We call them *shared* semantics. The other reason is that the three modalities have their own special semantics, which are different to other modalities. These non-textual private semantics is modality-specific and hard to be predicted only by textual data. Thus this kind of semantics from the non-textual modalities can help to detect the final sentiment more accurately. We call them *private* semantics.

Previous works usually don't distinguish the shared semantics and the private semantics but treat each modal semantics as a whole, lacking the ability to explicitly explore the interaction between

different modalities. In this paper, we propose a text-centered shared-private framework for multimodal sentiment analysis. In this framework, the textual modality is considered as the core modality, and we first design a cross-modal prediction task to explicitly distinguish the shared and the private semantics between the textual modality and the non-textual(visual, acoustic) modality and then propose the sentiment regression model including the shared and private modules to fuse the textual features with two types of non-textual features.

In order to explore the shared and private semantics from non-textual modalities, we design the cross-modal prediction task, which is like a machine translation framework. The source is a sequence of textual modal features and the target is a sequence of another modal (visual or acoustic) features. We can explore the shared and private semantics via training two cross-modal prediction models, textual-to-visual and textual-to-acoustic models. In specific, as shown in Figure 1, we apply the pre-trained textual-to-visual and textual-to-acoustic models to predict the targets. The features of the target modality with higher prediction losses are distinguished as private. For each word, those putting higher attention weights on this word are distinguished as shared.

After obtaining shared and private features, we propose the sentiment regression model to fuse the textual features with two types of features. The sentiment regression model mainly consists of three parts, shared module, private module, and regression layer. In the shared module, each textual feature interacts with the corresponding shared features to get the enhanced features, which are then fed into a fusion block to obtain the final shared representation. Meanwhile, in the private module, the private features of each non-textual modality are passed through the attention layer to obtain the final private representation. Finally, we feed the obtained representations into the regression layer to predict the sentiment score.

We conduct experiments on two multimodal sentiment analysis benchmarks: CMU-MOSI and CMU-MOSEI. The experimental results show that our model outperforms all baselines. This can demonstrate that the shared-private framework for multimodal sentiment analysis can explicitly use the shared semantics between different modalities to enhance the final performance of sentiment analysis, and meanwhile can explicitly use the private semantics of each modality as the supplemental clues for sentiment analysis. In addition, we can observe that our designed cross-modal prediction task can accurately distinguish the shared and private non-textual semantics.

Our contributions can be concluded as follows.

1. We propose a challenging text-centered shared-private framework for the multimodal sentiment analysis. This framework can effectively fuse textual and non-textual features benefitting from the unlabeled data.

2. We design a cross-modal prediction task to explore the shared and private semantics for each non-textual modality.

3. We achieve significant improvements from learning the shared and private semantics from different modalities compared to the algorithms without distinguishing the shared and private semantics.

2 Related Work

There are two lines of works conducted on multimodal sentiment analysis.

One is focusing on utterance-level multimodal feature fusion. These methods use the features of the overall utterance. For example, they first extract the frame-level visual or acoustic features and then average them to obtain the final features, which are called utterance-level features. The utterance-level textual features can be obtained by applying RNNs for words. The obtained utterance-level features are fed into the fusion model to get the multimodal representation. Some models have been proposed for effective multimodal feature fusion. Zadeh et al. (2017) proposed Tensor Fusion to explicitly capture unimodal, bimodal, and trimodal interactions. But this method uses the three-fold Cartesian product to fuse the multimodal features, which makes the time cost very high. To address it, Liu et al. (2018) presented the Efficient Low-rank Multimodal Fusion, which applies multimodal fusion using low-rank tensors to accelerate the fusion process. Mai et al. (2020) proposed a graph fusion network to model unimodal, bimodal, and trimodal interactions successively.

The utterance-level features mainly contain global information, which may fail to capture local information. Therefore, recent works are mostly focusing on word-level multimodal feature fusion.

And our work in this paper is also based on word-level features. To extract word-level features, the first step is applying force alignment to obtain the timestamps of each word including the start time and end time. And then following the timestamps, the utterance is split into some video clips. Finally, word-level visual or acoustic features are obtained by averaging the frame-level features of the video clips. Based on word-level features, lots of methods are proposed for performing word-level multimodal feature fusion. Zadeh et al. (2018a) proposed the Memory Fusion Network(MFN) to capture the interactions across both different modalities and timesteps. Inspired by the observation that the meaning of words often varies dynamically in different non-verbal contexts, Wang et al. (2019) proposed the Recurrent Attended Variation Embedding Network (RAVEN). This model applies the Attention Gating module to fuse the word-level features, which can dynamically use the non-verbal features to shift the word embeddings. Tsai et al. (2019) presented multimodal transformer (Mult), which uses the cross-modal attention to capture the bimodal interactions, motivated by the great success of transformer in NLP(Vaswani et al., 2017).

Besides, there is a related work (Pham et al., 2019) need to be noticed, which proposed that translation from a source to a target modality provides a way to learn joint representations and proposed the Multimodal Cyclic Translation Network model (MCTN) to learn joint multimodal representations. Comparing to this work, our model has a significant difference. That is we use the cross-modal prediction task to distinguish the shared and private non-textual features instead of training the model as an auxiliary task. In this way, we can obtain more useful information by deeply probing the cross-modal prediction model.

3 Approach

In this section, we will introduce our shared-private framework for multimodal sentiment analysis in detail. In this framework, we treat the textual modality as the core, then how to explore the shared and the private semantics of the non-textual modality compared to the textual modality, and how to fuse all three modal features are two important steps. For the first step, we design a cross-modal prediction task and obtain the shared and private features of the non-textual modalities via training two cross-modal prediction models, textual-to-visual and textual-to-acoustic models. And for the second step, we design a sentiment regression model to fuse the textual features and the two types of features.

3.1 Cross-Modal Prediction

Task Definition: The cross-modal prediction task is formalized as follows. Given a sequence of textual features denoted as $\mathbf{x}_l = \{x_l^t : 1 \leq t \leq L, x_l^t \in \mathbb{R}^{d_l}\}$, L is the length of the given sequence, t is the timestep, and the goal is to predict the corresponding sequence of visual or acoustic features denoted as $\mathbf{x}_i = \{x_i^t : 1 \leq t \leq L, x_i^t \in \mathbb{R}^{d_i}\}$, $i \in \{v, a\}$. Cross-modal prediction task is inspired by the machine translation task. The inputs are the textual features, and the generated outputs are the non-textual (visual or acoustic) features. During the translation from the textual modality to other modalities, we can exploit the shared and the private semantics of the non-textual modalities.

Prediction Model: We use the Seq2Seq model with attention (Bahdanau et al., 2015) as our model framework. The encoder takes the textual features $\mathbf{x}_l$ as inputs and outputs the hidden states $\mathbf{h}_{enc} = \{h_{enc}^t : 1 \leq t \leq L, h_{enc}^t \in \mathbb{R}^{d_h}\}$. The decoder takes the previous hidden state h_{dec}^{t-1} and hidden states of the encoder as inputs and predicts the non-textual feature x_i^t, $i \in \{v, a\}$, at the t timestep. We choose the MSE as our loss function. The prediction loss values are denoted as $\mathbf{e}_{l\to i} = \{e_{l\to i}^t : 1 \leq t \leq L\}$. The attention map of the prediction model is denoted as $\mathbf{m}_{i\to l}$. In practice, we apply LSTMs (Hochreiter and Schmidhuber, 1997) to implement our encoders and decoders. After training the cross-modal prediction models using textual-visual and textual-acoustic paired data, we can obtain two models, textual-to-visual and textual-to-acoustic models. We then use the obtained models to distinguish the shared and private features and record the results as shared and private masks, which will be passed to the sentiment regression model.

Shared Mask: We propose the shared mask to find out the shared semantics of the two kinds of non-textual modalities. The basic assumption is that during cross-modal prediction, if the prediction model wants to generate a non-textual feature as precisely as possible, it should pay more attention to the input textual features, that contain more shared semantics. Based on this assumption, we design the method to obtain the shared mask. Given

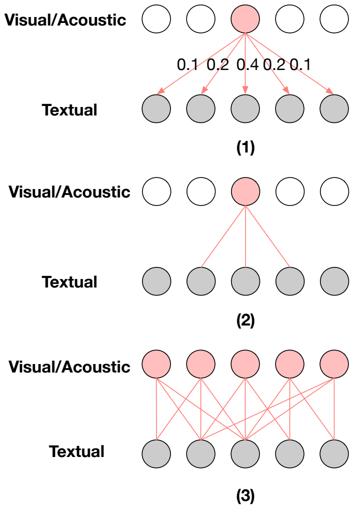

Figure 2: Obtaining the shared mask from the cross-modal prediction model.

$\mathbf{m}_{i\to l}$, $i \in \{v, a\}$, for each row t, we first sort the attention weights $\mathbf{m}^{t,*}_{i\to l}$ and then get the indexes S^t of the largest K_s values. Finally, we can get the shared mask $smask$, $smask \in \mathbb{R}^{L*L}$. $smask^{t_1,t_2}$ is 1 if the $t_1 \in S^{t_2}$ and 0 otherwise.

To describe this method intuitively, we show this process in Figure 2. There are three steps: (1) We build an attention graph and the values of edges mean the attention weights. We illustrate a part of it for simplicity. (2) We only keep the edges with larger values for each non-textual node and delete others. (3) We map the graph to the shared mask $smask$, $smask^{t_1,t_2}$ is 1 if there is a edge between textual node t_1 and non-textual node t_2 and 0 otherwise. The shared mask will be passed to the share module of the sentiment regression model to make the model focus on the shared features.

Private Mask: In order to find out the private semantics of the two kinds of non-textual modalities, we propose the private mask. The basic assumption is that the features containing modality-private information are difficult to be predicted by textual modality. The private mask of a given utterance is obtained as follows. Given an utterance which includes three modalities, textual, visual and acoustic, denoted as $\mathbf{x}_i = \{x_i^t : 1 \le t \le L, x_i^t \in \mathbb{R}^{d_i}\}$, $i \in \{l, v, a\}$, we first use the trained prediction models to get the loss values, $\mathbf{e}_{l\to v}$ and $\mathbf{e}_{l\to a}$. Then we sort the loss values to obtain the indexes P of the largest K_p values. Finally, We can get the private mask $pmask$, $pmask \in \mathbb{R}^L$. $pmask^t$ is 1 if the $t \in P$ and 0 otherwise. The private mask will be used by the private module of the sentiment regression model to force the model to focus on private features.

3.2 Regression

In this section, we study how to fuse the shared and private information obtained from Section 3.1. An illustration of our framework is given in **Figure 3**.

3.2.1 Input Layer

Given an utterance which includes three modalities, textual, visual and acoustic, the extracted multimodal features are denoted as $\mathbf{x}_i = \{x_i^t : 1 \le t \le L, x_i^t \in \mathbb{R}^{d_i}\}$, $i \in \{l, v, a\}$. We use three LSTM networks to encode the input multimodal features $\mathbf{x}_i$, producing $\mathbf{h}_i = \{h_i^t : 1 \le t \le L, h_i^t \in \mathbb{R}^{d_h}\}$.

$$\begin{aligned} \mathbf{h}_l &= \mathrm{LSTM_l}(\mathbf{x}_\mathrm{l}) \\ \mathbf{h}_v &= \mathrm{LSTM_v}(\mathbf{x}_\mathrm{v}) \\ \mathbf{h}_a &= \mathrm{LSTM_a}(\mathbf{x}_\mathrm{a}) \end{aligned} \tag{1}$$

3.2.2 Shared Module

The core idea of the shared module is leveraging the shared information from non-textual modal features to enhance the representations of words. To achieve it, we propose the masked cross-modal attention network, which can utilize the shared masks obtained from cross-modal prediction models to focus on the non-textual shared features.

In the masked cross-modal attention network, we first calculate the attention scores across the non-textual representations $\mathbf{h}_i$, $i \in \{v, a\}$, for each word. We denote the scores as $\mathbf{s}_{l\to i}$.

$$\begin{aligned} \mathbf{s}^{t_1,t_2}_{l\to v} &= W_2(tanh(W_1([h_l^{t_1}; h_v^{t_2}]) + b_1)) \\ \mathbf{s}^{t_1,t_2}_{l\to a} &= W_4(tanh(W_3([h_l^{t_1}; h_a^{t_2}]) + b_3)) \end{aligned} \tag{2}$$

where $W_1, W_3 \in \mathbb{R}^{d_h \times 2d_h}$, $W_2, W_4 \in \mathbb{R}^{1\times d_h}$, $b_1, b_3 \in \mathbb{R}^{d_h}$ are the parameters of the score functions.

To focus on the shared features, we first calculate the attention weights $\mathbf{w}_{l\to v}$ and $\mathbf{w}_{l\to a}$ using the softmax function and mask the other features out using the shared mask.

$$\begin{aligned} \mathbf{w}^{t_1,t_2}_{l\to v} &= \frac{e^{\mathbf{s}^{t_1,t_2}_{l\to v}}}{\sum_{t_3=1}^{L} e^{\mathbf{s}^{t_1,t_3}_{l\to v}}} \\ \mathbf{w}^{t_1,t_2}_{l\to a} &= \frac{e^{\mathbf{s}^{t_1,t_2}_{l\to a}}}{\sum_{t_3=1}^{L} e^{\mathbf{s}^{t_1,t_3}_{l\to a}}} \end{aligned} \tag{3}$$

$$\begin{aligned} \mathbf{w}_{l\to v} &= \mathbf{w}_{l\to v} \circ smask_{l\to v} \\ \mathbf{w}_{l\to a} &= \mathbf{w}_{l\to a} \circ smask_{l\to a} \end{aligned} \tag{4}$$

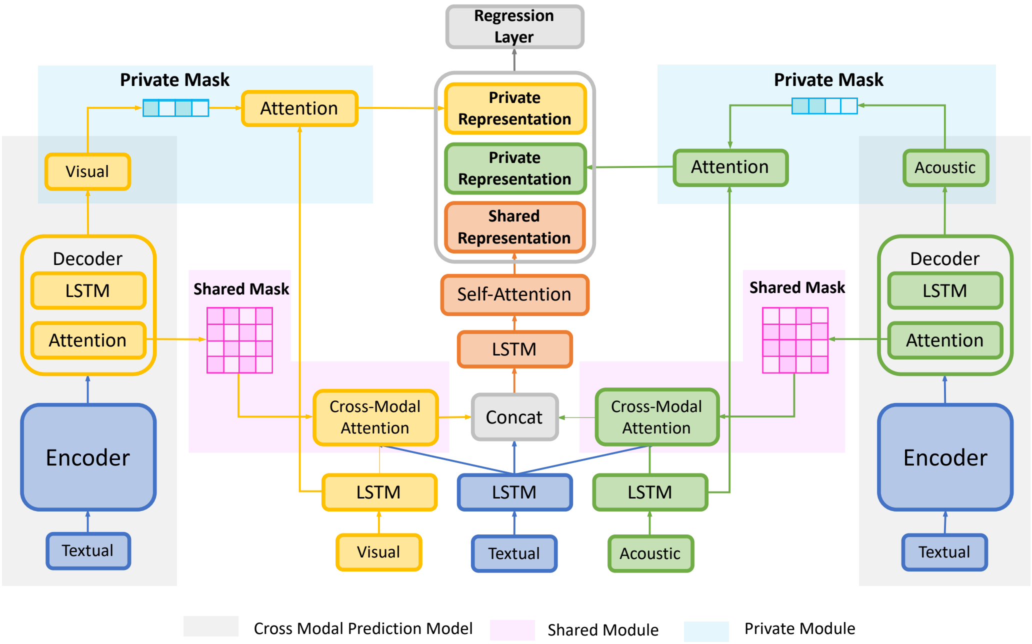

Figure 3: Illustration of our shared-private framework.

We obtain the non-textual shared context vectors $\mathbf{c}_v$ and $\mathbf{c}_a$. $\mathbf{c}_v, \mathbf{c}_a \in \mathbb{R}^{L \times d_h}$.

$$\begin{aligned} \mathbf{c}_v &= \mathbf{w}_{l \to v} \mathbf{h}_v \\ \mathbf{c}_a &= \mathbf{w}_{l \to a} \mathbf{h}_a \end{aligned} \tag{5}$$

To fuse textual and non-textual shared features, we concatenate $\mathbf{c}_v$, $\mathbf{c}_a$, and $\mathbf{h}_l$ and feed it into the fusion LSTM network, producing $\mathbf{r}_s \in \mathbb{R}^{L \times 3d_h}$. We further use a self-attention layer, which is denoted as $\mathrm{SelfAttentionLayer}$, to learn the final representation. The self-attention layer is similar to the cross-modal attention network. We use the last step representation of $\mathbf{r}_n$ as the shared representation, which is denoted as r_s.

$$\begin{aligned} \mathbf{r}_m &= \mathrm{LSTM}_{\mathrm{fusion}}([\mathbf{c}_{\mathrm{v}}; \mathbf{c}_{\mathrm{a}}; \mathbf{h}_{\mathrm{l}}]) \\ \mathbf{r}_n &= \mathrm{SelfAttentionLayer}(\mathbf{r}_{\mathrm{m}}) \end{aligned} \tag{6}$$

3.2.3 Private Module

To enable the model to capture the unique information contained in non-textual modalities, we design the private module. Specifically, we use the attention network to learn informative and modality-private representations.

$$\begin{aligned} \mathbf{s}_v^t &= W_5 h_v^t + b_5 \\ \mathbf{s}_a^t &= W_6 h_a^t + b_6 \end{aligned} \tag{7}$$

where $W_5, W_6 \in \mathbb{R}^{1 \times d_h}$, $b_5, b_6 \in \mathbb{R}$ are the parameters of the score functions.

We use private masks to ignore other features and apply the softmax function to get the attention weights.

$$\begin{aligned} \mathbf{s}_v &= \mathbf{s}_v + (1 - pmask_v) * (-10^8) \\ \mathbf{s}_a &= \mathbf{s}_a + (1 - pmask_a) * (-10^8) \end{aligned} \tag{8}$$

Finally, we compute the weighted sum and represent them as p_v and p_a, which are called the private representations.

$$\begin{aligned} \mathbf{w}_v^t &= \frac{e^{\mathbf{s}_v^t}}{\sum_{t_1=1}^{L} e^{\mathbf{s}_v^{t_1}}} \\ \mathbf{w}_a^t &= \frac{e^{\mathbf{s}_a^t}}{\sum_{t_1=1}^{L} e^{\mathbf{s}_a^{t_1}}} \end{aligned} \tag{9}$$

$$\begin{aligned} p_v &= \mathbf{w}_v \mathbf{h}_v \\ p_a &= \mathbf{w}_a \mathbf{h}_a \end{aligned} \tag{10}$$

3.2.4 Regression Layer

We design the regression layer, which is implemented by a two-layer network with ReLU activation function, to fuse the shared and private representations.

$$\hat{y} = W_o(ReLU(W_f([r_s; p_v; p_a]) + b_f)) + b_o \tag{11}$$

where $W_f \in \mathbb{R}^{d_h \times 5d_h}$, $W_o \in \mathbb{R}^{1 \times d_h}$, $b_f \in \mathbb{R}^{d_h}$, $b_o \in \mathbb{R}$.

4 Experiments

4.1 Datasets

We conduct experiments on two public datasets, CMU-MOSI (Zadeh, 2015) and CMU-MOSEI (Zadeh et al., 2018b) to evaluate our proposed model. CMU multimodal opinion-level sentiment intensity (CMU-MOSI) consists of 93 videos collected from the YouTube website. The length of the videos varies from 2-5 mins. These videos are split into 2,199 short video clips and labeled with sentiment scores from -3 (strongly negative) to 3 (strongly positive). CMU multimodal opinion sentiment and emotion intensity (CMU-MOSEI) consists of 23,453 annotated video utterances from 1,000 distinct speakers and 250 topics. Each utterance is annotated with sentiment scores from -3 (strongly negative) to 3 (strongly positive).

The multimodal features used in our experiments are described as follows. We use glove word embeddings (Pennington et al., 2014) to represent the words. The dimension of each word embedding is 300. We extract the visual features using Facet, which can extract 35 facial action units (Ekman et al., 1980; Ekman, 1992) from each frame resulting in a 35-dimensional vector. The acoustic features are obtained by applying COVAREP (Degottex et al., 2014), which includes 12 Mel-frequency cepstral coefficients (MFCCs) and other low-level features. The dimension of the acoustic feature is 74.

4.2 Evaluation Metrics

Following previous works, we take 2-class accuracy(Acc), f1 score(F1), mean absolute error (MAE), and correlation(Corr) as our evaluation metrics. As the prediction results are real values, we first use mean absolute error and Corr between prediction scores and ground truths to evaluate the models. In addition, we then map the sentiment scores into sentiment labels and use classification metrics, such as accuracy and f1 score, to assess the model performance.

4.3 Training Details

The hyperparameters of our model are listed in Table 1. In practice, we apply dropout before the last linear layer for regularization. We use Adam as the optimizer. The learning rate is decayed once the validation loss stops decreasing. The Selection Number is the number of selected shared/private features, K_s and K_p. We take the same value for K_s and K_p for simplicity.

4.4 Baselines

We compare our proposed model with the following baselines. **EF-LSTM** fuses the multimodal features by concatenating and applies an LSTM network to get the final representation. **LF-LSTM** first uses three LSTM networks to encode three modal features and concatenates three obtained representations to get the final representation. **MFN** (Zadeh et al., 2018a) captures the interactions across both the different modalities and time. **RAVEN** (Wang et al., 2019) first combines the nonverbal information with word representations and then feeds the modified word representations into an LSTM network to obtain the utterance representation. **MCTN** (Pham et al., 2019) learns joint multimodal representations by translating between modalities. **MulT** (Tsai et al., 2019) uses cross-modal transformers to fuse multimodal features. **Multimodal Routing** (Tsai et al., 2020) proposes a routing mechanism to capture the interactions between input modalities and outputs. **TCSP(Base)** is our base model. The model architecture is as same as our full model, but it doesn't use shared and private masks. Comparing TCSP(Base) and TCSP(Full), we can judge whether distinguishing the shared and private features of non-textual modalities is useful.

4.5 Experimental Results

We compare our model with several baselines and the experimental results are shown in Table 2. Comparing our base model with other baselines, our base model fails to obtain the best result and underperforms RAVEN and MulT for the Acc, F1

Table 2: Experimental results on the test sets of the MOSEI and MOSI dataset. The best results are in **bold**. As the Multimodal Routing model is designed for classification, we don't report the regression metrics of it for fair comparison.

Models	MOSI				MOSEI			
	Acc ↑	F1 ↑	MAE ↓	Corr ↑	Acc ↑	F1 ↑	MAE ↓	Corr ↑
TCSP	**80.9**	**81.0**	**0.908**	**0.710**	**82.8**	**82.7**	**0.576**	**0.715**
w/o Private Mask	79.9	79.8	0.930	0.663	82.2	82.1	0.576	0.710
w/o Shared Mask	79.0	79.0	0.965	0.660	82.3	82.1	0.585	0.701
w/o Both Masks	79.3	79.3	0.956	0.658	80.7	80.3	0.593	0.692

metrics on the MOSEI dataset. However, with the help of the cross-modal prediction task, our text-centered shared-private framework (TCSP) achieves the best performance and outperforms all baselines on both datasets. This can demonstrate that the shared-private framework proposed in this paper is effective for multimodal sentiment analysis. Furthermore, it can be observed that the shared and private features for each non-textual modality obtained from the cross-modal prediction task can provide useful clues for the interactions between different modalities. Thus, these non-textual shared-private features can be jointly fused with the textual features to improve the multimodal sentiment analysis.

We also observe that there is a larger margin between our full model and our base model on the MOSI dataset. We attribute it to the small data size of the MOSI dataset. It is insufficient for training the base model, which makes it benefit more from the shared and private information.

It should be noted that, in Table 2, we provide two results for each method on each dataset. The left result is obtained by rerunning the public codes in the same experimental setting, which refers to the same dataset split and the same extracted features of three modalities. The right result is copied from previous papers and the experimental settings are different. To guarantee the justice, we compare our TCSP model with the left results.

5 Analysis

5.1 Ablation Study

We conduct the ablation experiments to distinguish the contribution of each part. As shown in Table 3, ablating either shared mask or private mask hurts the model performance, which indicates that both masks are useful for the sentiment prediction. The shared mask can enable the sentiment regression model to get the modality-shared features resulting in a more robust regression model. The private mask makes the regression model focus on modality-private features, which provides extra information for sentiment prediction. With the help of shared and private masks, the regression model in the shared-private framework can fuse the textual features with two types of non-textual features individually, which is the more effective method for multimodal feature fusion.

5.2 Effect of Selection Number

Selection Number is the number of selected shared/private features, K_s and K_p. We take the same value for K_s and K_p for simplicity. We evaluate our model with different selected numbers from 1 to 8 on the MOSEI dataset to quantify the effect. The experimental results are shown in Figure 4. We can observe that our model achieves the best performance on the Acc and F1 metrics when the Selection Number is 5. The possible reason is that

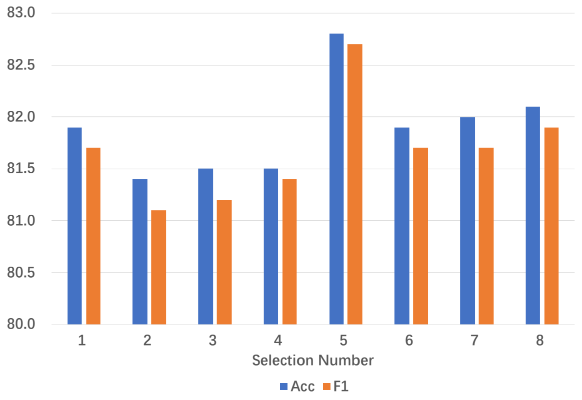

Figure 4: Experimental results with different selection numbers on the MOSEI dataset.

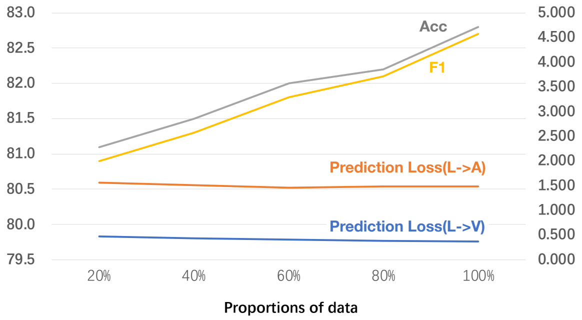

Figure 5: Experimental results on the MOSEI dataset with different proportions of data used for the cross-modal prediction model.

too small Selection Number makes the model only focus on few features. This could result in missing useful information. In contrast, too large one makes the model attend too many features, which weakens the effect of masks. For this reason, selecting a middle number could be better.

5.3 Effect of Cross-Modal Prediction Model

The cross-modal prediction task is the core of our shared-private framework, and it has been demonstrated that this task is effective from Table 3 and Section 5.1. In this section, we want to further explore the effect of cross model prediction for the final regression model.

In Figure 5, we design different cross-modal prediction models trained with different proportions (from 20% to 100%) of MOSEI data and then fuse the obtained shared and private information into the regression models. It should be noticed that all regression models are trained with all data of the MOSEI dataset. The results show that when we use more data, the final performance is better. And meanwhile, it can be observed that the two kinds of prediction losses (from textual to visual modality and from textual to acoustic modality) are decreased when the proportion of the used data is increased.

This can reveal that the cross-modal prediction model trained with more data can provide more informative supervision signals, which are the shared and private masks specifically. If the performance of cross-modal prediction model is low, it is impossible to teach the regression model to play the precise role in the shared-private framework.

6 Conclusion

In this paper, we propose a text-centered shared-private framework for multimodal sentiment analysis. In this framework, we treat the textual modality as the core and aim to use the other non-textual modalities to help enrich the semantics of the textual modality. For each non-textual modality, we consider two types of semantics, shared and private, which have different functions. Shared semantics can enhance the textual semantics to make the model more robust and the private semantics can provide extra information for more precise prediction.

To distinguish these two semantics, we design a cross-modal prediction task and record the results as share and private masks. We further propose a regression model utilizing the shared and private modules to fuse the textual features with two non-textual features. The experimental results demonstrate that distinguishing the shared and private non-textual semantics and explicitly modeling the interactions between textual and two non-textual semantics is a better way for the multimodal sentiment analysis than just treating each non-textual features as a whole. The analyses show that the regression model can benefit more from the better cross-modal prediction model, which also indicates that the cross-modal prediction process can produce useful supervision signals only using unlabeled data.

In future work, we plan to collect more unlabeled data to enhance our model. In addition, we would also like to explore other approaches using the unlabeled data to help multimodal feature fusion.

What Would a Teacher Do? Predicting Future Talk Moves

Ananya Ganesh, Martha Palmer and **Katharina Kann**
University of Colorado Boulder
{ananya.ganesh, martha.palmer, katharina.kann}@colorado.edu

Abstract

Recent advances in natural language processing (NLP) have the ability to transform how classroom learning takes place. Combined with the increasing integration of technology in today's classrooms, NLP systems leveraging question answering and dialog processing techniques can serve as private tutors or participants in classroom discussions to increase student engagement and learning. To progress towards this goal, we use the classroom discourse framework of academically productive talk (APT) to learn strategies that make for the best learning experience. In this paper, we introduce a new task, called future talk move prediction (FTMP): it consists of predicting the next talk move – an utterance strategy from APT – given a conversation history with its corresponding talk moves. We further introduce a neural network model for this task, which outperforms multiple baselines by a large margin. Finally, we compare our model's performance on FTMP to human performance and show several similarities between the two.

1 Introduction

The field of natural language processing (NLP) has made rapid progress over the last few years (Wang et al., 2019). Success on natural language understanding, dialogue generation, and question answering tasks has spurred advances in NLP-based systems for educational applications. (McNamara et al., 2013; Litman, 2016; Burstein et al., 2020). Systems that can simulate human teachers in specific situations such as small-group discussions have the potential to aid learning by promoting student engagement.

Research has shown that deep conceptual learning is heightened when students are active participants in the classroom and contribute to discussions with their questions and ideas (McNamara, 2011; Bransford et al., 1999). However, large class sizes often make it difficult for all students to actively participate. Discussions in sub-groups increase each student's speaking time, but, in turn, make it impossible for a single teacher to guide all individual conversations. In this paper, we present a first step towards a system that can solve this problem by taking the teacher's role in facilitating sub-group discussions.

Scenario: Learning about proportional relationships in a classroom. The teacher gives an example of toasting two slices in a toaster, for 2 minutes.
Teacher: So we've just seen that 2 slices of toast gets done in 2 minutes. (*None*) **Teacher:** What if I had 3 slices of toast? (*Press for Accuracy*) **Student:** 4 minutes! (*Wait*) **Teacher:** Why would it take 4 minutes? (*Press for Reasoning*) **Student:** Because you'd have to use the toaster twice. (*Wait*)
FTMP: Getting Students to Relate *(e.g., who else agrees it would be 4?)*

Table 1: Our proposed FTMP task; the teacher talk move corresponding to each utterance is shown in parentheses.

For this, we turn to a classroom discourse framework by Michaels et al. (2008) called academically productive talk (APT). This framework, which we describe in detail in Section 2, provides both teachers and students with a set of *talk moves* – a family of utterance strategies to use for productive and respectful in-class discussions. As a first step towards developing an NLP system that can guide academically productive discussions, we aim to design a model which can predict when which specific talk move is appropriate. Thus, we introduce the task of **future talk move prediction (FTMP)** – given a conversation history, the goal is to predict what the *next* teacher talk move should be. We formulate this as a multi-class classification problem, with the input being a sequence of previous utterances

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4739–4751
August 1–6, 2021.

and their corresponding talk moves, and the label being the next talk move.

We further propose a model for FTMP, which we call 3-E.[1] It consists of three recurrent neural network (RNN) encoders: one for individual utterances, one for utterance sequences, and one for talk move sequences. The model is trained on transcripts of classroom discussions where teacher utterances have been annotated for the talk moves they represent. We consider the actions of the teacher to be our gold standard data for FTMP. We show that our model strongly outperforms multiple baselines and that adding sentence representations from RoBERTa (Liu et al., 2019) or TOD-BERT (Wu et al., 2020) – a model trained on task-oriented dialogue – does not increase performance further.

Finally, we investigate the performance of human annotators on FTMP. Unlike the teacher, they do not have access to multi-modal signals, subject matter information, or knowledge of student behavior. This setting, which mimics the information available to our model, is significantly different from the teachers who generate the gold standard utterances captured in our data. We present a detailed analysis of their performance on a diagnostic test set, and highlight similarities to our model's performance. Our findings indicate that our model produces acceptable predictions a majority of the time. However, a gap between model and human performance on this task shows that there is still room for improvement.

2 Academically Productive Talk

In this section, we provide an overview of the APT discourse framework and introduce a new task within the broader research area of NLP for educational applications: FTMP.

2.1 Background on APT

Research in cognitive science and psychology highlights the importance of active participation as opposed to passive listening for achieving deep conceptual learning (McNamara, 2011; Bransford et al., 1999; Chi and Wylie, 2014). This can take the form of reflection on the lesson, as well as generation of new ideas, such as asking and answering questions, connecting concepts, and coming up with explanations. Chapin et al. (2009); Goldenberg (1992); Cobb; Cazden (1988) discuss the importance of classroom conversations in this process. Chapin (2003) present case studies that show how implementing structured discussions in classrooms over a period of two years results in measurable improvements in test scores in mathematics.

To formalize how such discussions can be facilitated, Michaels et al. (2008) present a classroom discourse framework called *academically productive talk* (APT; also called *accountable talk*). This includes strategies that teachers and students can use to promote engagement as well as deep conceptual learning through discussions.

Facets Michaels et al. (2008) present three facets of accountability that APT encompasses: *accountability to the learning community*, *accountability to standards of reasoning*, and *accountability to knowledge*. The first facet emphasizes the importance of listening to other students' contributions, and, subsequently, building on top of them. The second facet promotes talk that is based on evidence and reasoning, and involves getting students to provide explanations for their claims. The last facet covers talk which involves factual knowledge – such as introducing a new concept, or challenging a student's claim to correct misconceptions.

Teacher Talk Moves Michaels and O'Connor (2015) conceptualize the above facets as "tools" that can be used by teachers and students to engage in APT. For both teachers and students, these tools take the form of utterance strategies called *talk moves*, which they can employ in order to conduct meaningful discussions.

In this paper, we focus on the following six talk moves used by teachers: (1) ***Keeping Everyone Together*** refers to utterances that manage student interactions, and asks students to be active listeners; (2) ***Getting Students to Relate*** refers to utterances that ask a student to build on other students' ideas by agreeing, disagreeing, or following up; (3) ***Restating*** occurs when a teacher repeats a student's answer or claim verbatim with the purpose of ensuring it reaches the entire classroom; (4) ***Revoicing*** happens when a teacher paraphrases a student's ideas, but adds or removes information in order to correct a student or convey new knowledge; (5) ***Pressing for Reasoning*** refers to utterances that ask a student to explain a decision or to connect multiple ideas; and (6) ***Pressing for Accuracy*** refers to utterances that prompt for answers to a factual question, e.g., about a method or

---

[1] Code for all models is available at `https://nala-cub.github.io/resources/`

Talk Move	**Description**	**Example**
Keeping Everyone Together	Ask students to be active listeners	Raise your hand if you know the answer
Getting Students to Relate	Ask students to contribute to another's ideas	Do you or agree or disagree with Michael?
Revoicing	Repeat what a student says with adding words or rephrasing	S: It had two T: So it had two edges
Restating	Repeat what a student says verbatim	S: Hexagon T: Hexagon!
Press for Accuracy	Prompt for an answer	What is this called?
Press for Reasoning	Prompt for explanation of thinking	How did you decide?
None	*Fits into none of the above*	*Good morning*
Wait	*Teacher says nothing while student speaks*	*S: It's the same shape*

Table 2: An overview of all teacher talk moves, their purpose and an example utterance. *None* and *Wait* are not APT talk moves, and represent generic utterances and teacher pauses during student utterances, respectively.

a result.

Keeping Everyone Together, Getting Students to Relate, and *Restating* are part of accountability to the learning community; *Revoicing* and *Press for Reasoning* are part of accountability to standards of reasoning, and *Press for Accuracy* falls under accountability to knowledge. Examples for all talk moves are shown in Table 2.

Student Talk Moves While we do not focus on student talk moves in this work, we summarize them here for completeness. Student talk moves can also be grouped into the same accountability facets as teacher talk moves (O'Connor and Michaels, 2019). Under accountability to the learning community, we have *Relating to Another Student* – building on a classmate's ideas or asking questions about them, and *Asking for more info* – requesting help from the teacher on a problem. Under accountability to knowledge, there is *Making a Claim* – providing an answer or a factual statement about a topic. Under accountability to standards of reasoning, we have *Providing Evidence/Explanation* – explaining their thinking with evidence.

2.2 Future Talk Move Prediction

In order to build a system that can facilitate in-class discussion in the way a human would, we aim at automatically answering the question *What would a teacher do?* at each point within a classroom conversation. Specifically, we define the task of future talk move prediction (FTMP) as choosing the next appropriate teacher talk move to make, given the history of what has been discussed so far.

Formally, the input for FTMP is a dialogue context $C = c_0, c_1, ..., c_t$, with each context element consisting of an utterance u_i, a binary variable s_i indicating if the speaker is different from the previous utterance, and a teacher talk move label t_i, i.e., $c_i = (s_i, u_i, t_i)$. The goal then is to predict the next teacher talk move t_{t+1} out of the possible talk moves defined above. Note that the future utterances are unseen; the prediction of the next talk move is to be made only based on the conversation history.

3 Related Work

3.1 Promoting APT with NLP Systems

Ideas from APT have been incorporated with success into intelligent tutoring systems (Dyke et al., 2013; Tegos et al., 2016; Adamson et al., 2014). These systems provide an environment to simulate classroom discussions, for instance, as small groups collaboratively solving problems with a shared textual chat interface for communication. The intelligent agent then plays a role similar to a teacher – it monitors the conversations and makes decisions about when to intervene in order to promote student engagement and learning.

Adamson et al. (2014) study the effects of two specific interventions: using the *Revoicing* talk move as well as an *Agree/Disagree* talk move (which corresponds to the *Getting Students to Relate* talk move in our above categorization). These interventions are made by matching student utterances in the chat to an annotated set of concepts and misconceptions for the topic being taught. Through multiple case studies, they show that interventions by the agent have a positive effect on learning, as measured by test scores before and after using the system. The agent interventions also prove useful in increasing student talk frequency. Similarly, Tegos et al. (2015) find that an APT-based intervention called Linking Contributions, similar to *Getting Students to Relate*, improves explicit reasoning as well as learning outcomes in students.

The findings of the above work provide a strong motivation for building a conversational AI system that can produce academically productive talk. Unlike the above systems, which focused particularly on accountability to the learning community, we attempt to predict opportunities for intervention across all talk moves described in Section 2. Since we do not have access to gold annotations of statements corresponding to concepts and misconceptions, we make use of transcripts of classroom discourse with annotations for talk moves used by the teacher.

3.2 NLP for Educational Applications

Our work is a first step towards improving in-class discussions with the help of an NLP system and, thus, to improve student learning and engagement. Prior work in understanding classroom discourse using NLP includes Suresh et al. (2019) and Donnelly et al. (2016). They propose an application where feedback can be provided to teachers by automatically classifying their utterances into talk moves. Other applications of NLP to education include language learning assistance (Beatty, 2013; Carlini et al., 2014; Tetreault et al., 2014), writing assistance (Dahlmeier and Ng, 2011; Chollampatt and Ng, 2018; Chukharev-Hudilainen and Saricaoglu, 2016), and automated scoring (Burstein et al., 1998; Farag et al., 2018; Beigman Klebanov and Madnani, 2020).

3.3 Dialogue Systems

Our work is further related to research on dialogue systems. Similar to talk moves, dialogue acts provide a categorization for utterances, but, in contrast to talk moves, they apply to general-purpose conversations (Stolcke et al., 2000; Calhoun et al., 2010). Examples include *Statement, Question, Greeting*, and *Apology*. Dialogue act tagging, which is sometimes called dialogue act prediction, is the task of classifying an utterance into the category it belongs to (Yu and Yu, 2019; Khanpour et al., 2016; Wu et al., 2020). Analogous to FTMP, future dialogue act prediction is the task of predicting what the next dialogue act should be, given a conversation history (Tanaka et al., 2019).

Pretrained models have been successfully adapted to the task of dialogue generation (Zhang et al., 2020; Wu et al., 2020; Adiwardana et al., 2020; Roller et al., 2020). However, if directly used in the classroom, these models could potentially produce harmful or unsuitable dialogue as they are trained on large datasets comprising conversations from the internet (Bender et al., 2021). Additionally, we want a system to facilitate structured conversations, and not cause further diversions – this is in contrast to many task-oriented or open-domain dialogue systems whose purpose is to entertain and appear personable to the user. Hence, we propose FTMP as a crucial first step towards an NLP system capable of facilitating classroom discussions.

4 Model

In this section, we describe our proposed model for FTMP, cf. Figure 1. Following Tanaka et al. (2019)'s model for future dialogue act prediction, its main components are three encoders. We hence name our model **3-E**. Our model predicts the next teacher talk move t_{t+1}, given the last w context elements $c_{t-w+1}, \ldots, c_t$.

Utterance Encoder The first encoder – the utterance encoder – is a single-layer gated recurrent unit (GRU; Cho et al., 2014). It processes the sequence of vector representations $v(w_1), \ldots, v(w_m)$ of the words $w_1, \ldots, w_m$ that each utterance u_i consists of and computes the last hidden state as a vector representation of u_i:

$$\hat{a}_i = \text{GRU}(v(w_1), \ldots, v(w_m)) \tag{1}$$

Each utterance representation is then concatenated with a representation s_i of the speaker role. This representation is either 1 or 0, depending on if the speaker has changed from the previous utterance:

$$a_i = \text{cat}(\hat{a}_i, s_i) \tag{2}$$

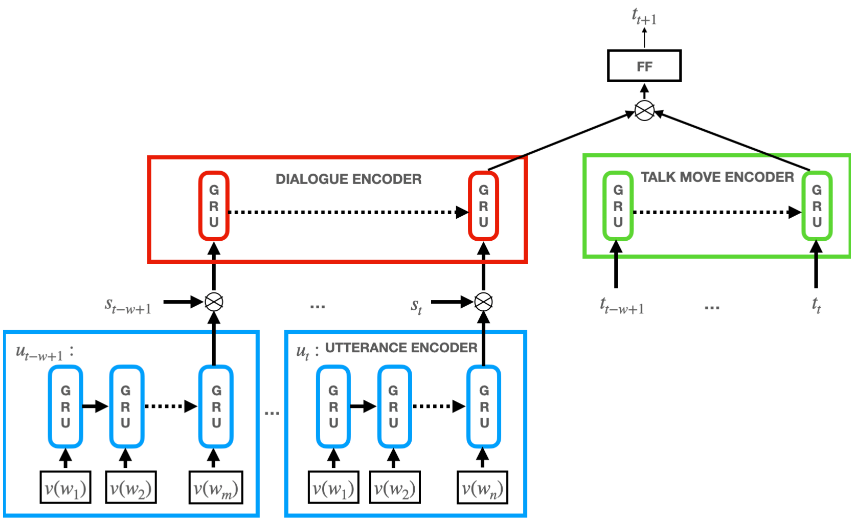

Figure 1: Our proposed model for FTMP, consisting of separate encoders for utterances, past task moves, and the overall context.

Dialogue Encoder Next, the sequence of all w utterance representations is passed to the dialogue encoder, which is also a single-layer GRU. The dialogue encoder processes the sequence, and we take the last hidden state as a representation of all utterances within our context window:

$$b_t = \text{GRU}(a_{t-w+1}, \ldots, a_t) \tag{3}$$

Talk Move Encoder The talk move encoder is a third single-layer GRU, which encodes the sequence of vector representations $v(t_{t-w+1}), \ldots, v(t_t)$ of talk moves $t_{t-w+1}, \ldots, t_t$:

$$d_t = \text{GRU}(v(t_{t-w+1}), \ldots, v(t_t)) \tag{4}$$

We obtain our final context representation r_t by concatenating the representation of all utterances and all talk moves within the context window:

$$r_t = \text{cat}(b_t, d_t) \tag{5}$$

Finally, we pass r_t through a two-layer feed-forward network and a softmax layer to obtain a probability distribution over possible future talk moves.

4.1 Adding a Pretrained Sentence Encoder

RoBERTa Pretrained models define the state of the art on a large variety of NLP tasks (Wang et al., 2019). Thus, we additionally experiment with concatenating an utterance representation computed by RoBERTa (Liu et al., 2019) to the output of 3-E's utterance encoder. Equation 2 then becomes:

$$a_i^* = \text{cat}(\hat{a}_i, s_i, \text{RoBERTa}(w_1, \ldots, w_m)) \tag{6}$$

We call the model with additional RoBERTa representations **3-E-RoBERTa**.

TOD-BERT Since there is a domain mismatch between the text that RoBERTa is trained on and our data, we further experiment with including a model trained on task-oriented dialogue, called TOD-BERT (Wu et al., 2020). TOD-BERT differentiates between user utterances and system utterances using two special tokens, [USR] and [SYS]. Correspondingly, we use the [USR] token to indicate student utterances and the [SYS] token to indicate teacher utterances. We then concatenate a context of w utterances, marked by speaker tokens when there is a change in speaker, to obtain c_{tod}. Finally, we encode c_{tod} using the pretrained TOD-BERT model and concatenate it with the output of the dialogue encoder and talk move encoder. Equation 5 then becomes:

$$r_t = \text{cat}(b_t, d_t, \text{TOD-BERT}(c_{tod})) \tag{7}$$

We call this model **3-E-TOD-BERT**. When pretrained sentence encoders are used, we use the respective BPE (Sennrich et al., 2016) tokenizer for each model.

4.2 Computing the Loss

We train all models using a cross-entropy loss. However, we observe a strong class imbalance in our training data, cf. Figure 2. Thus, we compute label weights inversely proportional to the frequency of a label's occurrence in the data and use them to weight the loss for each training example.

5 Experiments

5.1 Dataset

For our experiments, we make use of the dataset from Suresh et al. (2019). It consists of 216 annotated transcripts of classroom discourse collected in public schools in the US. The topic of instruction is mathematics. The transcripts have been collected from classes from kindergarten to grade 12 and are all in English. Each row in the transcripts consists of an utterance, the name of the speaker, and the talk move realized by this utterance.

The annotations assign each teacher utterance to one of the 6 APT talk moves described in Section 2. Utterances that do not fit into any talk move category are coded as *None*. In addition, we designate the teacher talk move corresponding to utterances made by a student as *Wait*. This category is needed as we eventually want to be able to detect when an in-class NLP system should remain quiet. The original annotations contain two additional categories that we remove due to sparsity: $Marking$ refers to repeated utterances, and we merge it with the $Restating$ category. Some student utterances are annotated as $Context$, which we merge with the $Wait$ category.

We create training, development and test data from 70%, 15%, and 15% of the available documents, respectively. Thus, we have 151 documents for training, and 32 documents for each of development and testing. Our training set consists of over 63k utterances, and the distribution of talk moves in the training set is shown in Figure 2.

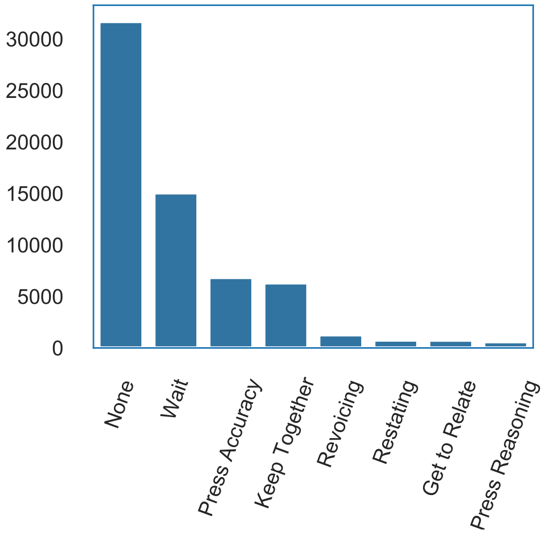

Figure 2: Distribution of talk moves in our training set.

Since 3-E's utterance encoder operates on the word level, we split each utterance into words using the NLTK word tokenizer (Loper and Bird, 2002).

5.2 Baselines

We compare our model to three baselines.

Random Baseline (RB) This baseline randomly selects one of the 8 talk moves for each input.

Talk Move Bigram Model (TMBM) For this baseline, we compute the conditional probability of every talk move in the training set, given the talk move realized by the previous utterance. We then pick the talk move with the highest conditional probability.

Talk Moves Only (TM-only) We further train a GRU model exclusively on the sequences of prior talk moves, i.e., this baseline has no access to actual utterances. We implement two variants of this baseline, one with class weights for training (TM-only-w), and one without (TM-only-z).

5.3 Metrics

Since the classes in our dataset are highly imbalanced, we do not evaluate using accuracy. Instead, we report precision, recall, and F1 score for all models. We compute F1 for all 8 classes individually, and additionally calculate macro-average F1 as an overall score for our dataset.

5.4 Results

Table 2 shows the performance of our proposed model 3-E as well as of 3-E-TOD-BERT, 3-E-RoBERTa, and all baselines. Looking at the macro-average F1 scores, we see that 3-E performs best with an F1 of 29.84. 3-E-RoBERTa, with 27.62 F1, performs worse; however, given that this model has more parameters and includes a strong pretrained component, this is an unexpected result.[2]

To reduce the domain mismatch between RoBERTa's training data and our classroom dialogue data, we substitute RoBERTa with TOD-BERT, which is also trained on dialogue. We see that, while 3-E-TOD-BERT performs better than 3-E-RoBERTa, 3-E still outperforms it. We also observe that on most individual talk move classes, 3-E-TOD-BERT performs equal to or better than 3-E. However, it does poorly on a few classes that

---

[2] We further experiment with directly finetuning RoBERTa on our task, but find its performance to be poor overall (around 17 F1). Hence, we do not report detailed results.

Model	Prec.	Recall	F1	None F1	Wait F1	Press Acc. F1	Keep Together F1	Revoicing F1	Getting Students to Relate F1	Restating F1	Press Reasoning F1

Table 3: Model and annotator performance on FTMP. Italics indicate results on a diagnostic test set of 300 examples taken from the development set.

Label	Prec.	Recall	F1
Macro average	43.76	42.65	42.44
None	68.30	77.76	72.72
Wait	71.48	80.45	75.70
Learning Community	29.59	14.10	19.10
Content Knowledge	27.86	21.47	24.25
Rigorous Thinking	21.56	19.44	20.45

Table 4: Performance of 3-E evaluated on facets.

are less prevalent in the data. We hypothesize that small changes in the quality of the utterance representations have negligible effect on our model, since it gets a large amount of information from the sequence of prior talk move labels. This hypothesis is supported by the fact that all baselines which only receive prior talk move labels as input, i.e., TM-only-w, TM-only-z and TMBM, obtain F1 scores of 20.40, 16.42, and 15.09, respectively. All of them strongly outperform a random baseline with an F1 of 8.50. Comparing 3-E to our baselines, we see that our proposed model is indeed strong on FTMP: 3-E outperforms the best baseline, TM-only-w, by 9.44 F1.

6 Analysis

6.1 FTMP on the Facet Level

In some cases, the distinctions between different talk moves are subtle. For instance, both the *Keeping Everyone Together* and *Getting Students to Relate* moves, which fall under the facet of accountability to the learning community, are made when the teacher wants the students to actively listen and respond to statements made in the classroom. To understand how well the model can distinguish between different accountability facets, we evaluate our best model, 3-E, on the facet level by binning all predicted talk moves into their corresponding facets for the computation of the F1 score.

In Table 4, we see that performance goes up by 12.60 points in this setting, indicating that 3-E is able to distinguish between labels at a coarse-grained level, but struggles with fine-grained distinctions.

6.2 Window Size and Class Weights

We further investigate the effect of weighting the loss as described in Section 4.2 and the influence of different context window sizes. Full results on the development set can be found in Table 6 in the appendix, and we provide a summary of our findings here.

Varying the window size leads to small changes in F1. For smaller window sizes of 1 and 2, F1 is slightly lower at 28.64 and 27.62. When the window size is increased to 5, F1 increases to 29.83. However, when the window size is increased further to 7, F1 drops slightly, to 29.05. We thus choose a window size of 5 to train all our models, and conclude that very large window sizes are not beneficial. We hypothesize that this might be due to the most relevant information for FTMP being

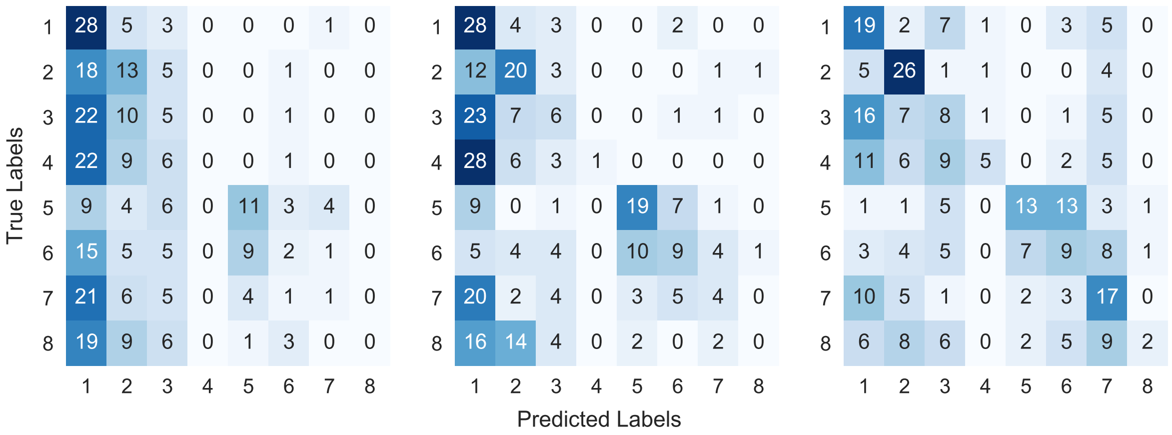

Figure 3: Confusion matrix on the diagnostic test set for 3-E (left) and our two annotators (middle and right). The talk move labels in order are: *None, Wait, Press for Accuracy, Keeping Everyone Together, Revoicing, Getting Students to Relate, Restating*, and *Press for Reasoning*.

Primary option: Annotators	
Inter-annotator agreement	46%
Annotator 1–ground truth agreement	29%
Annotator 2–ground truth agreement	33%
Both Annotators–ground truth agreement	17%
Primary option: Model	
Model–Annotator 1 agreement	48%
Model–Annotator 2 agreement	33%
Model–ground truth	20%
Acceptable options	
Annotator 1's primary accepted by Annotator 2	94%
Annotator 2's primary accepted by Annotator 1	91%
Ground truth accepted by Annotator 1	72%
Ground truth accepted by Annotator 2	79%
Model predictions accepted by Annotator 1	90%
Model predictions accepted by Annotator 2	84%

Table 5: Percentage agreement between our annotators, the ground truth, and the model's predictions on the diagnostic test set.

contained in the most recent dialogue history.

Further, class weighting during training increases 3-E's F1 score by 3, from 26.94 to 29.83. We thus, conclude that class weights are important to account for the label imbalance in our training set. [3]

6.3 Performance of Human Annotators

We further investigate (1) the difficulty of FTMP for human annotators, (2) the effect of multiple choices for the future talk move as opposed to a single answer, and (3) how annotator decisions differ from 3-E's predictions. While our gold standard are actions of a teacher, who also represent human performance, an FTMP annotator is different from a teacher since the former is presented with the exact same information as our model. In contrast, we expect a teacher's decisions to be informed by background knowledge about the students, knowledge about the content being discussed, and multi-modal information.

We recruit two annotators who have extensive experience with linguistic annotation tasks, and are familiar with talk moves. We present them with a diagnostic test set of 300 examples from the development set. Similar to the model input, each example consists of the past 5 utterances, the corresponding talk moves, and speaker information. Both annotators then provide (1) the most likely future talk move, referred to as the 'primary' option, and (2) a set of all acceptable future talk moves given the conversation history. As with our modeling setup, we consider the ground truth for the primary option to be the talk move made by the teacher in the classroom transcript. Each talk move is equally distributed in the ground truth, with 37 examples each of talk moves *None, Wait, Restating, Revoicing*, and 38 examples each of the other talk moves.

Primary Option The last 3 rows in Table 3 show the performance of our annotators' primary option and the model on the diagnostic test set. There is a significant gap of 10 F1 and 15 F1 respectively between the performance of the model and the two annotators. However, there are similarities in the class-wise breakdown. Both the annotators and the model achieve a high F1 on the classes *None, Wait,*

---

[3] We also experiment with downsampling the dominant classes and find its performance to be comparable to class weighting.

and *Restating*, and perform poorly on *Press for Reasoning* and *Getting Students to Relate*. *Press for Reasoning*, and *Getting Students to Relate* are the least prevalent classes in the data. However, the annotators' performance on these talk moves suggests that these classes are intrinsically more difficult to predict based on conversational cues alone. On the other hand, the model's poor performance on categories like *Revoicing* and *Keeping Everyone Together* in comparison to the annotators indicates that there is still room for improvement for our model.

The similarities between the model's predictions and the annotators' primary option is further illustrated by the confusion matrices in Figure 3. Both the model as well as our annotators erroneously predict *None* when the true label is another category, both confuse *Restating* and *Revoicing* for each other, and both erroneously predict *Keeping Everyone Together* when the true category is *Getting Students to Relate* or *Press for Reasoning*.

Acceptable Options Table 5 shows the percentage of responses for which the annotators agree with each other, the ground truth, and the model's predictions. On average, both annotators provide 3 acceptable options in addition to the primary – thus, roughly half the classes were viewed as acceptable for most examples. The impact of having a set of acceptable options in addition to a single correct option is evident here: while inter-annotator agreement is only around 46% on the primary option alone, the primary option of each annotator was one of the acceptable options by the other annotator in over 90% of the cases. Additionally, while agreement between the ground truth and the primary option is low with 29% and 33%, this increases to 72% and 79% when additional options are being considered.

Table 5 helps us contextualize our model's performance. Interestingly, the annotators agree with the predictions made by the model more often than they agree with the ground truth. This indicates that the model might truly be grasping overall patterns and cues from the training data, but probably struggles with finer-grained distinctions between the talk move classes. This is further substantiated by our analysis of how often the model's predictions featured in the set of acceptable options for each annotator. We find that the predictions were acceptable in 90% and 84% of all instances respectively for each annotator.

7 Conclusion

In this paper, we made use of the APT discourse framework to take a first step towards a system that can fill the role of a teacher in classroom discussions. We introduced the task of FTMP, which consists of predicting the next appropriate talk move given an in-class dialogue context. We then presented 3-E, a model for the task, which outperforms multiple baselines. Finally, we conducted an analysis of human performance on FTMP, and compared it to our model. Our results showed that, while the task is challenging, our model produces acceptable talk moves and can identify overall patterns, indicated by similarities with human performance.

Acknowledgments

We would like to thank the anonymous reviewers for their insightful feedback. We would also like to thank the researchers involved in the NSF TalkBack project at the University of Colorado for giving us access to this data, and for their assistance with this work. We would also like to thank Amanda Howard, Charis Clevenger and Jennifer Jacobs for their feedback and assistance with the human annotations, and the members of the NALA research group for their valuable suggestions. This research was supported by the NSF National AI Institute for Student-AI Teaming (iSAT) under grant DRL 2019805. The opinions expressed are those of the authors and do not represent views of the NSF.

Ethics and Impact Statement

The data used in this paper was collected after obtaining informed consent from all participants, and this research was approved by the University of Colorado Boulder's Institutional Review Board (protocol #18-0432). All authors completed appropriate training prior to accessing the data. Since this dataset was provided to us by its owners purely for the purpose of the research reported in this paper, we are not making it publicly available here.

Further, this research is part of the NSF National AI Institute for Student-AI Teaming. Several learning scientists and educators are participating in the institute and advising us on avoiding unintended consequences and harms that could stem from NLP research. The work described in this paper is preliminary, and will be used to inform strategies for additional data collection and model design. Field trials in carefully controlled classroom settings will be conducted before wider deployment.

Class weighting, window 7	33.21	28.64	29.05	58.27

Table 6: Tuning experiments on the development set

B Training and Hyperparameters

3-E is implemented in PyTorch (Paszke et al., 2019). For training, we use an Adam optimizer (Kingma and Ba, 2014) with an initial learning rate of $1e^{-4}$ and train for 30 epochs. The utterance encoder has an embedding size of 256, and a hidden layer size of 512. The talk move encoder has an embedding size of 32 and a hidden layer size of 64. The dialogue encoder has a hidden layer size of 1025. Finally, the feedforward layer uses a hidden layer size of 32. We do not use pretrained word embeddings in the 3-E model.

For the 3-E-RoBERTa model, we use the pretrained parameters of the Fairseq library's implementation of RoBERTa (Ott et al., 2019), and use representations with dimension 1024. For 3-E-RoBERTa, we further add dropout with a probability of 0.4 in two places to avoid over-fitting: on the layer where the two utterance representations are concatenated (c.f. Equation 6), and the layer where the utterance history and talk move history are concatenated (c.f. Equation 5).

For 3-E-TOD-BERT, we use the pretrained model provided by Wu et al. (2020) trained jointly on masked language modeling and response contrastive loss. We additionally add a dropout of 0.2 at the layer where the utterance representation is concatenated with talk move history (c.f. Equation 7).

The baseline models TM-only-w and TM-only-z are trained for 30 epochs using the same hyperparameters, with a batch size of 256 and a learning rate of 1e-4.

BioGen: Generating Biography Summary under Table Guidance on Wikipedia

Abstract

Capturing the salient information from an input article has been a long-standing challenge for summarization. On Wikipedia, most of the wiki pages about people contain a factual table that lists the basic properties of the people. Illuminatingly, a factual table can be regarded as a natural summary of the key information in the corresponding article. Thus, in this paper we propose the task of table-guided abstractive biography summarization, which utilizes factual tables to capture important information and then generate a summary of a biography. We first introduce the TaGS (Table-Guided Summarization) dataset[1], the first large-scale biography summarization dataset with tables. Next, we report some statistics about this dataset to validate the quality of the dataset. We also benchmark several commonly used summarization methods on TaGS and hope this will inspire more exciting methods.

1 Introduction

Text summarization generates a short text version of a long passage which retains the most important information. Recently, two kinds of approaches have been proposed for automatic text summarization. One is extractive summarization (Nallapati et al., 2017; Liu and Lapata, 2019), which directly selects salient sentences from the passage to create a summary. The other is abstractive summarization (See et al., 2017; Hsu et al., 2018a), which aims to concisely paraphrase the input article. In both methods, the summary should always focus on important information, though a document may include trivial facts.

To focus on the main information when generating summaries, some researchers propose to incorporate manifold information to improve the performance. Narayan et al. (2017) proposed to incorporate the figures and Gao et al. (2019b) investigated the using of reader comments for more effective summarization. As another type of side information, factual tables provide a natural summary of the biography document. On Wikipedia, in each wiki page about people, there is a factual table (infobox) on the right side of the page summarizing the main properties. Clearly, infobox is helpful for capturing the salient information during summarizing the biography. However, no existing work takes advantage of tables, though are widely available in the biography on Wikipedia.

In this paper, we propose *Table-Guided Summarization* (TaGS) dataset, the first large-scale biography summarization dataset with tables. And we report some statistics and three important characteristics of this dataset to verify its quality. The first one is it has the weak lead bias that makes it suitable for training both abstractive and extractive summarization methods. The second one is it has strong abstractness that is helpful for generating a more condensed summary. The most important characteristic is that the summary of the biography is guided by a table which contains the most salient facts described in the biography.

To verify the quality of this dataset, we employ some commonly used state-of-the-art summarization methods to conduct experiments on our proposed dataset. From these experimental results, we can see that the methods which simply incorporate the table information outperform the methods which do not use the table information. That demonstrates the effectiveness of incorporating table guidance when generating summaries of documents which have a factual table in it.

Our contributions are summarized as follows:

Figure 1: Relative locations of bigrams of ground truth summaries in the source text across different datasets.

- To the best of our knowledge, we are the first to use factual tables to guide the summarization procedure so as to generate better summaries.
- We release a large-scale abstractive biography summarization dataset with tables. Experiments conducted on this dataset demonstrate the effectiveness of incorporating table information in generating summaries.

2 Related Work

2.1 Text Summarization

Text summarization is an important task which can be classified into extractive and abstractive approaches. Extractive summarization (Narayan et al., 2018b; Chen et al., 2018; Jadhav and Rajan, 2018) tends to generate a summary by integrating the most salient sentences in the document. Cheng and Lapata (2016) first propose using recurrent neural network (RNN) to extract salient sentences. After that researchers explore many the neural based method (Nallapati et al., 2017; Liu and Lapata, 2019; Chen et al., 2018; Zhang et al., 2018; Zhou et al., 2018; Liu et al., 2019), and achieve the state-of-the-art performance (Liu and Lapata, 2019) on the benchmark dataset CNN/DailyMail. In the mean time, the Nallapati et al. (2016) firstly apply this text generation method to the abstractive summarization task and Gehrmann et al. (2018) achieve the state-of-the-art performance by using a data-efficient content selector.

2.2 Summarization with Side Information

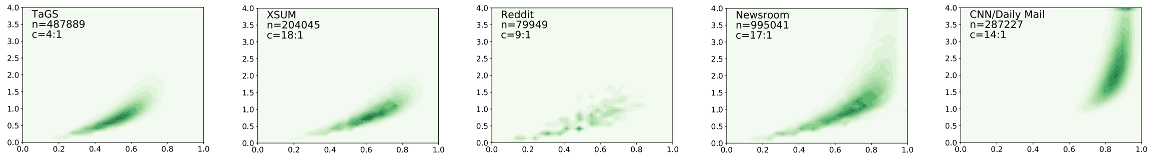
Traditional text summarization methods only use the document as input. However, the gist of the document may lie in side information, such as the title, image captions, or comments which are often available for news-wire articles. As such, various studies (Gao et al., 2020; Hu et al., 2008) have tried to use such information for more efficient and accurate summarization. However, to the best of our knowledge, no existing works consider the use of tables to guide biography summarization.

3 TaGS Dataset

Our dataset, named Table-Guide Summarization (TaGS), consists of over 500,000 document-summary pairs, along with their corresponding factual tables collected from Wikipedia. Concretely, following Chen et al. (2019), we use the leading paragraphs before the content outline as the summary, and following paragraphs as the document. The infobox in the right part of the webpage is extracted as the guided table.

Some key statistics of the factual table are described below. 7.31% of words from a document and 29.41% of words from a summary are included in a factual table. The average number of fields in a table is 12.89, and there are 46.83 words in a table in average. We show some detailed statistics of document-summary pairs in TaGS and compare them with other popular text summarization datasets in Table 1. We next discuss some abstractive characteristics of TaGS compared to existing summarization datasets.

Weak Lead Bias. Lead bias means that directly using the leading sentences of a document can produce a good performance in terms of the summarization evaluation metric ROUGE (Lin, 2004). This is a common problem in text summarization datasets, which mostly occurs in news-based documents. Figure 1 plots the density histograms for the relative locations of words from the ground truth summary in the input document. In the CNN/DailyMail and Newsroom datasets, the words are highly concentrated at the leading parts of the input document. In contrast, our TaGS dataset shows more uniform distributions across words in the document. This characteristic can be also found from the `LEAD` score shown in Table 2, where `LEAD` is a baseline method that selects the first few sentences in the input document as the summary. A high `LEAD` score implicitly indicates a strong lead bias. From Table 2, we find that TaGS has a much lower `LEAD` score than the CNN/DailyMail and Newsroom datasets, and



(a) TaGS (b) XSUM (c) Reddit (d) Newsroom (e) CNN/DailyMail

Figure 2: Density estimation of extractive diversity scores. Large variability along the y-axis suggests variation in the average length of source sequences present in the summary, while x-axis shows variability in the average length of extractive fragments to which summary words belong.

Table 1: Comparison of summarization datasets with respect to corpus size, average document (source) and summary (target) length (in terms of words and sentences) on both source and target.

Datasets	# docs (train/val/test)	avg. document length		avg. summary length	
		words	sentences	words	sentences
CNN/DailyMail (Hermann et al., 2015)	287,227/13,368/11,490	810.57	39.78	56.20	3.68
XSum (Narayan et al., 2018a)	204,045/11,332/11,334	431.07	19.77	23.26	1.00
Reddit (Kim et al., 2019)	79,949	342.00	18.02	9.33	1.03
Newsroom (Grusky et al., 2018)	995,041/108,837/108,862	658.60	31.43	26.70	1.42
TaGS	487,889/5,000/5,000	226.13	7.81	49.25	1.88

thus prevents the model from directly learning the salient information by locational bias.

Strong Abstractness. Table 2 reports the percentage of novel n-grams in the ground truth summary that do not appear in the input document. The result shows that our dataset comprises of 43.38% novel unigrams in the summary, 122.46% higher than the commonly-used benchmark dataset CNN/DailyMail. This indicates that summaries in TaGS are more abstractive. Besides, other two metrics, density and coverage, proposed by Grusky et al. (2018), are commonly used when evaluating the summarization dataset (Kim et al., 2019; Grusky et al., 2018). We plot the distributions of these two metrics in Figure 2, where small density and coverage reflects the summary has strong abstractness. The result shows that TaGS is similar to XSUM and Reddit in terms of density and coverage, and these datasets all have strong abstractness.

`PG/LEAD` in Table 2 is the ROUGE-L ratios of `PG` to `LEAD`, which quantifies the difficulty for extractive methods and the suitability for abstractive methods. CNN/DailyMail and Newsroom achieve low `PG/LEAD` scores, demonstrating that these datasets are more suitable for extractive based model. On the contrary, XSUM and TaGS have high `PG/LEAD`, showing that TaGS is potentially an excellent benchmark for evaluation of abstractive summarization systems.

Table Guided. The intrinsic difference between TaGS and other datasets lies in that each document-summary pair in TaGS is associated with a factual table. We judge whether the table is good guidance from two aspects: (1) word-level overlap percentage and (2) sentence-level mapping relation between document and table. From the word-level aspect, 7.31% words in the document are included in the table; from the sentence-level aspect, we found that 99.86% of document sentences have words in common with the factual table. This demonstrates that the table captures the majority of facts in the document. Thus, it is safe to conclude that the tables in TaGS can be utilized as a good guidance.

4 Experimental Setup

4.1 Comparison Methods

To evaluate the effectiveness of incorporating table, we conduct experiments using the following baselines: (1) **LEAD3**: selects the first three sentences of a document as the summary. (2) **S2S**: is the traditional sequence-to-sequence framework in (Sutskever et al., 2014) which has been used in many text generation tasks (Gao et al., 2019c, 2021; Chan et al., 2019a, 2020, 2019b). (3) **PG**: combines `S2S` with copy mechanism in See et al. (2017). (4) **Unified**: proposed by Hsu et al. (2018b), combines the strength of extractive and abstractive summarization. (5) **Transformer**: is solely based on attention mechanism

Table 2: Corpus bias towards extractive methods in datasets. We show the proportion of novel n-grams in gold summaries. We also report ROUGE scores for the LEAD baseline and the abstractive summarization method PG. Results are computed on the test set.

Datasets	% of novel n-grams in gold summary				LEAD			PG			PG/LEAD
	unigram	bigrams	trigrams	4-grams	R1	R2	RL	R1	R2	RL	Ratio (R-L)
CNN/DM	19.50	56.88	74.41	82.83	39.60	17.70	36.20	36.4	15.7	33.4	0.92x
XSum	35.76	83.45	95.50	98.49	16.30	1.61	11.95	29.7	9.2	23.2	1.93x
Reddit	48.97	84.42	94.66	97.82	3.40	0.00	3.30	19.0	3.7	15.1	5.59x
Newsroom	19.53	48.39	59.38	64.06	30.50	21.30	28.40	14.7	2.2	10.3	0.92x
TaGS	43.38	84.30	94.09	97.11	23.10	4.80	19.57	29.3	11.2	27.9	1.43x

proposed in Vaswani et al. (2017). (6) **CopyTransformer**: is a state-of-the-art generative summarization model (Gehrmann et al., 2018), which combines the `Transformer` with copy mechanism. (7) **TabWords**: just concatenates all the words in table as the summary.

Additionally, we select two best baselines, `Unified` and `CopyTransformer`, concatenating the original input document with tables as input, denoted as (9) **Unified+T** and (10) **CopyTransformer+T**, to determine whether the improvement of TGSG simply arises from the table information.

4.2 Evaluation Metrics

For evaluation metrics, we adopt the ROUGE scores (Lin, 2004) which is widely applied for summarization evaluation (Sun et al., 2018; Chen et al., 2018; Gao et al., 2019a). The ROUGE metrics compare the generated summary with the reference summary by computing overlapping lexical units, and include ROUGE-1, ROUGE-2 and ROUGE-L.

5 Experimental Results

We first examine the performance of these baselines, as shown in Table 3. Firstly, among models without table information, `Unified` achieves the highest performance. `PG` and `CopyTransformer` achieve the second best performance. Secondly, tables are indeed helpful for the summarization process. For models with additional table information, the ROUGE-1 score of `Unified+T` and `CopyTransformer+T` improves by 4.22 and 14.3, respectively. This observation demonstrates that factual tables can help the summarization model to capture the main idea of the table by emphasizing the key facts in the document. However, the performance of `TabWords` is much lower than `Unified+T` and `CopyTransformer+T`, which demonstrates only using the information from table is not sufficient for generating a good summary.

Table 3: ROUGE scores comparison between baselines and TGSG. All our ROUGE scores have a 95% confidence interval of at most ±0.23 as reported by the official ROUGE script.

	ROUGE-1	ROUGE-2	ROUGE-L
w/o table information			
LEAD3	23.10	4.80	19.57
S2S	26.31	10.07	25.13
PG	29.33	11.24	27.91
Unified	32.23	13.29	29.36
Transformer	27.67	14.87	27.02
CopyTransformer	29.17	16.15	28.43
with table information			
TabWords	30.43	12.58	23.73
Unified+T	36.45	15.80	32.93
CopyTransformer+T	43.47	29.14	42.49

6 Conclusion

In this paper, we proposed to use factual tables to guide biography summarization. To demonstrate the effectiveness of incorporating table information in generating biography summaries, we developed the first large-scale abstractive biography summarization dataset with tables. We employ several state-of-the-art summarization methods, and adapt these methods to table guided biography summarization task. These methods outperformed other summarization methods in terms of ROUGE which only use the document as input and ignore the table guidance.

Ethical Impact

In this paper, we propose a table guided biography summarization dataset on Wikipedia. In the real-world application which provided automatic biography summarization service, we will employ human editors to double-check the generated summary to ensure the correctness of content and grammar before publish the summary.

Abstract

Simultaneous machine translation (SIMT) involves translating source utterances to the target language in real-time before the speaker utterance completes. This paper proposes the *multilingual* approach to SIMT, where a single model simultaneously translates between multiple language-pairs. This not only results in more efficiency in terms of the number of models and parameters (hence simpler deployment), but may also lead to higher performing models by capturing commonalities among the languages. We further explore simple and effective multilingual architectures based on two strong recently proposed SIMT models. Our results on translating from two Germanic languages (German, Dutch) and three Romance languages (French, Italian, Romanian) into English show (i) the single multilingual model is on-par or better than individual models, and (ii) multilingual SIMT models trained based on language families are on-par or better than the universal model trained for all languages.[1]

1 Introduction

Simultaneous translation is the task of incrementally generating the translation while the source utterance is gradually spoken. It is crucial in multinational meetings, e.g., in business and politics, where the online simultaneous translation is required for one or multiple language-pairs. Simultaneous machine translation (SIMT) is an attempt to address the challenges of this translation scenario, i.e., trading off the translation quality and its latency (Cho and Esipova, 2016; Arivazhagan et al., 2019, 2020; Firat et al., 2016b).

In this paper, we investigate the *multilingual* SIMT setting, where a single model simultaneously translates between multiple language-pairs. This not only results in more efficiency in terms of the number of models and parameters (hence simpler deployment), but may also lead to higher performing models by capturing commonalities among the languages. The multilingual setting has been successful for the standard offline neural machine translation (NMT) and studied extensively (Johnson et al., 2017; Tan et al., 2019; Aharoni et al., 2019).

We explore simple and effective multilingual architectures based on two strong recently proposed SIMT models, i.e. the WAIT-K (Dalvi et al., 2018) and COUPLED POLICY (Arthur et al., 2020). The former waits to *read* a fixed number of k input tokens; afterward, it *writes* (generates) an output token for each newly received input token. The latter learns a policy, via an *agent*, for an adaptive waiting between reading and writing to reduce the translation delay while maintaining the quality.

COUPLED POLICY uses the adaptive waiting, generated from offline word alignments. It continues to read the source tokens until the corresponding word alignment to the target token appears.

Under these underlying SIMT models, we explore multi-task learning (MTL) framework, *full* and *partial* parameter sharing protocols across the languages with language indicators.

Our experiments show the effectiveness of the simple strategy of sharing all the SIMT components across the languages, with language tags specifying the translation task. The results on translating from two Germanic languages (German, Dutch) and three Romance languages (French, Italian, Romanian) into English show the single multilingual model is on-par or better than individual models. Furthermore, the results show that multilingual SIMT models trained based on language families are on-par or better than the universal model trained for all languages.

            $\theta_{\mathcal{E}}^{F}, \theta_{\mathcal{D}}^{E} \leftarrow \text{MLE}(\boldsymbol{x}, \boldsymbol{y}, \theta_{\mathcal{E}}^{F}, \theta_{\mathcal{D}}^{E})$
        end for
    end for
end while
```

2 Multilingual Simultaneous Translation

The original neural programmer-interpreter (NPI)-SiMT framework (Arthur et al., 2020) employs a trainable programmer θ_{prog} and interpreter θ_{intp}. The programmer/agent issues *read*/*write* commands to control the interpreter, i.e. the NMT model. The interpreter is constructed using an encoder $\theta_{\mathcal{E}}$ and a decoder $\theta_{\mathcal{D}}$. Each component is trained on triplet $\langle x, y, a \rangle$ where x is the source sentence, y is the target sentence, and a is the program oracle using behavioral cloning (Torabi et al., 2019). For notation clarity we rename the programmer into $\theta_{\mathcal{A}}$, resulting triplet of trainable modules $\theta_{\mathcal{A}}, \theta_{\mathcal{E}}, \theta_{\mathcal{D}}$.

Language-Specific Parameters We further extend this framework by distilling a parameter, specific to language θ_x^l, where x is a specific module and l is a specific language. This language-specific parameter is similar to Firat et al. (2016a); Dong et al. (2015); Ahmadnia and Dorr (2020) where parameters are separated based on the source and target languages. In the case of SiMT, the program a is affected by both languages. This framework enables us to use multiple parallel corpora $\mathcal{D}_i$ and train a language specific module using maximum likelihood estimation by updating particular θ_x^l based on $\mathcal{D}_i$. The training algorithm for our NPI-SiMT is shown in Algorithm 1.

Multilingual Parameter Sharing Multilingual parameter sharing is achieved by using only a single module for language-specific parameter θ_x^*. Depending on the module, we can disregard source (F) or target (E) completely. This allows us to share the parameter across different parallel corpora. However, the embedding matrix in different $\mathcal{D}_i$ can be different because of various tokenization and vocabulary construction methods. To remedy this, we can either train joint vocabulary spaces for source and target sides, or simply joining different spaces using union operation. Herein, we use the latter method.

Language Indicator Embedding When the interpreter is shared, it is difficult to communicate which pairs of languages are being processed. To deliver this, we pass the source and target language embedding information to the encoder and decoder, respectively. This information is then combined using addition operation with the word embedding. In the programmer, we use a concatenation of both source and target languages.

Batch of Multilingual Instances Algorithm 1 outlines the overall training procedure of multilingual SiMT. Here, it is crucial to construct a batch as a mixture of many language pairs to achieve good multilingual training. We also need to include the information of the source language to create language indicator embedding. If a module is language-agnostic, it will be responsible for consuming all the input; otherwise, language-specific modules will be used to process the specific item in the batch according to its language. Results from different languages will be aggregated using concatenation at the end.

3 Experiments

Our experiment aims to investigate the effects of multilingualism in SiMT architecture. To achieve this we first choose the language pairs from (1) the same family group and (2) mixing them all. This is enabled by investigating various parameter sharing strategies for the components of the SiMT architectures.

Datasets. We use IWSLT 2017 (Cettolo et al., 2017) datasets for all parallel corpora in which all translating to English. The choice was made due to its characteristics of spoken multilingual corpora from TED. We choose the Germanic language group, German (DE) and Dutch (NL), and the Romance language group, Italian (IT), French (FR), and Romanian (RO). The languages within the same group generally have high syntactic similarity and the same word order. Unless otherwise specified, we use the same settings and preprocessing as described in Arthur et al. (2020).[2]

---

[2] In our preliminary experiment, the pre-processing under concatenation of multilingual corpora with larger vocabulary

SIMT Systems We compared two SIMT baselines, COUPLED POLICY (Arthur et al., 2020) and the WAIT-K model (Ma et al., 2018). For a fair comparison, we choose a value of k, which achieves comparable translation quality to the COUPLED POLICY system. Following some initial experiments, we choose $k = 2$.

Parameter Sharing Since our model deals with the many-to-one translation task with an agent, we decided to separate i) encoder, ii) agent, and iii) encoder + agent. This idea came from the performance improvements that a number of studies demonstrated by separating the decoder in offline one-to-many MT (Dong et al., 2015; Sachan and Neubig, 2018). In SIMT, two modules, encoder and agent, are tied to the source, and therefore, reasonable to have them as language-specific parameters.

Evaluation. Following Arthur et al. (2020), we evaluate the systems based on their translation quality and delay. Translation quality can be measured by case sensitive BLEU (Papineni et al., 2002). [3] We adopt two delay measurements by previous studies: (1) average proportion (AP) (Cho and Esipova, 2016) is a fraction of reading source words per emitted target words, and (2) average lagging (AL) (Ma et al., 2019) is an average number of lagged source words until all inputs are read.

3.1 Results

In this section, we will describe the results of parameter sharing in SIMT. Following that, we present the comparison of multilingualism under different language groups.

Parameter Sharing Strategies. Table 1 presents the results of various parameter sharing strategies for FR/IT/RO in the Romance language family. When sharing all parameters across these three languages, WAIT-2 has a slight increase in delay, but the translation quality is comparable to or better than bilingual. In contrast, the best parameter sharing setting for COUPLE POLICY is to have language-specific encoders and share the rest of the parameters. This appears to have a clear advantage in both quality and delay; the BLEU score increases up to 0.8 units, with a reduction in AL, approximately 10% in FR and IT. In both architectures, the model size reduces drastically when trained on multilingual setting, and remains approximately the same across different sharing strategies. These results are consistent for DE/NL in the Germanic language family. Full results are included in the supplementary material.

			FR→EN		IT→EN		RO→EN		Model
$\theta_{\mathcal{E}}$	$\theta_{\mathcal{D}}$	$\theta_{\mathcal{A}}$	AL	BLEU	AL	BLEU	AL	BLEU	Size
				WAIT-2					
×	×	–	**2.22**	23.40	**2.73**	24.77	**2.55**	24.34	158.7M
×	✓	–	2.32	23.54	2.77	24.75	2.68	**24.43**	88.2M
✓	✓	–	2.35	**23.76**	2.77	**25.24**	2.72	24.10	84.1M
				COUPLED POLICY					
×	×	×	1.48	26.90	1.00	22.62	1.02	22.82	166.9M
×	✓	×	1.53	24.82	0.90	21.13	1.09	20.60	96.4M
×	✓	✓	**1.37**	**27.45**	0.92	**23.40**	**1.01**	**23.35**	90.9M
✓	✓	×	1.44	27.36	0.99	23.13	1.16	23.00	92.4M
✓	✓	✓	1.38	27.34	**0.89**	23.32	1.02	22.63	86.9M

Table 1: Parameter sharing under Romance language family: French, Italian, Romanian. ✓ and × indicate *shared* and *not sharing* components in the MTL architecture.

Multilingual Modelling Strategies. Table 2 shows the overall performance comparison of the multilingual setting. Multilingualism in SIMT evidently surpasses the bilingual baseline in translation delay, quality, and/or model size. Generally, SIMT trained on the same language family outperforms not only the bilingual baselines, but also the universal multilingual model. In the Germanic language, training under the same language group boosts up the BLEU up to 1 unit. Although baseline in WAIT-2 has a shorter delay, COUPLED POLICY surpasses both quality and delay. We observe that when the model runs universally, the BLEU score reaches back to or lower than that of the bilingual model.

On the other hand, the Romance language family has slightly different behavior across different SIMT models. COUPLED POLICY behaves similarly, where training SIMT under the same group positively influences the performance, but in WAIT-2, the universal model excels the best. This is particularly interesting because the Romance language family has the same word order as English, which WAIT-2 would be a perfect fit for such translation between two languages with the same word order. However, it is not the case, so mixing all the languages regardless of word order under WAIT-2 improves translation quality more while preserving the delay.

---

size does not impact performance.

Table 2: Multilingual results for WAIT-2 and COUPLED POLICY under Bilingual, Universal, and the same language family (Germanic and Romance). Fully shared architecture is selected for Universal model while the same language group model has language-specific parameters for encoder. The last column indicates model parameter size, where bilingual row adds up the model size of all the language pairs, i.e. $55.646\text{M} \times 5 \approx 278.2\text{M}$.

Under the same SIMT model, COUPLED POLICY has better performance when trained in the same language group. Also, the model size decreases 40% compared to the bilingual baseline, where the same language family has a total of 164.2M parameters and the bilingual has a total of 278.2M parameters. WAIT-2 seems to have slightly arguable results, where DE and NL have the highest BLEU when trained language-family-wise, but the Romance language family benefits the most from universally trained in all languages. Also, one should note that a lower delay in WAIT-K under the same k value does not mean outputting the target sentence faster: (1) Because of the nature of WAIT-K, the model follows the fixed READ and WRITE actions, and (2) the formulation of AL accounts for not only the lagging of translation but also the number of tokens produced as output and taken as input. Therefore, a lower AL indicates the changes in the probability of producing the end of the sentence. This will generate a shorter target sentence and/or stop the translation without fully observing the input, which impacts the delay. Nevertheless, under WAIT-2, the translation quality improves, and the model size decreases with multilingualism.

3.2 Discussion

The setting for parameter sharing in this experiment is inspired from the observation that the multilingual NMT can benefit from separating encoder and decoder parameters (Dong et al., 2015; Sachan and Neubig, 2018; Ahmadnia and Dorr, 2020). The motivation from Dong et al. (2015); Sachan and Neubig (2018) is that separating decoder parameters in one-to-many setting is beneficial because of the difficulty of one-to-many translation task. Our problem is SIMT where not only mapping from the source language to the target language is important, but also learning when to map is equally important. Hence, our assumption was that due to the difficulty of many-to-one SIMT task, assigning the encoder and the agent to language-specific would help the performance. Under WAIT-K, encoding the representation of the source language separately does not seem to benefit. However, Table 2 shows multilingual setting surpasses bilingual. This would be similar to the traditional NMT, that the model generalize the translation tasks across different languages and leverages the correlation across the source languages.

COUPLED POLICY is more complex architecture than WAIT-K as it also needs to learn the optimal policy from an oracle trajectory. However, this takes more advantages when trained on the same language family. Since its oracle is generated from offline word alignments between the source language and the target language, its mechanism of read/write is dependent on the word order and language properties. Our results in Table 2 also supports this as the model trained on the same language family surpasses both bilingual baselines and universal model. The interesting observation here is that, unlike WAIT-K, a separated encoder takes advantages more than fully shared architecture while separating both encoder and agent significantly degrades the performance in BLEU. This suggests that the language-specific encoder can form the representation of the source languages better than the shared one, but if the agent is separated together, the model struggles mapping from the source language to the target language. This reflects why separated encoder and agent in COUPLED POLICY has a BLEU decay while AL is not affected as significant. Therefore, because COUPLED POLICY takes advantages of the same word order from its oracle trajectory, its shared agent can capture the general representation of the same word order better while the language-specific encoder can help the agent by only focusing on encoding the representation of each source language.

4 Related Work

Simultaneous Machine Translation SIMT has been explored as a sequential decision-making translation problem. NPI architecture is employed to 1) choose whether to take more input token or produce output token using agent programmer and 2) translate partially observed input tokens to output using neural machine translation (NMT) interpreter (Satija and Pineau, 2016; Gu et al., 2016). The initial approaches were mainly training the agent using reinforcement learning with assigned rewards to balance the trade-off between translation quality and delay (Gu et al., 2016; Satija and Pineau, 2016; Alinejad et al., 2018). However, it has stability and robustness issues due to the sparse reward signals, so imitation learning using oracle actions has been independently attempted (Zheng et al., 2019; Arthur et al., 2020; Dalvi et al., 2018).

Multilingual Machine Translation In NMT, multilingual training is a popular MTL approach as it is very simple, but effective (Johnson et al., 2017; Sachan and Neubig, 2018; Dong et al., 2015; Dabre et al., 2020). Instead of choosing entirely different NLP tasks and increase complexity of implementation (Niehues and Cho, 2017; Zaremoodi and Haffari, 2018), multilingual setting only involves concatenating multiple bilingual language pairs for training (Johnson et al., 2017). The language pairs are the task space in MTL, which determines the performance of the model, and so, the selection of language pairs influences the overall performance of translation (Tan et al., 2019).

Parameter sharing in multilingual setting has also been extensively studied. Dong et al. (2015) initially had language-specific decoder under one-to-many translation. This was further extended to sharing decoder parameters partially (Sachan and Neubig, 2018). Ahmadnia and Dorr (2020) investigated hierarchically sharing parameters under the similarity between languages. This simple parameter sharing has shown to restrict sharing dissimilarity, improving translation quality of all the languages (Johnson et al., 2017; Sachan and Neubig, 2018; Cettolo et al., 2017).

5 Conclusions

In this paper, we have investigated multilingual SIMT using IWSLT 2017 datasets. We have explored simple and effective multilingual architectures based on two strong recently proposed SIMT models, namely WAIT-K and COUPLED POLICY. Experiments show that the best parameter sharing strategy for the WAIT-K model, when dealing with DE/NL (as Germanic languages) and RO/IT/FR (as Romance languages), is to share all SIMT components across the languages regardless of the language set. However, the best sharing strategy seems to depend on the language family when it comes to COUPLED POLICY. Under the best parameter sharing strategy, our results have shown that (i) the single multilingual model is on-par or better than individual models, and (ii) multilingual SIMT models trained based on language families are on-par or better than the universal model trained for all languages. Furthermore, (iii) COUPLED POLICY takes the advantages of the same word order, so it achieves the best performance with the language-specific encoder and training under the same language family

For the future work, we plan to extend this to a larger dataset. Aharoni et al. (2019) demonstrated the scales of parallel corpora draw different conclusions in multilingual NMT. To maintain the characteristics of spoken languages, translation datasets must be selected carefully. Secondly, we will investigate different language families, including Slavic languages and Austronesian languages. The consistent results in different families would make the claim in this paper more valid.

A Appendices

SIMT Architecture We used a single layer long short term memory (LSTM) SEQ2SEQ as the interpreter for both SIMT models. The programmer is an LSTM transducer with a binary softmax to generate a read or write action for COUPLED POLICY. WAIT-K followed the fixed oracle actions under $k = 2$ without the programmer. We used scheduled sampling of 5%, 15%, and 15% for training the NPI-SIMT framework as described in Arthur et al. (2020).

Training is done using Adam (Kingma and Ba, 2015) with initial learning rate 0.001, and halved it each time when perplexity increased on the development set. Early stopping is reached at the fourth learning rate. During testing we use a standard beam search algorithm similar to Gu et al. (2016) with $b = 5$. Training is done using single V-100 GPU for 6 hours for one source language. Multilingual experiments time scale linearly to the numbers of parallel corpora being used for the experiment.

Table 6: The details of parameters in COUPLED POLICY baseline. WAIT-K has no `agent` parameters and multilingual models has additional components in `model.encoder` or `agent` and an increase in the first dimension of `model.src_embedder` by the number of languages, e.g., `torch.Size([32004, 512])` for bilingual baseline to `torch.Size([64004, 512])` for Germanic family. Total number of parameters for encoder, agent, attention, decoder, input embedding, output embedding and action embedding are 2.0M, 2.8M, 512.5K, 19.1M, 15.6M, 15.6M and 2.0K, respectively.

Cross-Domain Review Generation for Aspect-Based Sentiment Analysis

Abstract

Supervised learning methods have proven to be effective for Aspect-Based Sentiment Analysis (ABSA). However, the lack of fine-grained labeled data hinders their effectiveness in many domains. To address this issue, unsupervised domain adaptation methods are desired to transfer knowledge from a labeled source domain to any unlabeled target domain. In this paper, we propose a new domain adaptation paradigm called cross-domain review generation (CDRG), which aims to generate target-domain reviews with fine-grained annotation based on the source-domain labeled reviews. To achieve this goal, we propose a two-step approach as a concrete realization of CDRG. It first converts a source-domain review to a domain-independent review by masking its source-specific attributes, and then converts the domain-independent review to a target-domain review with a masked language model pre-trained in the target domain. We further propose two ways to leverage the generated target-domain reviews for two cross-domain ABSA tasks. Extensive experiments demonstrate the superiority of our CDRG-based approaches over the state-of-the-art domain adaptation methods.

1 Introduction

Aspect-Based Sentiment Analysis (ABSA) has received considerable attention in recent years (Liu, 2020). The goal of ABSA is to extract the aspect terms mentioned in review sentences and predict the sentiments over them (Pontiki et al., 2016). For example, given the review "*The fish soup is delicious*", the aspect term and its sentiment are *fish soup* and *Positive*, respectively. With the recent advances in deep learning, many supervised neural models have been proposed for several ABSA tasks, e.g., aspect extraction (Liu et al., 2015; Xu et al., 2018), aspect-level sentiment classification (Wang et al., 2016b; Tang et al., 2016), and End-to-End ABSA (Zhang et al., 2015; Li et al., 2019a).

Although these neural models have obtained promising results in several product domains such as *Laptop* and *Restaurant* (Pontiki et al., 2014), the major obstacle to them is the lack of rich annotated resources in many new domains. Since ABSA requires fine-grained annotation of aspect terms and their sentiments in each review, it is extremely time-consuming to develop such resources for each domain, and the annotation process can be prohibitively expensive. To alleviate the annotation efforts, unsupervised domain adaptation methods are desired to transfer knowledge from a source domain with rich labeled data to a target domain with only unlabeled data.

The key challenge of domain adaptation is that the data distribution of the source domain usually differs from that of the target domain. To alleviate the domain discrepancy, many approaches have been proposed in coarse-grained sentiment classification based on the following two paradigms:

- **feature-based adaptation**, which aims to aims to learn a domain-invariant feature representation across domains (Blitzer et al., 2007; Glorot et al., 2011; Yu and Jiang, 2017; Ziser and Reichart, 2018; Ghosal et al., 2020)
- **instance-based adaptation**, which focuses on re-weighting labeled instances in the source domain for use in the target domain (Mansour et al., 2008; Dredze et al., 2010).

However, due to the challenges in fine-grained adaptation, only a few studies explore the domain adaptation problem for ABSA (Ding et al., 2017; Wang and Pan, 2018; Li et al., 2019b; Gong et al., 2020). Moreover, these studies still follow the above two domain adaptation paradigms, which suffer from two common limitations: (1) although

The [Macbook]$_{\text{Positive}}$ is lightweight, but the [battery]$_{\text{Negative}}$ never held a charge longer than 1 hour !

The [fish soup]$_{\text{Positive}}$ is delicious, but the [sushi]$_{\text{Negative}}$ never tastes as good as before !

Figure 1: Cross-Domain Review Generation with applications to the End-to-End ABSA task, in which the goal is to generate a target-domain review with fine-grained annotation given a labeled review in the source domain.

they can reduce the domain discrepancy by learning shared representations or re-weighting source instances, the supervision signals for their main task solely come from the labeled source domain; (2) both of them are lack of interpretability, as the shared representations or re-weighted instances offer little transparency regarding the knowledge transferred to the target domain.

To address the two limitations, we propose a new domain adaptation paradigm named **Cross-Domain Review Generation** (CDRG) with applications to the ABSA task. Given a labeled review in the source domain, the goal is to generate a target-domain review with fine-grained annotation, which converts the domain-specific attributes (e.g., aspects, opinions, and collocations) to the target domain while preserving its annotation and remaining contents. For example, in Fig. 1, a labeled review from the *Laptop* domain is transferred to the *Restaurant* domain by converting its source-specific attributes to target-specific attributes (e.g., *Macbook* to *fish soup*, *lightweight* to *delicious*, etc) but keeping other words and the labels unchanged. Different from existing text generation tasks, CDRG is challenging due to a couple of reasons. First, there is no paralleled corpus which aligns labeled source-domain reviews and unlabeled target-domain reviews. Second, given unparalleled corpus, it is non-trivial to achieve alignments between the domain-specific attributes. More importantly, the generated target review is required to have the fine-grained annotation.

To achieve this goal, we propose a simple yet effective two-step approach, containing a domain generalization step and a domain specification step. Specifically, the domain generalization step first identifies important domain-specific attributes[1], and then mask source-specific attributes in each source review to obtain a domain-independent review. Next, given the domain-independent review as input, the domain specification step employs a pre-trained masked language model from the target domain to generate a target review. In our two-step approach, the domain-independent review serves as a bridge to achieve word-to-word alignments in source and target reviews, and thus the fine-grained annotation from the source review can be directly transferred to the target review.

We further propose two training strategies to leverage the generated target-domain reviews for two cross-domain ABSA tasks, including cross-domain End-to-End ABSA (E2E-ABSA) and aspect extraction (AE). Experiment results on four benchmark datasets show that only using our generated target-domain reviews, the baseline BERT model already outperforms the state-of-the-art domain adaptation methods, and a joint usage of generated target reviews and labeled source reviews can further boost the performance significantly.

Our main contributions can be summarized as follows:

- We propose a new domain adaptation paradigm named **Cross-Domain Review Generation** (CDRG) with applications to the ABSA task, and then devise a simple yet effective two-step approach as a concrete realization of CDRG.
- With the help of generated target-domain reviews, our best training strategy outperforms the state-of-the-art method by an absolute improvement of 2.83% and 4.47% on Micro-F1 for cross-domain E2E-ABSA and cross-domain AE, respectively.
- As long as a source domain has sufficient annotated reviews, our two-step approach for CDRG can generate many annotated target reviews, which offer interpretable justification for domain adaptation.

---

[1] Domain-specific attributes can be words, phrases, syntactic structures, and expression styles only occurring in the source domain or the target domain. However, as aspect and opinion terms are the core of ABSA, we only consider domain-specific aspect and opinion terms in our approach.

2 Related Work

As two important tasks in ABSA, aspect extraction (Liu et al., 2015; Poria et al., 2016; Wang et al., 2016a, 2017; Li et al., 2018a; Xu et al., 2018) and aspect-level sentiment classification (Dong et al., 2014; Tang et al., 2016; Wang et al., 2016b; Yang et al., 2017; Ma et al., 2017; Wang et al., 2018) have been extensively studied in the literature. For practical applications, a number of recent studies handle them together in an end-to-end manner, in which many supervised learning methods with discrete linear features (Mitchell et al., 2013) and continuous neural features (Zhang et al., 2015; Li et al., 2019a) have been proposed. Despite obtaining promising results, their main limitation lies in the lack of annotated data in many new domains. To address this data sparsity problem, unsupervised domain adaptation methods are desired.

Most existing domain adaptation studies focus on coarse-grained sentiment classification to learn domain-invariant representations, including pivot-based methods (Blitzer et al., 2007; Pan et al., 2010; Yu and Jiang, 2016), auto-encoders (Chen et al., 2012; Zhuang et al., 2015), semi-supervised methods (He et al., 2018; Ye et al., 2020), and domain adversarial networks (Ganin et al., 2016; Li et al., 2018b). Besides, another line of work focuses on re-weighting source instances to automatically find useful source samples for the target domain (Jiang and Zhai, 2007; Mansour et al., 2008; Dredze et al., 2010; Xia et al., 2014). Due to the challenges in fine-grained adaptation, there exist only a few studies for cross-domain aspect and opinion extraction (Li et al., 2012; Ding et al., 2017; Wang and Pan, 2018), or End-to-End ABSA (Li et al., 2019b; Gong et al., 2020). However, these methods still follow the traditional domain adaptation paradigms to either learn shared representations or perform instance weighting. Different from these methods, we propose to accomplish domain adaptation for ABSA based on Cross-Domain Review Generation.

3 Problem Formulation

In this paper, we consider two ABSA tasks, i.e., End-to-End ABSA (E2E-ABSA) and Aspect Extraction (AE). Following Li et al. (2019b), we formulate both tasks as sequence labeling problems. Formally, given a sequence of input tokens $\mathbf{x} = \{w_1, w_2, ..., w_n\}$, its label sequence is denoted by $\mathbf{y} = \{y_1, y_2, ..., y_n\}$. Let $y_j \in \{$`B-POS`, `I-POS`, `B-NEG`, `I-NEG`, `B-NEU`, `I-NEU`, `O`$\}$ be the label space for the E2E-ABSA task, and $y_j \in \{$`B`, `I`, `O`$\}$ be the label space for the AE task.

Cross-Domain ABSA. We focus on the unsupervised domain adaptation setting, in which labeled data are only available from the source domain. Specifically, we assume access to a set of labeled reviews from the source domain $D_S = \{(\mathbf{x}_i^s, \mathbf{y}_i^s)\}_{i=1}^{N^s}$, and another set of unlabeled reviews from the target domain $D_U = \{\mathbf{x}_i^u\}_{i=1}^{N^u}$. The goal is to predict the label sequence for test data in the target domain: $\mathbf{y}_i^t = f_t(\mathbf{x}_i^t)$, $D_T = \{\mathbf{x}_i^t\}_{i=1}^{N^t}$.

4 Methodology

Overview. In this work, we propose a new domain adaptation paradigm named Cross-Domain Review Generation (CDRG). The goal is to transform a labeled source review to a labeled target review by converting its source-specific attributes to target-specific attributes while retaining the remaining contents and its labels. To achieve this goal, we propose a simple yet effective two-step approach, as shown in Fig. 2. In the domain generalization step, we first extract the domain-specific attributes from the labeled source data and the unlabeled target data. For each labeled source review, we mask its source-specific attributes to obtain a domain-independent review. In the domain specification step, a pre-trained BERT model is first re-trained with masked language modeling (MLM) on the unlabeled data from the target domain. Next, given the domain-independent review, we employ the target-domain MLM to generate a target review. As the domain-independent review serves as a bridge to achieve word-to-word alignments between the source and generated target reviews, the source labels can be directly transferred to the target review. Finally, we propose two strategies to leverage labeled target reviews for E2E-ABSA and AE tasks, including independent training and merge training.

4.1 Proposed Two-Step Approach for CDRG

Our proposed approach for CDRG consists of two steps: (1) a domain generalization step to convert each source-domain review to a domain-independent review; (2) a domain specification step to convert a domain-independent review to a target-domain review.

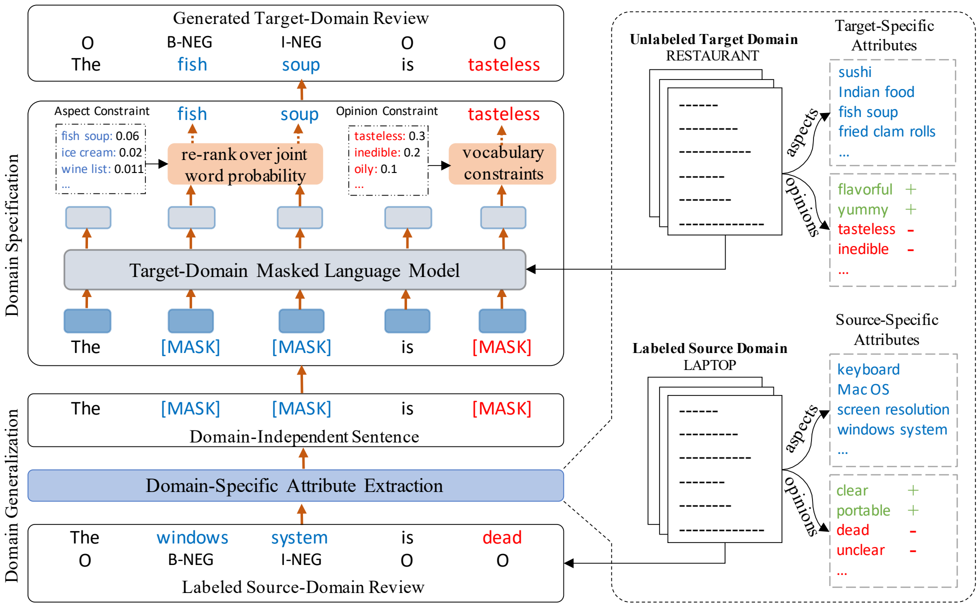

Figure 2: Overview of our two-step approach for Cross-Domain Review Generation, which contains a domain generalization step and a domain specification step. Note that we use Double Propagation to extract all the opinion terms together with their sentiments, and +, -, and 0 denote Positive, Negative, and Neutral sentiments, respectively.

4.1.1 Step 1: Domain Generalization

To convert each source-domain review to a domain-independent review, we first extract the domain-specific attributes from each domain, and then mask the source-specific attributes in source reviews.

Domain-Specific Attribute Extraction. We define domain-specific attributes as words, phrases, syntactic structures, and expression styles that only occur in the source domain or the target domain. However, it is often challenging to identify some attributes such as syntactic structures and expression styles, as most of them are implicitly expressed in the review. More importantly, since ABSA aims to jointly extract the aspects and sentiments, aspect and opinion terms tend to play more crucial roles than the other attributes. Therefore, we only consider domain-specific aspect terms and opinion terms as domain-specific attributes in this paper.

To extract aspect and opinion terms from the unlabeled target domain, we use a dependency relation-based unsupervised method named Double Propagation (Qiu et al., 2011). Specifically, given the unlabeled target reviews D_U, we first resort to a sentiment lexicon[2] to extract the opinion terms in D_U, and use the *conj* relation to expand the opinion term list. Next, we employ these opinion terms as seed words, and extract all the words holding the *amod* and *nsubj* relations towards any seed word. We then treat the extracted words as aspect terms[3], and use the *nn* relation to expand the aspect term list. The above three steps can be iterated until the aspect and opinion term lists are no longer updated.

Given the labeled source reviews D_S, we can easily obtain the aspect term list, as the aspect terms have been annotated in each review for both E2E-ABSA and AE tasks. For opinion terms, we also utilize Double Propagation to expand its list.

After obtaining the aspect and opinion term lists for each domain, we remove all the domain-independent terms that occur in both source and target domains, and obtain the domain-specific term lists. Let us use A_s and O_s to denote the source-specific aspect and opinion term lists, and A_t and O_t the target-specific aspect and opinion term lists.

Domain-Independent Reviews. Given each review in the source domain $\mathbf{x}^s = \{w_1, w_2, ..., w_n\}$, if its sub-sequence is a source-specific attribute in either A_s or O_s, we substitute each word in the sub-sequence with a special token `[MASK]` to obtain a domain-independent review, denoted by $\mathbf{x}^m$. For example, in Fig 2, the source-specific aspect term *windows system* and opinion term *dead* are replaced by two `[MASK]` tokens and one `[MASK]` token, respectively.

---

[2] https://www.cs.uic.edu/∼liub/FBS/sentiment-analysis.html#lexicon

[3] Since Double Propagation can only extract single-word aspect terms, we further expand them to multi-word aspect terms if their previous words have an *amod* or *nn* relation towards them (e.g., *Italian*$\xrightarrow{amod}$*food*, *fish*$\xrightarrow{nn}$*soup*, etc).

4.1.2 Step 2: Domain Specification

The domain specification step is responsible for incorporating target-specific attributes into each domain-independent review $\mathbf{x}^m$. In our work, we propose to transform it as a text infilling problem. To address this, we pre-train a Transformer network with the masked language modeling (MLM; Devlin et al. (2019)) task on unlabeled data in the target domain, followed by predicting a target-specific word for each masked token in $\mathbf{x}^m$.

Target-Domain MLM. Since the size of the unlabeled target-domain data D_U is typically small, we adopt a pre-trained BERT model (Devlin et al., 2019) and re-train the BERT model with MLM on D_U. Specifically, we create training instances by randomly replacing a subset of tokens with `[MASK]` in each unlabeled review $\mathbf{x}^u$, and the objective is to recover the masked tokens based on the hidden states from BERT.

With the target-domain MLM (TD-MLM), we can infill each masked position in $\mathbf{x}^m$ based on their context. Let us use $M = \{m_1, m_2, ..., m_K\}$ to denote the indexes of the masked tokens in $\mathbf{x}^m$, where K refers to the number of masked tokens. The predicted word for the j-th masked token can be computed as follows:

$$\begin{aligned} &p(w_{m_j}|\mathbf{x}^m) = \text{TD-MLM}(w_{m_j}|\mathbf{x}^m); \\ &o_{m_j} = \arg\max_{w_{m_j}} p(w_{m_j}|\mathbf{x}^m), \quad w_{m_j} \in V, \end{aligned} \tag{1}$$

where V denotes the whole vocabulary, and o_{m_j} is the output word with the highest probability.

However, the TD-MLM suffers from two major limitations: (1) the predicted token with the highest probability in Eqn. (1) may not be an aspect term or an opinion term; (2) each masked token is predicted independently, and thus it is possible that the predicted tokens for two consecutive masked positions are not coherent.

Target-Specific Aspect Constraint. To tackle these two limitations, we first propose to utilize the target-specific aspect terms (i.e., A_t) extracted in Section 4.1.1 as vocabulary constraints to limit the prediction space of each masked aspect term.

Specifically, if the masked aspect term corresponds to a single-word term in the source review (e.g., *keyboard*), the word selection in Eqn. (1) can be modified as follows:

$$o_{m_j} = \arg\max_{w_{m_j}} p(w_{m_j}|\mathbf{x}^m), \quad w_{m_j} \in A_t^1, \tag{2}$$

where A_t^1 refers to the sets of single-word aspect terms in A_t. Otherwise, if the masked aspect term corresponds to a multi-word term, we compute the joint word probabilities of each multi-word term in A_t followed by re-ranking them. Let us use k to denote the number of consecutive masked tokens, and $m_{j:j+k}$ to denote the span of the masked aspect term. The word selection for k consecutive masked tokens can thus be computed as follows:

$$\begin{aligned} &p(w_{m_{j:j+k}}|\mathbf{x}^m) = \prod_{i=j}^{j+k-1} p(w_{m_i}|\mathbf{x}^m); \\ &o_{m_{j:j+k}} = \arg\max_{w_{m_{j:j+k}}} p(w_{m_{j:j+k}}|\mathbf{x}^m), \end{aligned} \tag{3}$$

where $w_{m_{j:j+k}} \in A_t^k$, and A_t^k refers to the sets of k-word aspect terms in A_t.

Target-Specific Opinion Constraint. For each masked opinion term, it is important to keep the sentiment consistency when predicting its corresponding target-specific opinion term.

To achieve this, we resort to the Double Propagation algorithm, which relies on the sentiment lexicon to assign sentiment (i.e., Positive, Negative, and Neutral) to each aspect term and opinion term in a bootstrapping manner. Based on the output, we obtain the sentiment of all the source-specific and target-specific opinion terms (i.e., O_s and O_t) extracted in Section 4.1.1.

Next, we look up the sentiment of the masked source-specific opinion term, and then utilize all the target-specific opinion terms with the same sentiment in O_t as vocabulary constraints in Eqn. (2) and Eqn. (3) to generate the target-specific opinion terms. For example, in Fig 2, since *dead* is a source-specific negative opinion term, we use all the single-word target-specific opinion terms with the negative sentiment as vocabulary constraints in Eqn. (2) to generate the opinion term *tasteless*.

Generated Target-Domain Reviews. Based on Eqn. (2) and Eqn. (3), we can infill the masked positions in each domain-independent review $\mathbf{x}^m$, and obtain the generated target-domain review, denoted by $\mathbf{x}^g$. It is worth noting that if a source-domain review $\mathbf{x}^s$ does not contain any source-specific attributes, its generated target-domain review $\mathbf{x}^g$ will be the same as $\mathbf{x}^s$.

With the domain-independent review $\mathbf{x}^m$, our two-step approach essentially achieves word-to-word alignments between $\mathbf{x}^s$ and $\mathbf{x}^g$. Therefore, we can directly employ the sequence label of $\mathbf{x}^s$ as the fine-grained annotation of $\mathbf{x}^g$. Fig. 2 shows a label transferring example for the E2E-ABSA task.

Formally, we use $D_G = \{(\mathbf{x}_i^g, \mathbf{y}_i^s)\}_{i=1}^{N^s}$ to denote the set of the generated target-domain reviews.

R	Restaurant	6035	3877	2158
D	Device	3836	2557	1279
S	Service	2239	1492	747

Table 1: Basic statistics of our datasets.

4.2 Post-Generation Training for Main Tasks

After obtaining the set of generated target-domain reviews D_G, we further propose two strategies to leverage them to train effective E2E-ABSA and AE models for the target domain as follows.

Independent Training. An intuitive strategy is to solely treat D_G as training instances, and directly train a sequence labeling model over them. Following Gong et al. (2020), we adopt the pre-trained BERT model as the text encoder, followed by fune-tuning it on D_G.

Merge Training. Since the qualities of the generated target-domain reviews rely on the target-domain MLM as well as the aspect and opinion terms extracted by Double Propagation, it is inevitable that D_G contains a number of aspect and opinion terms with incorrect annotations. Therefore, we propose to merge the labeled source reviews D_S with D_G as the training instances, which may alleviate the annotation noise in D_G. Similar to Independent Training, a BERT-based sequence labeling model is trained over the merged corpus $D_S \cup D_G$.

5 Experiment

5.1 Experiment Settings

Datasets. We use four benchmark datasets including Laptop (L), Restaurant (R), Device (D), and Service (S) for experiments. L is from SemEval-2014 ABSA challenge (Pontiki et al., 2014), containing user reviews from the laptop domain. R refers to a combination of the restaurant datasets from SemEval ABSA challenge 2014, 2015, and 2016 (Pontiki et al., 2014, 2015, 2016). D is the union set of all the digital device reviews collected by Toprak et al. (2010). S contains reviews from web services, which is introduced by Hu and Liu (2004). The basic statistics are shown in Table 1.

Settings. We carry out experiments on 10 transfer pairs with the four domains above. Following previous work (Li et al., 2019b; Gong et al., 2020), we remove D→L and L→D, as the two domains are very similar. For each transfer pair, the training data is a combination of the labeled training data in the source domain and the unlabeled training data in the target domain. We report the evaluation results on the test data from the target domain. For fair comparison with previous work, we use the Micro-F1 score with the exact match as the evaluation metric, which means that the predicted labels can be counted as correct only if they are exactly matched with the golden labels.

5.2 Compared Systems & Hyperparameters

To show the effectiveness of our Cross-Domain Review Generation (CDRG)-based methods, we consider the following compared systems:

- DP (Qiu et al., 2011): the unsupervised Double Propagation method detailed in Section 4.1.1.
- Hier-Joint (Ding et al., 2017): An LSTM-based domain adaptation method with syntactic rule-based auxiliary tasks for cross-domain AE.
- RNSCN (Wang and Pan, 2018): A recursive neural structural correspondence network based on syntactic structures and auto-encoders.
- AD-SAL (Li et al., 2019b): A Selective Adversarial Learning method to achieve local semantic alignments for fine-grained domain adaptation.
- BERT_B and BERT_E: directly fine-tuning two versions of pre-trained encoders on the labeled source domain. BERT_B is the uncased BERT_base model from Devlin et al. (2019), and BERT_E is another uncased BERT_base model from Xu et al. (2019), which is pre-trained on E-commerce reviews from the Amazon Electronics dataset (He and McAuley, 2016) and the Yelp Challenge.
- BERT_B-UDA and BERT_E-UDA (Gong et al., 2020): our recent unified feature and instance-based domain adaptation method based on BERT_B and BERT_E, respectively.

Besides, we consider the following variants of our CDRG-based domain adaptation methods:

- BERT_B-CDRG-X: re-training BERT_B with the MLM task to obtain the Target-Domain MLM in Section 4.1.2, and employing BERT_B as the base model for the two training strategies in Section 4.2. Here X can be independent training and merge training.
- BERT_E-CDRG-X: replacing the BERT_B model in BERT_B-CDRG-X with BERT_E.

Table 3: Comparison results of different methods for Cross-Domain Aspect Extraction based on Micro-F1.

For re-training the MLM task in our two-step approach for CDRG, we employ the Adam optimizer (Kingma and Ba, 2014) with a batch size of 32 and a learning rate of 3e-5. For the two training strategies in Section 4.2, we also adopt the Adam optimizer, in which the learning rate, the dropout rate and the batch size are set to 5e-5, 0.1, 32 after a grid search over the combinations of [2e-5, 8e-5], [0.1, 0.3] and {16, 32, 64}. These hyper-parameters are tuned on 10% randomly held-out training data from the source domain. All the experiments are run on a Nvidia GTX 1080 Ti GPU.

5.3 Main Results for Cross-Domain ABSA

We report the comparison results on the cross-domain E2E-ABSA task in Table 2, and make the following observations: (1) Comparing *Indep Training* with all the baseline methods, we can see that solely fine-tuning BERT$_E$ on our generated target-domain reviews can already outperform all the existing domain adaptation approaches on average, including our recent unified feature and instance-based adaptation (UDA) method. This demonstrates the usefulness of our CDRG-based approach. (2) By merging the generated target-domain reviews with the labeled source reviews, our *Merge Training* strategy further boosts the average performance of *Indep Training*, which outperforms the state-of-the-art *UDA* approach by an absolute improvement of 3.00% and 2.83% based on BERT$_B$ and BERT$_E$ respectively. All these observations verify the superiority of our CDRG-based approach over the previous feature and instance-based adaptation methods.

Similar to the results on cross-domain E2E-ABSA, Table 3 shows that our *Indep Training* strategy obtains indistinguishable performance compared with the state-of-the-art method UDA based on BERT$_B$, and achieves significantly better performance than UDA based on BERT$_E$. Moreover, our *Merge Training* strategy can consistently achieve the best average performance on the cross-domain AE task, which outperforms UDA by an absolute improvement of 2.63% and 4.47% based on BERT$_B$ and BERT$_E$ respectively. This demonstrates the general effectiveness of our CDRG-based domain adaptation methods.

5.4 Ablation Study of Our Two-Step Approach for CDRG

To investigate the effectiveness of our two-step approach for CDRG, we conduct the ablation study of our target-domain masked language model with constraints (TD-MLM-C) approach, and consider the following variants: (1) *BERT$_E$*: The pre-trained BERT$_E$ model without re-training MLM on the un-

Source Domain: Laptop→Target Domain: Restaurant		
Source Review	1. The [screen graphics]$_{P}$ and [clarity]$_{P}$, and [sharp ##ness]$_{P}$ are great.	2. The [battery life]$_{P}$ is great.

Table 6: Comparison results of using the labeled reviews generated from different methods as training instances for our Independent Training strategy.

labeled target data; (2) *TD-MLM*: re-training the BERT$_{E}$ model with MLM on the unlabeled target data; (3) *TD-MLM-C*: adding target-specific attribute constraints into TD-MLM, as introduced in Section 4.1.2.

First, we propose to verify the closeness between the generated target-domain review set and the real test set from the target domain. Specifically, we employ BERT$_{E}$ to obtain the sentence representation of each review in the two sets, and then compute the distance between the two sets with Maximum Mean Discrepancy (Gretton et al., 2012). Based on the results in Table 5, we can observe that all the three methods can consistently reduce the discrepancy between source and target domains. This shows our two-step approach is generally useful for domain adaptation. Moreover, it is clear that the distance between the review set from *TD-MLM-C* and the test set is the smallest, which implies the distribution of its generated reviews is closest to the distribution of the target domain.

Second, we further treat the generated reviews as training instances for our *Indep Training* strategy, and compare their results on the cross-domain E2E-ABSA and AE tasks. From the results in Table 6, we can see that using the reviews from *TD-MLM-C* consistently achieves the best results, and outperforms the other methods with a significant margin.

5.5 Manual Evaluation on Generated Target-Domain Reviews

Since there is no ground-truth target review for each source review, we randomly select 200 source reviews from L→R and R→L transfer pairs, and manually evaluate the generated reviews in terms of coherence, label correctness, and domain-specific criteria. Based on our manual evaluation, we observe that our *TD-MLM-C* approach generates better target reviews than its two ablation systems for 152 source reviews; for the remaining 48 source reviews, we cannot determine the winning method, as all the three methods generate meaningful or unmeaningful target-domain reviews.

Table 4 shows four representative examples. We can find that *BERT$_{E}$* is generally insensitive to the target domain, which may still generate source-specific terms (e.g., *touch screen* in S2 and *flavorful* in S3). *TD-MLM* can produce better reviews, as it tends to convert source-specific terms to the target domain. However, it still suffers from generating non-aspect or non-opinion terms (e.g., *the prices* in S1 and *It* in S4). In contrast, with the vocabulary constraints, *TD-MLM-C* can successfully convert all the source-specific attributes to target-specific attributes in the four cases.

All these observations verify the importance of TD-MLM and vocabulary constraints in our two-step approach for cross-domain review generation.

6 Conclusion

In this paper, we propose a new domain adaptation paradigm named Cross-Domain Review Generation (CDRG) with applications to the ABSA task. Specifically, we first propose a two-step approach to generate labeled target-domain reviews based on labeled source-domain reviews for CDRG, and then propose two training strategies to leverage the generated reviews for two cross-domain ABSA tasks. Experiments on four benchmark datasets demonstrate that our CDRG-based approaches significantly outperform existing methods for cross-domain E2E-ABSA and cross-domain AE tasks.

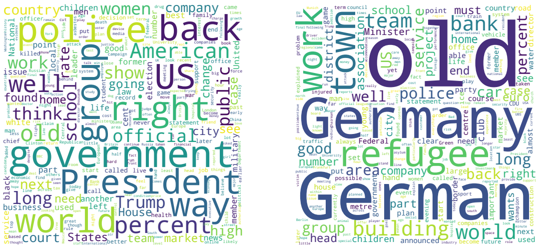
Abstract

Language coverage bias, which indicates the content-dependent differences between sentence pairs originating from the source and target languages, is important for neural machine translation (NMT) because the target-original training data is not well exploited in current practice. By carefully designing experiments, we provide comprehensive analyses of the language coverage bias in the training data, and find that using only the source-original data achieves comparable performance with using full training data. Based on these observations, we further propose two simple and effective approaches to alleviate the language coverage bias problem through explicitly distinguishing between the source- and target-original training data, which consistently improve the performance over strong baselines on six WMT20 translation tasks. Complementary to the translationese effect, language coverage bias provides another explanation for the performance drop caused by back-translation (Marie et al., 2020). We also apply our approach to both back- and forward-translation and find that mitigating the language coverage bias can improve the performance of both the two representative data augmentation methods and their tagged variants (Caswell et al., 2019).

1 Introduction

In recent years, there has been a growing interest in investigating the effect of original languages in parallel data on neural machine translation (Barrault et al., 2020; Edunov et al., 2020; Marie et al., 2020). Several studies have shown that target-original test examples[1] can lead to distortions in automatic and human evaluations, which should be omitted from machine translation test sets (Barrault et al., 2019; Zhang and Toral, 2019; Graham et al., 2020). Another branch of studies report that target-original test data leads to discrepant conclusions: back-translation only benefits the translation of target-original test data while harms that of source-original test data (Edunov et al., 2020; Marie et al., 2020). They attribute these phenomena to the reason that human-translated texts (i.e., *translationese*) exhibit formal and stylistic differences that set them apart from the texts originally written in that language (Baker et al., 1993; Volansky et al., 2015; Zhang and Toral, 2019).



(a) English-Original (b) German-Original

Figure 1: Example of language coverage bias illustrated by word clouds that are plotted at the English side of sentence pairs in the En-De test sets from WMT10 to WMT18. The test sets consist of English-original and German-original sentence pairs.

Complementary to the translationese bias, which is *content-independent* (Volansky et al., 2015), we identify another important problem, namely *language coverage bias*, which refers to the *content-dependent* differences in data originating from different languages. These differences stem from the diversity of regions and cultures. While the degree of the translationese bias varies across different translators (Toral, 2019), language coverage bias is an intrinsic bias between the source- and target-original data, which is hardly affected by the ability of the translator. Figure 1 shows an example, where the contents in English- and German-original texts differ significantly due to language coverage bias.

---

[1] Target-original test examples are sentence pairs that are translated from the target language into the source language.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4778–4790
August 1–6, 2021.

To investigate the effect of language coverage bias in the training data on NMT models, we propose an automatic method to identify the original language of each training example, which is generally unknown in practical corpora. Experimental results on three large-scale translation corpora show that there exists a significant performance gap between NMT models trained on the source- and target-original data, which have different vocabulary distributions, especially for content words. Since the target-original training data performs poorly in translating content words, using only the source-original data achieves comparable performance with using full training data. These findings motivate us to explore other data utilization methods rather than indiscriminately mixing the source- and target-original training data.

We propose to alleviate the language coverage bias problem by explicitly distinguishing between the source- and target-original training data. Specifically, two simple and effective methods are employed: *bias-tagging* and *fine-tuning*. Experimental results show that both approaches consistently improve the performance on six WMT20 translation tasks. Language coverage bias also provides another explanation for the failure of back-translation on the source-original test data, complementary to the translationese effect (Marie et al., 2020). We further validate our approach in the monolingual data augmentation scenario, where the language coverage bias problem would be more severe due to the newly introduced monolingual data.

Contributions The main contributions of our work are listed as follows:

- We demonstrate the necessity of studying the language coverage bias for NMT, and identify that using the target-original data can cause poor translation adequacy on content words.
- We address the language coverage bias induced by the target-original data by explicitly distinguishing the original languages, which can significantly improve the translation performance on six WMT20 translation tasks.
- We show that alleviating the language coverage bias also benefits monolingual data augmentation, which can improve both back- and forward-translation and their tagged variants (Caswell et al., 2019).

2 Experimental Setup

Data We conducted experiments on six WMT20 benchmarks (Barrault et al., 2020), including English⇔German (En⇔De), English⇔Chinese (En⇔Zh), and English⇔Japanese (En⇔Ja) news translation tasks. The preprocessed training corpora contain 41.0M, 21.8M, and 13.0M sentence pairs for En⇔De, En⇔Zh, and En⇔Ja, respectively. We used the monolingual data that is publicly available in WMT20 to train the proposed original language detection model (Section 3.1) and data augmentation (Section 4.2). The Appendix lists details about the data preprocessing.

For En⇔De and En⇔Zh, we used newstest2019 as the validation sets. For En⇔Ja, we split the official validation set released by WMT20 into two parts by the original language and only used the corresponding part for each direction. We used newstest2020 as the test sets for all the six tasks. We reported the Sacre BLEU (Post, 2018), as recommended by WMT20.

Model We used the Transformer-Big (Vaswani et al., 2017) model, which consists of a 6-layer encoder and a 6-layer decoder, and the hidden size is 1024. Recent studies showed that training on large batches can further boost model performance (Ott et al., 2018; Wu et al., 2018). Accordingly, we followed their settings to train models with batches of approximately 460k tokens. Please refer to the Appendix for more details about model training. We followed Ng et al. (2019) to use the Transformer-Big decoder as our language models, which are used to detect the original language and measure translation fluency. Language models are also trained with large batches (Ott et al., 2018).

3 Observing Language Coverage Bias

In this study, we first establish the existence of language coverage bias (Section 3.2), and show how the bias affects NMT performance (Section 3.3). To this end, we propose an automatic method to detect the original language of each training example (Section 3.1), which is often not available in large-scale parallel corpora (Riley et al., 2020).

3.1 Detecting Original Languages

Detection Method Intuitively, we use a large-scale monolingual dataset to estimate the distribution of the contents covered by each language. For each training example, we compare its similarities

Method	En-Zh	En-Ja	En-De
FT	83.6	83.7	86.6
Ours	**84.4**	**91.5**	**88.7**

Table 1: F1 scores of detecting original languages in the test sets. "FT" denotes the forward translation classifier proposed by Riley et al. (2020).

to the distributions of source and target languages, based on which we determine its original language.

Formally, let $\mathcal{D}_s$ and $\mathcal{D}_t$ denote the source-side and target-side distributions of the covered contents. Given a training example $\langle \mathbf{x}, \mathbf{y} \rangle$, the probability that it is covered by one language (represented as $\mathcal{D}_s$ and $\mathcal{D}_t$) can be expressed as

$$P(\mathcal{D}_s|\langle \mathbf{x}, \mathbf{y} \rangle) = \frac{P(\mathcal{D}_s)P(\langle \mathbf{x}, \mathbf{y} \rangle|\mathcal{D}_s)}{P(\langle \mathbf{x}, \mathbf{y} \rangle)},$$
$$P(\mathcal{D}_t|\langle \mathbf{x}, \mathbf{y} \rangle) = \frac{P(\mathcal{D}_t)P(\langle \mathbf{x}, \mathbf{y} \rangle|\mathcal{D}_t)}{P(\langle \mathbf{x}, \mathbf{y} \rangle)}.$$

We use a score function to denote the difference between the two probabilities:

$$\begin{aligned} score &= \log P(\mathcal{D}_s|\langle \mathbf{x}, \mathbf{y} \rangle) - \log P(\mathcal{D}_t|\langle \mathbf{x}, \mathbf{y} \rangle), \\ &= \log P(\langle \mathbf{x}, \mathbf{y} \rangle|\mathcal{D}_s) - \log P(\langle \mathbf{x}, \mathbf{y} \rangle|\mathcal{D}_t) + c, \end{aligned}$$

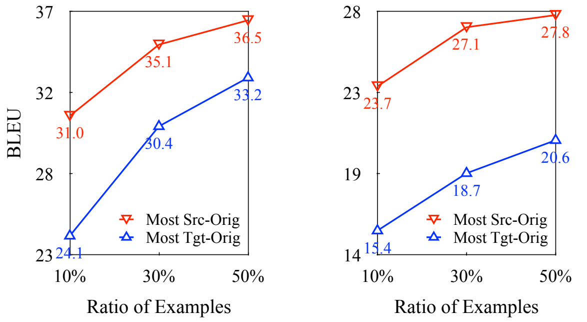
where $c = \log P(\mathcal{D}_s) - \log P(\mathcal{D}_t)$, which has a constant value when the source and target monolingual datasets are given. Intuitively, examples with higher score values are more likely to be source-original while those with lower score values are more likely to be target-original data. We train language models $\boldsymbol{\theta}_s^{lm}$ and $\boldsymbol{\theta}_t^{lm}$ on the source- and target-language monolingual data to estimate the conditional probabilities:

$$P(\langle \mathbf{x}, \mathbf{y} \rangle|\mathcal{D}_s) = P(\mathbf{x}|\boldsymbol{\theta}_s^{lm}),$$
$$P(\langle \mathbf{x}, \mathbf{y} \rangle|\mathcal{D}_t) = P(\mathbf{y}|\boldsymbol{\theta}_t^{lm}).$$

Accordingly, the score can be rewritten as

$$score = \log P(\mathbf{x}|\boldsymbol{\theta}_s^{lm}) - \log P(\mathbf{y}|\boldsymbol{\theta}_t^{lm}) + c. \quad (1)$$

We label examples as source-original if their score values are positive, and the other examples as target-original. To find a specific constant for each language pair, we tune the value of c to obtain the best classification performance on the validation sets, where the original languages are known.



(a) En⇒Zh (b) Zh⇒En

Figure 2: Translation performance on the validation sets of the En⇔Zh translation task for different ratios of most source- and target-original training examples.

Detection Accuracy We evaluated the detection method on the mixture of the test sets of bidirectional translation tasks in WMT20 for each language pair. For comparison, we re-implemented the CNN-based forward-translation (FT) classifier proposed by Riley et al. (2020). The FT classifier and the language models used in our method were trained on the same monolingual data sets. Table 1 shows that our method outperforms the FT classifier in all language pairs. In addition, our model also outperforms the FT approach on detecting noisy training data, which leads to an improvement in translation performance (please refer to Table 11 in the Appendix for more results).

3.2 Existence of Language Coverage Bias

In this section, we validate the existence of language coverage bias by (1) comparing the performance of NMT models trained on data with different original languages, and (2) directly calculating the divergence between the vocabulary distributions of the source- and target-original data.

Translation Performance Once all the training examples are assigned a score by the detection method (Eq. (1)), we regard $R\%$ of examples with the highest scores as the most source-original examples, and $R\%$ of examples with the least scores as the most target-original examples. We investigate the effect of $R\%$ on translation performance, as shown in Figure 2. Clearly, using the most source-original examples significantly outperforms using its target-original counterparts, demonstrating that the source- and target-original data indeed differ greatly from each other. To rule out the effect of data scale, we treat 50% of data with the highest scores as source-original data, and the same amount

Data	JS ($\times 10^{-5}$)		
	All	*Content*	*Function*
Random	4	10	0
S vs T	745	1503	261

Table 2: JS divergence of the vocabulary distributions between the source- and target-original data ("S vs T") on the training set of WMT20 En⇔Zh. "*All*", "*Content*", and "*Function*" denote all words, content words, and function words respectively. For reference, we also report the JS divergence between randomly selected 50% examples and the others ("Random").

Origin	*noun*	*verb*	*adj*	*noun*	*verb*	*adj*
Target	67.6	52.0	64.3	53.8	38.0	57.0
Source	69.7	54.0	**66.2**	**61.8**	**44.1**	**63.9**
Both	**69.9**	**54.1**	65.9	61.2	43.8	63.4

Table 4: Translation adequacy of different types of content words measured by F-measure (Neubig et al., 2019). The results are reported on the validation sets.

of data with the least scores as target-original data in the following experiments by default.

Since some recent works find that BLEU might be affected by the translationese problem (Edunov et al., 2020; Freitag et al., 2020), we have also conducted a side-by-side human-evaluation on the Zh⇒En development set, where 500 randomly sampled examples were evaluated by six persons (agreement (Fleiss, 1971): Fleiss' Kappa=0.46). 37.0% of outputs using the source-original data are better than using target-original data, and 21.0% are worse. By manually checking the outputs, we find using only the target-original data tends to omit important source contents (e.g., named entities) either by totally ignoring some contents or by using pronouns instead. The human-evaluation shows the same trend with the BLEU score presented in Figure 2. Given that conducting human-evaluation on all the six translation tasks is time-consuming and labor-intensive, we use automatic measures to further investigate this problem in Section 3.3.

Vocabulary Distributions Complementary to previous studies that focus on the *content-independent* stylistic difference (Volansky et al., 2015) between translationese and original texts (Riley et al., 2020; Edunov et al., 2020; Marie et al., 2020), we investigate the *content-dependent* language coverage bias between the source- and target-original data in this experiment. Intuitively, if the language coverage bias exists, the vocabulary distributions of the source- and target-original data should differ greatly from each other, since the covered issues tend to have different frequencies between them (D'Alessio and Allen, 2000). We use the Jensen-Shannon (JS) divergence (Lin, 1991) to measure the difference between two vocabulary distributions p and q:

$$\mathrm{JS}\,(p||q) = \frac{1}{2}\left(\mathrm{KL}(p||\frac{p+q}{2}) + \mathrm{KL}(q||\frac{p+q}{2})\right),$$

where $\mathrm{KL}(\cdot||\cdot)$ is the KL divergence (Kullback and Leibler, 1951) of two distributions.

Table 2 shows the JS divergence of the vocabulary distributions between the source- and target-original data. We also divide the words into content words and functions words based on their POS tags, since content words are more related to the language coverage bias, while the function words are more related to the stylistic and structural differences between the translationese and original texts (Lembersky et al., 2011; Volansky et al., 2015). The JS divergence between the source- and target-original data are 186× larger than that between randomly split data, which is mainly due to the difference between content words. Results for different ratios $R\%$ and other language pairs can be found in Appendix (Tables 12 and 13), where the trend holds in all cases, supporting our claim of the existence of language coverage bias.

3.3 Effect of Language Coverage Bias

In this section, we investigate the effect of language coverage bias on NMT models.

Using only the source-original data achieves comparable performance with using full data. Table 3 lists the translation performances of NMT models trained on only the source- or target-original data and on both of them. The results show that using only the source-original data significantly outperforms using the target-original data in all language pairs, which reconfirm the necessity of studying the language coverage bias for NMT. It should be emphasized that using only the source-original data (i.e. 50% of the whole training set) achieves translation performances on par with using full training data. In the following experiments, we investigate why using target-original data together cannot further improve the performance.

Using additional target-original data does not consistently improve translation adequacy. To rule out the effect of translationese and focus on the content-dependent difference caused by the language coverage bias, we examine the translation adequacy of content words in Table 4 [2]. We follow Raunak et al. (2020) to use F-measure (Neubig et al., 2019) to quantify the translation accuracy of specific types of words.

Compared with the source-original data, using only the target-original data greatly reduces the translation accuracy of content words, which we attribute to the divergence of the content word distributions between the source- and target-original data. The results also indicate that indiscriminately using all the training data can not consistently improve the translation adequacy of content words over using only source-original data, and in some cases using all the data is even harmful to the adequacy on content words. Table 5 shows an example, which suggests that using only the target-original data tends to omit content words. This problem is potentially caused by that some content words at the source-side are less or even not visible in the target-original data, and indiscriminately adding target-original data induces a distribution shift on the content word distribution.

Using additional target-original data only slightly improves the structural fluency. Recently, Edunov et al. (2020) claim that using additional back-translated data can improve translation fluency. Target-original bilingual data is similar to back-translated data since both of them are constructed by translating sentences from the target language into the source language. One question naturally arises: *can target-original bilingual data improve the fluency of NMT models?*

Input	大闸蟹是巴城最为知名的形象代言人。
Refer.	The hairy crab is the most famous image spokesperson in Bacheng.
Target Orig.	It is one of the city's most well-known image spokesmen.
Source Orig.	Hairy crabs are the most well-known image spokesmen of Bacheng.
Both	It is the best-known icon of Bacheng.

Table 5: An example of the outputs of NMT models trained on different sets of data. Using the target-original data tends to omit content words.

To answer the above question, we measure the fluency of outputs with language models trained on the monolingual data as described in Section 2. Previous study finds that different perplexities could be caused by specific contents rather than structural differences (Lembersky et al., 2011). Specifically, some source-original contents are of low frequency in the target-language monolingual data (e.g., "Bacheng" in Table 5), thus the language model trained on the target-language monolingual data tends to assign higher perplexities to outputs containing more source-original content words. To rule out this possibility and check whether the outputs are structurally different, we follow Lembersky et al. (2011) to abstract away from the content-specific features of the outputs to measure their fluency at the syntactic level. Table 6 shows the results. Although using only the source-original data results in high perplexities measured by vanilla language models, the perplexities of NMT models trained on different data are close to each other at the syntactic level. Using additional target-original data only slightly reduces the perplexity at the syntactic level over using only the source-original data.

4 Addressing Language Coverage Bias

In Section 3 we show that the target-original data performs poorly in translating content words due to the language coverage bias. Accordingly, simply using the full training data without distinguishing the original languages is sub-optimal for model training. Based on these findings, we propose to address the language coverage bias by explicitly distinguishing between the source- and the target-original data (Section 4.1). We then investigate whether the performance improvement still holds in

---

[2] We only list the results on En⇔Zh due to space limit. Please refer to Table 14 in the Appendix for the translation quality on other language pairs.

Data Origin	No Abs. PPL	No Abs. Diff.	Cont. Abs. PPL	Cont. Abs. Diff.

Table 6: Translation fluency measured by the perplexities (i.e., PPL) of language models with different levels of lexical abstraction, "Diff." means the relative change with respect to "Both". "No Abs." denotes no abstraction (i.e., vanilla LM), "Cont. Abs." denotes abstracting all content words with their corresponding POS tags. The results are reported on the validation sets.

the monolingual data augmentation scenario (Section 4.2), where the language coverage bias problem is more severe due to the newly introduced dataset in source or target language.

4.1 Bilingual Data Utilization

In this section, we aim to improve bilingual data utilization through explicitly distinguishing between the source- and target-original training data.

Methodology We distinguish original languages with two simple and effective methods:

- *Bias-Tagging*: Tagging is a commonly-used approach to distinguishing between different types of examples, such as different languages (Aharoni et al., 2019; Riley et al., 2020) and synthetic vs authentic examples (Caswell et al., 2019). In this work, we attach a special tag to the source side of each target-original example, which enables NMT models to distinguish it from the source-original ones in training.

- *Fine-Tuning*: Fine-tuning (Luong and Manning, 2015) is a useful method to help knowledge transmit among data from different distributions. We pre-train NMT models on the full training data that consists of both the source- and target-original data, and then fine-tune them on only the source-original data. For fair comparison, the total training steps of the pre-training and fine-tuning stages are the same as the baseline.

Translation Performance Table 7 depicts the results on the benchmarking datasets. For comparison, we also list the results of several baselines using the vanilla Transformer architecture trained on the constrained bilingual data in the WMT20 competition (Barrault et al., 2020). Clearly, both the bias tagging and fine-tuning approaches consistently improve translation performance on all benchmarks, which confirms our claim of the necessity of explicitly distinguishing target-original examples in model training.

Analysis Recent studies have shown that generating human-translation like texts as opposed to original texts can improve the BLEU score (Riley et al., 2020). To validate that the improvement is partially from alleviating the content-dependent language coverage bias, we examine the translation adequacy of content words on the test sets, as listed in Table 8. The results indicate that explicitly distinguishing between the source- and target-original data improves the translation of content words (e.g., nouns), which is closely related to the language coverage bias problem. Table 9 lists the translation fluency at the syntactic level, where the proposed approaches maintain the syntactic fluency.

4.2 Monolingual Data Augmentation

In this section, we aim to provide some insights where monolingual data augmentation improves translation performance, and investigate whether our approach can further improve model performance in this scenario that potentially suffers more from the language coverage bias problem.

For fair comparison across language pairs, we augment NMT models with the same English monolingual corpus as described in Section 2. We down-sample the large-scale monolingual corpus to the same amount as that of the bilingual corpus in each language pair, in order to rule out the effect of the scale of synthetic data (Edunov et al., 2018; Fadaee and Monz, 2018). We use back-translation (Sennrich et al., 2016a) to augment the English monolingual data for the task of translating from another language to English ("X⇒En"), and use forward-translation for the task in the opposite translation direction ("En⇒X"). Table 10 lists the results, where several observations can be made.

Explaining Data Augmentation with Language Coverage Bias Concerning the monolingual data augmentation methods (Rows 3-4), the vanilla

back-translation (Row 3) harms the translation performance on average, while the vanilla forward-translation improves the performance, which is consistent with the findings in previous studies (Edunov et al., 2020; Marie et al., 2020). Caswell et al. (2019) have shown that the tagging strategy works for back-translation while fails for forward-translation, and our results confirm these findings. Both phenomena can be attributed in part to the language coverage bias problem. Back-translated data originates from the target language, and thus suffers more from the language coverage bias problem. Accordingly, directly using the back-translated data is sub-optimal, while tagged back-translation recovers translation performance by distinguishing training examples with different origins, which is consistent with our results in Table 7. In contrast, the language coverage bias problem does not exist for source-side monolingual data (i.e. the same original language). Therefore, the vanilla forward-translation can improve translation performance, while tagged forward-translation performs worse.

Improving Data Augmentation Our approach (Row 2) achieves comparable improvements of translation performance with the monolingual data augmentation approaches (e.g. averaged BLEU: 31.2 vs. 30.7, and 37.6 vs. 37.9), while we do not use additional monolingual data to train the models.[3] Combining them can further improve performance (Rows 5-6), indicating that the two types of approaches are complementary to each other. This is straightforward, since our approach better exploits the bilingual data, while data augmentation introduces new knowledge from additional monolingual data. In addition, our approach consistently improves performance over both vanilla and tagged augmentation approaches, making it more robust in practical application across datasets.

5 Related Work

Our work is inspired by three lines of research in the NMT community.

"Fine-Tune" denotes fine-tuning the pre-trained NMT models on the source-original bilingual data, as described in Section 4.1.

5.1 Translationese

Recently, the effect of translationese in NMT evaluation has attracted increasing attention (Zhang and Toral, 2019; Bogoychev and Sennrich, 2019; Edunov et al., 2020; Graham et al., 2020). Graham et al. (2020) show that the source-side translationese texts can potentially lead to distortions in automatic and human evaluations. Accordingly, the WMT competition starts to use only source-original test sets for most translation directions since 2019. Our study reconfirms the necessity of distinguishing the source- and target-original examples and takes one step further to distinguish examples in training data. Complementary to previous works, we investigate the effect of language coverage bias on machine translation, which is related to the content bias rather than the language style difference. Shen et al. (2021) also reveal the context mismatch between texts from different original languages. To alleviate this problem, they proposed to combine back- and forward-translation by introducing additional monolingual data, while we focus on better exploiting bilingual data by distinguishing the original languages, which is also helpful for back- and forward-translation.

Lembersky et al. (2011, 2012) propose to adapt machine translation systems to generate texts that are more similar to human-translations, while Riley et al. (2020) propose to model human-translated texts and original texts as separate languages in a multilingual model and perform zero-shot translation between original texts. Riley et al. (2020) and our work both aim to better utilize the bilingual training data. They aim to guide NMT models to produce original text, while we focus on improving translation adequacy by alleviating the language coverage bias problem.

5.2 Data Augmentation

Concerning model training, recent works find that back-translation can harm the translation of source-original test set, and attribute the quality drop to the stylistic and content-independent differences between translationese and original texts (Edunov et al., 2020; Marie et al., 2020). In this work, we empirically show that language coverage bias is another reason for the performance drop of back-translation, as well as the different performances between tagged forward-translation and tagged back-translation (Caswell et al., 2019). In addition, we show that our approach is also beneficial for data augmentation approaches, which can further improve the translation performance over both back-translation and forward-translation.

5.3 Domain Adaptation

Since high-quality and domain-specific parallel data is usually scarce or even unavailable, domain adaptation approaches are generally employed for translation in low-resource domains by leveraging out-of-domain data (Chu and Wang, 2018). Languages can be also regarded as different domains, since articles in different languages cover different topics (Bogoychev and Sennrich, 2019). Starting from this intuition, we distinguish examples with different original languages with tagging (Aharoni et al., 2019) and fine-tuning (Luong and Manning, 2015), which are commonly-used in domain adaptation and multi-lingual translation tasks.

Our work also benefits domain adaptation: distinguishing original languages in general domain data consistently improves translation performance of NMT models in several specific domains (Table 16 in Appendix), making these models better start points for further domain adaptation.

6 Conclusion and Future Work

In this work, we first systematically examine why the language coverage bias problem is important for NMT models. We conducted extensive experiments on six WMT20 translation benchmarks. Empirically, we find that source-original data and target-original data differ significantly at the text content, and using target-original data together without discrimination is sub-optimal. Based on these observations, we propose two simple and effective approaches to distinguish the source- and target-original training data, which obtain consistent improvements in all benchmarks.

Furthermore, we link language coverage bias to two well-known problems in monolingual data augmentation, namely the performance drop of back-translation, and the different behaviors between tagged back-translation and tagged forward-translation. We show that language coverage bias can be considered as another reason for these problems, and fine-tuning on the source-original bilingual training data can further improve performance over both back- and forward-translation.

Future directions include exploring advanced methods to better alleviate the language coverage bias problem, as well as validating on other language pairs. It is also interesting to investigate the language coverage bias problem in multilingual translation, where we can better understand this problem by considering language family.

A Appendices

A.1 Data Preprocessing

We used all the parallel corpora provided by WMT20 and filtered sentences that are longer than 250 words. We tokenized English and German sentences with Moses (Koehn et al., 2007), and segmented Chinese and Japanese sentences with Jieba[4] and Mecab[5] respectively. We employed Byte pair encoding (BPE) (Sennrich et al., 2016b) with 32K merge operations for all language pairs. Specifically, we jointly trained the BPE code on both sides in En⇔De and independently learned the BPE code on each side in En⇔Zh and En⇔Ja.

As for the monolingual data, we combined the newscrawl data from 2017 to 2019 for English and German. Since the newscrawl corpora for Chinese and Japanese are significantly smaller, we augmented these two languages with the commoncrawl corpus. We preprocessed the monolingual data with the same rules as parallel data. Finally, we randomly selected 41.0M sentences for each language (i.e., En, De, Zh, Ja), which were used to train the language detection models. For data augmentation, to rule out the effect of the ratio between synthetic and authentic data, we downsampled the monolingual data to the same amount as the bilingual data for each language pair.

We used spaCy[6] to perform the Part-Of-Speech (POS) tagging for each language. Nouns, verbs, and adjectives belong to content words and the others belong to function words.

A.2 More Details of Model Training

In this work, we generally followed the default hyper-parameters used in Vaswani et al. (2017) except the batch size. Recent studies showed that training on large batches can further boost model performance (Ott et al., 2018; Wu et al., 2018). Accordingly, we followed them to train models with batches of approximately 460k tokens, using Adam (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 10^{-8}$. We used the same cosine learning rate schedule as Wu et al. (2018), where the learning rate was warmed up linearly in the first 10K steps, and then decayed following a cosine rate within a single cycle. By default, NMT models and language models were both trained for 30k steps with the aforementioned batch size. Each model was trained using 8 NVIDIA V100 GPUs for about 20 hours.

A.3 Effect of Detection Methods on Translation Performance

To further compare our proposed original language detection method and the FT classifier (Riley et al., 2020), we fine-tune the NMT model pre-trained on the whole training set using the source-original data detected by the two methods. Note that the two detection methods are developed using the same monolingual data sets. For fair comparison, the fine-tuning sets are of the same amount (50% of the whole training set) between the two methods in this experiment. Table 11 lists the results, indicating that our method performs better in detecting original languages in large-scale parallel data.

Fine-Tune Data	BLEU
×	27.5
FT	27.8
Ours	**28.4**

Table 11: Effect of original language detection methods. The results are reported on the validation set of the Zh⇒En translation task.

A.4 Divergence of Vocabulary Distributions

In this section, we report the JS divergence of the vocabulary distributions in more cases. Table 12 lists the results for different ratios $R\%$ on En⇔Zh, and Table 13 shows the results on all language pairs. The results show that the divergence of vocabulary distributions between the source- and target-original data is substantially larger than that between randomly split data, which reconfirms the existence of language coverage bias.

A.5 Effect of Language Coverage Bias for Other Language Pairs

Table 14 lists the translation adequacy of NMT models trained on only the source- or target-original data and on both of them. The results are reported on En⇔De and En⇔Ja, which exhibit the same trend as that on En⇔Zh (Table 4 in the main paper), indicating that the target-original data performs poorly in translating content words.

We split the whole validation set into several parts by the domain tag. “Ours” denotes the “Bias-Tagging” approach as described in Section 4.1. The results indicate that distinguishing data with different original languages in the general domain training data can improve the performance of NMT models in many specific domains, making the models better start points for further domain adaptation.

A.6 Translation Adequacy on Test Sets for Other Language Pairs

We report the translation adequacy on test sets for En⇔De and En⇔Ja in Table 15, corresponding to Table 8 in the main paper. The results show that explicitly distinguishing the source- and target-original training data can consistently improve the translation adequacy for content words on all the six translation tasks.

A.7 Translation Performance in Specific Domains

We evaluate NMT models trained with and without explicit distinguishing between the source- and target-original data in several specific domains. The results are shown in Table 16, suggesting that our method can improve the translation performance of NMT models in several specific domains, which can be combined with further domain adaptation approaches.

Named Entity Recognition via Noise Aware Training Mechanism with Data Filter

Abstract

Named entity recognition (NER) is a fundamental task in natural language processing, these is a long held belief that datasets benefit the model. However, not all the data help with generalization, and some samples may contain ambiguous entities or noisy labels. The existing methods can not distinguish hard samples from noisy samples well, and becomes particularly challenging in the case of overfitting. This paper proposes a new method called Noise-Aware-with-Filter (NAF) to solve the issues from two sides. From the perspective of the data, we design a Logit-Maximum-Difference (LMD) mechanism, which maximizes the diversity between different samples to help the model identify noisy samples. From the perspective of the model, we design an Incomplete-Trust (In-trust) loss function, which boosts L_{CRF} with a robust Distrust-Cross-Entropy(DCE) term. Our proposed In-trust can effectively alleviate the overfitting caused by previous loss function. Experiments on six real-world Chinese and English NER datasets show that NAF outperforms the previous methods, and which obtained the state-of-the-art(SOTA) results on the CoNLL2003 and CoNLL++ datasets.

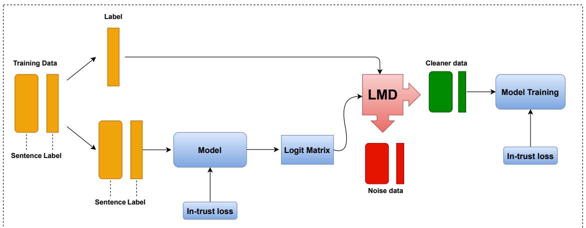

Figure 1: An overview of Noise-Aware-with-Filter(NAF). In-trust loss prevents model from overfitting and helps model generates logit matrices, which enters LMD mechanism with labels to filter noise data and get a cleaner data for model training.

1 Introduction

Named entity recognition (NER) is a primary task and which identifies both types and spans in sentences. NER models are becoming more and more accurate in prediction tasks, the potential improvement of existing architectures in real-world applications is often inherently limited by data quality (Pleiss et al., 2020). However, not all samples are completely correct in the NER datasets (Nooralahzadeh et al., 2019; Lange et al., 2019). Many real-world datasets generally contain samples which are "weakly-labeled" (Derczynski et al., 2017; Peng and Dredze, 2015). Specifically, some datasets which are annotated based on distant supervision (Yang et al., 2018; Liang et al., 2020) contain more noise labels, and manual annotators, especially on crowdsourcing platform, are prone to making labeling mistakes. Meanwhile labeling a huge datasets is an expensive and fallible process.

As the increase of training iteration epochs, the model will overfit noisy samples and hinder the generalization of the model (Pleiss et al., 2020). In NER task, it is impractical to get an absolutely clean dataset, and the existing datasets generally exist mislabeled samples (Flor et al., 2019) and ambiguous entity (Nadeau et al., 2006), even if some classical datasets (e.g., CoNLL2003 (Tjong Kim Sang and De Meulder, 2003)) still contain noisy samples (Wang et al., 2019b). It makes sense to obtain a cleaner dataset, but it would be very difficult to correct these real-world datasets manually, and the existing methods can't solve the issues automatically , especially in the case of existing ambiguous entities in sentences (Wang et al., 2019b).

From the CoNLL2003 NER dataset, we divide the samples into **Easy samples** which are correctly labeled and do not contain ambiguous entities, **Hard samples** are correctly labeled but contain ambiguous entities, and **Noisy samples** are misla-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4791–4803
August 1–6, 2021.

beled (Wang et al., 2019b). Such as:

- **Easy samples:{** third and final test between [England]{LOC} and [Pakistan]{LOC} at [the]{LOC}[Oval]{LOC} on **}**. The sample is labeled correctly and there is no ambiguous entity.
- **Hard samples:{** [Chicago]{ORG} won Game 1 with Derrick Rose scoring 25 points **}**. [Chicago] is a basketball team in NBA which is correctly marked as [Chicago]{ORG} here. Meanwhile [Chicago] is also a city in the United States, it is easy to mark that as [Chicago]{LOC} due to ambiguity.
- **Noisy samples:{** Soccer - [Japan]]{LOC} get lucky win, [China]{PER} in surprise defeat **}**. The [China]{PER} is mislabeled.

We can easily obtain the boundary between easy samples and noisy samples with utilizing loss values (Lin et al., 2017), but distinguishing hard samples from noisy samples still is a challenge (Wang et al., 2019b; Pleiss et al., 2020), and becomes particularly challenging in the case of overfitting (Wang et al., 2019b; Liu et al., 2020).

We propose a new method called Noise-Aware-with-Filter (NAF) to solve the issues from two sides. From the perspective of data, we design a Logit-Maximum-Difference (LMD) mechanism, which maximizes the diversity between different samples to help the model identify noisy samples. The difference between easy samples and noisy samples is very obvious in LMD score, meanwhile hard samples and noisy samples also can be well distinguished. From the perspective of model, we propose a noise tolerant term named Distrust-Cross-Entropy(DCE), which combines with L_{CRF} form the basis of the approach Incomplete-Trust (In-trust) loss function. In-trust not only improves the robustness of the model, but also helps LMD improve the accuracy of identifying noisy samples. Experiments on six real-world Chinese and English datasets show that NAF is more accurate than other methods in identifying noisy samples, meanwhile the datasets after filtering are cleaner.

In summary, our major contributions are the following:

- We propose a new method called Noise-Aware-with-Filter (NAF) to distinguish hard samples from noisy samples especially in the case of overfitting.
- To distinguish hard samples from noisy samples, we design a Logit-Maximum-Difference (LMD) mechanism. Meanwhile to alleviate the negative impact of overfitting, we propose Incomplete-Trust (In-trust) loss function, which utilizes both the incomplete correctness of labels and the relative correctness of the model output.
- We conduct extensive experiments on six real-world Chinese and English NER datasets show that NAF outperforms the previous methods, and which obtains the state-of-the-art(SOTA) results on the CoNLL2003 and CoNLL++ datasets. We release the source code publicly for further research [1].

2 Related Work

There are various approaches have been proposed to obtain a robust model. We summarize them into three categories: 1) Robust loss methods, 2) Training architectures methods, 3) Label correction methods.

Robust loss methods specifically design robust loss functions. They include Mean Absolute Error (MAE) (Ghosh et al., 2017), Improved MAE (Wang et al., 2019a) which is a reweighted MAE. Symmetric cross entropy (Wang et al., 2019b), by adding a symmetric reverse cross entropy after the cross entropy, makes the model have a certain noise tolerance, and Generalized cross entropy (Zhang and Sabuncu, 2018) is actually a new evolutionary form of MAE. Regularization (LSR) (Szegedy et al., 2016) is a technique using soft labels in place of one-hot labels to alleviate overfitting to noisy labels. ELR (Liu et al., 2020) is a kind of method that makes full use of early learning phenomenon to keep a large learning gradient for clean samples. But these methods can not effectively distinguish hard samples from noisy samples, and which are easy to confuse them.

Training architectures methods identify noisy samples from the perspective of model framework. Co-Tearching (Han et al., 2018; Yu et al., 2019) utilizes "early learning" phenomenon to maintain two networks in the process of training. All samples are sorted based on the loss values, and the noisy

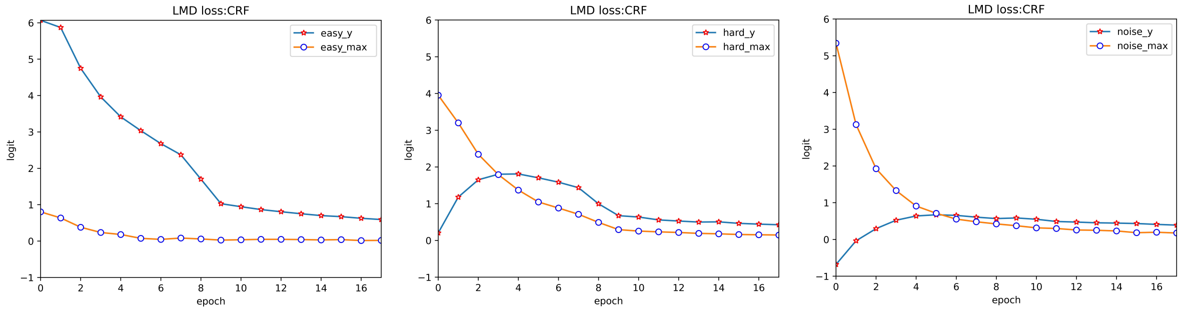

Figure 2: The graphs display logit value trajectories for easy sample (left), hard sample (middle) and noisy sample(right). The blue line: the logit value $Z_y^{(t)}$ corresponding to the label in logit matrix; the orange line: the maximal logit value $Z_{max}^{(t)}$ in logit matrix except $Z_y^{(t)}$. The x-axis refers to the number of training epochs, and the y-axis refers to the logit value. (Dataset: WUT-17)

samples are deleted according to the forgetting ratio (Jiang et al., 2018; Malach and Shalev-Shwartz, 2017). AUM (Pleiss et al., 2020) based on the output of the model to distinguish hard samples from noisy samples. CrossWeigh (Wang et al., 2019b) cover the label of a certain category in the datasets, and observes the model whether will predict the sample into another category. However, these methods always make the model to learn the easy samples and not consider the problem of overfitting (Chang et al., 2017).

Label correction methods are to improve the quality of raw labels. New labels equal to the probabilities estimated by the model (known as soft labels) or to one-hot vectors representing the model predictions (hard labels) (Tanaka et al., 2018; Yi and Wu, 2019). Another option is to set the new labels to equal a convex combination of the noisy labels and the soft or hard labels (Reed et al., 2015). However, these methods require the support from extra clean data or an expensive detection process to estimate the noise model.

3 Logit Maximum Difference Mechanism (LMD)

In this section, we propose a novel LMD mechanism. The LMD utilizes the tiny difference between hard samples and noisy samples in the model output. Meanwhile the LMD accumulates and expands the difference to identify noisy samples.

3.1 Preliminary

Easy samples and noisy samples are easy to distinguish(e.g., utilizing loss values (Han et al., 2018)), because of noisy samples are always contrary to the samples with correct tags. However, hard samples with ambiguous entity are difficult to distinguish from noisy samples, because hard samples also will produce large loss values (Song et al., 2020) in the early stage of training. This has become a major challenge in the denoising task (Song et al., 2020).

Utilizing Logit Matrix Neural network models will output a logit matrix in the training process, which goes through the softmax layer and then gets into loss function. The Softmax layer is a normalized exponential function, which will nonlinear increase the weight of maximum value in the logit matrix and bring unfairness for identifying noisy samples. LMD directly utilizes logit matrix to distinguish hard samples from noisy samples instead of loss values.

Given a sentence $x = [x_1, x_2, ..., x_n]$ and its tag sequence $y = [y_1, y_2, ...y_n]$, n is the sentence length. Every token x_i will obtain a corresponding logit matrix $Z = [z_1^i, z_2^i, ..., z_m^i]$, m denotes total number of tags. LMD utilizes the difference between the z_j corresponding to the class j and other values in the logit matrix.

Observing The Difference In Figure 2, the logit value $Z_y^{(t)}$ corresponding to tag y and epoch t, and the $Z_y^{(t)}$ is evidently higher than other values in easy samples(left). In hard samples(middle), the $Z_y^{(t)}$ is small at the beginning of training, then $Z_y^{(t)}$ begins to increase and become the maximum in the logit matrix with increasing epoch t. In noisy samples(right), the $Z_y^{(t)}$ is relatively smaller than other values, and the $Z_y^{(t)}$ becomes the maximum in the logit matrix when epoch exceeds 5 even if y is a negative tag, which indicates that overfitting occurs.

3.2 Identify Noisy Samples

Defining LMD We propose a new statistic LMD score, which averages the difference between $Z_y^{(t)}$ and the other values $Z_{other}^{(t)}$ at each epoch t. The tiny difference between hard samples and noisy samples are gradually accumulated and maximized, which will effectively help model identify noisy samples. The LMD score can be defined as:

$$LMD(x,y)=\frac{1}{T}\sum_{t=1}^{T}(min(Z_y^{(t)}-\max_{i\neq y} Z_i^{(t)})) \tag{1}$$

Where T is the total number of epoch. A sentence is the minimum unit of the input in the NER task. If the tag corresponding to single token is mislabeled in a sentence, we can consider that the sentence is negative. Therefore we choose the smallest LMD score in each sentence as the LMD score of the sentence, where every token will obtain a LMD score in the sentence.

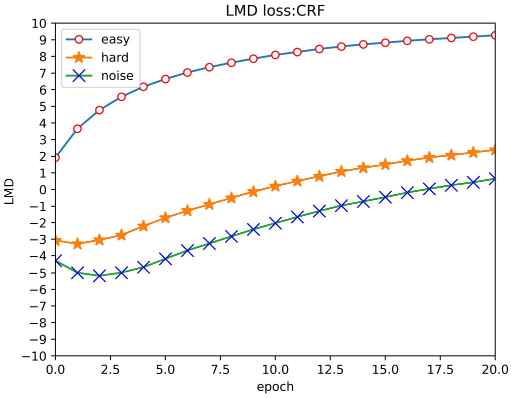

Figure 3: A record of LMD score in each epoch for easy, hard and noisy samples. We select 100 samples from the three sets respectively in WUT-17 dataset.

Working Mechanism In order to steadily enhance the discrimination between easy, hard and noisy samples, we stack the LMD scores of multiple epochs to get an average value. By utilizing the LMD mechanism, every sample will get a LMD score. The LMD scores of easy, hard and noisy samples have obvious differentiation in Figure 3. Then we sort the samples according to the LMD scores, and define samples under the noise ratio μ as noisy samples, finally delete them to get a cleaner training set. And the noise ratio μ is a hyperparameter. The model is trained again with utilizing a clean training set, which will obtain better performance without the interference of noisy samples.

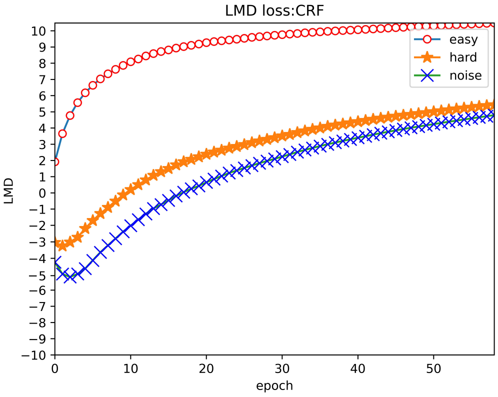

Figure 4: Compared with the experiment in Figure 3, we only adjusted the epoch to 60.

3.3 The Influence of Overfitting

Overfitting Appears We further explore the influence of overfitting in the denoising task from two sides. From the perspective of the LMD scores, the LMD scores of hard samples and noisy samples tend to be consistent with increasing epoch to 60 in the Figure 4. From the perspective of the logit values, the logit value $Z_y^{(t)}$ becomes the maximum in the logit matrix when epoch exceeds 5 even if y is a noise tag in the Figure 2.

Phenomenon Analysis As the increase of training iteration epochs, the model will overfit noisy samples. Meanwhile the model output of hard samples and noisy samples are almost consistent, which make it difficult to distinguish. This proposes another challenge that the model identifies noisy samples in the case of overfitting.

4 Incomplete-Trust Loss Function

In this section, we propose an Incomplete-Trust (In-trust) loss function. Previous loss functions (e.g., Cross Entropy) are easy to overfit noisy samples (Wang et al., 2019b), and they absolutely trust tags even if the tags are mislabeled. Meanwhile, neural networks have strong fitting ability, they can achieve zero training error even on datasets with randomly-assigned labels (Zhang et al., 2016). And deep neural networks have been observed to first fit the samples with clean tags during an “early learning” phase, before eventually memorizing the samples with mislabeled tags (Arpit et al., 2017; Zhang et al., 2016). With exploiting the early-learning phenomenon, our proposed In-trust utilizes both the model output which obtain the relative correctness after enough practices and the incomplete correctness of tags which maybe are mislabeled. We also provide theoretical analysis about the formulation and behavior of In-trust.

4.1 Definition

KL-divergence Given two distributions p and q, the relationship between entropy, cross entropy and KL-divergence is as follows:

$$KL(q||p)=H(q,p)-H(q) \tag{2}$$

In NER task, $q=q(k|x)$ is the one-hot distribution of the label in sample x, and $p=p(k|x)$ is the prediction distribution of the model for sample x. The model makes the $p=p(k|x)$ gradually approach the $q=q(k|x)$, this is also to minimize the KL-divergence between the two distributions.

Proposing DCE Term However, if the sample x is a noisy sample and the $q=q(k|x)$ is an incorrect distribution, it will cause negative impacts for model, so the label distribution $q=q(k|x)$ is not worthy of full trust. According to the phenomenon of early learning, the model always tends to learn the correct samples in the early stage of training. It means that even if some samples are mislabeled, the model still may predict the correct results in the early stage of training. We exploit this phenomenon to trust that not only the label distribution $q=q(k|x)$, but also the prediction distribution $p=p(k|x)$ before the model overfit noisy samples. Therefore, we design the robust Distrust-Cross-Entropy L_{DCE} term as follows:

$$L_{DCE}=-p\log(\delta p+(1-\delta)q) \tag{3}$$

Where δ is a hyperparameter, and its size determines that the model whether trust labels or model output. When δ is larger, the model will trust prediction distribution $p=p(k|x)$ more, on the contrary, the model will trust label distribution $q=q(k|x)$ more.

Forming In-trust We proposed an Incomplete-Trust (In-trust) loss function, which boosts L_{CRF} with L_{DCE} term.

$$L_{In-trust}=\alpha L_{CRF}+\beta L_{DCE} \tag{4}$$

Where L_{DCE} term is an acceleration regulator term, which can effectively prevent model from overfitting noisy samples. That will be proved in Appendix A. The L_{CRF} term is not noise tolerant (Ghosh et al., 2017), but which benefits the convergence of the model (Zhang and Sabuncu, 2018). α and β are two decoupled hyperparameters, α regulates the overfitting issue of L_{CRF} while β aims to flexibly explore the robustness of L_{DCE}.

Contrasting Logit Values Figure 5 shows the result of comparative experiment with Figure 2. The logit value $Z_y^{(t)}$ corresponding to mislabeled tag y is no longer the maximum in the logit matrix, this means that $L_{In-trust}$ effectively prevents model from overfitting noisy samples.

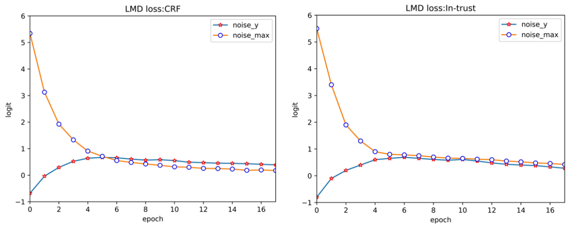

Figure 5: A comparative experiment of CRF (left) on noisy samples. We only replace the loss function to $L_{In-trust}$ (right), and other parameters are consistent.

Contrasting LMD Scores Figure 6 shows the result of comparative experiment with Figure 4. There is still obvious discrimination between hard samples and noisy samples when the epoch reaches 60, this indicates that $L_{In-trust}$ can help LMD mechanism identifies noisy samples accurately.

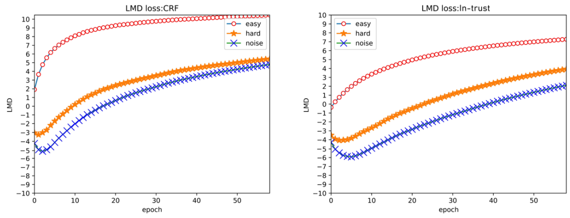

Figure 6: A comparative experiment between CRF (left) and $L_{In-trust}$ (right), other parameters are consistent.

4.2 Robustness Analysis

L_{DCE} Robustness Analysis: In order to simplify the calculation, we set α and β as 1 and derive the gradient of L_{DCE}. For brevity, we denote p_k, q_k as abbreviations for $p=p(k|x)$ and $q=q(k|x)$, the gradient of the L_{DCE} loss with respect to the logits Z_j can be derived as:

$$\frac{\partial L_{DCE}}{\partial Z_j}=(\sum_{k=1}^{K} p_k \times \log(\delta p_k+(1-\delta)q_k))^{'} \quad (5)$$

Where $\frac{\partial p_k}{\partial Z_j}$ can be further derived based on whether $k = j$:

$$\begin{cases} \dfrac{\partial p_k}{\partial Z_j} = p_k(1-p_k) & k=j \\ \dfrac{\partial p_k}{\partial Z_j} = -p_k p_j & k \neq j \end{cases} \quad (6)$$

For brevity, we denote $a_k=\delta p_k+(1-\delta)q_k$ and $b_k=p_k \log a_k+\frac{\delta p_k^2}{a_k}$. We know that $\frac{\partial p_k}{\partial Z_j}$ is a function of p_k from Eq.(5), let $L_{p_k}=\frac{\partial p_k}{\partial Z_j}$, and the gradient of the L_{p_k} with respect to the p_k can be derived as:

$$L_{p_k}^{'}=\sum_{k=1}^{K} b_k+(p_j-1)\frac{\partial b_j}{\partial p_j} \quad (7)$$

And the second derivative of L_{p_k} is:

$$L_{p_k}^{''}=2b^{'}+(p_j-1)b^{''} \quad (8)$$

Where $L_{p_k}^{''}$ is a monotone increasing function, when $q_j=1$ and $\delta \in [0.0, 0.1, ...]$, we obtain the corresponding relation between $L_{p_k}^{''}$ and p_j in the Figure 7. It is concluded that $L_{p_k}^{'}$ is a decreasing and then increasing function, which also shows that the acceleration of L_{DCE} first decreases and then increases with the increase of p_j corresponding to the label.

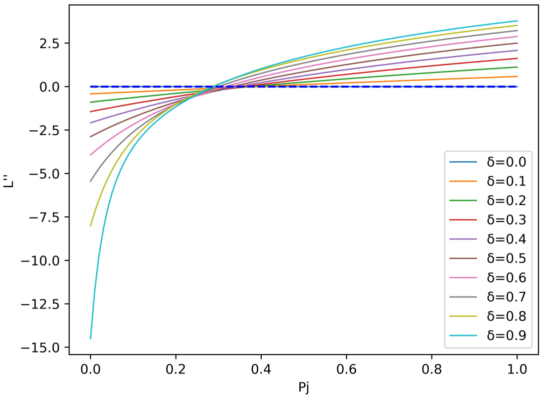

Figure 7: The acceleration record of LDC term.The LDC term produces different accelerations for different model outputs. The x-axis is p_j and the y-axis is the corresponding $L_{p_k}^{''}$ value. $\delta \in [0.0, 0.1, ...]$.

When p_j approaches to 1 with the q distribution is close to the p distribution, the model will believes correct tags more, and L_{DCE} has larger acceleration in learning correct samples. That benefits the model learns cleaner samples and prevents overfitting. On the contrary, the L_{DCE} term thinks that the model has relatively correct prediction result for noisy samples under the influence of learning other correct labels, and the acceleration is small which also effectively prevents the model overfitting and improves the noise tolerance. And other more detailed proofs are shown in the Appendix A.

$L_{In-trust}$ **Robustness Analysis:** According to Eq.(4), $L_{In-trust}$ consists of L_{CRF} and L_{DCE}. When $q_j = 1$, L_{DCE} term will provide a robust acceleration value, which benefits $L_{In-trust}$ obtains a correct loss value. Specifically, $L_{In-trust}$ will obtain a greater loss value when p_j approach to q, which will benefit the model learn this sample like L_{CRF}. On the contrary, L_{DCE} will prevent model from learning the sample unlike L_{CRF}. When $q_j = 0$, other loss functions will prevent the model from learning the direction, even if the model output p is greater in this direction. We believe that the model is relatively correct after learning a large number of samples. And L_{DCE} term will provide $L_{In-trust}$ with an acceleration to help the model to learn the direction. In addition, L_{DCE} term also prevent the model from learning when p is small. Therefore L_{DCE} term has no negative effect on the convergence of model.

5 Experiments

In this section, we verify the advantages of Noise-Aware-with-Filter (NAF) method by comparing experiments with other denoising methods.

5.1 Experimental Setup

NER Dataset

English NER Dataset We evaluate our method on English NER datasets include WUT-17 (Derczynski et al., 2017), CoNLL2003 (Tjong Kim Sang and De Meulder, 2003), CoNLL++ (Wang et al., 2019b) and OntoNotes5 (Pradhan et al., 2013). CoNLL2003 is in news domain and WUT-17 is user generated text. Compared with CoNLL2003, the test set of CoNLL++ is manually corrected. OntoNotes5 is a larger dataset and contains 18 entity types.

Dataset	Weibo NER	OntoNotes4	OntoNotes5	CoNLL2003	CoNLL++	WUT-17
CE	59.71	81.05	85.57	90.99	92.07	54.77
L_{CRF}	60.88	81.22	85.40	91.60	91.87	55.22
SCE	60.97	80.72	85.30	91.53	91.26	53.55
DSC	60.78	80.34	85.23	91.34	92.08	54.48
ELR	57.41	**81.54**	84.48	91.24	91.73	53.54
$L_{In-trust}$(our)	**61.97**	81.29	**86.23**	**91.67**	**92.68**	**56.13**
NAF(our)	**62.55**	**82.15**	**86.46**	**91.72**	**92.95**	**58.54**

Table 1: The result of NAF($L_{In-trust}$ + LMD) and other denoising methods in the **BERT** model.

Dataset	CoNLL2003	CoNLL++	WUT-17
CE	94.31	95.80	64.99
L_{CRF}	94.22	95.90	64.85
RCE	94.29	95.37	63.73
DSC	94.33	94.79	64.89
ELR	94.10	94.21	63.58
$L_{In-trust}$(our)	**94.45**	**96.13**	**66.44**
NAF(our)	**94.51**	**96.25**	**67.88**

Table 2: The result of NAF($L_{In-trust}$ + LMD) and other denoising methods in the **LUKE** model.

Chinese NER Dataset Chinese NER datasets include Weibo NER (Peng and Dredze, 2015) and OntoNotes4 (Pradhan et al., 2011). Weibo NER is in social domain, OntoNotes4 is in news domain.

In these six real-wold datasets, we use the same way of data segmentation as the original author. Since WUT-17 has no development set, we randomly select 10% samples from the training set as the development set.

Pre-trained Language Model **BERT** (Devlin et al., 2019) employs a Transformer encoder to learn a BiLM from large unlabeled text corpora and sub-word units to represent textual tokens. We use the $BERT_{base}$ model in our experiments. **LUKE** (Yamada et al., 2020)proposes new pretrained contextualized representations of words and entities based on the bidirectional transformer, which is the state-of-the-art(SOTA) model in English NER task.

Baseline We compare NAF with 3 recently proposed robust methods as well as the standard L_{CRF} : (1) CE:Cross Entropy; (2)SCE (Wang et al., 2019b): symmetric cross entropy loss; (3)DSC (Li et al., 2020): dice loss function; (4)ELR (Liu et al., 2020): early regularization; (5)In-trust (We proposed Incomplete-Trust loss function).

Evaluation Our primary evaluation metric is F1 score on the test set to compare the results of different methods.

5.2 Experimental Settings

In our experiments, we set the initial learning rate to $lr = 1e{-}5$ for all datasets. Since the scale of each dataset varies, we set different training batch size for different datasets. Specifically, we set the batch sizes of Weibo NER, OntoNotes4, WUT-17, CONLL2003 and CoNLL++ as 40, 40, 40,32 and 32 in **BERT**, and set the batch sizes of WUT-17, CONLL2003 and CoNLL++ as 2, 2 and 2 in **LUKE**. We stop the training when we find the best result in the development set.

5.3 Robustness Performance

Table 1 presents the results for the baseline and our methods in the **BERT**. Compared with other methods, NAF shows obvious advantage in the six real-wold datasets. Our method outperforms other methods by 1.58%, 0.61%, 0.29%, 0.87% and 3.77% in F1 score on Weibo NER, OntoNotes4, CoNLL2003, CoNLL++ and WUT-17 datasets. Table 2 presents the results in the **LUKE**, and our method has achieved new state-of-the-art (SOTA) with the F1 score reached to **94.51%** and **96.25%** on CoNLL2003 and CoNLL++ datasets.

Specifically, NAF has made more obvious progress on Weibo NER, WUT-17 and CoNLL++ datasets, and our analysis shows that the noise ratio of Weibo NER and WUT-17 are greater than others and there is a cleaner test set after manual correction in CoNLL++ dataset.

5.4 Manual Verification

Results Statistics In order to prove the effectiveness of our method, we manually verify the noisy samples which are selected from CoNLL2003, OntoNotes4 and WUT-17 (Table 4). We randomly select 100 samples from “Original” train set and we manually verify the proportion of noisy samples. After utilizing LMD or NAF method, we will obtain a new datasets, and then we randomly select

Dataset	**noisy samples**
CoNLL2003	**Soccer - KEANE signs four-years contract with Manchester United{LOC} .**
	Soccer - sharpshooter knup back in swiss{MISC} squad .
	Little{PER} change from today 's weather expected .
	9/16 - Luo Yigang (China) beat Hwang Sun-ho{MISC} (South Korea) 15-3 .
WUT-17	**Federal lawyers{O} fly to Minneapolis to investigate shooting**
	@janzensational at least may date ka na hahaha{O} . Goodluck zen ! : *

Table 3: noisy samples in CoNLL2003 and WNUI-17. The mislabel entities are marked with red.

Dataset	CoNLL2003	Weibo NER
$\delta = 0.1$	90.34%	60.58%
$\delta = 0.2$	90.52%	61.12%
$\delta = 0.3$	91.21%	61.32%
$\delta = 0.4$	90.43%	61.78%
$\delta = 0.5$	**91.72%**	61.44%
$\delta = 0.6$	91.47%	62.21%
$\delta = 0.7$	91.28%	**62.55%**
$\delta = 0.8$	91.32%	62.32%
$\delta = 0.9$	90.20%	61.70%

Table 5: The effect of δ in **In-trust**. We set α=1 and β=1 here.

100 samples from the new datasets for manually verifying. The probability of true negative samples is 5% in the "Original" CoNLL2003 dataset, and which reaches to 76% and 82% respectively with utilizing LMD and NAF methods. While for OntoNotes4 dataset, the probability is 8% in "Original" dataset and which reaches to 72% and 80% with LMD and NAF. In the WUT-17 dataset, the probability is 18% in "Original" dataset and which reaches to 58% and 71% with LMD and NAF.

Result Analysis The accuracy of identifying noisy samples will greater with the dataset that model performs better, and the excellent datasets will benefit the model identify noisy samples.

Dataset	Original	LMD(our)	NAF(our)
CoNLL2003	5%	**76%**	**82%**
OntoNotes4	8%	**72%**	**80%**
WUT-17	18%	**58%**	**71%**

Table 4: The accuracy of identifying noisy samples is verified manually. We select 100 samples from the Original train set, LMD and NAF separately, then verify the proportion of noisy samples manually. And the "Original" means raw data.

Demonstration of Examples The real noisy samples in CoNLL2003 and WUT-17 datasets are shown in Table 3, such as {Soccer - KEANE signs four-years contract with Manchester United}, the { **Manchester United**} is wrongly marked **{LOC}**. The { **Manchester United** } is a football club in Manchester England, and which should be marked **{ORG}**. In addition, the more noisy samples in datasets are shown in the Appendix C.

5.5 Ablation Experiment

As mentioned in the previous Section 4.1, δ provides flexibility between the model output distribution p=$p(k|x)$ and the label distribution q=$q(k|x)$. In this section, we explore the influence of hyperparameter δ, and we conducted experiments on Weibo NER and CoNLL2003 with α=1 and β=1 to explore how it manipulates the tradeoff. Experimental results are shown in Table 5. The highest F1 on CoNLL2003 datatset is 91.72% when δ is set to 0.5, meanwhile for Weibo NER, the highest F1 is 62.55% when δ is set to 0.7. The optimal value of δ is different in different noise ratio datasets, and when there are more noisy samples in the datasets, δ should be set larger. Because of the noise ratio of Weibo NER is larger than CoNLL2003 dataset, the optimal δ value of Weibo NER is larger. The experiment result of the other hyperparameters α and β are show in the Appendix B.

6 Conclusion

In this paper, we observe that the existing denoising methods can not effectively distinguish hard samples from noisy samples, and we proposed a new method called Noise-Aware-with-Filter (NAF), which contains LMD mechanism and In-trust loss function to solve the issues. Specifically, NAF can effectively improve the discrimination between hard samples and noisy samples even in the case of overfitting. In addition, our proposed the Logit-Maximum-Difference(LMD) mechanism which maximizes the diversity between different samples to help the model identify noisy samples. Meanwhile we design an Incomplete-Trust ($L_{In-trust}$) loss function, which boosts L_{CRF} with a noise robust Distrust-Cross-Entropy(DCE) term. In order to verify the effectiveness of our method, we also conduct manual verification for noisy samples and the results show that our method has higher accuracy on identifying noisy samples. Experiments on six real-world Chinese and English NER datasets show that NAF outperforms the previous methods, and which obtained the state-of-the-art(SOTA) results on the CoNLL2003 and CoNLL++ datasets.

A $L_{In-trust}$ Robustness Proof

We have know $L_{In-trust}$ is:

$$\begin{aligned} L_{In-trust} &= \alpha \times CRF + \beta \times L_{DCE} \\ &= \alpha \times CRF + \beta \times (-p \times \log(\delta p + (1-\delta) q)) \end{aligned} \tag{9}$$

And make:$a = \delta p + (1-\delta) q$

$$\begin{aligned} Eq9 &= \alpha \times CRF + \beta \times (-p \times \log a \\ &= \alpha \times CRF \\ &+ \beta \sum_{k=1}^{K} (-\frac{\partial p_k}{\partial Z_j} \log a_k + (-p_k \frac{a_k^{‘}}{a_k})) \end{aligned} \tag{10}$$

Meanwhile we have know:

$$\begin{aligned} \frac{\partial p_k}{\partial Z_j} &= \frac{\partial (\frac{Z_k}{\sum_{j=1}^{K} e^{Z_j}})}{\partial Z_j} \\ &= \frac{\frac{\partial e^{Z_k}}{\partial Z_j} (\sum_{j=1}^{K}) - e^{Z_k} \frac{\partial (\sum_{j=1}^{K} e^{Z_j})}{\partial Z_j}}{(\sum_{j=1}^{K} e^{Z_j})^2} \end{aligned} \tag{11}$$

When $k = j$:

$$\begin{aligned} \frac{\partial p_k}{\partial Z_j} &= \frac{\partial p_k}{\partial Z_k} \\ &= \frac{e^{Z_k} (\sum_{k=1}^{K} e^{Z_j}) - (e^{Z^k})^2}{(\sum_{k=1}^{K} e^{Z_k})^2} \\ &= \frac{e^{Z_k}}{\sum_{k=1}^{k} e^{Z_k}} - (\frac{e^{Z_k}}{\sum_{k=1}^{K} e^{Z_k}})^2 \\ &= p_k - {p_k}^2 \\ &= p_k (1 - p_k) \end{aligned} \tag{12}$$

When $k \neq j$:

$$\begin{aligned} \frac{\partial p_k}{\partial Z_j} &= \frac{0 (\sum_{k=1}^{K} e^{Z_j}) - e^{Z_k} e^{Z_j}}{(\sum_{k=1}^{K} e^{Z_j})(\sum_{k=1}^{K} e^{Z_j})} \\ &= - \frac{e^{Z_k}}{\sum_{k=1}^{K} e^{Z_j}} \frac{e^{Z_j}}{\sum_{k=1}^{K} e^{Z_j}} \\ &= - p_k p_j \end{aligned} \tag{13}$$

Gradient Calculation:

$$\begin{aligned} L_{DCE} &= - p \times \log(\delta p + (1-\delta) q) \\ \frac{\partial L_{DCE}}{\partial Z_j} &= (\sum_{k=1}^{K} p_k \times \log(\delta p_k + (1-\delta) q_k))' \\ &= \sum_{k=1}^{K} {p_k}' \log(\delta p_k + (1-\delta) q_k) \\ &+ \frac{\delta p_k {p_k}'}{\delta p_k + (1-\delta) q_k} \end{aligned} \tag{14}$$

For the convenience of calculation, we make $a = \delta p_k + (1-\delta) q_k$

$$\begin{aligned} \frac{\partial L_{DCE}}{\partial Z_j} &= \sum_{k=1}^{K} p_k^{‘} \log a_k + \frac{p_k a_k^{'}}{a_k} \\ &= \sum_{k=1}^{K} p_k^{'} \log a_k + \frac{\delta p_k p_k^{‘}}{a_k} \\ &= - p_j \sum_{k=1}^{k} (p_k \log p_k + \frac{\delta p_k^2}{a_k}) \\ &+ p_j \log a_j + \frac{\delta p_j^2}{\delta a_j} \end{aligned} \tag{15}$$

Make $b_k = p_k \log a_k + \frac{\delta p_k^2}{a_k}$

$$\begin{aligned} \frac{\partial L_{DCE}}{\partial Z_j} &= - p_j \sum_{k=1}^{K} b_k + b_j \\ \frac{\partial L_{DCE}}{\partial Z_j} &= p_j \sum_{k=1}^{K} b_k - b_j \end{aligned} \tag{16}$$

We hypothesis $L = p_j \sum_{k=1}^{K} b_k - b_j$

$$\begin{aligned} L^{'} = \frac{\partial L}{\partial p_j} &= \sum_{k=1}^{K} b_k + p_j (\sum_{k=1}^{K} b_k)^{‘} - \frac{\partial b_j}{\partial p_j} \\ &= \sum_{k=1}^{K} b_k + (p_j - 1) \frac{\partial b_j}{\partial p_j} \end{aligned} \tag{17}$$

And $L^{''} = 2b^{'} + (p_j - 1) b^{''}$

Meanwhile we can get:

$$\begin{aligned} b^{'} &= \log a + \frac{pa^{'}}{a} + \frac{2\delta p - \delta p^2 a^{'}}{a^2} \\ &= \log a + \frac{\delta p}{a} + \frac{2\delta p - \delta^2 p^2}{a^2} \\ &= \log a + \frac{3\delta p}{a} - (\frac{\delta p}{a})^2 \end{aligned} \tag{18}$$

$$\begin{aligned} b^{''} &= \frac{\delta}{a} + 3\delta \frac{(1-\delta) q}{a^2} - 2\delta^2 \frac{p}{a} \frac{(1-\delta) q}{a^2} \\ &= \frac{\delta}{a} + \frac{3\delta (1-\delta) q}{a_2} - \frac{2\delta^2 p (1 - \delta) q}{a^3} \end{aligned} \tag{19}$$

When $q_j = 0$:

$$\begin{aligned} L^{''} &= 2 \log(\delta + 2) + \frac{p-1}{p} \\ &= 2 \log \delta p + 4 + 1 - \frac{1}{p} \\ &= 2 \log \delta p + 5 - \frac{1}{p} \end{aligned} \tag{20}$$

When p approaches 0 : $L^{''}<0$

When p approaches 1 : $L^{''}=2\log\delta+4$

$E:\delta 1\in[0,1]$, make $L^{''}(\delta 1)>0$

Because $L^{''}$ is continuous function, so $L^{''}$ is Monotone increasing function

$E:\delta 2\in[0,1]$, make $L^{''}(\delta 2)=0$

So $L^{'}$ is Decreasing then increasing function and the inflection point is only related to δ.

When $q_j=1$:

$$b^{'}=\log a+\frac{3\delta p}{a}-(\frac{\delta p}{a})^2$$
$$b^{''}=\frac{\delta}{a}+\frac{3\delta(1-\delta)q}{a_2}-\frac{2\delta^2 p(1-\delta)q}{a^3}$$
$$=\frac{\delta a^2+3\delta a-3\delta^2 a-2\delta^2 p+2\delta^3 p}{a^3}$$

$$\begin{aligned}L^{''}&=2b^{'}+(p_j-1)b^{''}\\&=2\log a+\frac{6\delta p}{a}-\frac{2\delta^2p^2}{a^2}+\\&\frac{\delta a^2p+3\delta ap-3\delta^2ap-2\delta^2p^2+2\delta^3p^2}{a^3}+\\&\frac{-\delta a^2-3\delta a+a\delta^2 a+2\delta^2p-2\delta^3p}{a^3}\end{aligned}\tag{21}$$

Because $L^{''}$ is monotone increasing function

So when $p=0$:

$L^{''}=2\log(1-\delta)+\frac{-\delta a^2-3\delta a+3\delta^2 a}{(1-\delta)^3}<0$

When $p=1$:

In order to simplify the calculation, we make $\delta=0$

So $L^{''}=0$

When $\delta>0$, and $L^{''}>0$

So $L^{'}$ is Decreasing then increasing function and the inflection point is only related to δ.

In summary, when $q=0$ or $q=1$:

$L^{'}$ is Decreasing then increasing function and the inflection point is only related to δ.

We know $L^{'}(p=0)>0$, $L^{'}(p=1)>0$,

and $E:\mu\in[0,1]$, make $L^{'}(p=\mu)<0$

We observe that when δ is larger, the model tends to learn from the p of the model output, and when δ is smaller, the model tends to learn from the label q. Moreover, when the p_j corresponding to the label is larger and the model output is close to the label distribution, the acceleration of L_{DC} term is larger, which makes the model more inclined to learn the sample, which helps the model learn clean samples. When p_j is small, there is a big gap between the model output and label distribution. We think that the sample may be a noisy sample, and the acceleration of L_{DC} term is smaller, which makes the model more inclined to give up the learning of the sample, and prevents the model from over fitting the noisy sample.

A Multi-Task Approach for Improving Biomedical Named Entity Recognition by Incorporating Multi-Granularity Information

Yiqi Tong, Yidong Chen*, **Xiaodong Shi**
School of Informatics, Xiamen University, Xiamen, China
`yqtong@stu.xmu.edu.cn`
`{ydchen, mandel}@xmu.edu.cn`

Abstract

Neural biomedical named entity recognition (BioNER) methods usually require a large amount of annotated data, while the annotated BioNER datasets are often difficult to obtain and small in scale due to the limitations of privacy, ethics and high degree of specialization. To alleviate the lack of training samples, unlike conventional methods that only use token-level information, this paper proposes a method that simultaneously utilize the latent multi-granularity information in the dataset. Concretely, the proposed model is based on a multi-task approach, which leverages different training objectives by introducing auxiliary tasks, i.e. binary classification, multi-class and multi-token classification. Experimental results over three BioNER datasets show that the proposed model produces better performance over the BioBERT baseline and can get more than 3% improvements of F1-score in low-resource scenarios. Finally, we released our code at `https://github.com/zgzjdx/MT-BioNER`.

Figure 1: Examples from our constructed dataset. In our work, we designed three auxiliary tasks to help improving the main NER task. Two of them are sentence-level tasks and the other one is a token-level task. Concretely, the first sentence-level task predicts whether or not a sentence contains entities; the second sentence-level task predicts how many entities a sentence contains; and the token-level task predicts whether or not a given token belongs to a multi-token entity. Clearly, to support training the auxiliary tasks, additional labels have been added in our data. However, please note that, the additional labels could be derived from the original NER labels and do not need additional manual annotations. In a word, what we have done in this paper is try to use the multi-granularity information implied in the original dataset to improve the performance of BioNER.

1 Introduction

Biomedical named entity recognition (BioNER) aims to identify entity mentions such as gene/protein, disease and chemicals from unstructured text. Such information is useful for downstream natural language processing (NLP) tasks like relation extraction (Zhou et al., 2014), automatic abstracting (Mishra et al., 2014) and question answering (Athenikos and Han, 2010), etc. Different from those named entity recognition (NER) tasks for general domain like news, BioNER is particular challenge due to the naming complexity (Liu et al., 2015), large variations in same entity names (Jia et al., 2019; Kim et al., 2019), and new entity mentions rapidly reported in scientific publications (Luo et al., 2018). These various factors lead to the small number and size of current BioNER datasets. In recent years, neural BioNER has become a main approach because of its outstanding performance (Lample et al., 2016; Habibi et al., 2017; Yadav and Bethard, 2019). Some researchers have investigated introducing multi-task learning (Crichton et al., 2017; Khan et al., 2020) and pre-training (Peng et al., 2019; Lee et al., 2020) to solve the problem of lacking extensive training data and boost the performance of BioNER model. However, few of them combined these two methods together and tried to transfer sentence-level knowledge to tokens (Rei and Søgaard, 2019; Kruengkrai et al., 2020), which had proven to be effective in

August 1–6, 2021.

other domains (Abhishek et al., 2017).

In this paper, we focus on improving BioNER by exploiting multi-granularity information implied in the dataset, without depending on additional manually annotated data. As shown in Figure 1, Besides the main sequence labeling task, we employ three related classification tasks, i.e. a binary classification task for predicting whether a sentence contains entities or not, a multi-class classification task for predicting how many entities a sentence contains and a multi-token entity classification task (Hu et al., 2020). In the rest of this paper, these three tasks will be named bCLS, mCLS and mtCLS, respectively, while the main task will be named NER. Our primary motivation is to mine useful training signals from coarse-grained classification to guide a more robust and interpretable token-level representation.

Our key contributions can be summarized as follows:

- To take full advantage of the implicit information contained in NER dataset, we present a multi-task model for jointly learning sentence-level and token-level labels, which incorporates BioBERT (Lee et al., 2020) as text encoding layers and shares the hidden states between different tasks. To the best of our knowledge, we are the first to introduce different grained-level information in BioNER domain.
- Experimental results on three datasets show that our proposed method is effective, especially in the low-resource scenarios.
- We performed preliminary pair-wise comparison analysis to investigate the relations between tasks and pointed out that token-level labels are more helpful for sentence-level tasks. While at the same granularity, high-difficulty tasks are more helpful to low-difficulty tasks.

2 Related work

Traditional BioNER methods could be divided into rule- or dictionary-based approaches (Tjong Kim Sang and De Meulder, 2003; Kulick et al., 2004; Gerner et al., 2010). And recent works had shown neural network architecture based BioNER methods achieved promising results. Habibi et al. (2017) used a LSTM-CRF model, which was completely agnostic to entity types. Crichton et al. (2017), on the contrary, used a CNN-based model that takes tokens and their surrounding tokens as input. To solve the label inconsistent problem, Luo et al. (2018) proposed a Att-BiLSTM-CRF model and achieved better performance with little feature engineering.

The neural BioNER system is known to be extremely data-intensive, while the available training datasets are relatively small in scale. To tackle this problem, research has been conducted and language models and multi-task learning have been shown to be effective to deal with this problem (Peters et al., 2018; Liu et al., 2019). Jia et al. (2019) proposed a cross-domain NER model, which extracted knowledge from raw texts through a novel parameter sharing network. Yoon et al. (2019) proposed CollaboNet, which consists of multiple BiLSTM-CRF models where models could send information to one another for more accurate predictions, and got best F1-score at that time. Although these studies have exploited additional token-level information from auxiliary tasks or language models, they do not consider information from other levels that contained in the NER dataset.

More recently, a transformer-based (Vaswani et al., 2017) large-scale pre-training language model, called BERT (Devlin et al., 2018), led to impressive gains on several NLP benchmarks and the domain-specific BERTs, such as blueBERT (Peng et al., 2019), BioBERT (Lee et al., 2020), SciBERT (Beltagy et al., 2019) and PubmedBERT (Gu et al., 2020), have largely outperformed the previous state-of-the-art BioNER systems. But research on multi-task learning based on BERT is still few, and the association between tasks needed to be further explored (Khan et al., 2020; Vu et al., 2020).

The most similar work to ours is the findings of Kruengkrai et al. (2020). However, they only focused on introducing one auxiliary task that requires additional manual annotations, while we attempted to try multiple auxiliary tasks, and our proposed method did not rely on other additional annotations, except for BioNER.

3 The proposed model

3.1 Tasks

As mentioned in Section 1, our model involves four tasks: bCLS, mCLS, mtCLS and NER. The goal is to optimize the token-level representation of BioBERT by introducing auxiliary tasks (bCLS, mCLS, mtCLS) and improve the perfor-

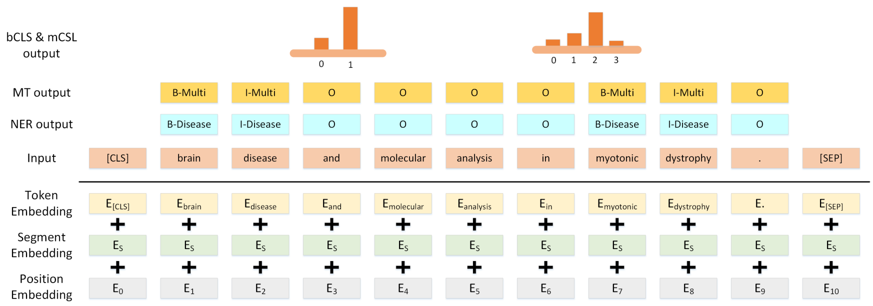

Figure 2: The input and output descriptions of the proposed model. Actually, our model involve three input embeddings and four outputs, and we adopt two special token [CLS] and [SEP] to represent the beginning and the end of the input sentence, respectively.

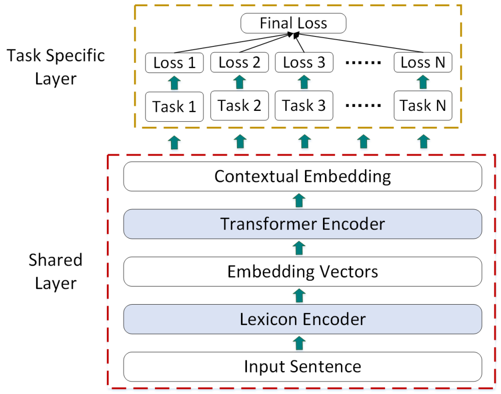

Figure 3: The architecture of our multi-task BioBERT-based model that can jointly learn sentence-level and token-level labels.

mance of the main task (NER). The pre-training model BioBERT are shared across all tasks by hard parameter sharing (Ruder, 2017). The input sequence and output labels of our proposed model are represented in Figure 2. Given a sentence $X = \{x_1, ..., x_i, ..., x_n\}$, where x_i is a token, n is the length of the input sequence. The first token of each X is always a special classification embedding [CLS] and the transformer encoder module maps X into a sequence of input embedding vectors, which are the sum of the token, segment and position embeddings. The detailed description of each task is shown as follows. **bCLS:** This is a sentence-level binary classification task. Given X, the goal is to predict whether it contains entities or not. In some cases, for X that do not contain entities, the model may incorrectly predicts that it contains entities. Or for X that contains entities, the model may incorrectly predicts that it not contain entities. Therefore, we design bCLS task with the hope of solving this problem by introducing a global guidance information.

mCLS: This is a sentence-level multi-classification task. Given X, the goal is to predict how many entities it contains. To balance label numbers, this paper set mCLS as a 4-classification task, which X contains 0, 1 and 2 entities is set to 0, 1 and 2, respectively, while X with more than 2 entities are all set to 3. Compared with bCLS, mCLS is more difficult and we introduce this task to alleviate the under- or over-recognition entity problem.

mtCLS: Multi-token classification is a token-level 3-classification problem. Given x_i in X, the goal is to predict whether it belongs to a multi-token entity like "brain disease" or a single-token entity like "peroxydase" or neither. Our motivation for introducing this task is that if the model knows whether x_i is multi-token entity or single-token entity or neither, it can alleviate the entity boundary problem.

NER: Given X, NER aims to predict corresponding labels $Y = \{y_1, ..., y_i, ..., y_n\}$, where y_i is predefined and differs according to the annotation scheme such as BIO and BIOES. We use this main task to measure the model performance and effectiveness of auxiliary tasks.

3.2 Architecture

The overall architecture of our proposed model is shown in Figure 3, which mainly includes two parts: the shared encoder and task-specific layers. We use multi-task learning to jointly train the main task and auxiliary tasks, which has been shown effective for transferring knowledge among multiple tasks (Yoon et al., 2019). For the shared encoder, we take cased BioBERT-base v1.1[1] as feature extractor and hard shared its parameters. Set X as an input sequence, where x_i denotes the $i-th$ token

---

[1] https://github.com/naver/biobert-pretrained

in X. We represent each x_i using the pre-trained BioBERT embeddings $h_i \in \mathbb{R}^d$, where d is the dimension of hidden states. And the task-specific layers have independent parameters, which include a project layer and a classifier for generating outputs. We use the output of the shared encoder, i.e. $H = \{h_1, ..., h_i, ..., h_n\}$, as the input of task-specific layers for both sentence- and token-level tasks, as described in detailed as follows.

Sentence-level tasks. As mentioned in subsection 3.1, bCLS and mCLS are two sentence-level classification tasks. Different from the standard BERT-based classification models, which optimize the [CLS] token (Sun et al., 2019) to perform classification. Our model aims at optimizing the token representations of the shared encoder by sentence-level labels. Therefore, we created a fixed size vector by applying mean/max pooling (Reimers and Gurevych, 2019) over H, which encourages the model to capture the most useful local features encoded in hidden states. Finally, the probability of class k is predicted by a linear layer and a logistic regression with softmax.

$$P(m|X) = softmax(Wh + b) \qquad (1)$$

where $h \in \mathbb{R}^d$ is the pooling output of model, $W \in \mathbb{R}^{d \times m}$ and $b \in \mathbb{R}^m$ are trainable weight matrix and bias. m denotes the number of category labels, which is 2 for bCLS and 4 for mCLS. Finally, the loss for our sentence-level task is calculated as follows:

$$L_S = -\sum_{m} \sigma(y_m = \hat{y}) log(P(m|X)) \qquad (2)$$

where $\sigma(y_m = \hat{y}) = 1$ if the classification $\hat{y}$ of X is the right ground-truth label for the class m. Otherwise, $\sigma(y_m = \hat{y}) = 0$.

Token-level tasks. As mentioned in subsection 3.1, mtCLS and NER are two token-level classification tasks[2]. Given the dataset D, which consists of N training samples, i.e. $D = (x_j, y_j)_{j=1}^{N}$, where j denotes the sentence index in D. To train the token-level tasks, we minimize the negative log-likelihood of the correct label sequences over D with the loss function defined as follows:

$$L_T = -\frac{1}{N} \sum_{j=1}^{N} log(P(y_j)|H_j) \qquad (3)$$

Algorithm 1 Training a MT-BioBERT model

```

where $H_j \in \mathbb{R}^{n \times d}$ is the hidden state of x_j.

Algorithm 1 provides the procedure for our cross-task joint training method, where α, β, γ, δ are hyper-parameters. Moreover, the final loss of the proposed model is calculated by weighted summing the losses of different tasks.

4 Experiments

4.1 Datasets

We evaluated the performance of proposed approach on three benchmark datasets[3] used by Wang et al. (2019b); Yoon et al. (2019); Lee et al. (2020); Khan et al. (2020). Table 1 gives the statics of these datasets. Following previous works, we merged the

---

[2] Generally, NER was treated as a sequence labeling problem. However, for a fair comparison with previous works, instead of using sequence labeling algorithms such as Conditional Random Field (CRF) (Wallach, 2004) in task-specific layers, we still use softmax for token-level tasks.

training and developing sets for the model training. As a part of the data preprocessing step, token labels were encoded using the standard BIO scheme (Reimers and Gurevych, 2017). In this scheme, for example, a token describing a disease entity is tagged with ”B-Disease” if it is at the beginning of the entity, and ”I-Disease” if it is inside the disease entity. Other tokens that not describing entities of interest are tagged as ”O”.

4.2 Settings

Following the work of Peng et al. (2020), all datasets are trained with the batch size of 32, maximum sequence length of 256 and a dropout (Srivastava et al., 2014) with the probability of 0.1 after the shared encoder. We use the Adam optimizer (Kingma and Ba, 2014) with a learning rate $5e^-5$ for BC2GM, BC5CDR-chem and $1e^-5$ for NCBI-disease. The training procedure contains 50 epochs for BC2GM, BC5CDR-chem and 100 epochs for NCBI-disease. A linear learning rate decay schedule with warm-up over 0.1, and a weight decay of 0.01 applied to every epochs of the training by following Liu et al. (2019). Finally, all models were trained on NVIDIA RTX TITAN and used standard F1 metrics[4] to evaluate the overall performance.

4.3 Performance

We compare our model with single-task models, such as LSTM-CRF (Habibi et al., 2017), BiLM-NER (Sachan et al., 2018), domain-specific BERTs (Devlin et al., 2019; Beltagy et al., 2019; Gu et al., 2020) and multi-task models, such as MTM-CW (Wang et al., 2019b), CollaboNET (Yoon et al., 2019), MT-BioNER (Khan et al., 2020).

Table 2 shows the overall performance of our model compared with the existing approaches on

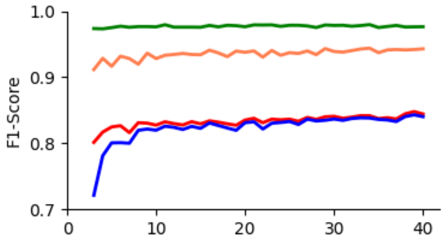
	Ours	We conclude that paternal transmission of congenital DM is rare and preferentially occurs with onset of DM ...

Table 5: Case study on three datasets, where words in red and in green represent incorrectly and correctly recognized entities, respectively.

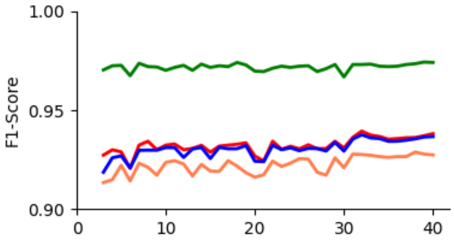
the three benchmark datasets, where the current SOTA model is BioBERT. In line with the expectations, Ours_MAX, which uses the max pooling strategy, achieved the best results, with the improvements of 0.40, 0.37 and 0.91 F1-scores for the three datasets, respectively. On the contrary, Ours_CLS and Ours_MEAN achieved negative results from our experiments. The above-mentioned phenomenon is consistent with Reimers and Gurevych (2019); Kruengkrai et al. (2020). Another interesting result is that our best model also achieves higher recall score than all the other approaches expect SOTA* result in BC2GM, which indicates that the introducing of coarse-grained tasks helps the model to predict more positive results.

To simulate low-resource scenarios, we also used the reduced training datasets by randomly removing sentences in training sets, while test sets are not modified. As shown in Table 3, CS-MTM was a multi-task model with cross-sharing structure proposed by Wang et al. (2019a), we record the performance of different situations and the best F1-score for each resource size are bolded. When training sets are reduced and test sets are kept, the missing information in removed sentences make all models produce worse results. However, for 50%-size, 25%-size and 10%-size datasets, our model can get an average of 0.56, 0.79 and 1.72 F1-score improvements over the BioBERT, which demonstrates our designed auxiliary tasks can regularize model to generate more robust token-level representations. For BC2GM, BC5CDR-chem and NCBI-disease in all data size, our model can get an average of 0.47, 0.95 and 1.26 improvements in F1-score, which the largest improvement is observed on NCBI-disease. The smaller the training set is the larger improvement could achived by our model. This finding proves our method is more effective in low-resource scenarios. Specifically, on 10%-size NCBI-disease, our model can get 3.29 F1-score improvements over the BioBERT.

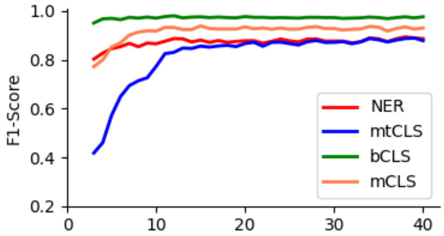
To prove that our joint training algorithm is effective, we plot the performance curve of different tasks, which can be found in Figure 4. Moreover, different task combinations can produce different results in multi-task learning. To measure the impact of our designed auxiliary tasks and training algorithm, we conducted ablation studies and showed in Table 4.



(a) BC2GM



(b) BC5CDR-chem



(c) NCBI-disease

Figure 4: Performance curves for different tasks of our proposed model. Where x-axis is the number of training epoch and y-axis is F1-score. During the model training process, the tasks complement each other and gradually converge.

From the results of the ablation experiment, removing the joint training algorithm leads to a consistent drop in the F1-scores. Compared with the results of Liu et al. (2019), Khan et al. (2020) and Peng et al. (2020), we point out that multi-task learning algorithms such as MT-DNN require a large amount of training data to achieve improvements. Furthermore, all of the auxiliary tasks are helpful to the main task but the impact of different tasks vary. Specifically, mtCLS is the best partner for BC2GM dataset and bCLS can bring the most improvement for BC5CDR-chem and NCBI-disease dataset. This phenomenon shows that different BioNER datasets have different recognition difficulties. For example, the recognition difficulty of BC2GM may mainly related to entity boundary problem, while the recognition difficulty of BC5CDR-chem and NCBI-disease is the entity sparsity problem. Therefore, for BC5CDR-chem and NCBI-disease, the model trends to incorrectly recognize entities in sentences that do not contain entities. This finding is consistent with our statistical results, where such cases are 2.38%, 2.71% and 2.87% on the three datasets, respectively. Compared to bCLS, mCLS is less helpful. This implies that the effect of auxiliary tasks in multi-task leaning is closely related to their performances. In fact, the classification performances of mCLS are lower than that of bCLS due to its higher difficulty.

4.4 Case study

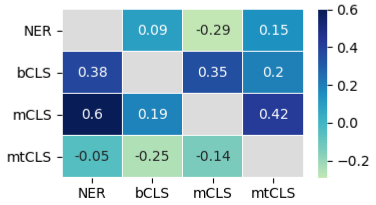
Table 5 shows the case study of three datasets. The BC2GM example showed the effect of bCLS task in that our model could correctly recognize the entity “TGF - beta1” while the BioBERT model fails. In the BC5CDR-chem example, the input sentence contains two entities “propofol” and “serotonin”, and the BioBERT model could only identify one of them, while our model could correctly recognize two entities by incorporating the mCLS task. For the NCBI-disease example, “congenital DM” is a multi-token entity and “DM” is a single-token entity. It could be found that without the help of the mtCLS task, the BioBERT model could not capture such difference and incorrectly recognized two “DM”. Overall, these examples confirm that supervised objectives at different granularities, i.e. global information and local information, can be combined to help producing better representations.

Although the case study show that our model with auxiliary tasks outperformed the BioBERT model, these tasks can not completely solve the above problems due to their coarser granularities. Take the bCLS task as an example, the model could noticed that current input sentence contains entities by sentence-level label, but still may trapped in the number of entities or entity boundary.

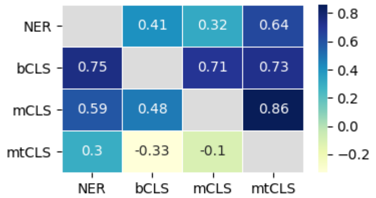
4.5 Impacts of the task relationship

In this subsection, we would like to preliminary study **the relationship between different tasks in the same domain**, such as the interaction between sentence-level tasks and token-level tasks, and whether or not tasks could help one other. Therefore, we conducted pair-wise comparison experiments, as shown in Figure 5, where x-axis is the secondary task and y-axis is the main task.

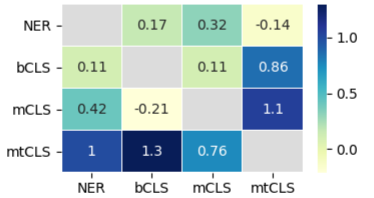
First, we point out the token-level labels are more helpful for the sentence-level tasks. For mCLS, it can get an average improvement of 0.79%, 0.54% and 0.15% on the three datasets by taking mtCLS, NER and bCLS as auxiliary tasks, respectively. Considering that mtCLS and NER are token-level tasks and bCLS is a sentence-level task,



(a) BC2GM



(b) BC5CDR-chem



(c) NCBI-disease

Figure 5: Results of the pair-wise experiments of our model on three datasets.

the results suggest that the coarse-grained tasks can significantly benefit from fine-grained tasks. This finding could be used to guide the choosing of the tasks for multi-task learning.

Second, the same granularity of information also contributes to each other. Concretely, bCLS and mCLS can get an average improvement of 0.39%, 0.15% from mCLS and bCLS, respectively. And mtCLS and NER can get an average improvement of 0.42%, 0.22% from NER and mtCLS, respectively. Meanwhile, the difficulty of task is also a factor that affects the effectiveness of multi-task learning, in that bCLS gets 0.24% more improvements compared to mCLS, and mtCLS gets 0.20% more improvements compared to BioNER.

In addition, the same task combinations performs differently on different datasets. For example, the combinations of mtCLS and mCLS got negative results of -0.25% and -0.33% on the BC2GM and BC5CDR-chem datasets, while achieved 1.3% boost on the NCBI-disease dataset. We guessed it may related to the transferability of specific dataset. So we visualized the task embedding of three datasets, which were generated with the method[5] proposed by Vu et al. (2020), using T-SNE (Belkina et al., 2019) dimension reduction algorithm and showed the results in Figure 6. From the visualization results, we found that the embedding distance between the same tasks (e.g., BC2GM-bCLS, BC5CDR-chem-bCLS, NCBI-disease-bCLS) or the same type of tasks is closer (e.g., NER and mtCLS, bCLS and mCLS). And the embedding distance between different types of tasks is farther (e.g., bCLS and NER), but more specific relations need further exploration.

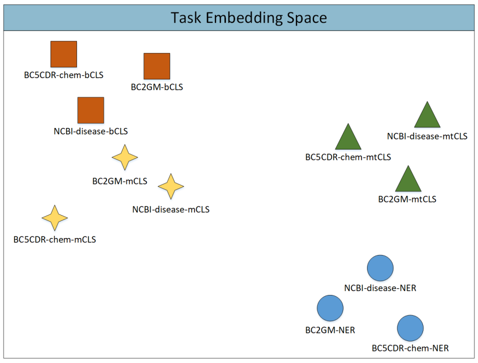


Figure 6: A 2D visualization of the tasks space.

5 Conclusion

In this work, we investigated whether coarse-grained label could benefit the token-level representation for BioNER. We had shown that the proposed BERT-based jointly sentence and token label model was valid without using external data and hand-crafted feature for BioNER in three datasets: BC2GM, BC5CDR-chem, NCBI-disease. Finally, we preliminary discussed the correlation between main task and auxiliary task.

For multi-task learning, describing and reasoning about the relations between tasks through experiments require an amount of computational resources. In future work, with domain related in mind, we will explore efficient methods for generating vectorial representations to measure the relationship between different NLP tasks.

Abstract

Pruning has been demonstrated as an effective way of reducing computational complexity for deep networks, especially CNNs for computer vision tasks. In this paper, we investigate the opportunity to accelerate the inference of large-scale pre-trained language model via pruning. We propose EBERT, a dynamic structured pruning algorithm for efficient BERT inference. Unlike previous methods that randomly prune the model weights for static inference, EBERT dynamically determines and prunes the unimportant heads in multi-head self-attention layers and the unimportant structured computations in feed-forward network for each input sample at run-time. Experimental results show that our proposed EBERT outperforms other state-of-the-art methods on different tasks.

1 Introduction

In the last few years, transformer-based (Vaswani et al., 2017) large-scale pre-trained language models, such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and GPT-3 (Brown et al., 2020), have achieved state-of-the-art results on many NLP tasks, including language understanding, question answering, and reading comprehension. Most recently, researchers also successfully applied transformer-based models to computer vision tasks, achieving comparable or superior performance compared to traditional convolutional networks. For example, Carion et al. (2020) propose detection transformer (DETR) for object detection, Dosovitskiy et al. (2021) design a transformer-based model, namely Vision Transformer (ViT), for image classification. However, due to the notable computational complexity and memory footprint, it is difficult for these models to deploy on hardware platforms under moderate computing and resource budget. Therefore, how to reduce model complexity to enable efficient inference for large-scale pre-trained language models is a critical issue.

Pruning is a commonly used technique for network compression, which has been widely explored to reduce computation and storage requirements of convolutional neural networks for computer vision tasks (Han et al., 2015, 2016; Li et al., 2016). However, *can transformer-based models benefit from pruning?* Michel et al. (2019) observe that a large percentage of attention heads can be removed with negligible performance drop, which indicates that the importance of different heads in same layer is different. Sanh et al. (2020) propose a simple, deterministic first-order weight pruning method which can prune lots of parameters with minimal accuracy loss. Although these methods are able to reduce the memory footprint, they cannot achieve real performance gain on general-purpose hardware, such as GPGPU, due to the unstructured sparsity after pruning.

Adaptive inference strategy is also proposed to accelerate the inference of BERT. It is based on two observations: 1) the input samples usually have different levels of difficulty. For a given model, it may over-calculate the simple samples while fail in complex samples (Liu et al., 2020); 2) similar to convolutional neural networks, the lower and higher layers of transformer extract different information, and features provided by the intermediate layers may be enough for some samples (Xin et al., 2020). FastBERT (Liu et al., 2020) and DeeBERT (Xin et al., 2020) are two state-of-the-art adaptive inference models for compressing BERT. Both of them insert extra classification layers between each layer of the network. During inference, each input sample only goes through part of model when the outputs of extra classifiers meet predefined criteria like entropy and uncertainty. Because the number of executed layers is reduced, real speedup can be achieved. However, skipping all the computations

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4814–4823
August 1–6, 2021.

of the remaining layers may be harmful to the accuracy.

In this paper, we propose EBERT, a hardware-friendly, simple yet effective algorithm that incorporates structured pruning with adaptive inference for efficient BERT inference. Specifically, EBERT inserts predictors for self-attention sub-layer and feed-forward sub-layer in each transformer block, as illustrated in Figure 1. During inference, the predictors dynamically determine which heads of self-attention layers and channels of feed-forward network can be pruned according to current input. Once a head or a channel is pruned, the corresponding computations and memory cost can be completely avoided. Compared with static pruning methods that permanently prune some parameters, it can avoid prune important parameters for current input samples which will cause large performance drop. To the best of our knowledge, it's the first time to apply dynamically structured pruning to BERT. Experimental results on different benchmark demonstrate that the proposed EBERT can achieve better trade-off between computation reduction and accuracy.

2 Related Work

Adaptive inference. As different input samples usually have different levels of difficulty, using fixed-size model to process all samples may be non-optimal in terms of computational efficiency. Therefore, the main goal of adaptive inference is to adaptively skip part of the computations according to each input sample to reduce complexity. FastBERT (Liu et al., 2020) adds student classifiers to the output of each transformer block and use self-distillation strategy to improve performance. The model architecture of DeeBERT (Xin et al., 2020) is similar to FastBERT, but it use entropy of output to decide whether to exit at early stages. PABEE (Zhou et al., 2020) proposes a novel early-exit criterion that dynamically stops forward computing when the output of internal classifiers keep unchanged for a pre-defined number of steps.

Pruning. Pruning is an intuitively simple yet effective technique for model compression, which removes unimportant computations based on certain criterion. Michel et al. (2019) observe that a large percentage of attention heads can be removed with negligible performance loss and propose a greedy pruning algorithm. Compressing BERT (Gordon et al., 2020) explores the effect of unstructured weight pruning with different levels of pruning and different training stages. McCarley et al. (2019) investigate the relationship between structured pruning and task-specific distillation. SNIP (Lin et al., 2020) proposes a structured pruning method to penalize an entire residual module in Transformer model toward an identity mapping.

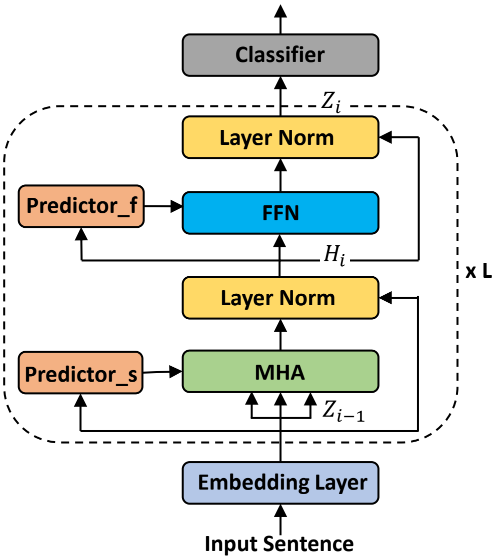

Figure 1: The overall architecture of EBERT. For each input sentence, the predictor dynamically determines which heads or channels can be pruned.

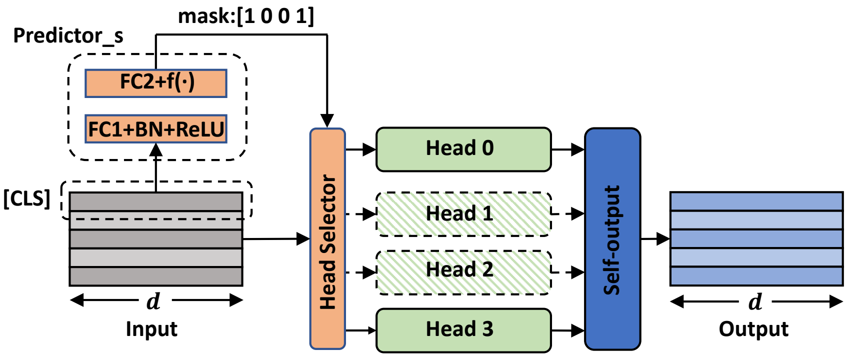
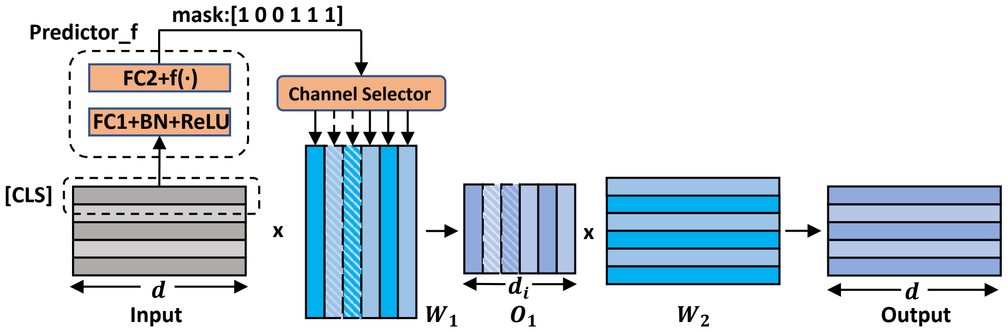
Distillation. Knowledge Distillation (Hinton et al., 2015) is an effective technique to get light models from heavy models without sacrificing too much performance. DistilBERT (Sanh et al., 2019) leverages knowledge distillation at pre-training phase to get a lighter pre-trained model, then directly fine-tunes on downstream tasks. BERT-PKD (Sun et al., 2019) proposes an incremental knowledge extraction process. Apart from learning from the final output of teacher model, student model also patiently learns from intermediate layers. TinyBERT (Jiao et al., 2020) performs distillation at both the pre-training and task-specific fine-tuning phase. Data augmentation is also used to improve the accuracy of student model.

3 Methods

In this section, we will first introduce the architecture of EBERT. As shown in Figure 1, it can be divided into BERT branch and predictor branch. Then we will describe the training and inference in details.



(a) Predictor_s in MHA.



(b) Predictor_f in FFN.

Figure 2: The details of predictors in MHA and FFN layer. Here we assume that $n = 4$, $h = 4$ and $d_i = 6$. Shadow area means that computations can be skipped.

3.1 BERT Branch

The architecture of BERT consists of three parts: the embedding layer, multi-layer bidirectional Transformer encoders and the task-specific classification layer. Given an input sentence $S = [s_0, s_1, ..., s_n]$ with length n, where s_0 is usually a special classification token $[CLS]$, the embedding layer will transform it to a sequence of vector representations:

$$E = Embedding(S), E \in R^{n \times d} \tag{1}$$

The Transformer encoder contains two sublayers: multi-head self-attention (MHA) layer and position-wise fully connected feed-forward network (FFN),

$$\begin{aligned} H_i &= LN(MHA(Z_{i-1}) + Z_{i-1}) \\ Z_i &= LN(FFN(H_i) + H_i) \end{aligned} \tag{2}$$

where $i = 1, 2, ..., L$ and $Z_0 = E$. LN is the Layer Normalization operation.

The final component of BERT is a task-specific classification layer. It accepts the representation to $[CLS]$ token as input to generate final results, as:

$$O = Classifier(Z_L[0, :]) \tag{3}$$

3.2 Predictor Branch

In order to prune unimportant heads and channels for individual input sentence, we add predictors for MHA and FFN in each layer, respectively. The predictor consists of two feed-forward layer, one batch normalization layer and a ReLU activation layer, as depicted in Figure 2. The output t of the second feed-forward layer will be transformed to a 0-1 mask by a function $f(\cdot)$:

$$\begin{aligned} t &= FC2(ReLU(BN(FC1(x)))) \\ m &= f(t), m \in \{0, 1\} \end{aligned} \tag{4}$$

where $x = Z[0, :]$. It means that the input of predictor is only $[CLS]$ representation. This choice is based on two reasons. 1) *Overhead.* Although using the whole representation of input sentence may improve the performance of predictors, the amount of computations increases linearly with the sentence length n. When n is large, the computational overhead of predictors can not be ignored. 2) *Representation ability.* Because the final hidden state to $[CLS]$ token in the last transformer block is used in task-specific classifier to generate classification results, we assume that $[CLS]$ representation encodes most of the useful information of the sentence. Note that the representation to $[CLS]$ token in the first MHA is independent with the input sentence, so we use average pooling of MHA as input.

Intuitively, t represents the probability of heads or channels being selected. In order to train the model end-to-end with back propagation, Gumbel-Softmax trick (Jang et al., 2017; Maddison et al., 2016) is adopted in our model. Given class probabilities $\pi_1, \pi_2, ...\pi_n$, discrete samples z can be drawn as:

$$z = one\_hot(\arg\max_i [g_i + log\pi_i]) \tag{5}$$

where g_i is a sample drawn from a Gumbel distribution. Gumbel-Softmax trick replaces $\arg\max$ operation with a softmax function, which is a continuous differentiable approximation to $\arg\max$:

$$y_i = \frac{exp((log(\pi_i) + g_i)/\tau}{\sum_{j=1}^{k} exp((log(\pi_j) + g_j)/\tau)} \tag{6}$$

As the value of mask m is binary (0 for prune and 1 for preserve), we can simplify the Gumbel-Softmax formulation (Verelst and Tuytelaars, 2020). For the output $t[i] \in (-\infty, \infty)$, we can convert it to probabilities π_1 and π_2 by using a sigmoid function σ:

$$\begin{aligned} \pi_1 &= \sigma(t[i]) \\ \pi_2 &= 1 - \sigma(t[i]) \end{aligned} \tag{7}$$

Substituting (7) into (6), we can get:

$$\begin{aligned} y_1 &= \sigma(\frac{t[i] + g_1 - g_2}{\tau}) \\ y_2 &= 1 - y_1 \end{aligned} \tag{8}$$

As $y_1 < y_2$ means the head or channel will be pruned, the final formulation is:

$$f(t[i]) = \begin{cases} 1, & if \quad y_1 > 0.5 \\ 0, & otherwise \end{cases} \tag{9}$$

3.3 Training

The entire training process can be divided into three stages: fine-tune the BERT branch, joint train both branches, and re-train the BERT branch.

Fine-tuning. In the first stage, only BERT branch is fine-tuned on downstream tasks with loss $\mathcal{L}_{task}$. The training strategy is the same as BERT in (Devlin et al., 2019).

Joint Training. In this stage, we jointly train the pre-trained BERT branch and randomly initialized predictor branch to make the average ratio of remaining Floating-point operations (FLOPs) reach a target value $C_t \in [0, 1]$. In order to achieve this goal, we add a loss to minimize the difference between real computational cost of the whole network and C_t:

$$\mathcal{L}_s = \left(\frac{F_c}{F_o} - C_t \right)^2 \tag{10}$$

Where F_o is the FLOPs of original network, and F_c is the average FLOPs of current model in a mini-batch.

In addition to the FLOPs constraint, we also add extra loss function to control the sparsity of each MHA and FFN, as in (11). The purpose is to avoid high sparsity of some layers that is harmful to the accuracy of the model.

$$\begin{aligned} \mathcal{L}_M &= \frac{1}{L} \sum_{l=0}^{L-1} \left(\frac{F_c^{lM}}{F_o^{lM}} - C_t \right)^2 \\ \mathcal{L}_F &= \frac{1}{L} \sum_{l=0}^{L-1} \left(\frac{F_c^{lF}}{F_o^{lF}} - C_t \right)^2 \end{aligned} \tag{11}$$

where F_c^{lM} and F_o^{lM} refer to the FLOPs of l-th MHA in current model and original model. The definition of F_c^{lF} and F_o^{lF} is similar. The final loss to be optimized is then given by

$$\mathcal{L} = \mathcal{L}_{task} + \lambda_1 \mathcal{L}_s + \lambda_2 (\mathcal{L}_M + \mathcal{L}_F) \tag{12}$$

where λ_1 and λ_2 control the magnitude of task and sparsity loss, respectively.

Re-training. As different input samples usually activate different parts of heads, the total update of a particular head is less than that of regular training process. As a result, the heads are probably not trained sufficiently. So do the channels in FFNs. Therefore, in this stage, we freeze the parameters of predictors and only re-train the BERT branch.

3.4 Inference

The computation flow during inference is shown in Figure 2. Given an input sequence, the predictor generates a mask by using the representation to $[CLS]$ token. For MHA, heads with mask '0' will not be executed. For FFN, as matrix-matrix multiplication can be transformed to multiple matrix-vector multiplications, we only need to complete part of computations where vector's mask is not zero.

BERT-base	L=12, h=12, d=768, $d_i = 3072$
Predictor_s	$768 \rightarrow 64 \rightarrow 12$
Predictor_f	$768 \rightarrow 64 \rightarrow 3072$

Table 1: The detailed setting of BERT and Predictors. RoBERTa is with the same setting.

Note that the exponential operation in (8) is typically expensive on hardware. Fortunately, this formulation can be simplified during inference by removing Gumbel noise. $f(\cdot)$ now can be rewritten as:

$$f(t[i]) = \begin{cases} 1, & if \quad t[i] > 0 \\ 0, & otherwise \end{cases} \tag{13}$$

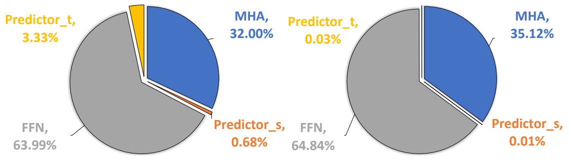
4 Experiments

4.1 Setup

Datasets and Metrics. To verify the effectiveness of EBERT, we conduct experiments on four classification tasks from GLUE benchmark (Wang et al., 2018): Multi-Genre Natural Language Inference Matched/Mismatched (MNLI-m/mm), Quora Question Pairs (QQP), Question Natural Language Inference (QNLI) and Stanford Sentiment Treebank (SST-2). We exclude other tasks as the results have large variance due to the number of training examples is very small (less than 9k). MNLI-m/mm, SST-2 and QNLI use accuracy as metric, while the average of F1 and accuracy is used for QQP.

Furthermore, we also conduct experiments on SQuAD1.1 (Rajpurkar et al., 2016) and SQuAD2.0 (Rajpurkar et al., 2018), both of which are large-scale reading comprehension datasets. SQuAD1.1 consists of more than 100k questions, and the answer to each question is a segment of text from the corresponding reading passage. SQuAD2.0 is more difficult as it contains over 50k unanswerable questions. We mainly report Exact Match (EM) and F1 scores.

Implementation details. We apply the proposed methods to both BERT-base and RoBERTa-base, and implement them with the HuggingFace Transformers Library (Wolf et al., 2020). The detailed setting of BERT and predictors is shown in Table 1. Figure 3 shows the ratio of FLOPs and parameters of each operation in one encoder. We can find that the extra cost of the predictors is very small. All experiments are completed on a single Nvidia GeForce RTX2080Ti GPU.



(a) #Params (b) #FLOPs

Figure 3: The ratio of FLOPs and parameters of each operation in one encoder.

For the GLUE benchmark, we set batch size to 32, learning rate to 3e-5, training epochs to 3 while other hyperparameters are kept unchanged from the library for all downstream tasks at backbone fine-tune stage. During joint training, we use $\lambda_1 = 4, \lambda_2 = 20$ for BERT while $\lambda_1 = 2, \lambda_2 = 10$ for RoBERTa. The learning rate for predictors' parameters is 0.02 and 0.01, respectively. The hyperparameters in the third stage is the same as the first stage.

For SQuAD1.1 and SQuAD2.0, the batch size is 12, learning rate is 3e-5 and training epoch is 2. Other settings are consistent with those for BERT on GLUE benchmark.

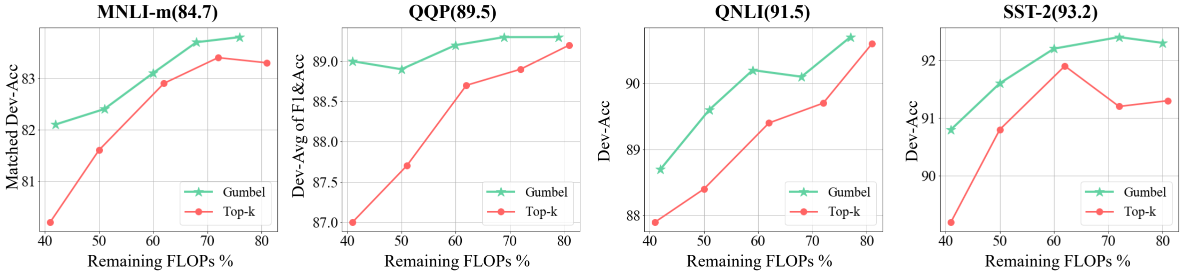
Baseline. In order to evaluate the effectiveness of EBERT, we implement a Top-k version of BERT that $f(\cdot)$ is as (14). We keep the sparsity of each layer the same, so the value of k can be decided by C_t. What's more, for a certain k, the sparsity is a fixed value, so no extra loss need to be added. The training objective is just $\mathcal{L}_{task}$. The training methods is the same as EBERT with Gumbel-Softmax.

$$f(t[i], k) = \begin{cases} 1, & if \quad t[i] \in topk(t) \\ 0, & otherwise. \end{cases} \tag{14}$$

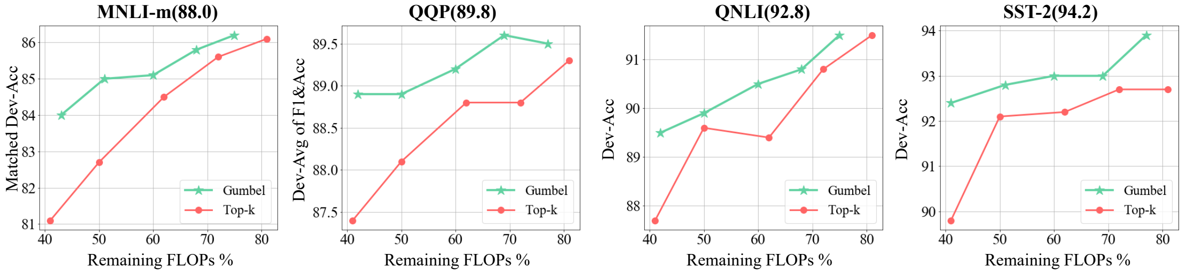
For convenience, in the following sections we will use the subscript t to represent Top-k version and use subscript g for Gumbel-Softmax version.

4.2 Results on the GLUE benchmark

The main results of our proposed method on the development set of GLUE benchmark are shown in Figure 4. For BERT-base, the results of Gumbel-Softmax is always better than Top-k with the same or even smaller ratio of remaining FLOPs on four tasks. For example, when remaining 50% FLOPs, EBERT_g only drops 0.6% on QQP task, while EBERT_t drops 1.8%. On the MNLI task, EBERT_g's accuracy with 77% remaining FLOPs is higher than the accuracy of EBERT_t with 81% remaining FLOPs.



(a) BERT-base



(b) RoBERTa-base

Figure 4: Results on the development set of GLUE benchmark.

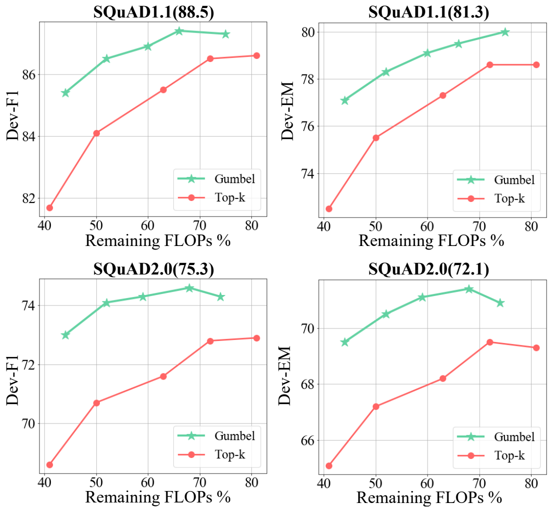


Figure 5: Results on the development set of SQuAD benchmark.

Figure 4(b) shows the performance of ERoBERTa, and we can find the similar result, *e.g.* with 50% remaining FLOPs, the performance of ERoBERTa$_g$ is 2.3% higher than ERoBERTa$_t$ on the MNLI task. This proves the generality of our proposed method to different model.

4.3 Results on the SQuAD benchmark

To further demonstrate the generality of our method, we conduct experiments on the SQuAD v1.1 and v2.0 benchmark, which are reading comprehension task that the model need to predict the answer text span in the text for a given question. The results are shown in Figure 5. Similar to the observation in Figure 4, our approach achieves consistent improvement on each ratio of remaining FLOPs compared with the Top-k version. For instance, with 50% remaining FLOPs, EBERT$_g$ improves the EM and F1 score by 2.8% and 2.4% on SQuAD v1.1, respectively. On SQuAD v2.0, the improvement of EM and F1 score is 3.3% and 3.4%.

4.4 Comparison with Other Methods

We compare our proposed EBERT with other state-of-the-art compression methods. For distillation methods, we compare with DistilBERT (Sanh et al., 2019), BERT-PKD(Sun et al., 2019) and BERT-of-Theseus (Xu et al., 2020). For pruning, we compare with SNIP (Lin et al., 2020). We also compare with other two dynamic methods: DeeBERT (Xin et al., 2020) and PABEE (Zhou et al., 2020). We do not compare with FastBERT (Liu et al., 2020) as they don't report results on the GLUE and SQuAD benchmark.

Note that other works don't report the FLOPs. However, as all of these methods try to reduce computational cost by reducing the number of layers dynamically or statically, it is reasonable to get FLOPs from speedup ratio or compression ratio under the assumption that the FLOPs is proportional to the execution time for a specific layer. For example, as the DistilBERT-6L only has half number of layers of BERT-base, we assume the ratio of remaining FLOPs is 50%.

	MNLI-m		SST-2		QQP		QNLI	
	Acc.	RF%.	Acc.	RF%.	F1/Acc.	RF%.	Acc.	RF%.
dev set

EBERT$_g$	82.4	50	92.8	50	70.1/88.8	50	89.2	50
	83.3	60	**93.4**	60	70.0/88.8	59	**89.6**	59

Table 2: Comparison with other compressed methods on the development and test set of MNLI, SST-2, QQP and QNLI. RF means the ratio of remaining FLOPs.

Table 2 lists the results on both development set and test set. The results on test set are provided by the GLUE evaluation server. Compared with other methods, our approach retains competitive performance with less FLOPs. For instance, our approach achieves the accuracy of 92.2% on SST-2 with 60% remaining FLOPs. On the test set of MNLI task, the accuracy of our method is 83.3% with only 60% remaining FLOPs, while DeeBERT' accuracy is 80.0% with 63% remaining FLOPs.

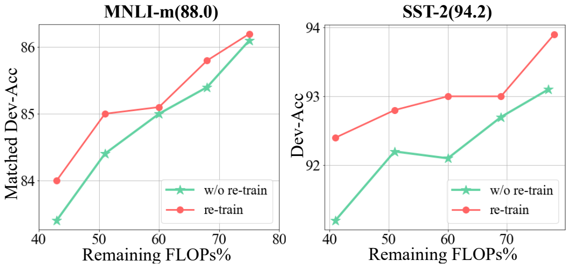

Figure 6: The effectiveness of re-training stage for RoBERTa on MNLI and SST-2.

4.5 Further Analysis

4.5.1 Impact of Re-training

The training process of EBERT contains three stages: fine-tuning, joint training and re-training. The purpose of re-training is to make each head and channel sufficiently trained. To evaluate the efficacy of this stage, we conduct experiments with RoBERTa on two tasks. Results are shown in Figure 6, we can see that the performance improvement is obvious. With 50% remaining FLOPs, the performance of the model is improved from 84.4% to 85.0% on MNLI and 92.2% to 92.8% on SST-2, respectively. The average performance improvement on MNLI and SST-2 is 0.4% and 0.8%, respectively. Comparing these two results, we find that the improvement is more obvious on small datasets. The reason for this phenomenon is that the parameters of the model are updated more frequently on large datasets, which makes the training of the model more sufficient at the joint training stage. As a result, re-training can be skipped for large datasets to make trade-offs.

4.5.2 Mask Distribution

Like in (Chen et al., 2019), we investigate the distribution of the learned masks. Although EBERT can dynamically generate mask for each head and channel for different samples, some masks may be constant of all time, which means that these masks are input-independent. Figure 8 is the layer-wise visualization of mask distribution in MHA and FFN on SST-2 task for masks that are 1) always one (on), 2) always zero (off), and 3) input-dependent. We can see that a large subset of the masks are input-dependent for both heads and channels, which indicates that our model learns to predict the im-

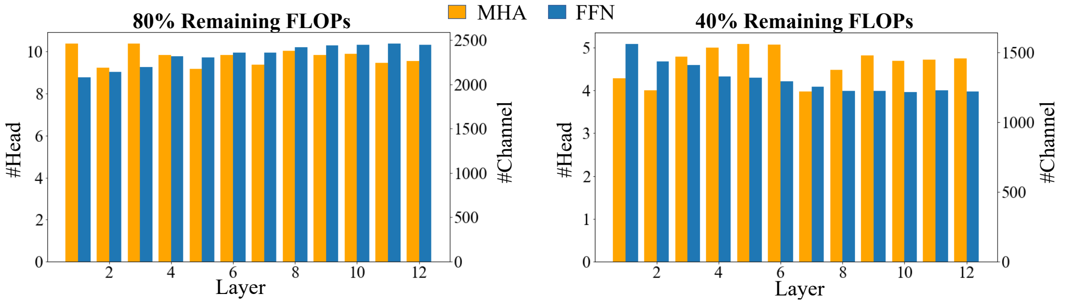

Figure 7: Average number of non-pruned heads of MHA and non-pruned channels of FFN by layer for RoBERTa-base with different remaining FLOPs on the SST-2 task.

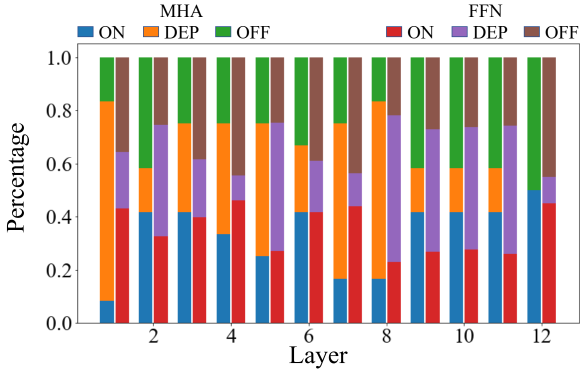

Figure 8: The distribution of masks in MHA and FFN for RoBERTa-base with 50% remaining FLOPs on SST-2 tasks. DEP refers to input-dependent.

portance of heads and channels for different input samples. For head, the proportion of masks that are input-dependent is higher in the shallow layers. For channel, the 2nd, 5th, 8th and 11th layer have higher proportion of input-dependent masks than other layers.

4.5.3 Layer Distribution

In Section 3.3, we add two extra loss $\mathcal{L}_M$ and $\mathcal{L}_F$ to prevent some layers from being too sparse. We conduct experiments on SST-2 task with RoBERTa to verify the effectiveness of these constraints. Figure 7 shows the average number of non-pruned heads of MHA and non-pruned channels of FFN with different ratio of remaining FLOPs. We can see that the number in each layer is quite close, which indicates the average amount of calculations is similar. More importantly, this value is near the target C_t. For example, when remaining 80% FLOPs, the number of non-pruned heads is around 9, which is exactly 80% of the number of heads in one MHA. Similarly, the number of non-pruned heads are around 4 and 5 when remaining 40% FLOPs. This phenomenon proves that $\mathcal{L}_M$ and $\mathcal{L}_F$ do limit the sparsity of each layer.

5 Conclusion and Future Works

In this paper, we propose a novel pruning method for efficient BERT inference, which is called EBERT. With the help of predictor branch, EBERT can dynamically prune unimportant heads in MHA and unimportant channels in FFN for each input sample at run-time. Compared with other compression methods, experiments on GLUE and SQuAD benchmarks demonstrate that EBERT can achieve better accuracy-efficiency trade-off.

As we talk about in Section 4.1, the performance of our method on small dataset has large variance. Similar observations also have been mentioned in other works (e.g. SNIP). In order to improve the generality of our method, it would be interesting to find out the exact reason and find the corresponding solution.

Abstract

How to combine several pieces of evidence to verify a claim is an interesting semantic task. Very complex methods have been proposed, combining different evidence vectors using an evidence interaction graph. In this paper, we show that in case of inference based on transformer models, two effective approaches use either (i) a simple application of max pooling over the Transformer evidence vectors; or (ii) computing a weighted sum of the evidence vectors. Our experiments on the FEVER claim verification task show that the methods above achieve the state of the art, constituting strong baseline for much more computationally complex methods.

1 Introduction

Automatic Fact Checking is quickly gaining attention of the NLP and AI communities. The FEVER.ai Fact Extraction and Verification Shared Task (Thorne et al., 2018) provides a benchmark for evaluating fact-checking systems. In FEVER, given a claim, C, and a collection of approximately five million Wikipedia pages, W, the task is to predict whether C is *supported* (`SUP`) or *refuted* (`REF`) by W, or whether there is *not enough information* (`NEI`) in W to support or refute C. If C is classified as `SUP` or `REF`, the respective evidence should be provided. Tab. 1 shows a FEVER claim and the gold-standard evidence refuting it.

Claim	**Evidence**
Coeliac disease is not treated by maintaining a gluten-free diet. (`REF`)	[(`Coeliac_disease`, "The only known effective treatment is a strict lifelong gluten-free diet....")]

Table 1: FEVER data examples

The overall task is complex, as one needs to retrieve the documents that contain the evidence (*document retrieval*, *DocIR*), select relevant evidence (*evidence selection*, *ES*) and label the claim given the evidence (*evidence reasoning*, *ER*), which is the focus of our work. Formally, given a claim, C, and a list top K evidence sentences, $(E_1, ..., E_K)$, retrieved with *DocIR* and selected by *ES* respectively, the *ER* task is to predict the claim label (`SUP`/`REF`/`NEI`).

There can be multiple inter-dependent evidence sentences per claim, thus joint modeling them allows for taking multiple clues into account, thus intuitively improving system accuracy. Indeed, individual sentences may not constitute standalone evidence, but they can contain several clues, which, together, can support or refute the claim. For example, Sentence 8 of the `Gluten-free_diet` Wikipedia page, *"..gluten-free diet is demonstrated as an effective treatment, but several studies show that about 79 % ... an incomplete recovery of the small bowel..."*, which is not listed as ground truth evidence for the claim, still supports the `REF` signal.

Given the above intuition, recent state-of-the-art (SOTA) approaches (Zhou et al., 2019; Ye et al., 2020; Liu et al., 2020; Zhong et al., 2020; Zhao et al., 2020) combine different pieces of evidence with graph networks, also increasing computational and space complexity. In this paper, we show that simple joint transformer-based methods achieve better performance than the best complex systems. Specifically, we (i) text-*concatenate* evidence sentences, (ii) apply *max pooling* to their individual embedding representation, or (iii) compute their *weighted sum*. Since June 1^{st} 2021, our baseline is sixth in terms of Label Accuracy (LA) and seventh in terms of FEVER score on the official task leaderboard[1], where the absolute difference from the fourth top LA is 0.2%.

We believe our results are important to enable

researchers to select the right scientific challenge, providing the appropriate baselines. For example, proposing complex models that are less accurate than our baselines can most likely mislead the research community, thus knowing our baselines can help to lead research in this area in the right directions. Additionally, our baselines are strong, simple to use, and easily reproducible, enabling fast comparison with innovative inference models.

2 Related work

SOTA approaches. Most recent approaches encode claim and evidence texts using Transformer-based language representation models (LRM), such as BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), and others. **GEAR** (Zhou et al., 2019) and **KGAT** (Liu et al., 2020) construct graphs with evidences as nodes and use deep graph neural ER networks to propagate knowledge; **DREAM** (Zhong et al., 2020) reasons on a graph built on top of a semantic role labeler output; **Transformer-XH** (Zhao et al., 2020) propagates knowledge between `[CLS]` tokens of different evidence pieces; **CorefBERT** (Ye et al., 2020) trains a BERT-based LRM, which employs an additional objective modeling coreference knowledge, and use it within KGAT architecture. The winners of the original FEVER competition (Nie et al., 2019) used older LRMs and a modified enhanced sequential inference model (ESIM) (Chen et al., 2017) to do ER.

The top-scoring *published* approach, **DOMLIN++** (Stammbach and Ash, 2020), simply text-concatenates evidence pieces and uses a RoBERTa-based classifier, thus supporting our thesis that simple models can be very effective. On the other hand, they use additional DocIR components and data (MultiNLI (Williams et al., 2018) corpus) for fine-tuning. To the best of our knowledge, their code/output are not available online yet[2], so we cannot compare to them directly at the moment.

Baselines. The baselines in the above works, apart from the previous SOTA systems, consist in applying a transformer-based classifier to (i) *concatenation* of C and all E_i, $i = 1..K$ (Zhou et al., 2019; Zhong et al., 2020; Zhao et al., 2020); or (ii) *separate* (C, E_i) pairs, $i = 1..K$, and aggregating the results heuristically (Zhou et al., 2019). The latter also considered *max-pooling* and *weighted-sum* baselines, but used them only on subsets of the development set with multiple gold evidence pieces per claim. In this work, we use them in the full-scale setting.

3 Strong baseline models

BERT for classification. BERT LRM and its version with the improved training procedure, RoBERTa, have obtained outstanding results on a number of NLP tasks. When using BERT-based architectures for classification, a special `[CLS]`[3] token is prepended to an input text sequence. Its embedding from the last layer of the transformer, $h^{[CLS]} \in \mathbb{R}^{h_{dim}}$ is a vector representation of the sequence. h_{dim} is the hidden dimension size. The final prediction is $p = softmax(L)$, where $L = Wh^{[CLS]} \in \mathbb{R}^N$, $W \in \mathbb{R}^{N \times h_{dim}}$, and N is the number of classes[4].

Baseline approaches. We investigate four simple Transformer-based baseline approaches: **Local**, **Concat**, **MaxPool**, **WgtSum**.

The input to the task are a claim, C, and a list of top K evidence sentences selected by an ES component, $E = \{E_i\}$, $i = 1, .., K$. Tab. 2 describes the input format. Following Liu et al. (2020), we incorporate E_i source page name into the input. We use cross-entropy loss to train all the models.

Local: for each E_i, we (i) use the standard 3-way classification Transformer-based model, T_{class}, to get an evidence-level label prediction, P_i, along with its corresponding $l_i = max(L_i)$ score, where $L_i \in \mathbb{R}^N$ is the logits vector produced by T_{class} for E_i; (ii) sort the predictions list, $P = [(P_i, l_i)]$, on l in the reverse order; (iii) create P', a sublist of P, where P_i is not `NEI` and $l_i > 0$. If P' is not empty, P'_1 is the claim label, otherwise it is `NEI`. We introduce P', because we want to capture the `SUP`/`REF` signal even if it is weaker compared to that of `NEI`.

Concat: T_{class} run on the input described in Tab. 2. **Local** and **Concat** are similar to the Bert-pair and Bert-Concat baselines, respectively introduced in (Zhou et al., 2019).

MaxPool: encodes each (C, E_i) pair with a transformer model, concatenates the resulting $h_i^{[CLS]}$ into a matrix $H^{[CLS]} \in \mathbb{R}^{h_{dim} \times K}$ and max-pools it, column-wise, into $h_{mp}^{[CLS]} \in \mathbb{R}^{h_{dim}}$. The output

---

[2] We could try to re-implement their pipeline following the high-level descriptions in their paper, however, our re-implementation still will not be able to re-produce their ER input due to the inevitable implementation differences

[3] This is standard for BERT, other language models can use a different token in a different position

[4] This strategy is employed by BERT. Practical implementations of the other models can also apply more transformations to $h^{[CLS]}$ to obtain L.

Baseline	**Input type example**
Local, **MaxPool**, **WgtSum**	`[CLS]` C `[SEP]` E_i^{page} `<psep>` E_i `[SEP]`
Concat	`[CLS]` C `[SEP]` E_1^{page} `<psep>` E_1 `[SEP]` ... `[SEP]` E_K^{page} `<psep>` E_K `[SEP]`

Table 2: Input data for the baselines. E_i^{page} is the name of the E_i source Wikipedia page. `[SEP]` and `[CLS]` are the standard "separator" and "classification" tokens used in BERT-like models. `<psep>` is delimiter separating page name from the evidence text. We use "`. `", while Liu et al. (2020) use `[SEP]`

is $p = softmax(W_{mp} h_{mp}^{[CLS]})$, $W_{mp} \in \mathbb{R}^{3 \times h_{dim}}$. It is inspired by the max pooling evidence aggregation procedure employed by (Hanselowski et al., 2018; Zhou et al., 2019).

WgtSum: encodes each (C, E_i) pair with a transformer, computes the weighted sum $h_{ws}^{[CLS]} = \sum_{i=1}^{K} \alpha_i h_i^{[CLS]} \in \mathbb{R}^{h_{dim}}$, $\alpha_i = softmax_i(W_{ws} h_i^{[CLS]})$, $W_{ws} \in \mathbb{R}^{1 \times h_{dim}}$. The weight α_i is intended to reflect the relative importance of E_i. The output is $p = softmax(W h_{ws}^{[CLS]})$, $W \in \mathbb{R}^{3 \times h_{dim}}$. **WgtSum** is similar to the Zhou et al. (2019)'s attention baseline in the sense that we aggregate pieces of evidence representations via a weighted summation. However, differently from us, they obtain the weights by computing attention between the claim and the evidence hidden states. We refer to **Concat**, **MaxPool** and **WgtSum** as *global* systems.

4 Experiments

Implementation. Our system is an AllenNLP pipeline (Gardner et al., 2017). Our code is available at `https://github.com/iKernels/reasoning-baselines`. We use the pre-trained BERT and RoBERTa LRMs from the *transformers*[5] library, namely *bert-base-cased*, *roberta-base* and *roberta-large*.

Training setup. We train for three epochs, with an evaluation checkpoint every 500 and 2500 training steps for global and local models correspondingly, thus having 14 checkpoints in total. We use $K = 5$ evidence pieces per claim. For all the models the batch size/number of gradient accumulation steps are 8/8 and 2/32 with base and large LRMs, respectively. We use Adam optimizer with slanted triangular learning rate (Howard and Ruder, 2018), $cut\_frac = 0.1$, ratio of 32[6].

When experimenting with *roberta-base* we tried learning rates [1e-5; 5e-5] with the step of 1e-5 and observed no noticeable difference between the rates in the range [2e-5; 5e-5]. Additional details are available in the appendix.

Split	**#SUP**	**#REF**	**#NEI**
TRAIN	80,035	29,775	35,639
DEV	6,666	6,666	6,666
TEST	6,666	6,666	6,666

Table 3: FEVER dataset statistics. # denotes the number of claims in a given class.

FEVER metrics. The primary shared task metric is FEVER[7]. It takes the correctness of the evidence set provided with the claim label[8] into account. The evidence set must contain all sentences belonging to at least one evidence[9] associated with a claim. No evidence is needed for `NEI` claims. *Label Accuracy (LA)* is another standard metric. *Oracle FEVER (OFEVER)* is the FEVER metric computed using oracle downstream components after DocIR or ES, i.e., it estimates downstream component's upper bound performance.

4.1 The dataset

We conduct our experiments on the official FEVER 1.0 Shared Task dataset[10]. Tab. 3 reports the FEVER 1.0 statistics. Verifiable (`SUP` or `REF`) claims are associated with at least one evidence. 35.23% of verifiable claims in DEV are associated with multiple evidence sentences, independent or inter-dependent.

Evidence Reasoning (ER) dataset. We run the ER experiments on the evidence sentences retrieved by Liu et al. (2020), published on their github[11] with ES OFEVER score of 96.25. Their *DocIR* module retrieves documents for a given claim via entity linking following (Hanselowski et al., 2018), and the ES module selects relevant evidence (*ES*) via BERT-based system with pairwise loss.

Following (Liu et al., 2020), when training and selecting the best checkpoint we use gold evidence completed with the non-gold evidence pieces retrieved by ES, so that the total amount of evidence pieces per claim is K. When evaluating on DEV we simply use top 5 evidence pieces retrieved by ES, i.e. the results in Sec. 4.2 are obtained on the

real-life gold standard-agnostic output of the *DocIR* and *ES* modules.

Note that by construction, we generate one train/test instance per each (C, E_i) pair when training/testing **Local** models and then aggregate the labels predicted for different evidence pieces, i.e the total amount of instances is around number of claims times K[12]. For example, we train **Local** on 722K examples, split into 548K `NEI`, 127K `SUP`, 48K `REF`. When training/testing **Concat**, **WgtSum** and **MaxPool**, we generate one instance per each claim.

4.2 Results

Tab. 4 reports the performance of the systems described in Sec. 3 on the official DEV set.

In previous work, systems employing KGAT ER architecture (Liu et al., 2020; Ye et al., 2020) achieve top performance in terms of FEVER. KGAT ER input data are publicly available enabling us to conduct fair comparison. Lines 1 and 2 report KGAT performance as in (Liu et al., 2020). We integrated their implementation of the KGAT ER component into our pipeline and obtained performance numbers comparable to those published (lines 3, 1). Interestingly, our runs with *roberta-base* outperform the published results of KGAT runs with *roberta-large* (lines 4, 6, 9). We also include its best result (that is an upperbound of KGAT) with *roberta-base* that we obtained with the learning rate of 3e-5. KGAT with *roberta-large* and learning rate of 2e-5 further pushes the performance 1 point up, while the training with the learning rates of 3e-5 and 5e-5 did not converge.

Local models. Lines 10-13 report performance of our local models with two evidence label aggregation heuristics. Heuristic 1 consists in applying the procedure described in Sec. 3 to the labels assigned to all evidence pieces by **Local**. Heuristic 2 is to simply pick the label assigned to the evidence sentence *top-ranked* by ES as in (Zhou et al., 2019). The aggregation heuristic 1 is more competitive.

Global models. Lines 14-22 report performance of the **Concat**, **WgtSum**, **MaxPool** global systems, which all clearly outperform **Local**. Note, that in the **Concat** setting C and E_i, $i = 1, .., K$, are concatenated, thus it is sensitive to the relative E_i order. Overall, all three models perform comparably between each other and to **KGAT** (lines 14-22 vs 5-7). **MaxPool** and **WgtSum** marginally outperform **Concat** with *roberta-large*.

We also trained **Concat** with *roberta-large* setting *K=1* both for training and predicting, i.e., using only top evidence piece retrieved by ES. The resulting LA of 79.57 is only approximately one point behind that of **Concat** (Line 16) and **KGAT** (Line 7). This suggests that good performance can be obtained on the FEVER dataset even without joint reasoning over multiple E_i-s, and that there is still room for further improvement for the systems able to reason upon multiple evidence pieces. Also this could be partially attributed to the observation by Schuster et al. (2019) who showed that FEVER claims contain certain linguistic biases and BERT model fine-tuned on the claim texts only significantly outperforms the majority baseline. Schuster et al. (2019) proposed a debiased symmetric test set, but its instances are claim-evidence pairs. This means that $K = 1$, and thus we did not evaluate our baselines on it as with $K = 1$ they all become equivalent to **Local**.

Comparison to the state of the art. Tab. 5 compares the performance of **MaxPool** and **WgtSum** to that of the SOTA systems as of June 1st, 2021. Our simple baselines outperform all the other systems on DEV, but we may have overfitted on it, as we report the performance of the best checkpoint.

---

[12] It can be less, as for some claims fewer evidence pieces were retrieved.

Table 5: FEVER state of the art. We mark results outperforming us with *underscore*. We mark the systems using exactly the same input to the ER component as us with *.

On the blind TEST data, **WgtSum** with *roberta-large* scores seventh in terms of FEVER and sixth in terms of LA on the official Codalab leaderboard.

Despite our best efforts, we were not able to track the publications related to the leaderboard submissions #1-#6. We do not know whether their superior performance is due to a better ER approach, a stronger LRM with billions of parameters, or to a better *DocIR/ES*. In the latter two cases, the baselines in this work still remain relevant.

The best-performing system with *published description*, DOMLIN++, uses *roberta-large* and the **Concat** approach. We cannot compare the results of our ER model directly, since they use a different ES system which might have better evidence recall. Note that we still marginally outperform them in terms of LA. This may indicate that even though our gold evidence recall may be lower due to a possibly less powerful DocIR/ES pipeline (resulting in lower FEVER score), we are still able to predict a correct label given the evidence sentences we have at our disposition. Then, they do additional pre-training on MultiNLI, while we do not exploit any external corpora.

Qualitative analysis We compared the outputs of the **Concat**, **MaxPool**, **WgtSum** and **KGAT** systems. We analyzed 50 DEV set examples where only one out of four systems produced the correct label. We aimed to understand the reason behind the correct prediction, but we have not observed any patterns explaining why one system outperforms the others. The systems seem to be equivalent in their abilities.

When analyzing the **WgtSum** output, we observed that when summing the weighted distributed representations of evidence pieces retrieved by KGAT ES for a specific claim (see Sec. 3), it tends to assign higher weights to the evidence pieces which are correct according to the gold standard.

5 Conclusion

We have proposed lightweight strong baselines for the FEVER fact-checking task and showed that they can outperform heavier models on the official leaderboard with blind TEST set. In our future work, we plan to capitalize from our results to build systems that can effectively trade-off efficiency for accuracy.

Acknowledgments.

We thank the anonymous reviewers for their valuable comments.

A Learning rate selection.

When experimenting with *roberta-base* we tried learning rates (lr) [1e-5; 5e-5] with the step of 1e-5. Table 6 summarizes the results. The results obtained with the learning rates in range [2e-5; 5e-5] are very similar, so we used the learning rate of 2e-5 in the majority of our experiments in this paper.

B Model complexity.

Abstract

Table-to-text generation refers to generating a descriptive text from a key-value table. Traditional autoregressive methods, though can generate text with high fluency, suffer from *low coverage* and *poor faithfulness* problems. To mitigate these problems, we propose a novel **S**keleton-based two-stage method that combines both **A**utoregressive and **N**on-**A**utoregressive generation (**SANA**). Our approach includes: (1) skeleton generation with an autoregressive pointer network to select key tokens from the source table; (2) edit-based non-autoregressive generation model to produce texts via iterative insertion and deletion operations. By integrating hard constraints from the skeleton, the non-autoregressive model improves the generation's coverage over the source table and thus enhances its faithfulness. We conduct experiments on both the WikiPerson and WikiBio datasets. Experimental results demonstrate that our method outperforms the previous state-of-the-art methods in both automatic and human evaluation, especially on coverage and faithfulness. In particular, we achieve PARENT-T recall of 99.47 in WikiPerson, improving over the existing best results by more than 10 points.

1 Introduction

Table-to-text generation is a challenging task which aims at generating a descriptive text from a key-value table. There have been a broad range of applications in this field, such as the generation of weather forecast (Mei et al., 2016), sports news (Wiseman et al., 2017), biography (Lebret et al., 2016; Wang et al., 2018), etc. Figure 1 illustrates a typical input and output example of this task.

Previous methods (Liu et al., 2018; Nie et al., 2018; Bao et al., 2018) are usually trained in an end-to-end fashion with the encoder-decoder architecture (Bahdanau et al., 2015). Despite generating text with high fluency, their lack of control in the generation process leads to *poor faithfulness* and *low coverage*. As shown in Figure 1, the case of *poor faithfulness* hallucinates the occupation "singer" not entailed by the source table, and the case of *low coverage* misses the information of the place of birth. Even if trained with a cleaned dataset, end-to-end methods still encounter these problems as it is too complicated to learn the probability distribution under the table constraints (Parikh et al., 2020).

key	value
Name_ID	Thaila Ayala
Place of birth	Brazil
Date of birth	April 14 1986
Occupation	Actress , Model

Poor Faithfulness: Thaila Ayala (born April 14, 1986 in Brazil) is an actress , model and singer .

Low Coverage: Thaila Ayala (born April 14, 1986) is an actress and model .

Figure 1: An example of table-to-text generation. The case of *poor faithfulness* hallucinates content not entailed by the table (marked in red color). The case of *low coverage* misses the information of the person's birth place (marked in blue color).

To alleviate these problems, recent studies (Shao et al., 2019; Puduppully et al., 2019; Ma et al., 2019) propose two-stage methods to control the generation process. In the first stage, a pointer network selects the salient key-value pairs from the table and arranges them to form a content-plan. In the second stage, an autoregressive seq2seq model generates text conditioned on the content-plan. However, such methods can cause the following problems: (1) since the generated content-plan may contain errors, generating solely on the content-

plan leads to inconsistencies; (2) even if a perfect content-plan is provided, the autoregressive model used in the second stage is still prone to hallucinate unfaithful contents due to the well-known *exposure bias* (Wang and Sennrich, 2020) problem; (3) there is no guarantee that the selected key-value pairs can be described in the generated text. As a result, these methods still struggle to generate faithful and informative text.

In this paper, we propose a **S**keleton-based model that combines both **A**utoregressive and **N**on-**A**utoregressive generation (**SANA**). SANA divides table-to-text generation into two stages: *skeleton construction* and *surface realization*. At the stage of skeleton construction, an autoregressive pointer network selects tokens from the source table and composes them into a skeleton. We treat the skeleton as part of the final generated text. At the stage of surface realization, an edit-based non-autoregressive model expands the skeleton to a complete text via insertion and deletion operations. Compared with the autoregressive model, the edit-based model has the following advantages: (1) the model generates text conditioned on both the skeleton and the source table to alleviate the impact of incomplete skeleton; (2) the model accepts the skeleton as decoder input to strengthen the consistency between the source table and generated text; (3) the model generates texts with the hard constraints from the skeleton to improve the generation coverage over the source table. Therefore, SANA is capable of generating faithful and informative text.

The contributions of this work are as follows:

- We propose a skeleton based model **SANA** which explicitly models skeleton construction and surface realization. The separated stages helps the model better learn the correlation between the source table and reference.

- To make full use of the generated skeleton, we use a non-autoregressive model to generate text based on the skeleton. To the best of our knowledge, we are the first to introduce non-autoregressive model to table-to-text generation task.

- We conduct experiments on WikiPerson and WikiBio datasets. Both automatic and human evaluations show that our method outperforms previous state-of-the-art methods, especially on faithfulness and coverage. Specially, we obtain a near-optimal PARENT-T recall of 99.47 in the WikiPerson dataset.

2 Related Work

Table-to-text Generation Table-to-text generation has been widely studied for decades (Kukich, 1983; Goldberg et al., 1994; Reiter and Dale, 1997). Recent works that adopt end-to-end neural networks have achieve great success on this task (Mei et al., 2016; Lebret et al., 2016; Wiseman et al., 2017; Sha et al., 2018; Nema et al., 2018; Liu et al., 2018, 2019a). Despite generating fluent texts, these methods suffer from poor faithfulness and low coverage problems. Some works focus on generating faithful texts. For example, Tian et al. (2019) proposes a confident decoding technique that assigns a confidence score to each output token to control the decoding process. Filippova (2020) introduces a "hallucination knob" to reduce the amount of hallucinations in the generated text. However, these methods only focus on the faithfulness of the generated text, they struggle to cover most of the attributes in the source table.

Our work is inspired by the recently proposed two-stage method (Shao et al., 2019; Puduppully et al., 2019; Moryossef et al., 2019; Ma et al., 2019; Trisedya et al., 2020). They shows that table-to-text generation can benefit from separating the task into content planing and surface realization stages. Compared with these methods, SANA guarantee the information provided by the first stage can be preserved in the generated text, thus significantly improving the the coverage as well as the faithfulness of the generated text.

Non-autoregressive Generation Although autoregressive models have achieved remarkable success in natural language generation tasks, they are time-consuming and inflexible. To overcome these shortcomings, Gu et al. (2018) proposed the first non-autoregressive (NAR) model that can generate tokens simultaneously by discarding the generation history. However, since a source sequence may have different possible outputs, discarding the dependency of target tokens may cause the degradation in generation quality. This problem also known as the "multi-modality" problem (Gu et al., 2018). Recent NAR approaches alleviate this problem via partially parallel decoding (Stern et al., 2019; Sun et al., 2019) or iterative refinement (Lee et al., 2018; Ghazvininejad et al., 2019; Gu et al., 2019). Specially, Stern et al. (2019) performs partially parallel decoding through insertion operation. Gu et al. (2019) further incorporates deletion operation to perform iterative refinement process. These edit-based models not only close the gap with autoregressive models in translation task, but also makes generation flexible by allowing integrates with lexical constrains. However, the multi-modality problem still exists, making it difficult to apply NAR models to other generation tasks, such as table-to-text generation, story generation, etc. In this work, we use the skeleton as the initial input of our edit-based text generator. The skeleton can provide sufficient contexts to the text generator, thus significantly reducing the impact of multi-modality problem.

3 Methods

The task of table-to-text generation is to take a structured table T as input, and outputs a descriptive text $Y = \{y_1, y_2, ..., y_n\}$. Here, the table T can be formulated as a set of attributes $T = \{a_1, a_2, ..., a_m\}$, where each attribute is a key-value pair $a_i = \langle k_i, v_i \rangle$.

Figure 2 shows the overall framework of SANA. It contains two stages: skeleton construction and surface realization. At the stage of skeleton construction, we propose a Transformer-based (Vaswani et al., 2017) pointer network to select tokens from the table and compose them into a skeleton. At the stage of surface realization, we use an edit-based Transformer to expand the skeleton to a complete text via iterative insertion and deletion operations.

3.1 Stage 1: Skeleton Construction

3.1.1 Table Encoder

The source table is a set of attributes represented as key-value pairs $a_i = \langle k_i, v_i \rangle$. Here, the value of an attribute a_i is flattened as a token sequence $v_i = \{w_i^1, w_i^2, ..., w_i^l\}$, where w_i^j is the j-th token and l is the length of v_i. Following Lebret et al. (2016), we linearize the source table by representing each token w_i^j as a 4-tuple $(w_i^j, k_i, p_i^+, p_i^-)$, where p_i^+ and p_i^- are the positions of the token w_i^j counted from the beginning and the end of the value v_i, respectively. For example, the attribute of "⟨*Name_ID*, {*Thaila Ayala*}⟩" is represented as "(*Thaila*, *Name_ID*, 1, 2)" and "(*Ayala*, *Name_ID*, 2, 1)". In order to make the pointer network capable of selecting the special token $\langle EOS \rangle$[1], we add a special tuple $(\langle EOS \rangle, \langle EOS \rangle, 1, 1)$ at the end of the table.

To encode the source table, we first use a linear projection on the concatenation $\left[\boldsymbol{w}_i^j; \boldsymbol{k}_i; \boldsymbol{p}_i^+; \boldsymbol{p}_i^-\right]$ followed by an activation function:

$$\boldsymbol{f}_i^j = \mathrm{Relu}(\boldsymbol{W}_f[\boldsymbol{w}_i^j; \boldsymbol{k}_i; \boldsymbol{p}_{\boldsymbol{i}}^+; \boldsymbol{p}_{\boldsymbol{i}}^-] + \boldsymbol{b}_f) \quad (1)$$

where $\boldsymbol{W}_f$ and $\boldsymbol{b}_f$ are trainable parameters. Then we use the Transformer encoder to transform each $\boldsymbol{f}_i^j$ into a hidden vector and flatten the source table into a vector sequence $\boldsymbol{H} = \{\boldsymbol{h}_1, \boldsymbol{h}_2, ..., \boldsymbol{h}_l\}$.

3.1.2 Pointer Network

After encoding the source table, we use a pointer network to directly select tokens from the table and compose them into a skeleton. Our pointer network uses a standard Transformer decoder to represent the tokens selected at the previous steps. Let $\boldsymbol{r}_t$ denote the decoder hidden state of previous selected token $\hat{y}_t$. The pointer network predict the next token based on the attention scores, which are computed as follows:

$$\alpha_{ti} = \frac{e^{u(\boldsymbol{r}_t, \boldsymbol{h}_i)}}{\sum_{j=1}^{l} e^{u(\boldsymbol{r}_t, \boldsymbol{h}_j)}} \quad (2)$$

$$u(\boldsymbol{r}_t, \boldsymbol{h}_i) = \frac{(\boldsymbol{W}_q \boldsymbol{r}_t) \cdot (\boldsymbol{W}_k \boldsymbol{h}_i)}{\sqrt{d_r}} \quad (3)$$

where $\boldsymbol{W}_q$ and $\boldsymbol{W}_k$ are trainable parameters, d_r is the embedding dimension of $\boldsymbol{r}_t$. According to the calculated probability distribution $\boldsymbol{\alpha}$, we select token based on the following formula:

$$P_{copy}(w) = \sum_{w=w_i} \alpha_{ti} \quad (4)$$

$$\hat{y}_{t+1} = \arg\max_{w} P_{copy}(w) \quad (5)$$

where $\hat{y}_{t+1}$ represents the output at the next timestep, and $P_{copy}(w)$ represents the probability of copying token w from the source. There may be multiple identical tokens in the table, so we sum up the attention scores of their corresponding positions.

The pointer network needs target skeletons as supervision, which are not provided by the table-to-text datasets. In this paper, we obtain the skeleton by collecting tokens in both the table and description except the stop words. The token order in the skeleton remains the same as their relative positions in the description. More details are described in Appendix A.

---

[1] $\langle EOS \rangle$ denotes the end of the skeleton.

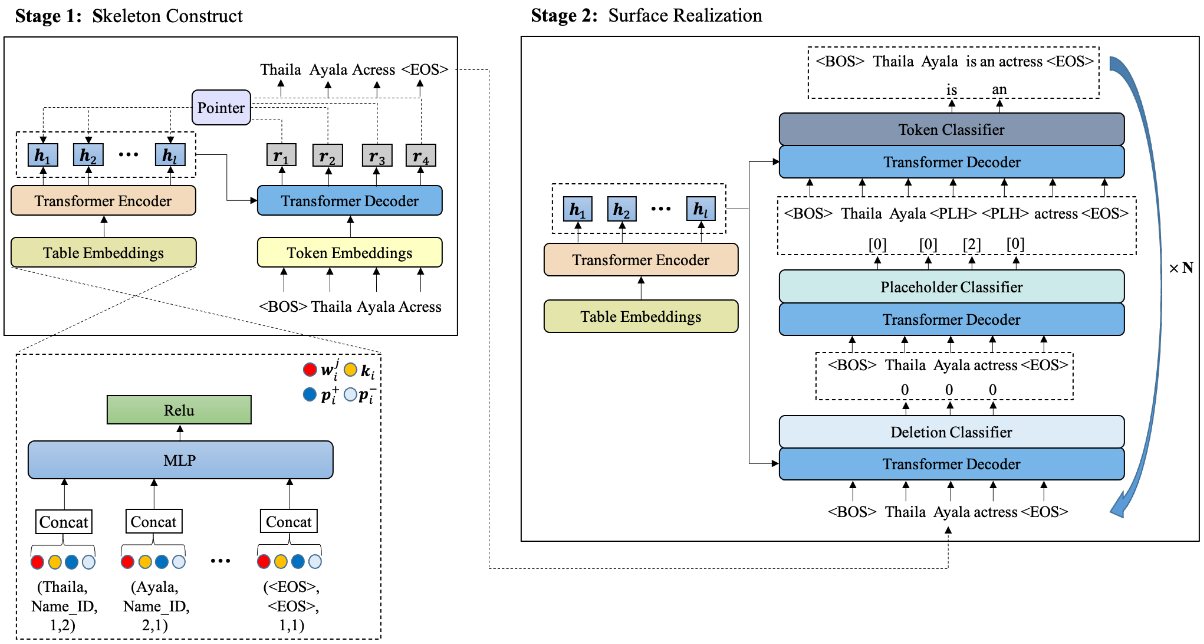

Figure 2: The overall diagram of SANA for generating description for *Thaila Ayala* in Fig 1.

Given the skeleton $S = \{s_1, s_2, ..., s_q\}$, the pointer network is trained to maximize the conditional log-likelihood:

$$\mathcal{L}_1 = -\sum_{t=1}^{q+1} \log P_{copy}(s_t | s_{0:t-1}, T), \quad (6)$$

where the special tokens $s_0 = \langle BOS \rangle$ and $s_{q+1} = \langle EOS \rangle$ denote the beginning and end of the target skeleton.

3.2 Stage 2: Surface Realization

At the surface realization stage, we use the same encoder as in the skeleton construction stage. The decoder is an edit-based Transformer decoder (Gu et al., 2019) that generates text via insertion and deletion operations. Different from the original Transformer decoder which predicts the next token in an left-to-right manner, the edit-based decoder can predict tokens simultaneously and independently. In this setting, we can use the full self-attention without causal masking.

3.2.1 Model Structure

To perform the insertion and deletion operations, we remove the softmax layer at the top of the Transformer decoder and add three operation classifiers: *Deletion Classifier*, *Placeholder Classifier* and *Token Classifier*. We denote the outputs of the Transformer decoder as $(\boldsymbol{z}_0, \boldsymbol{z}_1, ..., \boldsymbol{z}_n)$, details of these three classifiers are as follows:

1. *Deletion Classifier* which predicts for each token whether they should be "deleted"(1) or "kept"(0):

$$\pi_\theta^{\text{del}}(d|i, Y) = \text{softmax}(\boldsymbol{W}_{\text{del}} \boldsymbol{z}_i) \quad (7)$$

2. *Placeholder Classifier* which predicts the number of placeholders [PLH] to be inserted at each consecutive pair:

$$\pi_\theta^{\text{plh}}(p|i, Y) = \text{softmax}(\boldsymbol{W}_{\text{plh}}[\boldsymbol{z}_i; \boldsymbol{z}_{i+1}]) \quad (8)$$

3. *Token Classifier* which replaces each [PLH] with an actual token:

$$\pi_\theta^{\text{tok}}(t|i, Y) = \text{softmax}(\boldsymbol{W}_{\text{tok}} \boldsymbol{z}_i) \quad (9)$$

During decoding, we use the skeleton predicted from the first stage as the initial input of the decoder. We also use the full table information from encoder side to mitigate the impact of incomplete skeleton. As shown in Figure 2, the skeleton will pass through the three classifiers sequentially for several iterations. Benefiting from the full self-attention, each operation is allowed to condition on the entire skeleton, and thus reduces the probability of hallucinating unfaithful contents in the final text.

3.2.2 Training

Following Gu et al. (2019), we adopt imitation learning to train our model and simplify their training procedure. The iterative process of our model will produce various of *intermediate sequences*. To simulate the iterative process, we need to construct the intermediate sequence and provide an optimal operation $\boldsymbol{a}^*$ (either oracle insertion $\boldsymbol{p}^*$, $\boldsymbol{t}^*$ or oracle deletion $\boldsymbol{d}^*$) as the supervision signal during training. Given an intermediate sequence Y, the optimal operation $\boldsymbol{a}^*$ is computed as follows:

$$\boldsymbol{a}^* = \arg\min_{\boldsymbol{a}} \mathcal{D}(Y^*, \mathcal{E}(Y, \boldsymbol{a})) \qquad (10)$$

Here, $\mathcal{D}$ denotes the Levenshtein distance (Levenshtein, 1965) between two sequences, and $\mathcal{E}(Y, \boldsymbol{a})$ represents the output after performing operation $\boldsymbol{a}$ upon Y.

To improve the training efficiency, we construct the intermediate sequence via a simple yet effective way. Given a source table, skeleton and reference (T, S, Y^*), We first calculate the longest common subsequence X between S and Y^*, and then construct the intermediate sequence Y' by applying random deletion on Y^* except the part of X. We use Y' to learn the insertion and deletion operations. The learning objective of our model is computed as follows:

$$\mathcal{L}_{\text{edit}} = \mathcal{L}_{\text{ins}} + \lambda \mathcal{L}_{\text{del}} \qquad (11)$$

$$\begin{aligned} \mathcal{L}_{\text{ins}} = &- \sum_{p_i^* \in \boldsymbol{p}^*} \log \pi_\theta^{\text{plh}}(p_i^* | i, T, Y') \\ &- \sum_{t_i^* \in \boldsymbol{t}^*} \log \pi_\theta^{\text{tok}}(t_i^* | i, T, Y'') \end{aligned} \qquad (12)$$

$$\mathcal{L}_{\text{del}} = - \sum_{d_i^* \in \boldsymbol{d}^*} \log \pi_\theta^{\text{del}}(d_i^* | i, T, Y''') \qquad (13)$$

where Y'' is the output after inserting placeholders $\boldsymbol{p}*$ upon Y', Y''' is the output by applying the model's insertion policy π_θ^{tok} to Y''.[2] λ is the hyper parameter.[3]

3.2.3 Inference

As mentioned above, at the inference stage, we use the generated skeleton as the initial input of the decoder. The insertion and deletion operations will perform alternately for several iterations. We stop the decoding process when the current text does not change, or a maximum number of iterations has been reached.

In order to completely retain the skeleton in the generated text, we follow Susanto et al. (2020) to enforce hard constraints through forbidding the deletion operation on tokens in the skeleton. Specially, we compute a *constraint mask* to indicate the positions of constraint tokens in the sequence and forcefully set the deletion classifier prediction for these positions to "keep". The constraint masks are recomputed after each insertion and deletion operation.

4 Experiment Setups

4.1 Datasets

We conduct experiments on the **WikiBio** (Lebret et al., 2016) and **WikiPerson** (Wang et al., 2018) datasets. Both datasets aim to generate a biography from a Wikipedia table, but they have different characteristics. Their basic statistics are listed in Table 1.

Dataset	Train	Valid	Test	Avg Len
WikiBio	582,657	72,831	72,831	26.1
WikiPerson	250,186	30,487	29,982	70.6

Table 1: Statistics of WikiBio and WikiPerson datasets. **Avg Len** means the average target length of the datasets.

WikiBio This dataset aims to generate the first sentence of a biography from a table. It is a particularly noisy dataset which has 62% of the references containing extra information not entailed by the source table (Dhingra et al., 2019).

WikiPerson Different from the WikiBio whose reference only contains one sentence, the reference of WikiPerson contains multiple sentences to cover as many facts encoded in the source table as possible. In addition, WikiPerson uses heuristic rules to remove sentences containing entities that do not exist in the Wikipedia table, making it cleaner compared to the WikiBio dataset.

4.2 Evaluation Metrics

Automatic Metrics For automatic evaluation, we apply BLEU (Papineni et al., 2002) as well as PARENT (precision, recall, F1) (Dhingra et al., 2019) to evaluate our method. Different from BLEU which only compare the outputs with the references, PARENT evaluates the outputs that considers both the references and source tables. Following Wang et al. (2020), we further use their proposed PARENT-T metric to evaluate our method in WikiPerson dataset. PARENT-T is a variant of

---

[2] We do argmax from Equation (9) instead of sampling.

[3] In our experiment, $\lambda = 1$ gives a reasonable good result.

PARENT which only considers the correlation between the source tables and the outputs.

Human Evaluation Human ratings on the generated descriptions provide more reliable reflection of the model performance. Following Liu et al. (2019b), we conduct comprehensive human evaluation between our model and the baselines. The annotators are asked to evaluate from three perspectives: fluency, coverage (how much table content is recovered) and correctness (how much generated content is faithful to the source table). We hire 5 experienced human annotators with linguistic background. During the evaluation, 100 samples are randomly picked from the WikiPerson dataset. For each sample, an annotator is asked to score the descriptions generated by different models without knowing which model the given description is from. The scores are within the range of $[0, 4]$.

4.3 Implementation Details

We implement SANA using fairseq (Ott et al., 2019). The token vocabulary is limited to the 50K most common tokens in the training dataset. The dimensions of token embedding, key embedding, position embedding are set to 420, 80, 5 respectively. All Transformer components used in our methods adopt the base Transformer (Vaswani et al., 2017) setting with $d_{\text{model}} = 512, d_{\text{hidden}} = 2048, n_{\text{heads}} = 8, n_{\text{layers}} = 6$. All models are trained on 8 NVIDIA V100 Tensor Core GPUs.

For the skeleton construction model, the learning rate linearly warms up to 3e-4 within 4K steps, and then decays with the inverse square root scheduler. Training stops after 15 checkpoints without improvement according to the BLEU score. We set the beam size to 5 during inference.

For the surface realization model, the learning rate linearly warms up to 5e-4 within 10K steps, and then decays with the inverse square root scheduler. Training stops when the training steps reach 300K. We select the best checkpoint according to the validation BLEU.

4.4 Baselines

We compare SANA with two types of methods: end-to-end methods and two-stage methods.

For end-to-end methods, we select the following methods as baselines: (1) **DesKnow** (Wang et al., 2018), a seq2seq model with a table position self-attention to capture the inter-dependencies among related attributes; (2) **PtGen** (Pointer-Generator, See et al. (2017)), an LSTM-based seq2seq model with attention and copy mechanism; (3) **Struct-Aware** (Liu et al., 2018), a seq2seq model using a dual attention mechanism to consider both key and value information; (4) **OptimTrans** (Wang et al., 2020), a Transformer based model that incorporates optimal transport matching loss and embedding similarity loss. (5) **Conf-PtGen** (Tian et al., 2019), a pointer generator with a confidence decoding technique to improve generation faithfulness; (6) **S2S+FA+RL** (Liu et al., 2019b), a seq2seq model with a force attention mechanism and a reinforce learning training procedure; (7) **Bert-to-Bert** (Rothe et al., 2019), a Transformer encoder-decoder model where the encoder and decoder are both initialized with BERT (Devlin et al., 2019).

For two-stage methods, we select the following methods as baselines: (1) **Pivot** (Ma et al., 2019), a two stage method that first filter noisy attributes in the table via sequence labeling and then uses the Transformer to generate text based on the filter table; (2) **Content-Plan** (Puduppully et al., 2019), a two stage method that first uses a pointer network to select important attributes to form a content-plan and then uses a pointer generator to generate text based on the content-plan.

5 Results

5.1 Comparison with End-to-End Methods

We first compare SANA with end-to-end methods, Table 2 shows the experimental results. From Table 2, we can outline the following statements: (1) For WikiPerson dataset, SANA outperforms existing end-to-end methods in all of the automatic evaluation metrics, indicating high quality of the generated texts. Specially, we obtain a near-optimal PARENT-T recall of 99.47, which shows that our model has the ability to cover all the contents of the table. (2) For the noisy WikiBio dataset, SANA outperforms previous state-of-the-art models in almost all of the automatic evaluation scores except the PARENT precision, which confirms the robustness of our method. Although Conf-PtGen achieves the highest PARENT precision, its PARENT recall is significantly lower than any other method. Different from Conf-PGen, SANA achieves the highest recall while maintaining good precision. (3) It is necessary to prohibit deleting tokens in the skeleton. After removing this restriction (− *hard constrains*), our method has different degrees of decline in various automatic metrics. (4) SANA

Table 3: Comparison with two-stage methods. **P, R, F1** represent precision, recall and F1, respectively. "+ *Oracle*" means using oracle information (i.e., oracle skeleton or content-plan) as input.

performs poorly after removing the skeleton construction stage (− *skeleton*). This shows that the edit-based non-autoregressive model is difficult to directly apply to table-to-text generation tasks. The skeleton is very important for the edit-based model, which can significantly reduce the impact of the multi-modality problem. Combining both autoregressive and non-autoregressive generations, SANA achieves state-of-the-art performance.

5.2 Comparison with Two-Stage Methods

We further compare SANA with the two-stage methods. As shown in Table 3, there is an obvious margin between SANA and the two baselines, which shows that SANA can more effectively model the two-stage process. In order to prove that SANA can make use of the information provided by the first stage, we use the gold standard (i.e., the oracle skeleton or content-plan extracted from heuristics methods) as the input of the models used in the second stage. With this setup, SANA has made significant improvements in multiple automatic metrics while other methods have limited improvements. Specially, the improvements of Pivot are limited because its gold standard does not model the order of the attributes. Although the first stage of Content-Plan is similar to SANA, its PARENT scores (either precision, recall and F1) has not been obvious improved, especially on WikiPerson dataset. This shows that the edit-based decoder of SANA can make use of the oracle skeleton to produce high quality descriptions.

Model	**Fluency ↑**	**Coverage ↑**	**Correctness ↑**
Pivot	3.40	3.58	2.89
Content-Plan	3.39	3.70	2.98
Struct-Aware	3.31	3.60	2.94
DesKnow	3.45	3.42	3.07
SANA	**3.46**	**3.72**	**3.11**

Table 4: Human evaluation on WikiPerson for SANA and baselines. The scores (higher is better) are based on fluency, coverage and correctness, respectively.

5.3 Human Evaluation

We report the human evaluation result on the WikiPerson dataset in Table 4. From the demonstrated results, it can be found that SANA outperforms the other end-to-end or two-stage models on all the human evaluation metrics. This is consistent with our model's performance in the automatic evaluation. In the evaluation of fluency, though the

(1) Name_ID: William Edward Ayrton **(2) Place_of_burial**: Brompton Cemetery **(3) Place_of_birth**: London **(4) Educated_at**: University College London **(5) Date_of_birth**: 14 September 1847 **(6) Occupation**: Physicist **(7) Date_of_death**: 8 November 1908 **(8) Aware_received**: Fellow of the Royal Society **(9) Child**: Barbara Ayarton-Gould

Model	Miss	Output
DesKnow	**(9)**	William Edward Ayrton Fellow of the Royal Society (14 September 1847 – 8 November 1908) was a British Physicist . Brompton Cemetery he was born in London the son of Sir Thomas and his wife Mary (nee Fleming) . he was educated at University College School and University College London .
Struct-Aware	**(1) (2) (9)**	William Edward Keeler Fellow of the Royal Society (14 September 1847 – 8 November 1908) was a British Physicist and Physicist . he was elected a Fellow of the Royal Society in 1889 and was a member of the Royal Society of London and the Royal Society of London and the Royal Society of London . he was educated at the University College London and at the University College London where he was a pupil of the chemist William.
OptimTrans	**None**	William Edward Ayrton Fellow of the Royal Society (14 September 1847 – 8 November 1908) was an English Physicist . William was born in London and educated at University College London. he is buried in Brompton Cemetery London . he was elected a Fellow of the Royal Society in 1901. he was the father of Barbara Ayrton-Gould .
SANA	**None**	William Edward Ayrton Fellow of the Royal Society (14 September 1847 – 8 November 1908) was an English Physicist . he is buried in Brompton Cemetery London . he studied physics at University College London . Ayrton was born in London . he was the father of Barbara Ayrton-Gould.

Table 5: Example outputs from different methods. The red text stands for the hallucinated content in each generated description. Given the table, all the models **except SANA** generate unfaithful content to varying degrees. Meanwhile, both DesKnow and Struct-Aware miss some table facts, while SANA recovers them all.

models except for Struct-Aware reach similar performances, SANA performs the best, which demonstrates that its generation has fewer grammatical and semantic mistakes. In the evaluation coverage, SANA outperforms the Content-Plan model and defeats the other models by a large margin. This result is consistent with our proposal that SANA can cover sufficient information in the source table, and it can ensure the informativeness of generation. As to correctness, the advantage of SANA over the other models indicates that our model generates more faithful content and suffers less from the hallucination problem. It should be noted that although Content-Plan and DesKnow are on par with SANA on coverage and correctness respectively, they fail to perform well on both metrics in contrast with SANA. This indicates that our model generates both informative and faithful content.

5.4 Case Study

Table 5 shows the descriptions generated by different methods from the test set of WikiPerson.[4] DesKnow and Struct-Aware miss some attributes and hallucinate unfaithful contents (marked in red). Although OptimTrans achieves better coverage, it hallucinates the unfaithful content "in 1901" not entailed by the table. Compared to these methods, our method can cover all the attributes in the table and does not introduce any unfaithful contents. In addition, the generation length of SANA is shorter than Struct-Aware and OptimTrans, which shows that SANA can use more concise text to cover the facts of the table. These results indicate our method is capable of generating faithful and informative text. We put more generation examples in Appendix B.

6 Conclusion

In this paper, we focus on faithful and informative table-to-text generation. To this end, we propose a novel skeleton-based method that combines both autoregressive and non-autoregressive generations. The method divides table-to-text generation into skeleton construction and surface realization stages. The separated stages helps model better learn the correlation between the source table and reference. In the surface realization stage, we further introduce an edit-based non-autoregressive model to make full use of the skeleton. We conduct experiments on the WikiBio and WikiPerson datasets. Both automatic and human evaluations demonstrate the effectiveness of our method, especially on faithfulness and coverage.

---

[4] For fair comparison, we use the generation examples of baselines provided by Wang et al. (2020)

A Automatic Skeleton Annotation

Algorithm 1 describes the automatic skeleton annotation process. Given a table and its corresponding description, we first collect tokens appearing in both the table and description except the stop words, then these tokens are sorted based on their positions in the description in ascending order. In this way, we can obtain a sequence composed of the selected tokens. We regard this sequence as a skeleton.

B More Generation examples

We further provide a case study, using another two examples (including a very challenging example which needs to recover a large number of facts), to show the effectiveness of our method SANA. In the following pages, we show the example outputs in Table 6 and 7. In these examples, the SANA model shows much better capability of generating informative and faithful descriptions compared with the baselines.

Algorithm 1 Automatic Skeleton Annotation

```
Input: A stop word set $W$, a parallel dataset $D = \{(T_1, Y_1^*), (T_2, Y_2^*), ..., (T_{|D|}, Y_{|D|}^*)\}$;
Output: A skeleton list $S$;
Initial the skeleton list $S = []$
for $(T_i, Y_i^*) \in D$ do
    $T_i = ((k_1, v_1), (k_2, v_2), ..., (k_m, v_m))$
    $V_i = (v_1, v_2, ..., v_m)$
    $Y_i^* = (y_1^*, y_2^*, ..., y_n^*)$
    Initialize the skeleton list $S_i = []$
    for $y_j^* \in Y_i^*$ do
        if $y_j^* \in V_i$ and $y_j^* \notin W$ then
            Append token $y_j^*$ to the skeleton list $S_i$
        end if
    end for
    collect the skeleton list $S$ += $S_i$
end for
```

Abstract

Conventional autoregressive models have achieved great success in text generation but suffer from the exposure bias problem in that token sequences in the training and in the generation stages are mismatched. While generative adversarial networks (GANs) can remedy this problem, existing implementations of GANs directly on discrete outputs tend to be unstable and lack diversity. In this work, we propose **TILGAN**, a **T**ransformer-based **I**mplicit **L**atent **GAN**, which combines a Transformer autoencoder and GAN in the latent space with a novel design and distribution matching based on the Kullback-Leibler (KL) divergence. Specifically, to improve local and global coherence, we explicitly introduce a multi-scale discriminator to capture the semantic information at varying scales among the sequence of hidden representations encoded by Transformer. Moreover, the decoder is enhanced by an additional KL loss to be consistent with the latent-generator. Experimental results on three benchmark datasets demonstrate the validity and effectiveness of our model, by obtaining significant improvements and a better quality-diversity trade-off in automatic and human evaluation for both unconditional and conditional generation tasks.[1]

1 Introduction

In recent years, Transformer-based autoregressive (AR) models have made a dramatic impact in text generation tasks such as machine translation (Vaswani et al., 2017; Wang et al., 2019) and dialogue systems (Le et al., 2019; Ham et al., 2020), especially with the emergence of large pre-trained language models (Radford et al., 2019; Brown et al., 2020; Wu et al., 2020). However, AR models predict the next token conditioned on the ground truth during training and on its own previously generated token during inference, which leads to a mismatch between training and generation stages, and this causes low quality of generated texts and bad generalization ability of models on unseen data (Wiseman and Rush, 2016; Welleck et al., 2020).

Generative adversarial networks (GANs, Goodfellow et al., 2014) provide a promising approach to solve the exposure bias problem (Yu et al., 2017; Kusner and Hernández-Lobato, 2016; Zhang et al., 2017). This is because GANs aim at matching the distributions of the generated and real data instead of forcing the model output to align with the single correct sequence, and thus provide the potential to bypass the discrepancy issue. However, it is non-trivial to apply GANs to discrete data since the gradients cannot be normally back-propagated through discrete tokens. Existing approaches have implemented the adversarial discrete generation training by reinforcement learning (RL) (Yu et al., 2017; Lin et al., 2017; Guo et al., 2018; Fedus et al., 2018) and Gumbel-Softmax (Kusner and Hernández-Lobato, 2016). Nevertheless, these approaches suffer from the high variance problem which causes unstable performance and slow convergence, leading to other methods based on feature matching (Zhang et al., 2017; Zhao et al., 2018; Chen et al., 2018).

In this work, we propose **TILGAN**, a **T**ransformer-based **I**mplicit **L**atent **GAN**, which combines a Transformer autoencoder and a GAN in the latent space with novel designs and a learning formulation based on the Kullback-Leibler (KL) divergence to enhance the text generation performance in both fidelity and diversity. Specifically, inspired by the representation capacity of Transformer AR models, we firstly incorporate Transformer architectures to improve GANs in text generation. Note that the previous latent feature matching methods are mostly RNN-based and assume

a single vector in the latent space, which do not directly handle a sequence of latent representations encoded by a Transformer. However, single latent vector representation hinders the incorporation of correlations among different tokens, leading to the loss of crucial semantic information captured by a Transformer structure. This is especially problematic for local and global coherence (Bińkowski et al., 2020). In this paper, we directly match the distributions of multi-token sequences in the latent space, which is better suited for the Transformer structure. To do so, we have to resolve two challenges, the first being how to do distribution matching. We introduce a multi-scale discriminator over the Transformer latent space to utilize the semantic information on different scales, where a global discriminator takes the entire sequence of latent representations as the input, and a local discriminator takes only a randomly-sampled local neighborhood. The second challenge is how to train the decoder reliably. We enhance an autoencoder loss by another KL loss optimized by GAN, forcing the latent representations of the decoding output to be compatible with the generated latent representations from the latent-generator.

We provide a theoretical justification for the proposed formulation by connecting it to the standard goal of generative modeling. Experimental results on three datasets illustrate that TILGAN outperforms all baselines in both unconditional and conditional generation tasks, achieving state-of-the-art performance. Particularly, TILGAN exhibits a better quality-diversity trade-off evaluated by automatic metrics such as SelfBLEU and TestBLEU as well as human evaluation. Further analyses also confirm the effectiveness of each component of our method, where decoder enhancement greatly benefits generation quality, while the multi-scale discriminator and KL objective provide great performance gains in generation diversity, and the implicit prior contributes to both.

2 The Approach

2.1 Model and Formulation

In this section, we introduce the proposed model and the learning formulation. Let $\boldsymbol{x} \in \mathcal{X}$ denote a sentence following the real data distribution $p_r(\boldsymbol{x})$ with $\mathcal{X} = \mathcal{V}^n$ where $\mathcal{V}$ is the vocabulary, $m = |\mathcal{V}|$ is the vocabulary size, and n is the sequence length, and $\boldsymbol{z} \in \mathcal{Z}$ be the latent variable following a prior distribution $p_z(\boldsymbol{z})$. We consider a probabilistic model containing an encoder $E_\phi : \mathcal{X} \to \mathcal{Z}$ and a decoder $G_\theta : \mathcal{Z} \to \mathcal{X}$. Both are generally stochastic mappings with parameters ϕ and θ, and induce the encoder conditional distribution $q_\phi(\boldsymbol{z}|\boldsymbol{x})$ and the decoder conditional $p_\theta(\boldsymbol{x}|\boldsymbol{z})$ respectively. Note that previous approaches to text generation use deterministic encoders and decoders (Zhao et al., 2018), which restricts the expressiveness of the modeled distribution family. We first ensure the consistency between E_ϕ and G_θ by minimizing the negation of the expected reconstruction log-likelihood

$$L_c(\phi, \theta) = -\mathbb{E}_{\boldsymbol{x}\sim p_r}\mathbb{E}_{\boldsymbol{z}\sim q_\phi(\boldsymbol{z}|\boldsymbol{x})}[\ln p_\theta(\boldsymbol{x}|\boldsymbol{z})], \quad (1)$$

which coincides with the reconstruction term in the evidence lower bound (ELBO).

The generated data distribution is given by $p_G(\boldsymbol{x}) = \mathbb{E}_{\boldsymbol{z}\sim p_z}[p_\theta(\boldsymbol{x}|\boldsymbol{z})]$. To achieve good generation performance, we design the model so that the distribution family of $p_G(\boldsymbol{x})$ is large enough to contain the real one $p_r(\boldsymbol{x})$. As described in Section 2.3, we use Transformer to model E and G, which we assume to have sufficient capacity to reconstruct data well and learn informative latent representations. In this way, $p_\theta(\boldsymbol{x}|\boldsymbol{z})$ is assumed to be expressive enough. To further enhance the capacity of $p_G(\boldsymbol{x})$, we propose to use an implicit prior p_z, by transforming samples from a simple distribution with a deep neural network.

Consider a random vector $\epsilon \in \mathcal{E}$ following some simple distribution p_ϵ like a standard Gaussian. We then propose to learn a latent-generator $g_\beta : \mathcal{E} \to \mathcal{Z}$ with parameter β so that the distribution of $g_\beta(\epsilon)$ matches that of $E_\phi(\boldsymbol{x})$, by minimizing the KL divergence

$$L_g(\phi, \beta) = D_{\mathrm{KL}}(q_\phi(\boldsymbol{z}) \| p_\beta(\boldsymbol{z})),$$

where $p_\beta(\boldsymbol{z})$ denotes the distribution of $g_\beta(\epsilon)$ and $q_\phi(\boldsymbol{z}) = \mathbb{E}_{\boldsymbol{x}\sim p_r}[q_\phi(\boldsymbol{z}|\boldsymbol{x})]$ is the distribution of $E(\boldsymbol{x})$, a.k.a., the aggregated posterior. The advantage of KL divergence is that it imposes a heavy penalty when $q_\phi(\boldsymbol{z}) > 0$ but $p_\beta(\boldsymbol{z}) \approx 0$, which means that it favors a g that covers all the diverse modes of $q_\phi(\boldsymbol{z})$. This is commonly known and verified empirically in Shen et al. (2020). Hence minimizing KL encourages a better diversity in generation compared with the Jensen–Shannon (JS) divergence or Wasserstein distance which are often used in the literature on generative models.

Therefore, we formulate the overall objective

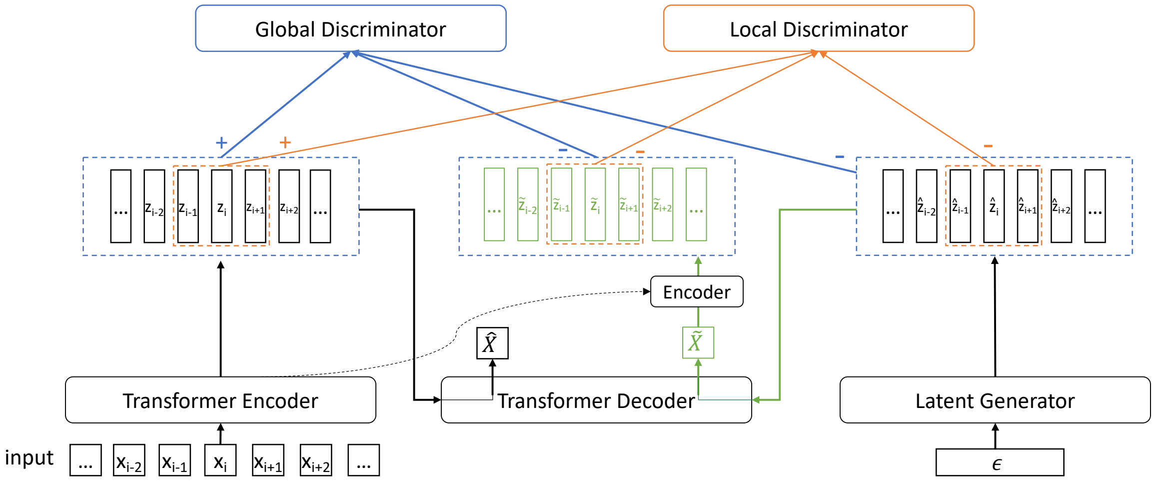

Figure 1: The overall architecture of TILGAN. Blue and orange stand for the global and local discriminators, respectively, and green denotes the route of the enhanced decoder.

function to be minimized as follows

$$L_c(\phi, \theta) + \lambda L_g(\phi, \beta), \tag{2}$$

where $\lambda > 0$ is a coefficient to balance both terms.

Decoder Enhancement During testing, a new sentence is generated by first sampling $\epsilon \sim p_\epsilon$, then computing the latent variable $g(\epsilon)$ and finally generating $G(g(\epsilon))$, which means the decoder takes the output of the latent-generator g as the input which it has never seen throughout the training. Although the KL term aims at matching the distributions of $g(\epsilon)$ and $E(\boldsymbol{x})$, it is possible that they do not match perfectly. In such cases, the decoder may generate data with poor fidelity and far from being real data. To resolve this and reliably train the decoder, we propose to enhance the decoder by letting it see the generated latent $g(\epsilon)$ during training. Formally, let $\tilde{p}_g$ be the distribution of $E(G(g(\epsilon)))$. We add another term to the loss function (2) with coefficient $\lambda_1 > 0$:

$$\lambda_1 D_{\mathrm{KL}}(q_\phi(\boldsymbol{z}) \| \tilde{p}_g(\boldsymbol{z})). \tag{3}$$

Since this term is designed to enhance the decoder, we regard the encoder and prior parameters ϕ and β as fixed constants. In other words, in optimization, we do not propagate gradients of this term with respect to ϕ and β and only update the decoder parameter θ.

2.2 Algorithm

In this section, we propose a GAN-based algorithm for the optimization of the above formulation. Since $p_\beta(\boldsymbol{z})$ is implicit, the KL term L_g in (2) does not allow a closed form to be optimized directly. We introduce a discriminator to estimate the gradients, following Shen et al. (2020). In Lemma 1, we present the gradient formulas of L_g.

Lemma 1. *Let* $\mathcal{D}(\boldsymbol{z}) = \ln(q_\phi(\boldsymbol{z})/p_\beta(\boldsymbol{z}))$. *Then*

$$\begin{aligned}
\nabla_\phi L_g &= \mathbb{E}[\nabla_{\boldsymbol{z}} \mathcal{D}(E_\phi(\boldsymbol{x}))^\top \nabla_\phi E_\phi(\boldsymbol{x})],\\
\nabla_\beta L_g &= -\mathbb{E}[s_{\mathcal{D}}(g_\beta(\epsilon)) \nabla_{\boldsymbol{z}} \mathcal{D}(g_\beta(\epsilon))^\top \nabla_\beta g_\beta(\epsilon)],
\end{aligned}$$

where $s_{\mathcal{D}}(\boldsymbol{z}) = e^{\mathcal{D}(\boldsymbol{z})}$ *is the scaling factor and the expectations are taken over all the randomness.*

Since $\mathcal{D}$ depends on the unknown densities q_ϕ and p_β so that the gradients in Lemma 1 can not be directly computed from the data, we estimate the gradients by training a discriminator D_ψ with parameter ψ via the empirical logistic regression:

$$\min_\psi \left[\sum_{\boldsymbol{z} \in S_e} \frac{\ln(1 + e^{-D_\psi(\boldsymbol{z})})}{|S_e|} + \sum_{\boldsymbol{z} \in S_g} \frac{\ln(1 + e^{D_\psi(\boldsymbol{z})})}{|S_g|} \right],$$

where S_e and S_g are finite samples from $q_\phi(\boldsymbol{z})$ and $p_\beta(\boldsymbol{z})$ respectively. This leads to a GAN algorithm. The optimization of the enhanced loss (3) is similar.

However, GAN is commonly known to suffer from unstable training or gradient vanishing. To stabilize our algorithm, we adopt the scaling clipping technique from Shen et al. (2020) and clip the scaling factor into a range of $[r_0, 1/r_0]$, where $r_0 = 0.5$ turns out to work well in all our experiments. Denote the clipped scaling by $s'_D(\boldsymbol{z}) = \max\{\min\{s_D(\boldsymbol{z}), 2\}, 0.5\}$.

For the optimization of the consistency loss L_c, we adopt the reparametrization trick from Kingma and Welling (2014) and estimate it by

```
Algorithm 1: TILGAN
Input: initial $\phi, \theta, \beta, \psi, \xi$, batch-size $N$, local size $M$
while not convergence do
    // Update discriminators
    Sample $\{\boldsymbol{x}_i\}_{i=1}^N \sim p_r(\boldsymbol{x})$, $\{\epsilon_i\}_{i=1}^N \sim p_\epsilon$
    Compute
      $\boldsymbol{z}_i = E_\phi(\boldsymbol{x}_i), \hat{\boldsymbol{z}}_i = g_\beta(\epsilon_i), \tilde{\boldsymbol{z}}_i = E_\phi(G_\theta(\hat{\boldsymbol{z}}_i))$
    Update $\psi$ by descending the gradient:
      $\frac{1}{N}\sum_{i=1}^N \nabla_\psi[\ln(1+e^{-D_\psi(\boldsymbol{z}_i)})+\ln(1+e^{D_\psi(\hat{\boldsymbol{z}}_i)})]$
    Randomly sample local blocks $\boldsymbol{z}'_i$ and $\hat{\boldsymbol{z}}'_i$ with size
      $M$
    Update local discriminator by descending:
      $\frac{1}{N}\sum_{i=1}^N \nabla_\xi[\ln(1+e^{-d_\xi(\boldsymbol{z}'_i)})+\ln(1+e^{d_\xi(\hat{\boldsymbol{z}}'_i)})]$
    // Update encoder, decoder and latent-generator
    Obtain $\boldsymbol{x}_i, \epsilon_i, \boldsymbol{z}_i, \hat{\boldsymbol{z}}_i, \tilde{\boldsymbol{z}}_i, \boldsymbol{z}'_i$ and $\hat{\boldsymbol{z}}'_i$ as above
    Compute $\phi$-gradient:
      $\frac{1}{N}\sum_{i=1}^N[\nabla_\phi \hat{L}_c(\boldsymbol{x}_i, \boldsymbol{z}_i)+\lambda\nabla_\phi D_\psi(\boldsymbol{z}_i)+\lambda\nabla_\phi d_\xi(\boldsymbol{z}'_i)]$
    Compute $\beta$-gradient:
      $-\frac{1}{N}\sum_{i=1}^N \lambda[s'_D(\hat{\boldsymbol{z}}_i)\nabla_\phi D_\psi(\hat{\boldsymbol{z}}_i)+s'_d(\hat{\boldsymbol{z}}'_i)\nabla_\phi d_\xi(\hat{\boldsymbol{z}}'_i)]$
    Compute $\theta$-gradient:
      $\frac{1}{N}\sum_{i=1}^N[\nabla_\theta \hat{L}_c(\boldsymbol{x}_i, \boldsymbol{z}_i)+\lambda_1 s'_D(\tilde{\boldsymbol{z}}_i)\nabla_\phi D_\psi(\tilde{\boldsymbol{z}}_i)]$
    Update parameters $\phi, \theta, \beta$ using the gradients
Return: $\phi, \theta, \beta$
```

$\frac{1}{n}\sum_{i=1}^n \hat{L}_c(\boldsymbol{x}_i, \boldsymbol{z}_i)$ where $\boldsymbol{x}_i \sim p_r(\boldsymbol{x})$, $\boldsymbol{z}_i = E_\phi(\boldsymbol{x}_i)$, and $\hat{L}_c(\boldsymbol{x}_i, \boldsymbol{z}_i) = -\ln p_\theta(\boldsymbol{x}_i|\boldsymbol{z}_i)$. The whole training procedure is summarized in Algorithm 1, where the colored parts stand for the enhanced decoder (green) and the multi-scale discriminator (blue and orange) introduced later.

2.3 Architecture

In this section, we present the Transformer-based architecture incorporated with multi-scale discriminators. We propose a Transformer autoencoder framework where both the encoder and decoder are self-attention layers with three novel ingredients specific to improve the generation performance in both quality and diversity: (i) a latent-generator g to transform Gaussian noises into an implicit prior distribution, (ii) decoder enhancement, and (iii) multi-scale discriminators. Figure 1 illustrates the entire architecture of TILGAN.

As mentioned in Section 1, we introduce multiple discriminators over the Transformer's latent space to utilize the semantic information on different scales, each of which operates on a different window of representations as the input. Specifically, given an input sentence $\boldsymbol{x} = [x_1, x_2, \ldots, x_n]$ where x_i stands for the i-th word, it is passed through the Transformer encoder which results in a sequence of latent states $\boldsymbol{z} = [z_1, z_2, \ldots, z_n]$ where z_i is the vector representation corresponding to x_i. We introduce a global discriminator D_ψ taking the whole sequence of representations $\boldsymbol{z}$ as the input, and a local discriminator d_ξ with parameter ξ taking only a local neighborhood of the M randomly-sampled adjacent representations, e.g., $\boldsymbol{z}' = [z_{i-1}, z_i, z_{i+1}]$ with $M = 3$, as the input. [2] Notably, the local discriminator takes the generated pieces of sequences into account, so it provides signals of phrase-level fidelity and local coherence, while the global discriminator is able to assess the general realism and the degree of natural coherence for the whole sequence.

2.4 Extension to Conditional Generation

Our proposed framework can be readily extended to conditional generation tasks such as story completion. To be specific, the goal is to learn a conditional real data distribution $p_r(\boldsymbol{x}|\boldsymbol{c})$ where $\boldsymbol{c}$ is the given context following $p_r(\boldsymbol{c})$ with some missing content $\boldsymbol{x}$ to complete. We propose to feed $\boldsymbol{c}$ into all three components—encoder E, decoder G, and latent-generator g—of our model, and modify the terms in objective function (2) as follows

$$L'_c(\phi, \theta) = -\mathbb{E}_{p_r(\boldsymbol{x},\boldsymbol{c})}\mathbb{E}_{q_\phi(\boldsymbol{z}|\boldsymbol{x},\boldsymbol{c})}[\ln p_\theta(\boldsymbol{x}|\boldsymbol{z}, \boldsymbol{c})],$$
$$L'_g(\phi, \beta) = D_{\mathrm{KL}}(q^c_\phi(\boldsymbol{z})\|p^c_\beta(\boldsymbol{z})),$$

where $p_r(\boldsymbol{x}, \boldsymbol{c}) = p_r(\boldsymbol{x}|\boldsymbol{c})p_r(\boldsymbol{c})$, and the marginal distributions of $E(\boldsymbol{x}, \boldsymbol{c})$ and $g(\epsilon, \boldsymbol{c})$ are given by $q^c_\phi(\boldsymbol{z}) = \mathbb{E}_{p_r(\boldsymbol{x},\boldsymbol{c})}[q_\phi(\boldsymbol{z}|\boldsymbol{x}, \boldsymbol{c})]$ and $p^c_\beta(\boldsymbol{z}) = \mathbb{E}_{p_r(\boldsymbol{x},\boldsymbol{c})}[p_\beta(\boldsymbol{z}|\boldsymbol{x}, \boldsymbol{c})]$ respectively. Then the final objective is to minimize $L'_c(\phi, \theta) + \lambda L'_g(\phi, \beta)$.

3 Theoretical Justification

The goal of generative modeling is to learn the generated distribution $p_G(\boldsymbol{x})$ that is close to the real data distribution $p_r(\boldsymbol{x})$. Our proposed formulation in (2), however, does not explicitly optimize a distance measure between p_G and p_r, so it is unclear whether our method can match the distributions in the data space. In this section, we provide justification for the proposed formulation (2) by connecting it with the above goal, based on the analysis of WAE (Tolstikhin et al., 2018).

Let $\mathbb{P}_G$ and $\mathbb{P}_r$ be the induced probability measures of $p_G(\boldsymbol{x})$ and $p_r(\boldsymbol{x})$ respectively. We have the Kantorovich's formulation of the optimal transport (OT) problem with the L_1 cost:

$$W_1(\mathbb{P}_r, \mathbb{P}_G) = \inf_{\Gamma \in \mathcal{P}(\boldsymbol{x}\sim\mathbb{P}_r, \boldsymbol{y}\sim\mathbb{P}_G)} \mathbb{E}_{\boldsymbol{x},\boldsymbol{y}\sim\Gamma}[c(\boldsymbol{x}, \boldsymbol{y})],$$

---

[2] We have considered sampling multiple different neighborhoods within a given sequence as well, whose empirical performance was shown to be comparable with our proposed scheme with one local neighborhood, so we only reported the latter since it is simpler to implement.

TASK	UG		CG
DATASET	MSCOCO	WMTNEWS	ROCSTORY
VOCAB	27842	5728	20000
AVG LEN.	10.4	27.8	10.0
TRAIN S#	120K	278K	390K
DEV S#	-	-	50K
TEST S#	10K	10K	50K

Table 1: The statistics of the datasets. Avg Len. means the average length of sentences. S# refers to number of sentences. UG and CG stand for unconditional generation and conditional generation, respectively.

where $c(\boldsymbol{x}, \boldsymbol{y}) = \|\boldsymbol{x} - \boldsymbol{y}\|_1$ is the cost function and $\mathcal{P}(\boldsymbol{x} \sim \mathbb{P}_r, \boldsymbol{y} \sim \mathbb{P}_G)$ is a set of all joint distributions of $(\boldsymbol{x}, \boldsymbol{y})$ with marginals $\mathbb{P}_r$ and $\mathbb{P}_G$ respectively. Note that $W_1(\mathbb{P}_r, \mathbb{P}_G)$ is also known as the 1-Wasserstein distance between $\mathbb{P}_r$ and $\mathbb{P}_G$. Then we have the following theorem which gives an upper bound of the 1-Wasserstein distance, whose proof is given in Appendix B.

Theorem 1. *Let $p_\theta(\boldsymbol{x}|\boldsymbol{z})$ be a multivariate multinomial distribution with mean matrix $\bar{G}(\boldsymbol{z}) \in \mathbb{R}^{m\times n}$ which is a common choice for text modeling, i.e., each one-hot token $x_i|\boldsymbol{z}$ follows a multinomial with mean $\bar{G}_i(\boldsymbol{z}) \in$ simplex Δ^{m-1} for $i = 1, \ldots, n$. Then we have $W_1(\mathbb{P}_r, \mathbb{P}_G)$ is upper bounded by*

$$\inf_{q(\boldsymbol{z}|\boldsymbol{x}):q_z(\boldsymbol{z})=p_\beta(\boldsymbol{z})} -2\mathbb{E}_{\boldsymbol{x}\sim p_r}\mathbb{E}_{\boldsymbol{z}\sim q(\boldsymbol{z}|\boldsymbol{x})}[\ln p_\theta(\boldsymbol{x}|\boldsymbol{z})], \tag{4}$$

where $q_z(\boldsymbol{z}) = \mathbb{E}_{\boldsymbol{x}\sim p_r(\boldsymbol{x})}[q(\boldsymbol{z}|\boldsymbol{x})]$ is the aggregated posterior and $p_\beta(\boldsymbol{z})$ is the implicit prior.

Hence by minimizing (4) with respect to θ and β, we learn the composite generator $G_\theta(g_\beta(\epsilon)) : \mathcal{E} \to \mathcal{X}$ that minimizes an upper bound of $W_1(\mathbb{P}_r, \mathbb{P}_G)$, which is consistent with the standard goal of generative modeling. However, this optimization problem is generally intractable due to the equality constraint and the nonparametric nature. Our formulation (2) can be regarded as an approximate problem of it by parametrizing $q(\boldsymbol{z}|\boldsymbol{x})$ with a distribution family induced by a stochastic encoder mapping E_ϕ, and relaxing the hard constraint $q_z(\boldsymbol{z}) = p_\beta(\boldsymbol{z})$ by introducing the relative entropy regularization $D_{\mathrm{KL}}(q_z(\boldsymbol{z})\|p_\beta(\boldsymbol{z}))$.

4 Experiment Settings

4.1 Datasets

We conduct our experiments on three benchmark datasets, **MSCOCO** (Lin et al., 2014), **WMTNEWS** (Guo et al., 2018), and **ROCSTORY** (Mostafazadeh et al., 2016). All of the preprocessing steps are the same as Chen et al. (2018) and Wang and Wan (2019). The statistics of the resulting datasets are reported in Table 1.

4.2 Baselines

Unconditional Generation Three simplified variants of TILGAN are implemented for comparison:

- **TILGAN$_{\text{P}}$**: a plain baseline using our backbone model, that is, a Transformer autoencoder and a GAN in the latent space based on KL divergence.
- **TILGAN$_{\text{E}}$**: TILGAN$_{\text{P}}$ equipped with decoder enhancement.
- **TILGAN$_{\text{MD}}$**: TILGAN$_{\text{P}}$ with the multi-scale discriminator.

In addition, the following existing models are adopted: recurrent neural network language model (RNNMLE), SeqGAN (Yu et al., 2017), RankGAN (Lin et al., 2017), GSGAN (Kusner and Hernández-Lobato, 2016), LeakGAN (Guo et al., 2018), textGAN (Zhang et al., 2017), FM-GAN (Chen et al., 2018), ARAE (Zhao et al., 2018), Transformer language model (TMLE) (Vaswani et al., 2017).

Conditional Generation For conditional generation, we compare our model with Transformer (Vaswani et al., 2017), IE+MSA (Guan et al., 2019), Seq2Seq (Bahdanau et al., 2015), HLSTM (Li et al., 2015), CVAE (Sohn et al., 2015), and T-CVAE (Wang and Wan, 2019).

4.3 Automatic Evaluation Metrics

Unconditional Generation

- **TESTBLEU** (Yu et al., 2017): a quality metric comparing the n-gram similarity between generated samples and the whole test set.
- **SELFBLEU** (Zhu et al., 2018): a diversity metric calculating the similarity between one generated sentence and the whole remaining generation. The lower the SelfBLEU score is, the higher diversity we obtain in the generation.

Specifically, following Chen et al. (2018), we report BLEU-2/3/4/5 for TestBLEU and BLEU-2/3/4 for SelfBLEU.

Conditional Generation

- **BLEU** (Papineni et al., 2002): the BLEU score is calculated by taking the geometric mean of the n-gram BLEU scores where n is from 1 to 4.
- **DIVERSITY** (Li et al., 2016): the proportion of distinct n-grams in the generated results which evaluates the degree of diversity. D1 and D2 are reported for unigram and bigram, respectively.

Table 2: SelfBLEU and TestBLEU results on MSCOCO and EMNLP WMTNews datasets. Q and D denote the quality and diversity evaluated by human, respectively. The results of previous baselines are listed in the top region, our method TILGAN together with simplified variants are shown in the middle, and more variants for further ablation studies are at the bottom. The bold numbers are the best results in each column.

- **ADVERSARIAL SUCCESS** (Li et al., 2017): the fraction of instances in which a model is capable of fooling a fine-tuned BERT classifier with the above 95% accuracy on the development set of the classification task. Higher values are better. The positive examples are original stories and negative examples are stories consisting of a random sentence from another story.

4.4 Implementation

Unconditional Generation We implement a Transformer-based autoencoder with 2 layers, 4 heads, 512 embedding dimensions, and 512 hidden dimensions. The generator and discriminator are implemented by 3 layers multi-layer perceptron (MLP). We set the maximum sequence length to 15 and 32 for MSCOCO and WMTNews, respectively. During training, each sentence is padded to the maximum length when fed into the encoder, and then the encoder produces a latent vector for every input token. During testing, the latent-generator generates a sequence of latent vectors with the same maximum length, and then, conditional on the latent vectors, the decoder generates a sentence which ends when a special token, <EOS>, is generated. We adopt Adam (Kingma and Ba, 2015) as the optimizer with a learning rate of 0.00025 and 0.0001 for autoencoder and GAN structure, respectively with a dropout rate of 0.3.

Conditional Generation We adopt the same Transformer encoder-decoder architecture as the backbone model and similar setups as Wang and Wan (2019). The Transformer structure has 6 layers, 8 self-attention heads, 512 dimensions for hidden states, and uses shared attention layers for encoder and decoder which allows the decoder to attend to the encoder state and the decoder state at the same time to make the completed story more coherent. The generator has 3 layers and the discriminator has 4 layers. We adopt Adam (Kingma and Ba, 2015) as the optimizer with a learning rate of 0.0001 and a dropout rate of 0.15.

More details of the experimental setup and hyperparameter settings are shown in the Appendix A.

5 Experimental Results

5.1 Unconditional Generation

• **Generation Quality** The first experiment is to compare the quality of generated sentences of different models. In general, as shown in Table 2, TILGAN outperforms all baseline models in TestBLEU on both MSCOCO and WMTNews datasets, which clearly indicates the advantages of our proposed framework. We make five main observations. Firstly, we notice that TMLE is comparable to most GAN baselines, which shows the powerful fitting capacity of the Transformer architecture as well as the inferior performance of previous GAN implementations. Despite this, TILGAN$_{P}$ outperforms TMLE by a wide margin, demonstrating that our backbone model combining a Transformer autoencoder and a GAN can not only take advantage of the Transformer's capacity, but also exhibit benefits from our GAN formulation to further boost the performance. Furthermore, compared with TILGAN$_{\mathrm{P}}$, our full version TILGAN achieves an improvement of 13.3% and 13.2% for TestBLEU5 on MSCOCO and News, respectively. This confirms the effectiveness of the proposed multi-scale discriminators and decoder enhancement. In detail, when comparing the simplified variants TILGAN$_{\mathrm{E}}$ v.s. TILGAN$_{\mathrm{MD}}$, the improvement of TILGAN$_{\mathrm{E}}$ over the plain baseline TILGAN$_{\mathrm{P}}$ is larger than that of TILGAN$_{\mathrm{MD}}$, which illustrates that incorporating TILGAN$_{\mathrm{E}}$ is more crucial to improving the generation quality. Lastly, we compare TILGAN with all previous methods and observe an average improvement of 6.3% for TestBLEU5 on two datasets against the previous state-of-the-art FMGAN, which suggests the superiority of our method.

• **Generation Diversity** The generation diversity is evaluated by SelfBLEU scores, which are shown in Table 2. First, compared with the baselines with comparable and worse TestBLEU, e.g., FMGAN and LeakGAN, our TILGAN achieves lower SelfBLEU scores, which indicates a better quality-diversity trade-off from TILGAN. We notice that RNNMLE achieves the best SelfBLEU score on WMTNews but its quality shown by TestBLEU is pretty low and tends to generate incoherent or meaningless segments, which can be confirmed by the generated samples in Appendix C. In addition, from the results of TILGAN$_{\mathrm{MD}}$, we find that incorporating the multi-scale discriminator leads to a significant drop in SelfBLEU, suggesting that most of the performance gains in generation diversity are attributed to our design of multi-scale discriminators in contrast to decoder enhancement. Moreover, when comparing the performance across two datasets, we find that the SelfBLEU scores of our models are lower on MSCOCO than that on WMTNews, illustrating that it is easier to generate more diverse texts on MSCOCO. One possible reason is that the texts in MSCOCO are shorter than the texts in WMTNews as shown in Table 1. When generating long sequences, models are prone to generate repeated tokens and phrases. The same phenomenon was also observed for many other baseline models like ARAE and FMGAN.

5.2 Conditional Generation

In addition to unconditional generation, we test our model in a story completion task to verify its ability in conditional generation. Table 3 shows the automatic metrics in four metrics, with several observations. (i) Overall, among all models, TILGAN achieves new state-of-the-art results on the ROCStory dataset, showing the superiority of our method. (ii) Our model obtains substantial improvement in the quality metrics of generated answers, with 0.32% gains in BLEU, 6.92% gains in the adversarial success. It demonstrates that the generated plots are in high coherence, which not only share a higher proportion of word overlap with ground-truth answers, but also have a higher success rate fooling the BERT classifier. (iii) As for diversity, TILGAN improves upon the state-of-the-art methods from 3.63% to 3.88% on D1 and 23.46% to 25.61% on D2, showing that TILGAN produces stories consisting of more diverse and distinct n-grams.

5.3 Human Evaluation

Due to the limitations of automatic evaluation metrics, we invite 5 judges to rate 100 sentences generated by different models on a scale from 1 to 5 for both unconditional and conditional generation tasks. The results for unconditional generation are shown in Table 2. TILGAN shows a superior performance, which confirms that our model is able to generate more realistic samples than the baseline models on two datasets. Among all baseline models, FMGAN has a high quality score but a low diversity score, which indicates that most of its generated samples are repeated sentences that lack diversity. Additional evidence is shown through the case study in Section 6.2.

In addition, the human evaluation results on story completion are shown in Table 3 where we only compare TILGAN with the best baseline, i.e., T-CVAE. We use Gram metric to evaluate whether the generated story plot proceeds naturally, and Logic metric to evaluate whether the plot is reasonable and coherent following Wang and Wan (2019). Compared with T-CVAE, TILGAN is better in both Gram and Logic, demonstrating that the generated story plots of TILGAN are more natural and coherent.

METHODS	BLEU%	D1%	D2%	AS%	GRAM	LOGIC
SEQ2SEQ	2.90	2.69	15.95	80.97	-	-
HLSTM	2.31	2.63	14.80	72.46	-	-
CVAE	3.03	2.72	16.32	81.18	-	-
TRANS.	3.05	2.93	16.75	82.51	-	-
T-CVAE	4.25	3.63	23.46	87.54	3.32	3.24
TILGAN	**4.57**	**3.88**	**25.61**	**94.46**	3.58	3.60

Table 3: Results on story completion task. AS refers to adversarial success score. TRANS. denotes a vanilla Transformer model.

6 Analyses

6.1 Ablation Study

To examine the impact of KL loss and the implicit prior, we conduct ablation studies of different designs. We construct three variants of TILGAN and conduct experiments on two datasets of unconditional generation, whose results are shown in the bottom region of Table 2.

• **Impact of KL Loss** First, we implement two variants named JSGAN (Goodfellow et al., 2014) and WGAN (Arjovsky et al., 2017) by replacing the KL loss term with JS divergence and Wasserstein distance, while keeping the same architectures. In general, TILGAN_P outperforms JSGAN and WGAN in terms of SelfBLEU and TestBLEU on two datasets. Particularly, it is observed that with KL loss, the SelfBLEU4 score drops from 51.8% and 69.0% to 18.2% over JSGAN and WGAN on MSCOCO, and similar downward trends are observed on WMTNews. It demonstrates that minimizing KL loss indeed benefits the generation diversity, which is consistent with previous findings in Shen et al. (2020). In addition, the TestBLEU of TILGAN_P achieves an improvement of 28.9% and 27.4% for TestBLEU5 on MSCOCO over JSGAN and WGAN, respectively.

• **Implicit Prior v.s. Implicit Posterior** In addition to imposing an implicit prior, one can instead impose an implicit posterior as well by moving the transformation network of the latent-generator to the encoder and leaving a Gaussian prior. This results in a variant with nearly the same total number of parameters, named IMP_POST. We see from Table 2 that IMP_POST performs worse than TILGAN_P with an implicit prior, suggesting that enlarging the distribution family of posterior $q_\phi(\boldsymbol{z}|\boldsymbol{x})$ contributes less to improving the overall generation performance than enlarging that of prior $p_z(\boldsymbol{z})$, which is consistent to the analysis in the second paragraph of Section 2.1.

6.2 Case Study

To further analyze the real quality and diversity of the generated sentences, some are examined and presented in Table 4 and more examples are shown in Appendix C. First, the samples generated by TILGAN are more coherent and semantically meaningful. The majority of texts of TILGAN are in subject–verb–object order while those of other models are not. In addition, TILGAN exhibits more diverse sentence structures and word choices than others. For example, although each sentence generated by FMGAN looks good in quality, there are many repeated sentences or phrases, leading to a low diversity. The case study is consistent with the human evaluation results in Section 5.3.

7 Related Work

Conventional text generation models leverage maximum likelihood estimation (MLE) with teacher forcing and have shown powerful generation capabilities (Mikolov et al., 2010; Cho et al., 2014; Bahdanau et al., 2016; Radford et al., 2019; Brown et al., 2020) but they suffer from the exposure bias problem. To address this, several solutions were introduced including scheduled sampling (Bengio et al., 2015), professor forcing (Lamb et al., 2016), and Gibbs sampling (Su et al., 2018).

GAN-based text generation methods can be categorized into three classes: reinforcement learning (RL) based methods, Gumbel-Softmax (GS) based methods and latent feature matching methods. RL-based methods (Yu et al., 2017; Lin et al., 2017; Che et al., 2017; Guo et al., 2018; Fedus et al., 2018) design a reward incorporated with the discriminators, and use policy gradient or actor-critic approaches to update the generator to resolve the gradient propagating issue over discrete tokens. However, they suffer from high variance and mode collapse issues caused by the unstable policy gradient training process and the lack of a reliable guiding signal (Zhang et al., 2017; Chen et al., 2018). GS-based methods (Kusner and Hernández-Lobato, 2016) apply Gumbel-Softmax which is a continuous relaxation technique for transforming the output of a generator to be as close to one-hot as possible in order to make the samples from a discrete distribution like a multinomial differentiable with respect to the distribution parameters.

Latent feature matching methods (Zhang et al., 2017; Zhao et al., 2018) learn a manifold in the latent space instead of the discrete output space.

RankGAN:	(1) *A blue blue train sits on tracks with his residential asian toys.* (2) *A reflection of two birds walking by a sidewalk.*
FMGAN:	(1) *A man is standing on a table with a dog.* (2) *A man is standing on a table with a dog on a field.* (3) *A man is standing on a field of a large building.*
TILGAN:	(1) *A little boy sitting on a bench with a little girl.* (2) *A blue and white public transit bus is driving down acity street.* (3) *A train is going down the tracks in a forest.*

Table 4: Examples of generated sentences from RankGAN, FMGAN and our model.

This kind of methods usually incorporates an autoencoder to build the feature space and force the generator's latent output distribution to approach the real data latent distribution. Our method also resides in this category. To ease adversarial training, Zhang et al. (2017) introduce adversarial feature matching method by incorporating a kernelized discrepancy metric to match high-dimensional latent representations of real and synthetic sentences. ARAE (Zhao et al., 2018) extends AAE (Makhzani et al., 2015) to model discrete sequences and learns a parameterized prior by a generative model trained with WGAN. In contrast to our TILGAN whose Transformer-based encoder and decoder are both stochastic, ARAE uses RNN-based encoder and decoder which are both deterministic, as required in their theory, which reduces the model expressiveness and results in much poorer performance than ours as shown in Table 2. iVAE (Fang et al., 2019) proposes a VAE (Kingma and Welling, 2014) with an implicit posterior which is inferior to the implicit prior that we adopt according to the ablation study in Section 6.1. WAE-S (Bahuleyan et al., 2019) is a WAE(Tolstikhin et al., 2018) with a stochastic encoder trained using MMD with a distinct goal of improving the reconstruction ability.
