Message from the Program Chairs

Welcome to the *Findings* of ACL: ACL-IJCNLP 2021! To continue the success of *Findings* of ACL: EMNLP 2020, we decided to follow this initiative to produce this accompanying volume, consisting of papers that are not accepted for publication in the main conference, but nonetheless have been assessed by the Program Committee as solid work with sufficient substance, quality and novelty. Out of the $3,350$ full submissions to ACL-IJCNLP 2021, 493 papers were invited to be included in the *Findings*. Thirty-six papers declined the offer, leading to 457 papers (118 short and 339 long) to be published in the *Findings* of ACL: ACL-IJCNLP 2021.

Papers published in *Findings* of ACL count as full publications. They are not assigned a presentation slot in the main conference, but rather are published online in a separate volume in the ACL Anthology. There are a number of motivations for this new publication, from allowing timely work to be published quickly, to being more accepting of solid work, and helping to manage the increasing reviewing burden on the community. To increase the visibility of the *Findings* papers, this year the authors of *Findings* papers can choose to make a 3-minute video to be included in the virtual conference. Our workshop chairs also helped to pair *Findings* papers with ACL-IJCNLP 2021 workshops, and as a result, more than 100 *Findings* papers will be presented at those workshops.

The reviewing process for *Findings* is largely the same as for the main conference and accordingly we wish to thank all involved in ACL-IJCNLP 2021 for their efforts, as detailed in the Preface to the Proceedings of ACL-IJCNLP 2021. We would like to specifically thank:

- The whole **Program Committee** for reviewing the submissions, and in particular, the **Senior Area Chairs** for making paper recommendation decisions for *Findings*.
- The **Ethics Advisory Committee**, chaired by Min-Yen Kan, Malvina Nissim, and Xanda Schofield, for their hard work to ensure that all the accepted *Findings* papers have addressed the ethical issues appropriately.
- The **Publication Co-Chairs**, Jing-Shin Chang, Yuki Arase, and Yvette Graham, for their tremendous effort in making the volume of *Findings* of ACL: ACL-IJCNLP 2021.
- The **Workshop Chairs**, Kentaro Inui and Michael Strube, for connecting *Findings* paper authors with individual workshops for possible presentations.
- The **Program Co-Chairs of EMNLP 2020**, Trevor Cohn, Yulan He and Yang Liu, for sharing their experience with *Findings* papers.

We hope that *Findings* will continue to serve as a companion to future conferences, and become an important venue for excellent, widely-read, and highly cited work in NLP.

Abstract

We propose an explainable inference approach for science questions by reasoning on grounding and abstract inference chains. This paper frames question answering as a *natural language* abductive reasoning problem, constructing *plausible* explanations for each candidate answer and then selecting the candidate with the *best* explanation as the final answer. Our method, *ExplanationLP*, elicits explanations by constructing a weighted graph of relevant facts for each candidate answer and employs a linear programming formalism designed to select the optimal subgraph of explanatory facts. The graphs' weighting function is composed of a set of parameters targeting relevance, cohesion and diversity, which we fine-tune for answer selection via Bayesian Optimisation. We carry out our experiments on the WorldTree and ARC-Challenge datasets to empirically demonstrate the following contributions: (1) ExplanationLP obtains strong performance when compared to transformer-based and multi-hop approaches despite having a significantly lower number of parameters; (2) We show that our model is able to generate plausible explanations for answer prediction; (3) Our model demonstrates better robustness towards semantic drift when compared to transformer-based and multi-hop approaches.

1 Introduction

Answering science questions remain a fundamental challenge in Natural Language Processing and AI as it requires complex forms of inference, including causal, model-based and example-based reasoning (Jansen, 2018; Clark et al., 2018; Jansen et al., 2016; Clark et al., 2013). Current state-of-the-art (SOTA) approaches for answering questions in the science domain are dominated by transformer-based models (Devlin et al., 2019; Sun et al., 2019). Despite remarkable performance on answer prediction, these approaches are black-box by nature, lacking the capability of providing *explanations* for their predictions (Thayaparan et al., 2020; Miller, 2019; Biran and Cotton, 2017; Jansen et al., 2016).

Explainable Science Question Answering (XSQA) is often framed as a *natural language abductive reasoning* problem (Khashabi et al., 2018; Jansen et al., 2017). Abductive reasoning represents a distinct inference process, known as *inference to the best explanation* (Peirce, 1960; Lipton, 2017), which starts from a set of complete or incomplete observations to find the hypothesis, from a set of plausible alternatives, that *best* explains the observations. Several approaches (Khashabi et al., 2018; Jansen et al., 2017; Khot et al., 2017a; Khashabi et al., 2016) employ this form of reasoning for multiple-choice science questions to build a set of plausible explanations for each candidate answer and select the one with the best explanation as the final answer.

XSQA solvers typically treat explanation generation as a multi-hop graph traversal problem. Here, the solver attempts to compose multiple facts that connect the question to a candidate answer. These *multi-hop* approaches have shown diminishing returns with an increasing number of hops (Jansen et al., 2018; Jansen, 2018). Fried et al. (2015) conclude that this phenomenon is due to *semantic drift* – i.e., as the number of aggregated facts increases, so does the probability of drifting out of context. Khashabi et al. (2019) propose a theoretical framework, empirically supported by Jansen et al. (2018); Fried et al. (2015), attesting that ongoing efforts with *very long* multi-hop reasoning chains are unlikely to succeed, emphasising the need for a *richer* representation with fewer hops and higher importance to abstraction and grounding mechanisms.

Consider the example in Figure 1A where the central concept the question examines is the understanding of *friction*. Here, an inference solver's

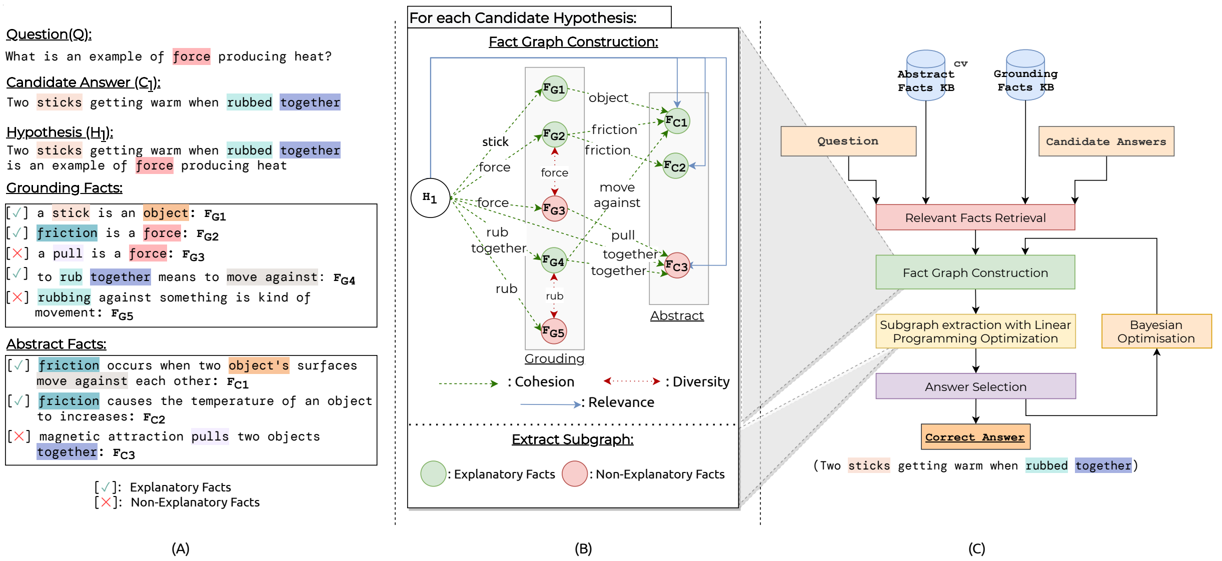

Figure 1: Overview of our approach: (A) Depicts a question, answer and formulated hypothesis along with the set of facts retrieved from a fact retrieval approach (B) Illustrates the optimisation process behind extracting explanatory facts for the provided hypothesis and facts. (C) Details the end-to-end architecture diagram.

challenge is to identify the core scientific facts (**Abstract Facts**) that best explain the answer. To achieve this goal, a QA solver should be able first to go from *force* to *friction*, *stick* to *object* and *rubbing together* to *move against*. These are the **Grounding Facts** that link generic or abstract concepts in a core scientific statement to specific terms occurring in question and candidate answer (Jansen et al., 2018). The grounding process is followed by the identification of the abstract facts about *friction*. A complete explanation for this question would require the composition of five facts to derive the correct answer successfully. However, it is possible to reduce the global reasoning in two hops, modelling it with grounding and abstract facts.

In line with these observations, this work presents a novel approach that explicitly models abstract and grounding mechanisms. The contributions of the paper are:

1. We present a novel approach that performs natural language abductive reasoning via grounding-abstract chains combining Linear Programming with Bayesian optimisation for science question answering (Section 2).

2. We obtain comparable performance when compared to transformers, multi-hop approaches and previous Linear Programming models despite having a significantly lower number of parameters (Section 3.1).

3. We demonstrate that our model can generate plausible explanations for answer prediction (Section 3.2) and validate the importance of grounding-abstract chains via ablation analysis (Section 3.3).

2 ExplanationLP: Abductive Reasoning with Linear Programming

ExplanationLP answers and explains multiple-choice science questions via abductive natural language reasoning. Specifically, the task of answering multiple-choice science questions is reformulated as the problem of finding the candidate answer that is supported by the best explanation. For each Question Q and candidate answer $c_i \in C$, ExplanationLP converts to a hypothesis h_i and attempts to construct a plausible explanation.

Figure 1C illustrates the end-to-end framework. From an initial set of facts selected using a retrieval model, ExplanationLP constructs a fact graph where each node is a fact, and the nodes and edges have a score according to three properties: *relevance*, *cohesion* and *diversity*. Subsequently, an optimal subgraph is extracted using Linear Programming, whose role is to select the best sub-set of facts while preserving structural constraints imposed via grounding-abstract chains. The subgraphs' global scores computed by summing up the nodes and edges scores are adopted to select the final answer. Since the subgraph scores depend on the sum of nodes and edge scores, each property is multiplied by a learnable weight which is optimised via Bayesian Optimisation to obtain the best possible combination with the highest accuracy for answer selection. To the best of our knowledge, we are the first to combine a parameter optimisation method with Linear Programming for inference. The rest of this section describes the model in detail.

2.1 Relevant facts retrival

Given a question (Q) and candidate answers $C = \{c_1,\ c_2,\ c_3, ...,\ c_n\}$ we convert them to hypotheses $\{h_1,\ h_2,\ h_3, ...,\ h_n\}$ using the approach proposed by Demszky et al. (2018). For each hypothesis h_i we adopt fact retrieval approaches (e.g: BM25, Unification-retrieval (Valentino et al., 2021)) to select the top m relevant *abstract* facts $F_A^{h_i} = \{f_1^{h_i}, f_2^{h_i}, f_3^{h_i}, ..., f_m^{h_i}\}$ from a knowledge base containing abstract facts (*Abstract Facts KB*) and top l relevant *grounding* facts $F_G^{h_i} = \{f_1^{h_i}, f_2^{h_i}, f_3^{h_i}, ..., f_l^{h_i}\}$ from a knowledge base containing grounding facts (*Grounding Facts KB*) that *at least* connects one abstract fact with the hypothesis, such that $F^{h_i} = F_A^{h_i} \cup F_G^{h_i}$ and $l+m = k$.

2.2 Fact graph construction

For each hypothesis h_i we build a weighted undirected graph $G^{h_i} = (V^{h_i},\ E^{h_i},\ \omega_v,\ \omega_e)$ with vertices $V^{h_i} \in \{\{h_i\} \cup F^{h_i}\}$, edges E^{h_i}, edge-weight function $\omega_e(e_i; \theta_1)$ and node-weight function $\omega_v(v_i; \theta_2)$ where $e_i \in E^{h_i}$, $v_i \in V^{h_i}$ and $\theta_1, \theta_2 \in [0, 1]$ is a learnable parameter which is optimised via Bayesian optimisation.

The model scores the nodes and edges based on the following *three* properties (See Figure 1B):

(1) Relevance: We promote the inclusion of highly relevant facts in the explanations by encouraging the selection of sentences with higher lexical relevance and semantic similarity with the hypothesis. We use the following scores to measure the relevance and the semantic similarity of the facts:

Lexical Relevance score (L): Obtained from the upstream facts retrieval model (e.g: BM25 score/ Unification score (Valentino et al., 2021)).

Semantic Similarity score (S): Cosine similarity obtained from neural sentence representation models. For our experiments, we adopt Sentence-BERT (Reimers et al., 2019) since it shows state-of-the-art performance in semantic textual similarity tasks.

(2) Cohesion: Explanations should be cohesive, implying that grounding-abstract chains should remain within the same context. To achieve cohesion, we encourage a high degree of overlaps between different hops (e.g. hypothesis-grounding, grounding-abstract, hypothesis-abstract) to prevent the inference chains from drifting away from the original context. The overlap across two hops is quantified using the following scoring function:

Cohesion score (C): We denote the set of unique terms of a given fact $f_i^{h_i}$ as $t(f_i^{h_i})$ after being lemmatized and stripped of stopwords. The overlap score of two facts $f_j^{h_i}$ and $f_j^{h_i}$ is given by:

$$C(f_j^{h_i}, f_k^{h_i}) = \frac{|t(f_j^{h_i}) \cap t(f_k^{h_i})|}{max(|t(f_j^{h_i})|, |t(f_k^{h_i})|)}$$

Therefore, the higher the number of term overlaps, the higher the cohesion score.

(3) Diversity: While maximizing relevance and cohesion between different hops, we encourage diversity between facts of the same type (e.g. abstract-abstract, grounding-grounding) to address different parts of the hypothesis and promote completeness in the explanations. We measure diversity via the following function:

Diversity score (D): We denote the overlaps between hypothesis h_i and the fact $f_i^{h_i}$ as $t_{h_i}(f_i^{h_i}) = t(f_i^{h_i}) \cap t(h_i)$. The diversity score of two facts $f_j^{h_i}$ and $f_j^{h_i}$ is given by:

$$D(f_j^{h_i}, f_k^{h_i}) = -1 \frac{|t_{h_i}(f_j^{h_i}) \cap t_{h_i}(f_k^{h_i})|}{max(|t_{h_i}(f_j^{h_i})|, |t_{h_i}(f_k^{h_i})|)}$$

The goal is to maximise diversity and avoid redundant facts in the explanations. Therefore, if two facts overlap with different parts of the hypothesis, they will have a higher diversity score compared to two facts that overlap with the same part.

Given these premises, the weight functions of the graph is designed as follows:

$$\omega_e(v_j, v_k; \theta_1) = \begin{cases} \theta_{gg} D(v_j, v_k) & v_j, v_k \in F_G^{h_i} \\ \theta_{aa} D(v_j, v_k) & v_j, v_k \in F_A^{h_i} \\ \theta_{ga} C(v_j, v_k) & v_j \in F_G^{h_i}, v_k \in F_A^{h_i} \\ \theta_{qg} C(v_j, v_k) & v_j \in F_G^{h_i}, v_k = h_i \\ \theta_{qa} C(v_j, v_k) & v_j \in F_A^{h_i}, v_k = h_i \end{cases}$$

$$\omega_v(v_i^{h_i}; \theta_2) = \begin{cases} \theta_{lr} L(v_j, h_i) + \theta_{ss} S(v_j, h_i) & v_j \in F_A^{h_i} \\ 0 & v_i \in F_G^{h_i} \\ 0 & v_i = h_i \end{cases}$$

where $\theta_{gg},\ \theta_{aa},\ \theta_{ga},\ \theta_{gq},\ \theta_{qa} \in \theta_1$ and $\theta_{lr},\ \theta_{ss} \in \theta_2$.

2.3 Subgraph extraction with Linear Programming (LP) optimisation

The construction of the explanation graph has to be optimised for the downstream answer selection task. Specifically, from the whole set of facts retrieved by the upstream retrieval models, we need to select the optimal subgraph that maximises the performance of answer prediction. To achieve this goal, we adopt a Linear Programming approach.

The selection of the explanation graph is framed as a rooted maximum-weight connected subgraph problem with a maximum number of K vertices (R-MWCS$_K$). This formalism is derived from the generalized maximum-weight connected subgraph problem (Loboda et al., 2016). R-MWCS$_K$ has two parts: objective function to be maximized and constraints to build a connected subgraph of explanatory facts. The formal definition of the objective function is as follows:

Definition 1. Given a connected undirected graph $G = (V, E)$ with edge-weight function $\omega_e : E \rightarrow \mathbb{R}$, node-weight function $\omega_v : V \rightarrow \mathbb{R}$, root vertex $r \in V$ and expected number of vertices K, the rooted maximum-weight connected subgraph problem with K number of vertices (R-MWCS$_K$) problem is finding the connected subgraph $\hat{G} = (\hat{V}, \hat{E})$ such that $r \in \hat{V}$, $|V| \leq K$ and

$$\Omega(\hat{G};\theta_3) = \theta_{vw} \sum_{v\in\hat{V}} \omega_v(v;\theta_1) + \theta_{ew} \sum_{e\in\hat{E}} \omega_e(e;\theta_2) \rightarrow max$$

where $\theta_{vw},\ \theta_{ew} \in \theta_3$, $\theta_3 \in [0,1]$ and θ_3 is a learnable parameter optimized via Bayesian optimisation. The LP solver will seek to extract the optimal subgraph with the highest possible sum of node and edge weights. Since the solver seeks to obtain the highest possible score, it will avoid negative edges and will prioritise high-value positive edges resulting in higher diversity, cohesion and relevance. We adopt the following binary variables to represent the presence of nodes and edges in the subgraph:

1. Binary variable y_v takes the value of 1 iff $v \in V^{h_i}$ belongs to the subgraph.
2. Binary variable z_e takes the value of 1 iff $e \in E^{h_i}$ belongs to the subgraph.

In order to emulate the grounding-abstract inference chains and obtain a valid subgraph, we impose the set constraints described in Table 1 for the LP solver.

2.4 Bayesian Optimisation for Answer Selection

Given Question Q and choices $C = \{c_1,\ c_2,\ c_3, ...,\ c_n\}$ we extract the optimal explanation graphs $\hat{G}^Q = \{\hat{G}^{c_1},\ \hat{G}^{c_2},\ \hat{G}^{c_3}, ...,\ \hat{G}^{c_n}\}$ for each choice. We consider the hypothesis with the highest relevance, cohesion and diversity to be the correct the answer. Based on this premise we define the correct answer as $c_{ans} = \arg\max_{h_i}\ (\Omega(\hat{G}^{h_i}))$.

In order to automatically optimize the Linear Programming model (i.e, $\theta_1,\ \theta_2,\ \theta_3$) we use Bayesian optimisation. The algorithm is defined as below (Here $\mathcal{GP}$ is Gaussian Process and LP is the Linear Programming module).

Algorithm 1: Bayesian Optimisation

```
$\theta_1, \theta_2, \theta_3$ = initRandom(seed)
$G^Q$ = fact-graph-construction($\omega_e(\theta_1'),\ \omega_v(\theta_2')$)
$\hat{G}^Q$ = LP($G^Q,\ \Omega(\theta_3)$)
$X$ = evaluate-accuracy($G^Q$)
model = $\mathcal{GP}(X, \{\theta_1, \theta_2, \theta_3\})$
iteration = 0
while iteration $\leq N$ do
    $\theta_1', \theta_2', \theta_3'$ = get-next-exploration-point()
    $G^{Q'}$ = fact-graph-construction($\omega_e(\theta_1'),\ \omega_v(\theta_2')$)
    $\hat{G}^{Q'}$ = LP($G^{Q'},\ \Omega(\theta_3')$)
    $X'$ = evaluate-accuracy($G^{Q'}$)
    model.update($X', \{\theta_1', \theta_2', \theta_3'\}$)
    iteration = iteration + 1
end
Result: Best accuracy for model and respective
        parameters $\theta_1, \theta_2, \theta_3$
```

3 Empirical Evaluation

Background Knowledge: We construct the required knowledge bases using the following sources.

(1) Abstract KB: Our Abstract knowledge base is constructed from the WorldTree Tablestore corpus (Xie et al., 2020; Jansen et al., 2018). The Tablestore corpus contains a set of common sense and scientific facts adopted to create explanations for multiple-choice science questions. The corpus is built for answering elementary science questions encouraging possible knowledge reuse to elicit explanatory patterns. We extract the core scientific facts to build the Abstract KB. Core scientific facts

$y_{v_i} = 1 \quad \text{if } v_i = h_i \quad (1)$ $y_{v_i} \leq \sum_j y_{v_j} \quad \forall v_j \in N_{G^{h_i}}(v_i) \quad (2)$ $z_{v_i,v_j} \leq y_{v_i} \quad \forall e_{(v_i,v_j)} \in E \quad (3)$ $z_{v_i,v_j} \leq y_{v_j} \quad \forall e_{(v_i,v_j)} \in E \quad (4)$ $z_{v_i,v_j} \geq y_{v_i} + y_{v_j} - 1 \quad \forall e_{(v_i,v_j)} \in E \quad (5)$	**Chaining constraint**: Equation 1 states that the subgraph should always contain the hypothesis node. Inequality 2 states that if a vertex is to be part of the subgraph, then at least one of its neighbors with a lexical overlap should also be part of the subgraph. Equation 1 and Inequality 2 restrict the LP method to construct explanations that originate from the hypothesis and perform multi-hop aggregation based on the existence of lexical overlap. Inequalities 3, 4 and 5 state that if two vertices are in the subgraph then the edges connecting the vertices should be also in the subgraph. These inequality constraints will force the LP method to avoid grounding nodes with high overlap regardless of their relevance.
$\sum_i y_{v_i} \leq K \quad \forall v_i \in F_A^{h_i} \quad (6)$	**Abstract fact limit constraint**: Equation 6 limits the total number of abstract facts to K. Instead of limiting of total selected number of nodes to K, by limiting the abstract facts we dictate the need for grounding facts based on the number of terms present in the hypothesis and in the abstract facts.
$\sum_{v_j} y_{v_i} - 2 \geq -2(1 - y_{v_j}) \quad \forall v_i \in N_{G^{h_i}}(v_j),\ v_i \in \{F_A^{h_i} \cup h_i\},\ v_j \in F_G^{h_i} \quad (7)$	**Grounding neighbor constraint**: Inequality 7 states that if a grounding fact is selected, then at least two of its neighbors should be either both abstract facts or a hypothesis and an abstract fact. This constraint ensures that grounding facts play the linking role connecting hypothesis-abstract facts.

Table 1: Linear programming constraints employed by ExplanationLP to emulate grounding-abstract inference chains and extract the optimal subgraph

are independent from the specific questions and represent general scientific and commonsense knowledge, such as `Actions` (*friction occurs when two object's surfaces move against each other*) or `Affordances` (*friction causes the temperature of an object to increase*).

(2) Grounding KB: The grounding knowledge base consists of definitional knowledge (e.g., synonymy and taxonomy) that can take into account lexical variability of questions and help it link it to abstract facts. To achieve this goal, we select the *is-a* and *synonymy* facts from ConceptNet (Speer et al., 2017) as our grounding facts. ConceptNet has high coverage and precision, enabling us to answer a wide variety of questions.

Question Sets: We use the following question sets to evaluate ExplanationLP's performance and compare it against other explainable approaches:

(1) WorldTree Corpus: The 2,290 questions in the WorldTree corpus are split into three different subsets: *train-set* (987), *dev-set* (226) and *test-set* (1,077). We use the *dev-set* to assess the explainability performance and robustness analysis since the explanations for *test-set* are not publicly available.

(2) ARC-Challenge Corpus: ARC-Challenge is a multiple-choice question dataset which consists of question from science exams from grade 3 to grade 9 (Clark et al., 2018). We only consider the Challenge set of questions. These questions have proven to be challenging to answer for other LP-based question answering and neural approaches. ExplanationLP rely only on the *train-set* (1,119) and test on the *test-set* (1,172). ExplanationLP does not require *dev-set*, since the possibility of over-fitting is non-existent with only ten parameters.

Relevant Facts Retrieval (FR): We experiment with two different fact retrieval scores. The first model – i.e. *BM25 Retrieval*, adopts a BM25 vector representation for hypothesis and explanation facts. We apply this retrieval for both Grounding and Abstract retrieval. We use the IDF score from BM25 as our downstream model's relevance score. The second approach – i.e. *Unification Retrieval (UR)*, represents the BM25 implementation of the Unification-based Reconstruction framework described in Valentino et al. (2021). The unification score for a given fact depends on how often the same fact appears in explanations for similar questions.

Baselines: The following baselines are replicated on the WorldTree corpus to compare against ExplanationLP:

(1) Bert-Based models: We compare the ExplanationLP model's performance against a set of BERT baselines. The first baseline – i.e. $BERT_{Base}$/$BERT_{Large}$, is represented by a standard BERT language model (Devlin et al., 2019) fine-tuned for multiple-choice question answering. Specifically, the model is trained for binary classification on each question-candidate answer pair to maximize the correct choice (i.e., predict 1) and minimize the wrong choices (i.e., predict 0). During inference, we select the choice with the highest prediction score as the correct answer. BERT baselines are further enhanced with explanatory facts retrieved by the retrieval models. *BERT + BM25* and *BERT + UR*, is fine-tuned for binary classification by complementing the question-answer pair with grounding and abstract facts selected by BM25 and Unification retrieval, respectively.

Similarly, the second model *BERT + UR* complements the question-answer pair with grounding and abstract facts selected using BM25 and Unification retrieval, respectively.

(2) PathNet (Kundu et al., 2019): PathNet is a neural approach that constructs a single linear path composed of two facts connected via entity pairs for reasoning. PathNet also can explain its reasoning via explicit reasoning paths. They have exhibited strong performance for multiple-choice science questions by composing two facts. Similar to Bert-based models, we employ PathNET with the top k facts retrieved utilizing Unification (*PathNet + UR*) and BM25 (*PathNet + BM25*) retrieval. We concatenate the facts retrieved for each candidate answer and provide as supporting facts.

Further details regarding the hyperparameters and code used for each model, along with information concerning the knowledge base construction and dataset information, can be found in the Supplementary Materials.

#	Model	Accuracy Easy	 Challenge
1	BERT$_{Base}$	51.04	28.75
2	BERT$_{Large}$	54.58	29.39
3	BERT$_{Base}$ + BM25 (k=10)	53.92	42.72
4	BERT$_{Large}$ + BM25 (k=10)	54.05	43.45
5	BERT$_{Base}$ + UR (k=10)	52.87	42.17
6	BERT$_{Large}$ + UR (k=10)	58.50	43.72
7	PathNet + BM25 (k=20)	43.32	36.42
8	PathNet + UR (k=15)	47.64	33.55
9	Ours + BM25 (k=30)	63.82	48.24
10	Ours + UR (k=30)	**66.23**	**50.15**

Table 2: Accuracy on Easy (764) and Challenge split (313) of WorldTree *test-set* corpus from the best performing k of each model

#	Model	Explainable	Accuracy
1	BERT$_{Large}$	No	35.11
2	IR Solver (Clark et al., 2016)	Yes	20.26

3.1 Answer Selection

WorldTree Corpus: We retrieve the top l relevant grounding facts from Grounding KB and the top m relevant abstract facts from Abstract KB such that $l + m = k$ and $l = m$. To ensure fairness across the approaches, the same amount of facts are presented to each model. We experimented with $k = \{10, 20, 30, 40, 50\}$ and report the accuracy across Easy and Challenge split of the best performing setting in Table 2. We draw the following conclusions:

(1) Despite having a smaller number of parameters to train (BERT$_{Base}$: 110M parameters, BERT$_{Large}$: 340M parameters, ExplanationLP: 9 parameters), the best performing ExplanationLP (#10) overall outperforms all the BERT$_{Base}$ and BERT$_{Large}$ models on both Challenge and Easy split. We outperform the best performing BERT model with facts (BERT$_{Large}$ (#6)) by 7.74% in Easy and 6.43% in Challenge. We also outperform best performing BERT without facts (BERT$_{Large}$ (#2)) by 11.66% in Easy and 20.76% in Challenge.

(2) BERT is inherently a black-box model, not being entirely possible to explain its prediction. By contrast, ExplanationLP is fully explainable and produces a complete explanatory graph.

(3) Similar to ExplanationLP, PathNet is also explainable and demonstrates robustness to noise.

CASE I: All the selected facts are in the gold explanation (**Frequency**: 33%)

Question: A company wants to make a game that uses a magnet that sticks to a board. Which material should it use for the board? **Answer:** steel
Explanations: (1) steel is a metal (*Grounding*), (2) if a magnet is attracted to a metal then that magnet will stick to that metal (*Abstract*), (3) a magnet attracts magnetic metals through magnetism (*Abstract*),

CASE II: At least one selected facts are in the gold explanation (**Frequency**: 58%)

Question: A large piece of ice is placed on the sidewalk on a warm day. What will happen to the ice? **Answer**: It will melt to form liquid water.
Explanations: (1) drop is liquid small amount (*Grounding*), (2) forming something is change (*Grounding*), (3) ice wedging is mechanical weathering (*Grounding*), (4) melting means changing from a solid into a liquid by adding heat energy (*Abstract*), (5) weathering means breaking down surface materials from larger whole into smaller pieces by weather (*Abstract*),

CASE III: No retrieved facts is in the gold explanation (**Frequency**: 9%)

Question:Wind is a natural resource that benefits the southeastern shore of the Chesapeake Bay. How could these winds best benefit humans? **Answer:** The winds could be converted to electrical energy
Explanations: (1) renewable resource is natural resource (*Grounding*), (2) wind is a renewable resource (*Abstract*), (3) electrical devices convert electricity into other forms of energy (*Abstract*)

Table 4: Case study of explanation extracted by ExplanationLP

ExplanationLP also outperforms PathNet's best performance setting (#8) by 18.59% in Easy and 16.60% in Challenge.

(4) ExplanationLP consistently exhibits better scores on both BM25 and UR than BERT and PathNet, demonstrating independence of the upstream retrieval model for performance.

ARC-Challenge : We also evaluated our model on the ARC-Challenge corpus (Clark et al., 2018) to evaluate ExplanationLP on a more extensive general question set and compare against contemporary approaches that provide explanations for an inference that has *only* been trained on ARC corpus. Table 3 reports the results on the *test-set*. We compare ExplanationLP against published approaches that are fully/partly explainable. Here explainability indicates if the model produces an explanation/evidence for the predicted answer. A subset of the approaches produces evidence for the answer but remains intrinsically black-box. These models have been marked as *Partial*.

As depicted in the Table 3, we outperform the best performing fully explainable (#4 TableILP) model by 13.28%. We also outperform specific neural approaches with larger parameter sets (#5 - #9) that provide explanations for their inference and BERT (#1). Despite having a smaller number of training parameters, we also exhibit competitive performance with a state-of-the-art Bert-based approach (#10) that do not use external resources to train the QA system.

3.2 Explainability

Approach	**Precision**	**Recall**	**F1**
PathNet + UR (k=20)	21.56	36.55	29.06
Ours + UR (k=30)	**57.96**	**49.92**	**48.13**

Table 5: Explanation retrieval performance on the WorldTree Corpus *dev-set*.

Table 5 shows the Precision, Recall and F1$_{Macro}$ score for explanation retrieval for PathNet and ExplanationLP. These scores are computed using gold abstract explanations from WorldTree corpus. We outperform PathNet across all spectrum by a significant margin.

Table 4 reports three representative cases that show how explanation generation relates to correct answer prediction. The first example (Case I) represents the situation in which all the selected sentences are annotated as gold explanations in the WorldTree corpus (dev-set). The second example (Case II) shows the case in which at least one sentence in the explanation is labelled as gold. Finally, the third example (Case III) represents the case in which the explanation generated by the method does not contain any gold fact. We observe Case I and Case II occur over 91% of the questions, demonstrating that the correct answers are mostly derived from plausible explanations.

3.3 Ablation Study

In order to understand the contribution lent by different components, we choose the best setting

#	Approach	Accuracy WT	 ARC
1	ExplanationLP **(Best)**	**61.37**	**40.21**
Structure			
2	Grounding-Abstract Categories	58.33	35.13
3	Edge weights	43.78	29.45
4	Node weights	42.80	27.87
Cohesion			
5	Hypothesis-Abstract cohesion	38.71	30.37
6	Hypothesis-Grounding cohesion	59.33	38.73
7	Grounding-Abstract cohesion	59.12	38.14
Diversity			
8	Abstract-Abstract diversity	60.16	37.62
9	Grounding-Grounding diversity	60.44	37.71
Relevance			
10	Hypothesis-Abstract semantic similarity	55.38	35.49
11	Hypothesis-Abstract lexical relevance	54.68	36.01

Table 6: Ablation study, removing different components of ExplanationLP. The scores reported here are accuracy for answer selection on the WorldTree (WT) and ARC-Challenge (ARC) test-set.

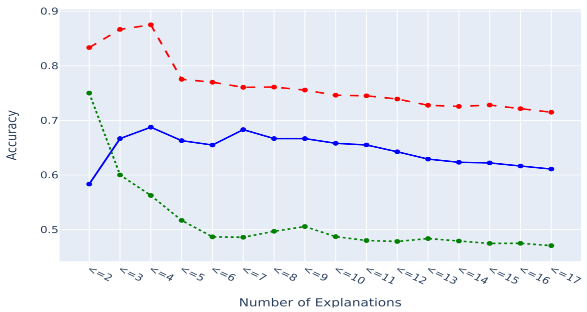

Figure 2: Change in accuracy of answer prediction the development set varying across different models with increasing explanation length for WorldTree *dev-set*. Red dashed line represents ExplanationLP + UR (k=30), blue line represents BERT$_{Large}$ + UR (k=10) and green dotted line represents PathNet + UR (k=20)

(*WorldTree*: ExplanationLP + UR (k=30) and *ARC*: ExplanationLP + BM25 (k=40)) and drop different components to perform an ablation analysis. We retain the ensemble after removing each component. The results are summarized in Table 6.

(1) The grounding-abstract chains (#2) play a significant role, particularly in the reasoning mechanism on a challenging question set like ARC-Challenge.

(2) As observed in #3, #4 removing node weights and edge weights lead to a dramatic drop in performance. This drop indicates that both are fundamental for the final prediction, highlighting the role of graph structure in explainable inference.

(3) The importance of cohesion varies across different types of facts. We observe that Hypothesis-Abstract cohesion (#5) is significantly more important than the others. We attribute this to the fact that without Hypothesis-Abstract cohesion, multi-hop inference can quickly go out of context.

(4) From the ablation analysis, we can see how lexical relevance and semantic similarity (#10, 11) complements each other towards the final prediction. For WorldTree corpus, the relevance score has a higher parameter score translating into a higher impact and vice-versa for ARC.

(5) Diversity plays a smaller role when compared to cohesion and relevance. The impact of diversity in ARC is higher than that of WorldTree.

Semantic Drift To validate the performance across an increasing number of hops, we plot the accuracy against explanation length as illustrated in Figure 2. As demonstrated in explanation regeneration (Valentino et al., 2021; Jansen and Ustalov, 2019), the complexity of a science question is directly correlated with the explanation length – i.e. the number of facts required in the gold explanation. Unlike BERT, PathNet and ExplanationLP use external background knowledge, addressing the multi-hop process in two main reasoning steps. However, in contrast to ExplanationLP, PathNet combines only two explanatory facts to answer a given question. This assumption has a negative impact on answering complex questions requiring long explanations. This is evident in the graph, where we observe a sharp decrease in accuracy with increasing explanation length. Comparatively, ExplanationLP achieves more stable performance, showing a lower degradation with an increasing number of explanation sentences. These results crucially demonstrate the positive impact of grounding-abstract mechanisms on semantic drift. We also exhibit consistently better performance when compared with BERT as well.

4 Related Work

Our approach broadly falls into Linear Programming based approaches for science question answering. LP-based approaches perform inference over either semi-structured tables (Khashabi et al., 2016) or structural representations extracted from the text (Khashabi et al., 2018; Khot et al., 2017a). These approaches treat all facts homogeneously and attempt to connect the question with the correct answer through long hops. While they have exhibited good performance with no supervision, the performance tends to be lower when answering complex questions requiring long explanatory chains. In contrast, our approach performs inference over unstructured text by imposing structural constraints via grounding-abstract chains, lowering the hops, and also combine parametric optimisation to extract the best performing model.

The other class of approaches that provide explanations are graph-based approaches. Graph-based approaches have been successfully applied for open-domain question answering (Fang et al., 2020; Qiu et al., 2019; Thayaparan et al., 2019) where the question only requires only two hops. PathNet (Kundu et al., 2019) operates within the same design principles and has been applied on OpenbookQA science dataset. As indicated in the empirical evaluation, it struggles with long-chain explanations since it relies only on two facts. Graph-based approaches have also been employed for mathematical reasoning (Ferreira and Freitas, 2020a,b) and textual entailment (Silva et al., 2019, 2018).

The third category of partially explainable approaches employs black-box neural models in combination with a retrieval approach. The SOTA model for Science Question (Khashabi et al., 2020) answering is pretrained across multiple datasets and is not explainable. The current partially explainable SOTA approach that does not rely on external resource (Yadav et al., 2019b) employs a large parameter BERT model for question answering resulting. In contrast, with a low number of parameters, we have introduced a model that demonstrates competitive performance and leaves a smaller carbon footprint in terms of energy consumption (Henderson et al., 2020). Other methods construct explanation chains by leveraging explanatory patterns emerging in a corpus of scientific explanations (Valentino et al., 2020, 2021).

5 Conclusion

This paper presented a robust, explainable and efficient science question answering model that performs abductive natural language inference. We also presented an in-depth systematic evaluation demonstrating the impact on the various set of design principles via an in-depth ablation analysis. Despite having a significantly lower number of parameters, we demonstrated competitive performance compared with contemporary explainable approaches while also showcasing its robustness, explainability and interpretability.

A Supplementary Material

This section consists of all the hyperparameters, code and libaries used in our approach. We present this in the hope it fosters reproducibility.

A.1 Linear Programming Optimization

The components of the linear programming system is as follows:

- Solver: CPLEX optimization studio V12.9.0 `https://www.ibm.com/products/ilog-cplex-optimization-studio`

The hyperparatemers used in the LP constraints:

- Maximum number of abstract facts (K): 2
- Average time per epoch: 6 minutes for train-set
- Number of Epochs: 200

Infrastructures used:

- CPU Cores: 32
- CPU Model: Intel(R) Core(TM) i7-6700 CPU @ 3.40GHz
- Memory: 128GB
- OS: Ubuntu 18.04 LTS

A.2 Parameter tuning

Our work employed Bayesian optmization with Gaussian process for hyperparamter tuning. We used the `https://github.com/fmfn/BayesianOptimization`: Bayesian-Optimization python library to implement the code. These parameters are as follows:

- Gaussian Kernels:
  - RationalQuadratic Kernel with default parameters
  - WhiteKernel with noise level of 1e-5, noise level bounds (1e-10, 1e1) and rest of the default parameters
- Number of iterations: 200
- alpha (α): 1e-8
- random state: 1

A.3 Sentence-BERT for Semantic Similarity Scores

We use: *roberta-large nli-stsb mean-tokens* model to calculate the semantic similarity scores.

A.4 BERT model

The BERT model was taken from the Hugginface Transformers (`https://github.com/huggingface/transformers`) library and fine-tuned using 4 Tesla V100 GPUs for 10 epochs in total with batch size 16 for BERT$_{Large}$ and 32 for for BERT$_{Base}$. The hyperparameters adopted for BERT are as follows:

- gradient accumulation steps: 1
- learning rate: 1e-5
- weight decay: 0.0
- adam epsilon: 1e-8
- warmup steps: 0
- max grad norm: 1.0
- seed: 42

A.5 PathNet

We use the code and dependencies provided by the PathNet github repository (`https://github.com/allenai/PathNet`).
We used the training config provided for OpenBookQA as a baseline: `https://github.com/allenai/PathNet`, file name: *blob/master/training_configs/config_obqa.json*.

A.6 Relevant facts retrieval

The code for BM25 and Unification retrieval approaches were adopted from the Unification Explanation Retrieval GitHub repository (`https://github.com/ai-systems/unification_reconstruction_explanations`).

A.7 Code

The code for reproducing the ExplanationLP and the experiments described in this paper are attached with the code appendix and will be available at the following GitHub repository (with a Dockerized container): `https://github.com/ai-systems/explanationlp`.

A.8 Data

WorldTree Dataset : The 2,290 questions in the WorldTree corpus are split into three different subsets: *train-set* (987), *dev-set* (226), and *test-set* (1,077). We only considered questions with explanations for our evaluation. The reasoning behind omitting questions without explanations was to ensure fact coverage for all questions. For AbstractKB building we excluded facts from 'KINDOF' and 'SYNONYMY' table, as these are the one primarily composed of grounding facts.

ARC-Challenge Dataset : Only used the Challenge split: `https://allenai.org/data/arc`.

LV-BERT: Exploiting Layer Variety for BERT

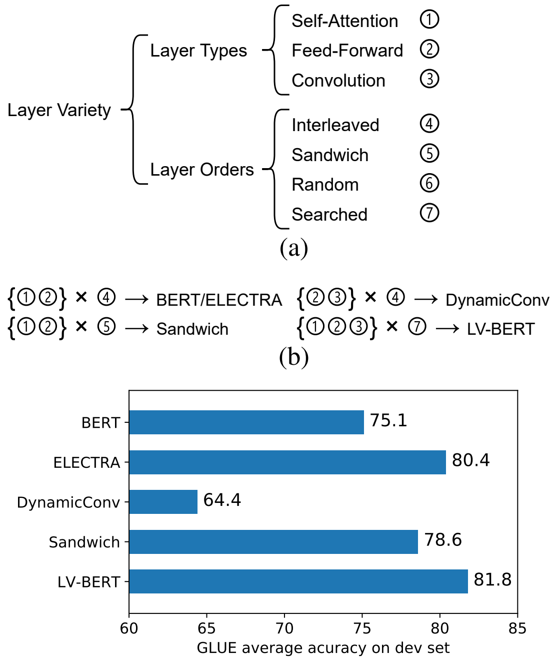
Abstract

Modern pre-trained language models are mostly built upon backbones stacking self-attention and feed-forward layers in an interleaved order. In this paper, beyond this stereotyped layer pattern, we aim to improve pre-trained models by exploiting *layer variety* from two aspects: the layer type set and the layer order. Specifically, besides the original self-attention and feed-forward layers, we introduce convolution into the layer type set, which is experimentally found beneficial to pre-trained models. Furthermore, beyond the original interleaved order, we explore more layer orders to discover more powerful architectures. However, the introduced layer variety leads to a large architecture space of more than billions of candidates, while training a single candidate model from scratch already requires huge computation cost, making it not affordable to search such a space by directly training large amounts of candidate models. To solve this problem, we first pre-train a supernet from which the weights of all candidate models can be inherited, and then adopt an evolutionary algorithm guided by pre-training accuracy to find the optimal architecture. Extensive experiments show that LV-BERT model obtained by our method outperforms BERT and its variants on various downstream tasks. For example, LV-BERT-small achieves 78.8 on the GLUE testing set, 1.8 higher than the strong baseline ELECTRA-small. [1]



(a)

(b)

(c)

Figure 1: (a) Illustration of layer variety. This concept consists of two aspects: layer type and layer order. (b) Different models represented by layer variety. (c) Performance of different models with hidden size of 256 on GLUE (Wang et al., 2018) development set. Except BERT pre-trained with the Masked Language Modeling objective (Devlin et al., 2019), the other models are pre-trained with Replaced Token Detection objective (Clark et al., 2020) to save computation cost.

1 Introduction

In recent years, pre-trained language models, such as the representative BERT (Devlin et al., 2019) and GPT-3 (Brown et al., 2020), have gained great success in natural language processing tasks (Peters et al., 2018a; Radford et al., 2018; Yang et al., 2019; Clark et al., 2020). The backbone architectures of these models mostly adopt a stereotyped layer pattern, in which the *self-attention* and *feed-forward* layers are arrayed in an interleaved order (Vaswani et al., 2017). However, there is no evidence supporting that this layer pattern is optimal (Press et al., 2020). We then consider a straightforward and interesting question: Could we change the layer pattern to improve pre-trained models? We attempt to answer this question by exploiting more *layer variety* from two aspects, as shown in Figure 1(a): the layer type set and the layer order.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 13–27
August 1–6, 2021. ©2021 Association for Computational Linguistics

We first consider the layer types. In previous pre-trained language models, the most widely-used layer set contains the self-attention layer for capturing global information and the feed-forward layer for non-linear transformation. However, some recent works have unveiled that some self-attention heads in pre-trained models tend to learn local dependencies due to the inherent property of natural language (Kovaleva et al., 2019; Brunner et al., 2020; Jiang et al., 2020), incurring computation redundancy for capturing local information. In contrast, convolution is a local operator (LeCun et al., 1998; Krizhevsky et al., 2012; Simonyan and Zisserman, 2015; He et al., 2016) and has shown effectiveness on extracting local information for language models (Zeng et al., 2014; Kim, 2014; Kalchbrenner et al., 2014; Wu et al., 2018, 2019b; Jiang et al., 2020). Thus, we propose to augment the layer set by including convolution for local information extraction.

For layer orders, most of the existing pre-trained models adopt an interleaved order to arrange the different types of layers. Differently, Press et al. (2020) presented the sandwich order, *i.e.*, stacking consecutive self-attention and feed-forward layers at the bottom and top, respectively, while keeping the interleaved order in the middle. It has been shown that the sandwich order can bring improvement on language modeling task, indicating the layer order contributes to model performance. However, Press et al. (2020) did not show the generalization capability of this order to other tasks. There is still a large room for exploring more effective orders for pre-trained models. We show the different layer variety designs of existing models in Figure 1(b), including BERT (Devlin et al., 2019)/ELECTRA (Clark et al., 2020), DynamicConv (Wu et al., 2018) and Sandwich (Press et al., 2020). Their performance is summarized in Figure 1(c). It can be seen that layer variety significantly influences model performance. We thus claim it is necessary to investigate layer variety for promoting pre-trained models. However, to perform such investigation for a common model backbone, *e.g.*, with 24 layers, we need to evaluate performance of every candidate within an architecture space of $3^{24} \approx 2.8 \times 10^{11}$ candidates. Pre-training a single language model already needs to consume a large amount of computation, *e.g.*, 2400 P100 GPU days for pre-training BERT (Lin et al., 2020). It is barely affordable to pre-train such a large amount of model candidates from scratch. To reduce the computation cost, inspired by recent works on Neural Architecture Search (NAS) (Guo et al., 2020; Cai et al., 2019), we construct a supernet according to the layer variety discussed above and pre-train it with Masked Language Modeling (MLM) (Devlin et al., 2019) objective. After obtaining the pre-trained supernet, we develop an evolutionary algorithm guided by MLM evaluation accuracy to search an effective architecture with specific layer variety. We call the resulted model LV-BERT. Extensive experiments show that LV-BERT outperforms BERT and its variants. The contributions of our paper are two-fold. Firstly, to the best of our knowledge, this work is the first to exploit layer variety w.r.t. both layer types and orders for pre-trained language models. We found convolutions and layer orders both benefit pre-trained model performance. We hope our observations would facilitate the development of pre-trained lauguage models. Secondly, our obtained LV-BERT shows superiority over BERT and its variants. For example, LV-BERT-small achieves 79.8 on GLUE testing set, 1.8 higher than the baseline ELECTRA-small (Clark et al., 2020).

2 Related Work

Pre-trained Language Models Pre-trained language models have achieved great success and promoted the development of NLP techniques. Instead of separate word representation (Mikolov et al., 2013a,b), McCann et al. (2017) and Peters et al. (2018b) propose CoVe and ELMo respectively which both utilize LSTM (Hochreiter and Schmidhuber, 1997) to generate contextualized word representations. Later, Radford et al. (2018) introduce GPT that changes the backbone to transformers where self-attention and feed-forward layers are arrayed interleavedly. They also propose generative pre-training objectives. BERT (Devlin et al., 2019) continues to use the same layer set and order for backbone but employs different pre-training objectives, *i.e.*, Masked Language Modeling and Next Sentence Prediction. Then more works introduce new effective pre-training objectives, like Generalized Autoregressive Pretraining (Yang et al., 2019), Span Boundary Objective (Joshi et al., 2020) and Replaced Token Detection (Clark et al., 2020). Besides designing pre-training objectives, some other works try to extend BERT by incorporating knowledge (Zhang et al., 2019; Peters et al., 2019; Liu et al., 2020; Xiong et al., 2020) or with multiple languages (Huang et al., 2019; Conneau and Lample, 2019; Chi et al., 2019). These works utilize the stereotyped layer pattern, which is unnecessarily optimal (Press et al., 2020), inspiring us to further investigate more layer variety to improve pre-trained models. To the best of our knowledge, we are the first to exploit layer variety from both the layer type set and the layer order for pre-trained language models.

Neural Architecture Search Manually designing neural architecture is a time-consuming and error-prone process (Elsken et al., 2019). To solve this, many neural architecture search algorithms are proposed. Pioneering works utilize reinforcement learning (Zoph and Le, 2017; Baker et al., 2017) or evolutionary algorithm (Real et al., 2017) to sample architecture candidates and train them from scratch, which demand huge computation that ordinary researchers can not afford. To reduce computation cost, recent methods (Pham et al., 2018; Liu et al., 2018; Xie et al., 2018; Brock et al., 2018; Cai et al., 2018; Bender et al., 2018; Wu et al., 2019a; Guo et al., 2020) adopt a *weight sharing* strategy that a supernet subsuming all architectures is trained only once and all architecture candidates can inherit their weights from the supernet. Despite the boom of NAS research, most works focus on computer vision tasks (Chen et al., 2019; Ghiasi et al., 2019; Liu et al., 2019a), while NAS on NLP is not fully investigated. Recently, So et al. (2019) and Wang et al. (2020) search architectures of transformers for translation tasks. Chen et al. (2020) leverage differentiable neural architecture to automatically compress BERT with task-oriented knowledge distillation for specific tasks. Zhu et al. (2020) utilize architecture search to improve models based on pre-trained BERT for the relation classification task. However, these methods only focus on specific tasks or the fine-tuning phase. Besides, Khetan and Karnin (2020) employ pre-training loss to help prune BERT, but their method can not find new architectures. Different from them, our work is the first to use NAS to help explore new architectures in a pre-training scenario for general language understanding.

3 Method

An overview of our approach is shown in Figure 2. We first define the layer variety to introduce a large architecture search space, and then pre-train a supernet subsuming all candidate architectures, followed by an evolutionary algorithm guided by pre-training MLM (Devlin et al., 2019) accuracy to search an effective model. In what follows, we will give detailed descriptions.

3.1 Layer Variety

As shown in Figure 1(a), the proposed layer variety contains two aspects: layer type and layer order, both of which are important for the performance of pre-trained models but not exploited before.

Layer Type The layer type set of current BERT-like models consists of self-attention for information communication and feed-forward for non-linear transformation. However, as a global operator, self-attention needs to take as input all tokens to compute attention weights for each token, which is inefficient in capturing local information (Wu et al., 2019b; Jiang et al., 2020). We notice that convolution (LeCun et al., 1998; Krizhevsky et al., 2012), as a local operator, has been successfully applied in language models (Zeng et al., 2014; Kim, 2014; Kalchbrenner et al., 2014; Wu et al., 2018, 2019b; Jiang et al., 2020). A typical example is the dynamic convolution (Wu et al., 2018) for machine translation, language modeling and summarization. Therefore, we augment the layer type set by introducing dynamic convolution as a new layer type. The layer set considered in this work thus contains three types of layers,

$$\mathcal{L}^{\text{type}} = \{L^{\text{SA}}, L^{\text{FF}}, L^{\text{DC}}\}, \quad (1)$$

where the set elements denote self-attention, feed-forward and dynamic convolution layers respectively. See Appendix for more detailed formulation description on them.

Layer Order The other variety aspect is layer order. The most widely-used order for pre-trained models is the interleaved order (Vaswani et al., 2017; Devlin et al., 2019). For a model with 24 layers, the interleaved order can be expressed by the following list,

$$[L_1^{\text{SA}}, L_2^{\text{FF}}, L_3^{\text{SA}}, L_4^{\text{FF}}, ..., L_{23}^{\text{SA}}, L_{24}^{\text{FF}}]. \quad (2)$$

Similarly, the sandwich order (Press et al., 2020) can be expressed as

$$\begin{aligned}&[L_1^{\text{SA}}, L_2^{\text{SA}}, ..., L_5^{\text{SA}},\\ &L_6^{\text{SA}}, L_7^{\text{FF}}, L_8^{\text{SA}}, L_9^{\text{FF}}, ..., L_{18}^{\text{SA}}, L_{19}^{\text{FF}},\\ &L_{20}^{FF}, L_{21}^{FF}, ..., L_{24}^{\text{FF}}].\end{aligned} \quad (3)$$

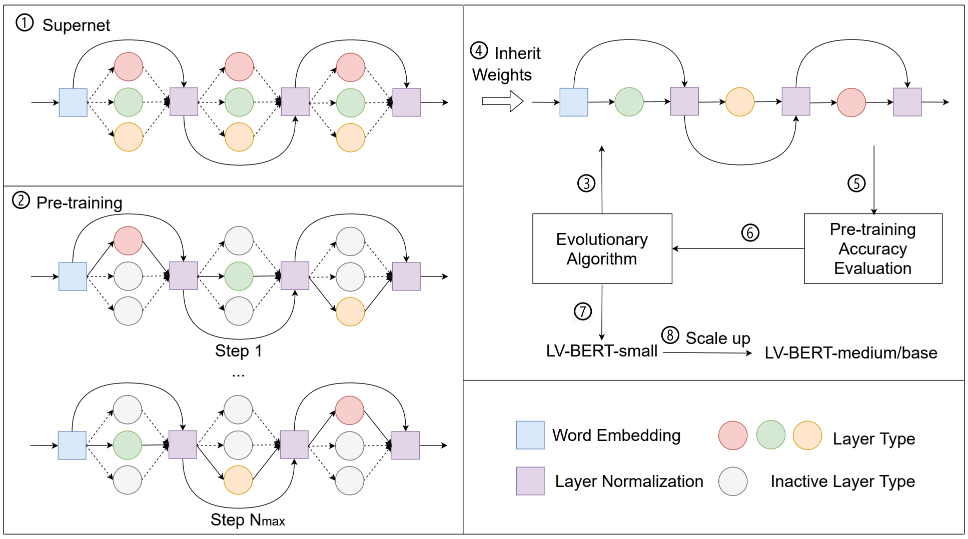

Figure 2: Overview on how to search LV-BERT. ① Construct a supernet with small hidden size by including all types of layers at each layer. ② Pre-train the supernet with Masked Language Modeling (MLM) objective (Devlin et al., 2019) by only uniformly sampling one type of layer into training at each layer. ③ Apply evolutionary algorithm to produce candidate models. ④ The candidate models inherit their weights from the supernet. ⑤ The candidate models with inherited weights are directly evaluated with pre-training MLM accuracy on validation set. ⑥ The accuracy is used to guide the evolutionary algorithm for generating new candidate models. ⑦ After T iterations, the candidate with best pre-training accuracy is output as LV-BERT-small. ⑧ LV-BERT-small can be scaled up to LV-BERT-medium/base with larger hidden size.

Beyond the above manually designed orders, we take advantage of neural architecture search to identify more effective layer orders for pre-trained models. The order to be discovered can be expressed as

$$[L_1, L_2, ..., L_i, ..., L_N], \tag{4}$$

where $L_i \in \mathcal{L}^{\text{type}}$ and N is the number of layers. Here, N is set to 24, following common practice.

3.2 Supernet

The layer variety introduced above leads to a huge architecture space of $3^{24} \approx 2.8 \times 10^{11}$ candidate models to be explored. Thus, it is not affordable to pre-train every candidate model in the space from scratch to evaluate their performance since the pre-training procedure requires huge computations. To reduce the search computations, recent NAS works (Pham et al., 2018; Guo et al., 2020; Cai et al., 2019) exploit a weight sharing strategy. It first trains a supernet subsuming all candidate architectures, and then each candidate architecture can inherit its weights from the trained supernet to avoid training from scratch. Inspired by this strategy, we construct a supernet where each layer contains all types of layers, *i.e.*, self-attention, feed-forward, and dynamic convolution. The supernet architecture can be expressed as

$$\mathcal{A} = [\{L_1^{\text{SA}}, L_1^{\text{FF}}, L_1^{\text{DC}}\}, \{L_2^{\text{SA}}, L_2^{\text{FF}}, L_2^{\text{DC}}\}, ..., \{L_N^{\text{SA}}, L_N^{\text{FF}}, L_N^{\text{DC}}\}]. \tag{5}$$

Masked Language Modeling (MLM) (Devlin et al., 2019) is utilized as the pre-training objective to pre-train the supernet since MLM accuracy can reflect the model performance on downstream tasks (Lan et al., 2020). Most weight sharing approaches on NAS (Wu et al., 2019a; Liu et al., 2018) train and optimize the full supernet: the output of each layer is the weighted sum of all types of candidate layers. However, it cannot guarantee the sampled single type of layer also works (Guo et al., 2020).

To handle this issue, we propose to randomly sample a submodel from the supernet to participate in forward and backward propagation per training step (Cai et al., 2018; Guo et al., 2020). The sampled submodel architecture can be expressed as

$$a = [L_1, L_2, ..., L_i, ..., L_N], \tag{6}$$

where $L_i \in \mathcal{L}^{\text{type}} \sim U$ with uniform probability distribution $Pr = 1/3$. In this pre-training method, the optimized supernet weights can be expressed

Algorithm 1: Evolutionary Search Guided by Pre-training MLM Accuracy

```
Input: $W_{\mathcal{A}}$: supernet weights; $P$: population size; $D_{\text{val}}$: pre-training validation set; $T$: # iteration; $N^{\text{cro}}$: # crossover; $N^{\text{mut}}$: # mutation; $p$: mutation probability; $k$: # top candidates for crossover and mutation
Output: $a^*$: the architecture with the best pre-trianing MLM validation accuracy
$S_0 := \text{Init}(P)$; // Randomly generate $P$ architecture candidates
$S^{\text{topk}} := \emptyset$; // The set of top $k$ candidates
for $i = 1 : T$ do
    $S_{i-1}^{\text{MLM}} := \emptyset$;
    for $a$ in $S_{i-1}$ do
        $\text{MLM}_{\text{val}}^{a} := \text{Inference}(\mathcal{N}(a, W_{\mathcal{A}}(a)), D_{\text{val}})$;
        $S_{i-1}^{\text{MLM}} := S_{i-1}^{\text{MLM}} \cup \text{MLM}_{\text{val}}^{a}$;
    $S^{\text{topk}} := \text{Update}(S^{\text{topk}}, \text{S}_{i-1}, S_{i-1}^{\text{MLM}})$;
    $S^{\text{cro}} := \text{Crossover}(S^{\text{topk}}, N^{\text{cro}})$;
    $S^{\text{mut}} := \text{Mutation}(S^{\text{topk}}, N^{\text{mut}}, p)$;
    $S_i := \text{S}^{\text{cro}} \cup \text{S}^{\text{mut}}$;
return $a^* = \text{argmax}_{a \in S^{\text{topk}}} \text{MLM}_{\text{val}}^{a}$;
```

as

$$W_{\mathcal{A}} = \underset{W}{\text{argmin}}\, \mathbb{E}_{a \sim U(A)}[\mathcal{L}_{\text{pre-train}}(\mathcal{N}(a, W(a)))], \tag{7}$$

where $W(a)$ denotes the submodel weights inherited from the supernet, $\mathcal{N}$ means the submodel with specific architecture and weights, $\mathcal{L}_{\text{pre-train}}$ denotes the pre-training MLM loss and $a \sim U(\mathcal{A})$ means a is uniformly sampled from $\mathcal{A}$.

3.3 Evolutionary Search

Inspired by the recent NAS works (Elsken et al., 2019; Ren et al., 2020; Guo et al., 2020; Wang et al., 2020), we adopt an evolutionary algorithm (EA) to search the model. Previously Real et al. (2017) utilized an evolutionary method in NAS but they trained each candidate model from scratch which is costly and inefficient. Instead, thanks to the supernet mentioned above, we do not need to train the candidate models from scratch since their weights can be inherited from the supernet. Next problem is how to select indicator of the candidate models to guide the EA. Note that our goal is to search a general pre-trained model to benefit a variety of downstream tasks instead of a specific task. Traditional NAS methods (Chen et al., 2020; Zhu et al., 2020) use downstream task performance as the objective to search for task-specific models. Instead, similar to the work by Khetan and Karnin (2020) that utilize pre-training loss to prune BERT, our method uses pre-training MLM accuracy to search for a unified architecture that can generalize well to different downstream tasks. Besides, using this accuracy, candidate models can be directly evaluated on pre-training validation set without any fine-tuning on specific tasks, which can help save computations.

The detailed algorithm description is shown in Algorithm 1. $\text{Crossover}(S^{\text{topk}}, N^{\text{cro}})$ means the procedure to generate N^{cro} new candidate architectures that two candidate architectures randomly selected from top k candidate set S^{topk} are crossed to produce a new one. Similarly, $\text{Mutation}(S^{\text{topk}}, N^{\text{mut}}, p)$ denotes the procedure to generate N^{mut} new candidates that a random candidate from S^{topk} mutates its every layer choice with probability p to generate a new one. Finally, the candidate architecture with highest pre-training validation accuracy in S^{topk} is returned as LV-BERT. The algorithm is set with population size P of 50, search iteration number T of 20, crossover number N^{cro} of 25, mutation number M^{mut} of 25, mutation probability p of 0.1, top candidate number k of 10 for crossover and mutation.

4 Experiments

4.1 Datasets

Pre-training Datasets Devlin et al. (2019) propose WikiBooks corpus for training BERT including English Wikipedia and BooksCorpus (Zhu et al., 2015). However, BooksCorpus is no longer publicly available. To ease reproduction, we train models on OpenWebText (Gokaslan and Cohen, 2019) that is open-sourced and of similar size with the corpus used by BERT. When pre-training the supernet, we leave 2% data as our validation set for evolutionary search.

Fine-tuning Datasets To compare our model with other pre-trained models, we fine-tune LV-BERT on GLUE (Wang et al., 2018), including various tasks for general language understanding, and SQuAD 1.1/2.0 (Rajpurkar et al., 2016, 2018) for question answering. See Appendix for more details of all tasks.

Model	**Layer Variety**				**Params**		**GLUE**

Table 1: Performance of the models with different layer types and orders on the GLUE development set. DC, SA and FF denote dynamic convolution, self-attention and feed-forward layers respectively. For each design of layer type set, "Random" means the best order among five randomly generated ones that are estimated by training model from scratch. "Randomly searched" or "EA searched" are both based on the supernet. "Randomly searched" denotes the orders searched at random while "EA searched" denotes ones searched by evolutionary algorithm. * denotes the methods implemented by us for language pre-training. All models are pre-trained on OpenWebText by 1M steps with sequence length 128 using ELECTRA (Clark et al., 2020) pre-training objective except BERT-small using MLM objective.

Table 2: Performance of different models in different sizes on GLUE development set. * denotes results obtained by running official code. † denotes the methods implemented by us for language pre-training. All models are pre-trained on OpenWebText by 1M steps with sequence length 128 using ELECTRA (Clark et al., 2020) pre-training objective.

4.2 Implementation Details

Model Size Similar to Devlin et al. (2019), Clark et al. (2020) and Jiang et al. (2020), we define different model sizes, *i.e.*, "small", "medium" and "base", with the same layer number of 24 but different hidden sizes of 256, 384, and 768, respectively. The detailed hyperparameters are shown in Appendix.

Pre-training Supernet To reduce training cost, we construct the supernet only in small size. Since the layer number of models in medium and base sizes are the same as that of the small-sized one, the obtained architecture of LV-BERT-small can be easily scaled up to the ones of medium and base sizes. We use Adam (Kingma and Ba, 2015) to pre-train the supernet with MLM loss (Devlin et al., 2019) , learning rate of 2e-4, batch size of 128, max sequence length of 128 and pre-training step number of 2 million. See Appendix for more details.

Evaluation Setup To compare with other pre-trained models, we pre-train the searched LV-BERT architecture for 1M steps from scratch on the OpenWebText (Gokaslan and Cohen, 2019) using Replaced Token Detection (Clark et al., 2020) since it can save computation cost. We fine-tune LV-BERT on GLUE (Wang et al., 2018) and SQuAD (Rajpurkar et al., 2016, 2018) downstream tasks with most hyperparameters the same as those of ELECTRA (Clark et al., 2020) for fair comparison. For GLUE tasks, the evaluation metrics are Matthews correlation for CoLA, Spearman correlation for STS, and accuracy for other tasks, which are averaged to get GLUE score. We utilize evaluation metrics of Exact-Match (EM) and F1 for SQuAD 1.1/2.0. Some of the fine-tuning datasets are small, and consequently, the results may vary substantially for different random seeds. Similar to ELECTRA (Clark et al., 2020), we report the median of 10 fine-tuning runs from the same pre-trained model for each result. See Appendix for more evaluation details.

4.3 Ablation Study

Layer Variety Various models are constructed with different layer variety designs, and their results on GLUE development set are shown in Table 1. For the layer types, if only two layer types are provided, selecting self-attention and feed-forward yields the best result, which can always achieve performance higher than 80 under different search methods. With only dynamic convolution and feed-forward, the performance drops dramatically to around 65. Surprisingly, without feed-forward, the layer set of dynamic convolution and self-attention can still achieve relatively good score, near 80. When using all the three layer types, we can obtain the best 81.8 score, 1.4 higher than the strong baseline ELECTRA (80.4) and 0.6 higher than the model searched with only self-attention and feed-forward (81.2). This indicates that it is effective to augment the layer type set by including convolution to extract local information for pre-trained models.

For layer orders, with the same layer types, the models with either EA or randomly searched orders perform better than those with randomly sampled orders, reflecting the importance of investigating layer orders. For example, with the same layer types of self-attention and feed-forward, the EA searched model obtains 81.2 score, improving BERT/ELECTRA by 6.1/0.8 as well as Sandwich by 2.6.

Search Method Table 1 shows the results with different search methods. "Random" means for each design of layer type set, the order is the best one among 5 randomly generated orders that are estimated by training models from scratch. "Randomly searched" and "EA searched" are both supernet-based methods, in which the weights of candidate models are inherited from the supernet. "Randomly searched" produces candidate models at random for estimation while "EA searched" generates candidate models with evolutionary algorithm guided by the pre-training MLM accuracy. With the same layer types, EA searched orders are generally better than randomly searched ones while the randomly searched ones are generally better than random ones. Figure 3 plots the pre-trianing MLM evaluation accuracy over search iterations with both random and evolutionary search methods. It shows that the accuracy of evolutionary search is obviously higher than that of random search, demonstrating the effectiveness of evolutionary search.

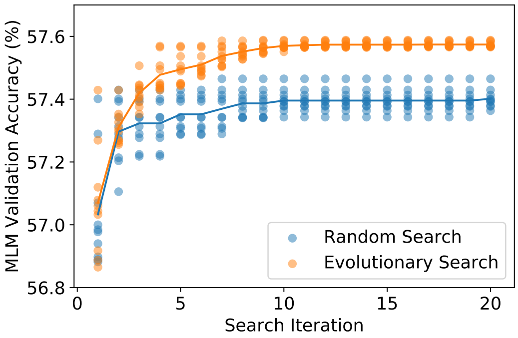

Figure 3: The pre-training MLM validation accuracy comparison between random search and evolutionary search with the layer set of all three types of layers. Blue and yellow dots denote the accuracy of top 10 candidates for each method respectively, while the plots mean their averages.

4.4 LV-BERT Architecture

As shown in Table 1, LV-BERT achieves the best performance. Its architecture is

$$\begin{aligned}[&L_1^{\mathrm{DC}}, L_2^{\mathrm{DC}}, L_3^{\mathrm{SA}}, L_4^{\mathrm{FF}}, L_5^{\mathrm{FF}}, L_6^{\mathrm{SA}},\\ &L_7^{\mathrm{DC}}, L_8^{\mathrm{FF}}, L_9^{\mathrm{FF}}, L_{10}^{\mathrm{SA}}, L_{11}^{\mathrm{DC}}, L_{12}^{\mathrm{DC}},\\ &L_{13}^{\mathrm{SA}}, L_{14}^{\mathrm{FF}}, L_{15}^{\mathrm{DC}}, L_{16}^{\mathrm{FF}}, L_{17}^{\mathrm{SA}}, L_{18}^{\mathrm{DC}},\\ &L_{19}^{\mathrm{FF}}, L_{20}^{\mathrm{DC}}, L_{21}^{\mathrm{SA}}, L_{22}^{\mathrm{SA}}, L_{23}^{\mathrm{FF}}, L_{24}^{\mathrm{SA}}].\end{aligned} \tag{8}$$

Pre-trained with MLM from scratch by 1M steps (sequence length 128) on OpenWebText, LV-BERT-small can achieve 61.2% MLM accuracy while BERT-small is 60.4%. More specific architectures of the models in Table 1 are listed in Appendix.

LV-BERT-small	1.2e18 (1x)[‡]	13M	77.1	84.1	71.0	73.7
LV-BERT-medium	3.1e18 (2.6x)[‡]	23M	79.6	86.4	74.9	77.5
LV-BERT-base	1.8e19 (15x)[‡]	100M	**84.8**	**90.8**	**80.9**	**83.7**

Table 4: Performance of models with similar model size on SQuAD 1.1/2.0 development set. * denotes knowledge distillation methods that rely on large pre-trained teacher models and are orthogonal to other methods. [†] denotes results obtained by running official code. [‡] We set the sequence length as 128 for pre-training to save computation although it hurts the performance.

When running the evolutionary method with different seeds, we see that the resulting models prefer stacking dynamic convolutions at the bottom two layers for extracting local information and self-attention at the top layer to fuse the global information. According to these observation, for ELECTRA-small, if we replace the bottom two layers with dynamic convolutions or the top layer with self-attention, the performance can be improved by 0.3 or 0.5 respectively on GLUE development set. If we replace the bottom 8 layers with manually designed 'ccsfccsf' ('c', 's' and 'f' denote dynamic convolution, self-attention and feed-forward layers, respectively) and replace the top 8 layers with manually designed 'ssfsssfs' together, we observe 0.7 performance improvement. These results show that it is helpful to stack dynamic convolution at the bottom and self-attention at the top.

4.5 Generalization to Larger Models

We only investigate layer variety and search models in a small-sized setting to save computation cost. It is interesting to know whether the searched models can be generalized to larger models with large hidden size. The results are shown in Table 2. For larger model size "medium" and "base", LV-BERTs still outperform other baseline models, demonstrating the good generalization in terms of model size.

4.6 Comparison with State-of-the-arts

We compare LV-BERT with state-of-the-art pre-trained models (Radford et al., 2018; Devlin et al., 2019; Clark et al., 2020; Sanh et al., 2019; Jiao et al., 2020; Sun et al., 2020) on GLUE testing set and SQuAD 1.1/2.0 to show its advantages. Although more pre-training data/steps and lager model size can significantly help improve performance (Yang et al., 2019; Liu et al., 2019b; Lan et al., 2020), due to the computation resource limit, we only pre-train our models in small/medium/base sizes for 1M steps with OpenWebText (Gokaslan and Cohen, 2019). We leave evaluating models with more pre-training data/steps and larger model size for future work. We also list some knowledge distillation methods for comparison. However, note that these methods rely on a pre-trained large teacher network and thus are orthogonal to LV-BERT and other methods.

Table 3 presents the performance of LV-BERT and other pre-trained models on GLUE testing set. It shows that LV-BERT outperforms other pre-trained models with similar model size. Remarkably, LV-BERT-small/base achieve 79.8/85.1, 1.8/1.6 higher than strong baselines ELECTRA-small/base. Even compared with knowledge distillation based model MobileBERT (Sun et al., 2020), LV-BERT-medium still outperforms it by 0.3.

Since there is nearly no single model submission on SQuAD leaderboard[2], we only compare LV-BERT with other pre-trained models on the development sets. The results are shown in Table 4. We find that LV-BERT-small outperforms ELECTRA-small significantly, like F1 score 73.7 versus 69.4 on SQuAD 2.0. However, when we generalize LV-BERT-small to base size, the gap between LV-BERT and ELECTRA with base size is narrower than that with small size. One reason may be LV-BERT-small is searched by our method while LV-BERT-base is only generalized from LV-BERT-small with larger hidden size.

5 Conclusion

We are the first to exploit layer variety for improving pre-trained language models, from two aspects, *i.e.*, layer types and layer orders. For layer types, we augment the layer type set by including convolution for local information extraction. For layer orders, beyond the stereotyped interleaved one, we explore more effective orders by using an evolutionary based search algorithm. Experiment results show our obtained model LV-BERT outperforms BERT and its variants on various downstream tasks.

Acknowledgments

We would like to thank the anonymous reviewers for their insightful comments and suggestions. This research/project is supported by the National Research Foundation, Singapore under its AI Singapore Programme (AISG Award No: AISG-100E/-2019-035). Jiashi Feng was partially supported by MOE2017-T2-2-151, NUS_ECRA_FY17_P08 and CRP20-2017-0006. The authors also thank Quanhong Fu and Jian Liang for the help to improve the technical writing aspect of this paper. The computational work for this article was partially performed on resources of the National Supercomputing Centre, Singapore (https://www.nscc.sg). Weihao Yu would like to thank TPU Research Cloud (TRC) program and Google Cloud Research Credits Program for the support of computational resources.

A Details about Layer Types

For a layer, assume its input is $I \in \mathbb{R}^{s\times c}$ and output is $O \in \mathbb{R}^{s\times c}$, where s is the sequence length and c is the hidden size (channel dimension). For simplicity, c takes the same value for the input and output.

Self-Attention The self-Attention layer, also known as multi-head self-attention (Vaswani et al., 2017), transforms the input by three linear transformations into the key K, query Q and value V vectors respectively,

$$\begin{aligned} K &= \mathrm{Reshape}(IW^{\mathrm{K}} + b^{\mathrm{K}}) \\ Q &= \mathrm{Reshape}(IW^{\mathrm{Q}} + b^{\mathrm{Q}}) \\ V &= \mathrm{Reshape}(IW^{\mathrm{V}} + b^{\mathrm{V}}), \end{aligned} \tag{9}$$

where $K, Q, V \in \mathbb{R}^{h\times s\times d}$, $W^{\mathrm{K}}, W^{\mathrm{Q}}, W^{\mathrm{V}} \in \mathbb{R}^{c\times c}$, and $b^{\mathrm{K}}, b^{\mathrm{Q}}, b^{\mathrm{V}} \in \mathbb{R}^{c}$. Notice that $h \times d = c$ where h is the number of heads and d is the head dimension.

The above K and Q are used to compute their similarity matrix M which is then used to generate new value V':

$$\begin{aligned} M &= \mathrm{Softmax}(KQ^{\top}/\sqrt{d}) \\ V' &= \mathrm{Reshape}(MV), \end{aligned} \tag{10}$$

where $M \in \mathbb{R}^{h\times s\times s}$ and $V' \in \mathbb{R}^{s\times c}$. Finally, a linear transformation is used to exchange information between different heads, followed by shortcut connection and layer normalization,

$$O = \mathrm{Norm}(V'W_O + b_O + I), \tag{11}$$

where $W_O \in \mathbb{R}^{c\times c}$ and $b_O \in \mathbb{R}^{c}$.

Feed-Forward The feed-forward layer (Vaswani et al., 2017) includes two linear transformations with a non-linear activation, followed by a shortcut connection and layer normalization,

$$\begin{aligned} N &= \mathrm{GELU}(IW_1 + b_1) \\ O &= \mathrm{Norm}(NW_2 + b_2 + I), \end{aligned} \tag{12}$$

where $W_1 \in \mathbb{R}^{c\times rc}$ and $W_2 \in \mathbb{R}^{rc\times c}$ with a ratio r. $\mathrm{GELU}(\cdot)$ denotes the Gaussian Error Linear Unit (Hendrycks and Gimpel, 2016).

Dynamic Convolution Dynamic convolution is introduced by Wu et al. (2018) to replace self-attention, which shows strong competitiveness in the tasks of machine translation, language modeling and summarization. The dynamic convolution first uses gated linear unit (GLU) (Dauphin et al., 2017) to generate new representation,

$$V = \mathrm{GLU}(I). \tag{13}$$

Different from the vanilla dynamic convolution that directly generates dynamic kernel from $V \in \mathbb{R}^{s\times c}$, in this work, we supplement a separate convolution (Howard et al., 2017) with depthwise weights $W^{\mathrm{Dep}} \in \mathbb{R}^{k\times c}$ (k is the convolution kernel size, set as 9 in this paper) and pointwise weights $W^{\mathrm{Poi}} \in \mathbb{R}^{c\times c}$ to extract local information to help the following kernel generation. Denoting the output as $S \in \mathbb{R}^{s\times c}$, the separate convolution can be formulated as

$$S_{i,:} = \left(\sum_{j=1}^{k} W^{\mathrm{Dep}}_{j,:} \cdot V_{i+j-\frac{k+1}{2},:} \right) W^{\mathrm{Poi}}. \tag{14}$$

Then the output of separate convolution is used to generate dynamic kernels,

$$D = \mathrm{Softmax}(\mathrm{Reshape}(SW^{\mathrm{Dyn}})), \tag{15}$$

where $W^{Dyn} \in \mathbb{R}^{c \times hk}$ and $D \in \mathbb{R}^{h \times s \times k}$. Then lightweight convolution is applied to the reshaped $V' = \mathrm{Reshape}(V) \in \mathbb{R}^{h \times s \times d}$. The output $C \in \mathbb{R}^{h \times s \times d}$ can be expressed as

$$C_{p,i,:} = \sum_{j=1}^{k} D_{p,i,j} \cdot V'_{p,i+j-\frac{k+1}{2},:}. \tag{16}$$

Finally, C is reshaped to $C' = \mathrm{Reshape}(C) \in \mathbb{R}^{s \times c}$ and a linear transformer is applied to fuse the information among multiple heads, followed by a short connection and layer normalization,

$$O = \mathrm{Norm}(C' W^{\mathrm{Out}} + b^{\mathrm{Out}} + I), \tag{17}$$

where $W^{\mathrm{Out}} \in \mathbb{R}^{c \times c}$ and $b^{\mathrm{Out}} \in \mathbb{R}^{c}$.

B Details about Datasets

B.1 GLUE Dataset

Introduced by Wang et al. (2018), General Language Understanding Evaluation (GLUE) benchmark is a collection of nine tasks for natural language understanding, where testing set labels are hidden and predictions need to be submitted to the evaluation server[3]. We provide details about the GLUE tasks below.

CoLA The Corpus of Linguistic Acceptability (Warstadt et al., 2019) is a binary single-sentence classification dataset for predicting whether an sentence is grammatical or not. The samples are from books and journal articles on linguistic theory.

MRPC The Microsoft Research Paraphrase Corpus (Dolan and Brockett, 2005) is a dataset for the task to predict whether two sentences are semantically equivalent or not. It is extracted from online news sources with human annotations.

MNLI The Multi-Genre Natural Language Inference Corpus (Williams et al., 2018) is a dataset of sentence pairs. Each pair has a premise sentence and a hypothesis sentence, requiring models to predict its relationships containing *ententailment*, *contradiction* or *neutral*. It is from ten distinct genres of spoken and written English.

SST The Stanford Sentiment Treebank (Socher et al., 2013) is a dataset for the task to predict whether a sentence is positive or negative in sentiment. The dataset is from movie reviews with human annotations.

determine whether a pair of questions are semantically equivalent or not.

STS The Semantic Textual Similarity Benchmark (Cer et al., 2017) is a collection of sentence pairs with human-annotated similarity score on a 1-5 scare.

WNLI Winograd NLI (Levesque et al., 2012) is a small dataset for natural language inference. However, there are issues with the construction of this dataset[4]. Therefore, this dataset is exclude in this paper for comparison as BERT (Devlin et al., 2019) *etc*.

B.1.1 SQuAD dataset

The Stanford Question Answering Dataset (**SQuAD 1.1**) (Rajpurkar et al., 2016) is a dataset of more than 100K questions which all can be answered by locating a span of text from the corresponding context passage. Besides this data, the upgraded version **SQuAD 2.0** (Rajpurkar et al., 2018) supplements it with over 50K unanswerable questions.

C Pre-training Details

For supernet, We pre-train it for 2M steps with hyperparameters listed in Table 5, using Masked Language Modeling (MLM) pre-training objective (Devlin et al., 2019). This objective masks 15% input tokens that require the model to predict. The reason to use this objective is that the MLM validation accuracy can reflect the performance of models on downstream tasks (Lan et al., 2020).

For pre-training LV-BERTs and other compared baselines like DynamicConv (Wu et al., 2018) and Sandwich (Press et al., 2020) from scratch, we utilize Replaced Token Detection (RTE) pre-training objective (Clark et al., 2020). This objective employs a small generator to predict masked tokens and utilize a larger discriminator to determine predicted tokens from the generator are the same as original ones or not. RTE can help save computation cost but achieve good performance (Clark et al., 2020). We pre-train the models for 1M steps, mostly using the same hyperparameters as ELECTRA (Clark et al., 2020). We set the pre-training sequence length 128 that can help us save computation cost. For downstream task SQuAD 1.1/2.0 that needs longer input sequence length, we pre-train more 10% steps with the sequence length of 512 to learn the position embedding before fine-tuning. The hyperparameters are listed in Table 5.

D Fine-tuning Details

For fine-tuning on downstream tasks, most of the hyperparameters are the same as ELECTRA (Clark et al., 2020). See Table 6.

E Searched Architectures

The different searched architectures are listed in Table 7.

Abstract

Event detection tends to struggle when it needs to recognize novel event types with a few samples. The previous work attempts to solve this problem in the identify-then-classify manner but ignores the trigger discrepancy between event types, thus suffering from the error propagation. In this paper, we present a novel unified model which converts the task to a few-shot tagging problem with a double-part tagging scheme. To this end, we first propose the **P**rototypical **A**mortized **C**onditional **R**andom **F**ield (PA-CRF) to model the label dependency in the few-shot scenario, which approximates the transition scores between labels based on the label prototypes. Then Gaussian distribution is introduced for modeling of the transition scores to alleviate the uncertain estimation resulting from insufficient data. Experimental results show that the unified models work better than existing identify-then-classify models and our PA-CRF further achieves the best results on the benchmark dataset FewEvent. Our code and data are available at `http://github.com/congxin95/PA-CRF`.

1 Introduction

Event detection (ED) systems extract events of specific types from the given text. Traditionally, researchers use pipeline approaches (Ahn, 2006) where a trigger identification (TI) system is used to identify event triggers in a sentence and then a trigger classifier (TC) is used to find the event types of extracted triggers. Such a framework makes the task easy to conduct but ignores the interaction and correlation between the two subtasks, being susceptible to cascading errors. In the last few years, several neural network-based models were proposed to jointly identify triggers and classify event types from a sentence (Chen et al., 2015; Nguyen and Grishman, 2015, 2018; Liu et al., 2018; Yan et al., 2019; Cui et al., 2020b,a). These models have achieved promising performance and proved the effectiveness of solving ED in the joint framework. But they almost followed the supervised learning paradigm and depended on the large-scale human-annotated dataset, while new event types emerge every day and most of them suffer from the lack of sufficient annotated data. In the case of insufficient resources, existing joint models cannot recognize the novel event types with only few samples, i.e., Few-Shot Event Detection (FSED).

Marry	It served as the location of Bogart's [wedding] to Bacall.
E-Mail	If you have a better idea, please [e-mail] me.

Figure 1: An example from FewEvent dataset revealing the trigger discrepancy. "[·]" marks the event trigger.

One intuitive way to solve this problem is to first identify event triggers in the conventional way and then classify the event types based on the few-shot learning (Vinyals et al., 2016; Snell et al., 2017; Sung et al., 2018), these two subtasks can be trained jointly by parameter sharing. Such identify-then-classify paradigm (Deng et al., 2020) seems to be convincing because TI aims to recognize triggers and does not need to adapt to novel classes, so we just need to solve the TC in the few-shot manner. Unfortunately, our preliminary experiments reveal that TI tends to struggle when recognizing triggers of novel event types because novel events usually contain completely different triggers with the semantic distinction from the known events, i.e., **Trigger discrepancy** problem. Figure 1 gives an example that the trigger "e-mail" would only occur in event *E-Mail* but not in *Marry* and triggers of two events have disparate context. And experiments on FewEvent (a benchmark dataset for FSED) show that 59.21% triggers in the test set do not trigger

any events in the training set and the F1 score of TI with the SOTA TI model BERT-tagger (Yang et al., 2019) is only 31.06%. Thus, the performance of the identify-then-classify paradigm will be limited by the TI part due to the cascading errors.

In this paper, we present a new unified method to solve FSED. Specifically, we convert this task to a sequence labeling problem and design a double-part tagging scheme using trigger and event parts to describe the features of each word in a sentence. The key to the sequence labeling framework is to model the dependency between labels. Conditional Random Field (CRF) is a popular choice to capture such label dependency by learning transition scores of fixed label space in the training dataset. Nevertheless, in FSED, CRF cannot be applied directly due to the **label discrepancy** problem, that is the label space of the test set is non-overlapping with the training set since FSED aims to recognize novel event types. Therefore, the learned transition scores of CRF from the training set do not model the dependency of the novel labels in the test set.

To address the label discrepancy problem, we propose **P**rototypical **A**mortized **C**onditional **R**andom **F**ield (PA-CRF), which approximates the transition scores based on the label prototypes (Snell et al., 2017) instead of learning by optimization. Specifically, we first apply the self-attention mechanism to capture the dependency information between labels and then map the label prototype pairs to the corresponding transition scores. In this way, PA-CRF can produce label-specific transition scores based on the few supportive samples, which can adapt to arbitrary novel event types. However, predicting the transition score as a single fixed value actually acts as the point estimation, which usually acquires a large amount of annotated data to achieve accurate estimation. Estimated from the handful of samples, the transition scores may suffer from the statistical uncertainty due to the random fluctuation of scant data. To release this issue, inspired by variational inference (Kingma and Welling, 2014; Yoon et al., 2018; Gordon et al., 2019), we treat the transition score as the random variable and utilize the Gaussian distribution to approximate its distribution to model the uncertainty. Thus, our PA-CRF is to estimate the parameters of the Gaussian distribution rather than the transition scores directly, i.e., in the amortized manner (Kingma and Welling, 2014; Gordon et al., 2019). The Probabilistic Inference (Gordon et al., 2019) is employed based on the Gaussian distribution to make the inference robust by taking the possible perturbation of transition scores into account since the perturbation is also learned in a way that coherently explains the uncertainty of the samples.

To summarize, our contributions are as follows:

- We devise a tagging-based unified model for FSED. To the best of our knowledge, we are the first to solve this task in a unified manner, free from the cascading errors.
- We propose a novel model, PA-CRF, which estimates the distributions of transition scores for modeling the specific label dependency in the few-shot sequence labeling setting.
- Experimental results show that our proposed PA-CRF outperforms other competitive baselines on the FewEvent dataset. Further analyses show the effectiveness of our unified model and the limitation of the identify-then-classify models.

2 Related Work

Few-shot Event Detection Event Detection (ED) aims to recognize the specific type of events in a sentence. In recent years, various neural-based models have been proposed and achieved promising performance in ED (Chen et al., 2015; Nguyen and Grishman, 2015, 2018; Liu et al., 2018; Yan et al., 2019; Cui et al., 2020b). Chen et al. (2015) and Nguyen and Grishman (2015) proposed the convolution architecture to capture the semantic information in the sentence. Nguyen et al. (2016) introduced the recurrent neural network to model the sequence contextual information of words. Recently, GCN-based models (Nguyen and Grishman, 2018; Liu et al., 2018; Yan et al., 2019; Cui et al., 2020b) have been proposed to exploit the syntactic dependency information and achieved state-of-the-art performance. However, all these models are data-hungry, limiting dramatically their usability and deployability in real-world scenarios.

Recently, there has been an increasing research interest in solving event detection in the few-shot scenarios (Deng et al., 2020; Lai et al., 2020a,b), by exploiting the Few-Shot Learning (Vinyals et al., 2016; Snell et al., 2017; Finn et al., 2017; Sung et al., 2018; Cong et al., 2020). Lai et al. (2020a) proposed LoLoss which splits the part of the support set to act as the auxiliary query set to train the model. Lai et al. (2020b) introduced two regularization matching losses to improve the performance of models. These works only focus on the few-shot trigger classification which classifies the event type of the annotated trigger according to the context based on few samples. This is unrealistic as triggers of novel events are predicted by some existing toolkits in advance. Deng et al. (2020) first proposed the benchmark dataset, *FewEvent*, for FSED and designed the DMBPN based on the dynamic memory networks. They train a conventional trigger identifier and a few-shot trigger classifier jointly and evaluated the model performance in the identify-then-classify paradigm. Moreover, our preliminary experiments reveal that the conventional trigger identification model tends to struggle when recognizing triggers of novel event types because of the trigger discrepancy between different event types. Thus, errors of the trigger identifier might be propagated to the event classification. Different from the previous identify-then-classify framework, for the first time, we solve Few-Shot Event Detection with two subtasks in a unified manner.

Few-shot Sequence Labeling In recent years, several works (Fritzler et al., 2019; Hou et al., 2020; Yang and Katiyar, 2020) have been proposed to solve the few-shot named entity recognition using sequence labeling methods. Fritzler et al. (2019) applied the vanilla CRF in the few-shot scenario directly. Hou et al. (2020) proposed a collapsed dependency transfer mechanism (CDT) into CRF, which learns label dependency patterns of a set of task-agnostic abstract labels and utilizes these patterns as transition scores for novel labels. Yang and Katiyar (2020) trains their model on the training data in a standard supervised learning manner and then uses the prototypical networks and the CDT for prediction in the inference phase. Different from these methods learning the transition scores by optimization, we build a network to generate the transition scores based on the label prototypes instead. In this way, we can generate exact label-specific transition scores of arbitrary novel event types to achieve adaptation ability. And we further introduce the Gaussian distribution to estimate the data uncertainty. Experiments prove the effectiveness of our method over the previous methods.

3 Problem Formulation

We convert event detection to a sequence labeling task. Each word is assigned a label that contributes to detecting the events. Labels consist of two parts: the word position in the trigger and the event type. We use the "BI" (Begin, Inside) signs to represent the position information of a word in the event trigger. The event type information is obtained from a predefined set of events. Label "O" (Other) means that the corresponding word is independent of the target events. Thus, the total number of labels is $2N + 1$ (N for *B-EventType*, N for *I-EventType*, and an additional *O* label), where N is the number of predefined event types.

Furthermore, we formulate the Few-Shot Event Detection in the typical N-way-K-shot paradigm. Let $\boldsymbol{x} = \{w_1, w_2, \ldots, w_n\}$ denote an n-word sequence, and $\boldsymbol{y} = \{y_1, y_2, \ldots, y_n\}$ denote the label sequence of the $\boldsymbol{x}$. Given a *support set* $\mathcal{S} = \{(\boldsymbol{x}^{(i)}, \boldsymbol{y}^{(i)})\}_{i=1}^{N \times K}$ which contains N event types and each event type has only K instances, FSED aims to predict the labels of a unlabeled *query set* $\mathcal{Q}$ based on the *support set* $\mathcal{S}$. Formally, a $\{\mathcal{S}, \mathcal{Q}\}$ pair is called a N-way-K-shot task $\mathcal{T}$. There exist two datasets consisting of a set of tasks : $\mathcal{D}_{train} = \{\mathcal{T}^{(i)}\}_{i=1}^{M_{train}}$ and $\mathcal{D}_{test} = \{\mathcal{T}^{(i)}\}_{i=1}^{M_{test}}$ where M_{train} and M_{test} denote the number of the task in two datasets respectively. As the name suggests, $\mathcal{D}_{train}$ is used to train models in the training phase while $\mathcal{D}_{test}$ is for evaluation. It is noted that these two datasets have their own event types, which means that the label space of two datasets is disjoint with each other.

4 Methodology

4.1 Overview

As described above, we formulate FSED as the few-shot sequence labeling task with interdependent labels. Following the widely used CRF framework, we propose a novel PA-CRF model to model such label dependency in the few-shot setting, and decode the best-predicted label sequence. Our PA-CRF contains three modules: 1) Emission Module: It first computes the prototype of each label based on the support set, and then calculates the similarity between prototypes and each token in the query set as the emission scores. 2) Transition Module: It exploits the prototypes to generate the parameters of Gaussian distribution of the transition scores for decoding. 3) Decoding Module: Based on the emission scores and Gaussian distributed transition scores, the Decoding Module calculates the probabilities of possible label sequences for the given query set and decodes the predicted label sequence.

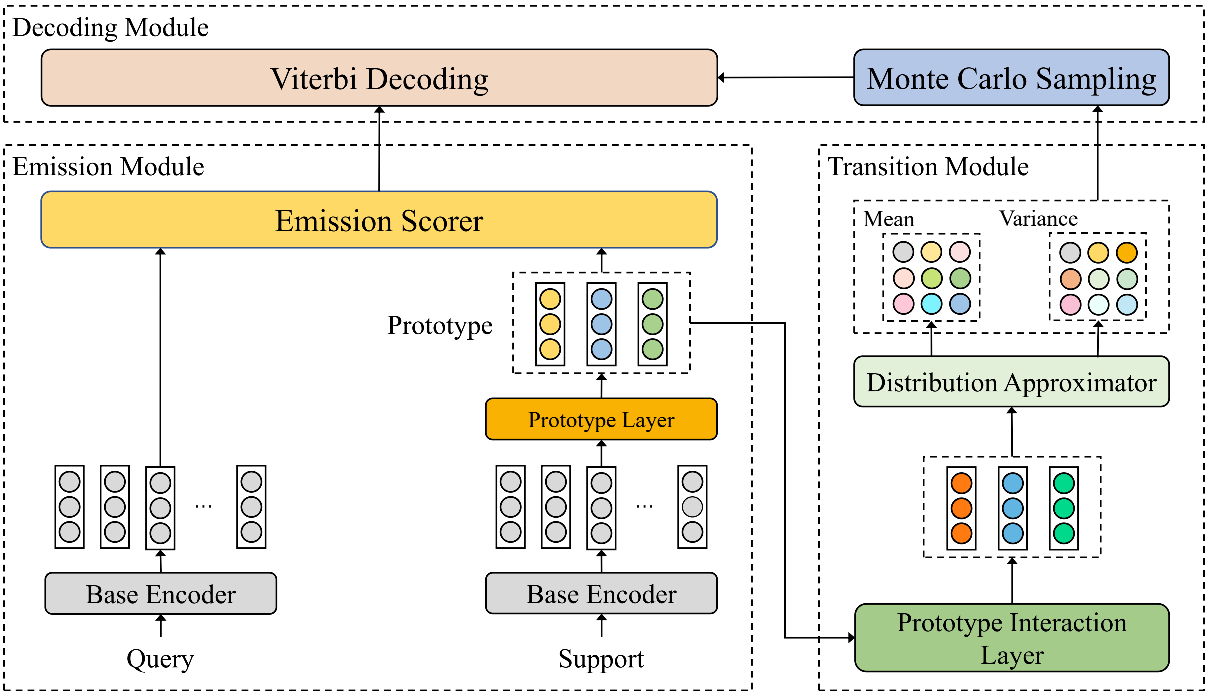

Figure 2: Architecture of our proposed PA-CRF. It consists of three modules: a) Emission Module calculates the emission scores for the query instance based on the prototypes derived from the support set. b) Transition Module generates the Gaussian distributed transition scores with respect to prototypes. c) Decoding Module exploits the emission scores and approximated Gaussian distributed transition scores to decode the predicted label sequence with the Monte Carlo Sampling.

Figure 2 gives an illustration of PA-CRF. We detail each component from the bottom to the top.

4.2 Emission Module

The Emission Module assigns the emission scores to each token of sentences in the query set $\mathcal{Q}$ with regard to each label based on the support set $\mathcal{S}$.

4.2.1 Base Encoder

Base Encoder aims to embed tokens in both support set $\mathcal{S}$ and query set $\mathcal{Q}$ into real-value embedding vectors to capture the semantic information.

Since BERT (Devlin et al., 2019) shows its advanced ability to capture the sequence information and has been widely used in NLP tasks recently, we use it as the backbone. Given an input word sequence $\boldsymbol{x}$, BERT first maps all tokens into hidden embedding representations. We denote this operation as:

$$\{\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_n\} = \mathrm{BERT}(\boldsymbol{x}) \tag{1}$$

where $\mathbf{h}_i \in \mathbb{R}^{d_h}$ refers to the hidden representation of token w_i, d_h is the dimension of the hidden representation.

4.2.2 Prototype Layer

Prototype Layer is to derive the prototypes of each label from the support set $\mathcal{S}$. As described in the problem formulation, we use the BIO schema to annotate the event trigger and N event types could contain $2N+1$ labels. Thus, indeed, we could get $2N+1$ prototypes. Following the previous work (Snell et al., 2017), we calculate the prototype of each label by averaging all the word representations with that label in the support set $\mathcal{S}$:

$$\mathbf{c}_i = \frac{1}{|\mathcal{S}(y_i)|} \sum_{w \in \mathcal{S}(y_i)} \mathbf{h}, \quad i = 1, 2, \ldots, 2N+1, \tag{2}$$

where $\mathbf{c}_i$ denotes the prototype for label y_i, $\mathcal{S}(y_i)$ refers to the token set containing all words in the support set $\mathcal{S}$ with label y_i, $\mathbf{h}$ represents the corresponding hidden representation of token w, and $|\cdot|$ is the number of set elements.

4.2.3 Emission Scorer

Emission Scorer aims to calculate the emission score for each token in the query set $\mathcal{Q}$. The emission scores are calculated according to the similarities between tokens and prototypes. The computation of the emission score of the label y_i for the word w_j is defined as:

$$f_E(y_i, w_j, \mathcal{S}) = d(\mathbf{c}_i, \mathbf{h}_j), \tag{3}$$

where $d(\cdot,\cdot)$ is the similarity function. In practice, we choose the dot product operation to measure the similarity.

Finally, given a word sequence $\boldsymbol{x}$, the emission score of the whole sentence with its corresponding ground-truth label sequence $\boldsymbol{y}$ is computed as:

$$\mathrm{EMIT}(\boldsymbol{y}, \boldsymbol{x}, \mathcal{S}) = \sum_{i=1}^{n} f_E(y_i, w_i, \mathcal{S}). \tag{4}$$

4.3 Transition Module

In vanilla CRF, the transition scores are learnable parameters and optimized from large-scale data to model the label dependency. However, in the few-shot scenarios, the learned transition scores cannot adapt to the novel label set due to the disjoint label space. To overcome this problem, we use neural networks to generate the transition scores based on the label prototypes instead of learning transition scores by optimization to achieve adaptation ability. In this case, a problem needing to be solved is that using few support instances with random data fluctuation to generate transition scores would cause uncertain estimation and result in wrong inference. To model the uncertainty, we treat the transition score as a random variable and use the Gaussian distribution to approximate its distribution. Specifically, the Transition Module is to generate the distributional parameters (mean and variance) of transition scores based on the label prototypes. It consists of two layers: 1) Prototypical Interaction Layer and 2) Distribution Approximator. Details of each layer are listed in the following parts.

4.3.1 Prototype Interaction Layer

Since the transition score is to model the dependency between labels, the individual prototype for each event type with rare dependency information is hard to generate their transition scores. Thus, we propose a Prototype Interaction Layer which exploits the self-attention mechanism to capture the dependency between labels.

We first calculate the attention scores of each prototype $\mathbf{c}_i$ with others:

$$\alpha_{ij} = \frac{\exp(\mathbf{c}_i^{(q)} \cdot \mathbf{c}_j^{(k)})}{\sum_{m=1}^{2N+1} \exp(\mathbf{c}_i^{(q)} \cdot \mathbf{c}_m^{(k)})}, \tag{5}$$

where $\mathbf{c}_i^{(q)}$ and $\mathbf{c}_i^{(k)}$ are transformed from $\mathbf{c}_i$ by two linear layers respectively:

$$\begin{aligned} \mathbf{c}_i^{(q)} &= W^{(q)}\mathbf{c}_i + b^{(q)} \\ \mathbf{c}_i^{(k)} &= W^{(k)}\mathbf{c}_i + b^{(k)} \end{aligned} \tag{6}$$

Getting the attention scores, the prototype $\tilde{\mathbf{c}}_i$ with dependency information is calculated as follows:

$$\tilde{\mathbf{c}}_i = \sum_{j=1}^{2N+1} \alpha_{ij}\mathbf{c}_j^{(v)}, \tag{7}$$

where $\mathbf{c}_i^{(v)}$ is also transformed linearly from $\mathbf{c}_i$:

$$\mathbf{c}_i^{(v)} = W^{(v)}\mathbf{c}_i + b^{(v)} \tag{8}$$

4.3.2 Distribution Approximator

This module aims to generate the mean and variance of Gaussian distributions based on the prototypes with dependency information.

Given the label set $\mathcal{Y}$ with total $2N+1$ labels, we first denote the transition score matrix as $T_r \in \mathbb{R}^{(2N+1)\times(2N+1)}$ for all label pairs, and denote the the i-th row j-th column element of T_r as $[T_r]_{ij}$ which refers to the transition score for i-th label transiting to j-th label in the label set $\mathcal{Y}$. As treating $[T_r]_{ij}$ as random variable, we use the Gaussian distribution $[\tilde{T_r}]_{ij} \sim \mathcal{N}(\mu_{ij}, \sigma_{ij}^2)$ to approximate $[T_r]_{ij}$, where $\mathcal{N}(\cdot,\cdot)$ refers to the Gaussian distribution. To estimate the mean μ_{ij} and variance σ_{ij} of $[\tilde{T_r}]_{ij}$, we concatenate the corresponding prototypes $\tilde{\mathbf{c}}_i$ and $\tilde{\mathbf{c}}_j$ and feed into two feed-forward neural networks respectively:

$$\mu_{ij} = W^{(\mu)}\left[\tilde{\mathbf{c}}_i \| \tilde{\mathbf{c}}_j\right] + b^{(\mu)} \tag{9}$$

$$\sigma_{ij}^2 = \exp\left(W^{(\sigma^2)}\left[\tilde{\mathbf{c}}_i \| \tilde{\mathbf{c}}_j\right] + b^{(\sigma^2)}\right) \tag{10}$$

where $[\cdot\|\cdot]$ means the concatenation operation. Given a label sequence $\boldsymbol{y}$, the transition score of the whole label sequence is approximated by:

$$\mathrm{TRANS}(\boldsymbol{y}, \tilde{T_r}) = \sum_{i=1}^{n-1} [\tilde{T_r}]_{\mathbb{I}(y_i)\mathbb{I}(y_{i+1})} \tag{11}$$

where $\mathbb{I}(y_i)$ refers to the label index in $\mathcal{Y}$ of y_i.

4.4 Decoding Module

Decoding Module derives the probabilities for a specific label sequence of the query set according to the emission scores and approximated Gaussian distributions of transition scores.

Since the approximated transition score is Gaussian distributional and not a single value, we denote the probability density function of the approximated transition score matrix as $q(\tilde{T_r}|\mathcal{S})$. According to the Probabilistic Inference (Gordon et al., 2019), the probability of label sequence $\boldsymbol{y}$ of a word sequence $\boldsymbol{x}$ based on the support set $\mathcal{S}$ is calculated as:

$$P(\boldsymbol{y}|\boldsymbol{x},\mathcal{S}) = \int P(\boldsymbol{y}|\boldsymbol{x},\mathcal{S},\tilde{T}_r)q(\tilde{T}_r|\mathcal{S})\mathrm{d}\tilde{T}_r \tag{12}$$

Following the CRF algorithm, the probability can be calculated based on the Equation 4 and Equation 11:

$$P(\boldsymbol{y}|\boldsymbol{x},\mathcal{S}) = \int \frac{1}{Z}\exp\left(\mathrm{EMIT}(\boldsymbol{y},\boldsymbol{x},\mathcal{S}) + \mathrm{TRANS}(\boldsymbol{y},\tilde{T}_r)\right) q(\tilde{T}_r|\mathcal{S})\mathrm{d}\tilde{T}_r \tag{13}$$

where

$$Z = \sum_{\boldsymbol{y}'\in Y} \exp\left(\mathrm{EMIT}(\boldsymbol{y}',\boldsymbol{x},\mathcal{S}) + \mathrm{TRANS}(\boldsymbol{y}',\tilde{T}_r)\right) \tag{14}$$

and Y refers to all possible label sequences.

In the training phase, we use negative log-likelihood loss as our objective function:

$$\mathcal{L} = -\mathop{\mathbb{E}}_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{Q}}[\log P(\boldsymbol{y}|\boldsymbol{x},\mathcal{S})] \tag{15}$$

Due to the hardness to compute the integral of Equation 13, in practice, we use the Monte Carlo sampling technique (Gordon et al., 2019) to approximate the integral. To make the sampling process differentiable for optimization, we employ the reparameterization trick (Kingma and Welling, 2014) for each transition score $[\tilde{T}_r]_{ij}$:

$$[\tilde{T}_r]_{ij} = \mu_{ij} + \epsilon\sigma_{ij}, \text{where } \epsilon \sim \mathcal{N}(0,1) \tag{16}$$

In the inference phase, the Viterbi algorithm (Forney, 1973) is employed to decode the best-predicted label sequence for the query set.

5 Experiment

5.1 Dataset

We conduct experiments on the benchmark *FewEvent* dataset introduced in the previous work (Deng et al., 2020), which is the currently largest few-shot dataset for event detection. It contains 70,852 instances for 100 event types and each event type owns about 700 instances on average. Since Deng et al. (2020) do not share their split train/dev/test set, we re-split the FewEvent in the same ratio as Deng et al. (2020). We use 80 event types as the training set, 10 event types as the dev set, and the rest 10 event types as the test set. More statistics of FewEvent dataset are listed in Appendix A.

5.2 Evaluation

We follow the evaluation metrics in previous event detection works (Chen et al., 2015; Liu et al., 2018; Cui et al., 2020b), an event trigger is marked correct if and only if its event type and its offsets in the sentence are both correct. We adopt the standard micro F1 score to evaluate the results and report the averages and standard deviations over 5 randomly initialized runs.

6 Implementation Details

We employ *BERT-BASE-UNCASED* (Devlin et al., 2019) as the base encoder. The maximum sentence length is set as 128. Our model is trained using *AdamW* optimizer with the learning rate of 1e-5. All the hyper-parameters are tuned on the dev set manually. In the training phase, we follow the widely used episodic training (Vinyals et al., 2016) in few-shot learning. Episodic training aims to mimic N-way-K-shot scenario in the training phase. In each epoch, we randomly sample N event types from the training set and each event type randomly sample K instances as support set and other M instances as the query set. We train our model with 20,000 iterations on the training set and evaluate its performance with 3,000 iterations on the test set following the episodic paradigm. We run all experiments using PyTorch 1.5.1 on the Nvidia Tesla T4 GPU, Intel(R) Xeon(R) Silver 4110 CPU with 256GB memory on Red Hat 4.8.3 OS.

6.1 Baselines

To investigate the effectiveness of our proposed method, we compare it with a range of baselines and state-of-the-art models, which can be categorized into three classes: fine-tuning paradigm, identify-then-classify paradigm and unified paradigm.

Fine-tuning paradigm solves the FSED in the standard supervised learning, i.e., pre-training on the large scale dataset and fine-tuning on the handful target data. We adopt the state-of-the-art model, **PLMEE** (Yang et al., 2019), of the standard ED into the FSED directly.

Identify-then-classify models first perform trigger identification (named as TI) and then classify the event types based on the few-shot learning methods (named as FSTC). We investigate two typed of identify-then-classify paradigms: separate and multi-task. For the separate models, the trigger identifier and few-shot trigger classifier are

Paradigm	Model	5-Way-5-Shot	5-Way-10-Shot	10-Way-5-Shot	10-Way-10-Shot
Fine-tuning	PLMEE	4.43 ± 0.19	4.69 ± 0.85	2.52 ± 0.28	2.76 ± 0.55
Separate	LoLoss	30.14 ± 0.30	30.91 ± 0.29	29.33 ± 0.40	30.08 ± 0.39
	MatchLoss	29.78 ± 0.14	30.75 ± 0.15	28.75 ± 0.23	29.59 ± 0.21
Multi-task	LoLoss	31.51 ± 1.56	31.70 ± 1.21	30.46 ± 1.38	30.32 ± 0.89
	MatchLoss	30.44 ± 0.99	30.68 ± 0.78	28.97 ± 0.61	30.05 ± 0.93
	DMBPN	37.51 ± 2.60	38.14 ± 2.32	34.21 ± 1.45	35.31 ± 1.69
Unified	Match	39.93 ± 1.67	46.02 ± 1.20	30.88 ± 1.08	35.91 ± 1.19
	Proto	50.11 ± 0.77	52.97 ± 0.95	43.51 ± 1.16	42.70 ± 0.98
	Proto-Dot	58.82 ± 0.88	61.01 ± 0.23	55.04 ± 1.62	58.78 ± 0.88
	Relation	28.91 ± 1.13	29.83 ± 0.78	18.49 ± 1.25	21.47 ± 1.40
	Vanilla CRF	59.01 ± 0.81	62.21 ± 1.94	56.00 ± 1.51	59.35 ± 1.09
	CDT	59.30 ± 0.23	62.77 ± 0.12	56.41 ± 1.09	59.44 ± 1.83
	StructShot	57.69 ± 0.91	61.54 ± 1.23	54.54 ± 0.95	57.14 ± 0.79
	PA-CRF	**62.25*** ± 1.42	**64.45*** ± 0.49	**58.48*** ± 0.68	**61.64*** ± 0.81

Table 1: F1 scores (10^{-2}) of different models on the FewEvent test set. Bold marks the highest number among all models, underline marks the second-highest number, and ± marks the standard deviation. * marks statistically significant improvements over the best baseline with $p < 0.01$ under a boostrap test.

trained separately without parameter sharing. We first exploit the state-of-the-art BERT-tagger for the TI task. It uses BERT (Devlin et al., 2019) and a linear layer to tag the trigger in the sentence as a sequence labeling task. Since TI just aims to recognize the occurrence of the trigger, the label set only contains three labels: *O*, *B-Trigger*, *I-Trigger*. For the FSTC task, we reimplement two FSTC models: **LoLoss** (Lai et al., 2020a), **MatchLoss** (Lai et al., 2020b). In the multi-task models, we reimplement **DMBPN** (Deng et al., 2020) and replace its encoder with BERT for the fair comparison. DMBPN combines a conventional trigger identification module and a few-shot trigger classification module by parameter sharing. But in the inference phase, it detects the event trigger still in the identify-then-classify paradigm. Additionally, we also provide the multi-task version of the LoLoss and MatchLoss which are trained jointly with BERT-tagger with shared BERT parameters.

Unified models perform few-shot event detection with a single model without task decomposition. Because we are the first to solve this task in a unified way, there is no previous unified model that can be compared. But for the comprehensive evaluation of our proposed PA-CRF model, we also construct two groups of variants of PA-CRF: non-CRF models and CRF-based models. Non-CRF models use emission scores to predict via softmax and do not take the label dependency into consideration. We implement four typical few-shot classifiers: 1) **Match** (Vinyals et al., 2016) uses cosine function to measure the similarity, 2) **Proto** (Snell et al., 2017) uses Euclidean Distance as the similarity metric, 3) **Proto-Dot** uses dot product to compute the similarity, 4) **Relation** (Sung et al., 2018) builds a two-layer neural networks to measure the similarity. Since CRF with the capacity of modeling label dependency is widely used in sequence labeling task, we implement three kinds of CRF-based models as our baselines: 1) **Vanilla CRF** (Fritzler et al., 2019): We adopt the vanilla CRF in the FSED task without considering the adaptation problem. 2) **CDT** (Hou et al., 2020): As the SOTA of the few-shot NER task, we reimplement it according to the official code and adapt it in the FSED task to replace our Transition Module. 3) **StructShot** (Yang and Katiyar, 2020): It is also a few-shot NER model. It first pre-trains on the training set and utilizes the prototypical networks and the CDT for prediction based on the support set in the inference phase. For the fair comparison, the emission module of these CRF-based baseline models is the same as our PA-CRF.

6.2 Main Results

Table 1 summarizes the results of our PA-CRF against other baseline models on the FewEvent test set.

Comparison with fine-tuning model It is obvious that PLMEE performs poorly in all four few-shot settings and all few-shot-based methods outperform it with an absolute gap, which powerfully proves that the conventional supervised methods is incapable of solving FSED.

Comparison with identify-then-classify models (1) Most of unified models (except Relation) perform higher than all identify-then-classify models, especially for PA-CRF with huge gaps about 30%, proving the effectiveness of the unified framework. (2) Comparing with the separate paradigm, the multi-task paradigm is able to improve performance but it still cannot catch up with the unified paradigm. (3) DMBPN works better than other two models but still works poorly to handle the FSED due to the limitation of the TI. We will discuss the bottleneck of the identify-then-classify paradigm in Section 6.3.

Comparison with unified models (1) Over the best non-CRF baseline model Proto-Dot, PA-CRF achieves substantial improvements of 3.43%, 3.44%, 3.44% and 2.86% on four few-shot scenarios respectively, which confirms the effectiveness and rationality of PA-CRF to model the label dependency. (2) Vanilla CRF performs better than other non-CRF baseline methods, which demonstrates that CRF is able to improve the performance by modeling the label dependency, even if the learned transition scores do not match the label space of the test set. (3) Compared to Vanilla CRF, both CDT and StructShot achieve slightly higher F1 scores, indicating the transition scores of abstract BIO labels can improve the model adaptation ability to some extent. (4) CDT exceeds the StructShot since CDT is trained based on the episodic training, which makes it learns the class-agnostic token representations. (5) PA-CRF outperforms CDT (2.95%, 1.68%, 2.07% and 2.20% in four few-shot settings respectively) with absolute gaps. We consider that it is because CDT learning the transition scores of the abstract labels cannot model the exact dependency of specific label set, so its adaptation ability is limited. In contrast, PA-CRF generates the label-specific transition scores based on the label prototype, which can capture the dependency for specific novel event types. (6) Comparing four few-shot scenarios, we can find that the F1 score increases as the K-shot increases, which shows that more support samples can provide more information of the event type. The F1 score decreases as the N-way increases when the shot number is fixed, which reveals that the larger way number causes more event types to predict which increases the difficulty of the correct detection.

Model	TI	FSTC	FSED
LoLoss	31.06	95.27	30.14
DMBPN	40.64	95.44	37.51
DMBPN(CDT-TI)	54.69	95.49	53.93
PA-CRF	63.68	96.76	62.25

Table 2: Comparison of PA-CRF and baselines on two subtasks. F1 scores are reported on the FewEvent test set in the 5-way-5-shot setting.

To summarize, we can draw the conclusion that (1) The identify-then-classify paradigm is incapable of solving the FSED task. (2) Compared to the identify-then-classify paradigm, the unified paradigm works more effectively for the FSED task. (3) Approximating transition scores based on the label prototypes not by optimization, our PA-CRF achieves better adaptation on novel event types.

6.3 Bottleneck Analysis

To investigate the bottleneck of the identify-then-classify paradigm, we evaluate LoLoss (separate model), DMBPN (multi-task model) and PA-CRF (unified model) on two subtasks: TI and FSTC separately in the 5-way-5-shot setting on the FewEvent test set. To reduce the influence of the cascading errors, we use the ground truth trigger span for evaluation in the FSTC. The experimental results are reported in Table 2. From Table 2, we find that: (1) All models achieve more than 95% F1 score on the FSTC task, indicating that both identify-then-classify and unified models is capable enough of solving the FSTC problem. (2) For the TI task, two identify-then-classify baselines perform 31.06% and 40.64% F1 score respectively, which demonstrates that the conventional TI module has difficulty in adapting to novel event triggers. Hence, due to the cascading errors, the poorly-performed TI module limits the performance of the identify-then-classify models. (3) PA-CRF achieves 63.68% F1 score on TI task, which exceeds the two kinds of identify-then-classify models significantly. Unlike identify-then-classify models recognizing triggers based on seen triggers, PA-CRF utilizes the trigger representations from the support set of the novel event types to identify novel triggers so our unified

Model	5-Shot	10-Shot
PA-CRF	44.39	51.06
- Distribution Estimation	43.47	49.41
- Interaction Layer	41.62	45.74
- Transition Score	39.83	45.07

Table 3: Ablation study of PA-CRF in 5-Way settings. F1 scores are reported on the FewEvent dev set.

model works better in the TI task of FSED. In conclusion, the conventional trigger identifier cannot identify novel triggers in FSED, and exploiting the support set of novel event types is necessary.

6.4 Effectiveness Analysis

To verify the effectiveness of the unified framework, we adapt our best baseline model, CDT, to replace TI module of DMBPN to solve trigger identification in the few-shot manner. It identifies triggers based on the emission scores between tokens and label prototypes calculating from the support set and learned abstract transition scores. In this case, we rename it as DMBPN(CDT-TI) and evaluate it in TI and FSTC subtasks. Results are also reported based on the 5-way-5-shot setting in Table 2 and we observe that: The CDT-TI-based DMBPN achieve 54.69% in TI task, exceeding the conventional TI based models, which shows that solving TI in the few-shot manner by utilizing the support set can reduce the trigger discrepancy to some extent. Although the performance of FSTC is similar to the original DMBPN, owing to the improvements of TI task, the final performance of FSED exceeds the original DMBPN by 16.42% but they are still inferior to PA-CRF with a huge gap (8.99% on TI task). Therefore, we draw the conclusion that solving FSED in the unified manner can utilize the correlation between two subtasks to improve the model performance significantly.

6.5 Ablation Study

To study the contribution of each component in our PA-CRF model, we run the ablation study on the FewEvent dev set. From these ablations (see Table 3), we find that: (1) - Distribution Estimation: To study whether distributional estimation is helpful to improve the performance, we remove it and make the Distribution Approximator generate a single value as the transition score directly as the point estimation. And the inference is based on the generated transition scores without Probabilistic Inference. As a result, the F1 score drops 1.02% and 1.65% in two scenarios, respectively. We attribute these gaps to our proposed Gaussian-based distributional estimation which can model the data fluctuation to relieve the influence of data uncertainty. (2) - Interaction Layer: To certify that the Prototype Interaction Layer contributes to capturing the information between prototypes, we remove it and evaluate in two scenarios. We read from Table 3 that F1 scores decrease significantly by 2.77% and 5.32% respectively, which indicates that the Prototype Interaction Layer is able to capture the dependency among prototypes. (3) - Transition Score: To prove the contribution of the label dependency, we remove the Transition Module and only use the emission score for prediction. Results show that without transition scores, the performance of the model drops dramatically by 4.56% and 5.99% respectively, which powerfully proves that the transition score can improve the performance of the few-shot sequence labeling task.

Furthermore, we have conducted case study and error analysis to validate the strength of our PA-CRF and explore its weakness. Details are listed in Appendix B and Appendix C.

7 Conclusion

In this paper, we explore a new viewpoint of solving few-shot event detection in a unified manner. Specifically, we propose a prototypical amortized conditional random field to generate the transition scores to achieve adaptation ability for novel event types based on the label prototypes. Furthermore, we present the Gaussian-based distributional estimation to approximate transition scores to relieve the statistical uncertainty of data fluctuation. Finally, experimental results on the benchmark FewEvent dataset prove the effectiveness of our proposed method. In the future, we plan to adapt our method to other few-shot sequence labeling tasks such as named entity recognition.

A Dataset Statistics

	Training Set	Dev Set	Test Set
# Cls.	80	10	10
# Sent.	67982	2173	697
# Tok./sent	36.5	38.6	30.8

Table 4: Statistics of FewEvent Dataset.

Table 4 lists the statistics of FewEvent dataset containing the number of event type (#Cls.), the number of sentence(# Sent.), the number of token per sentence (# Tok./sent) for the train/dev/test set.

Figure 3 demonstrates the data imbalance problem of FewEvent dataset. Event “Marry” has the most instance (26135 instances) while event “E-Mail” only has 30 instances. 69% event types have less than 100 instances while 7% event types have more than 1000 instances. However, since we use episodic training (Vinyals et al., 2016) to train our model, the data imbalance problem can be relieved to some extent.

B Case Study

We compare our method with the best identify-then-classify baseline, DMBPN and the best unified baseline, CDT in some cases, as shown in Table 5.

As demonstrated by the first example of a *Sponsorship* event, DMBPN, in the identify-then-classify paradigm, fails to identify the trigger *sponsorship*. According to our statistics about the FewEvent dataset, 95.16% triggers of *Sponsorship* event do not occur in the training set. Since DMBPN uses the conventional TI module which is trained on the training set to identify the event trigger, it is incapable of identifying the *Sponsorship* event trigger. Although the classification module of DMBPN succeeds to distinguish the event type as *Sponsorship*, due to the cascading errors, the final prediction of event trigger (containing the span and type) is incorrect. As a result, the performance of DMBPN as an identify-then-classify model on the FSED task is limited. In contrast, our unified PA-CRF is successful to detect the event trigger *sponsorship* of this case since PA-CRF utilizes the information of the support set of *Sponsorship* event in which word *sponsorship* appears and acts the trigger.

In the second example, the best unified baseline, CDT, tags the first trigger word *locked* with *I-Jail* label wrongly. That is because CDT learns the abstract transition scores among a set of abstract labels which cannot model the label dependency for this specific event type accurately. Thanks to the PA-CRF which models the label dependency based on the label prototypes from the support set of *Jail* event, our model is capable of tagging the word *locked* with *B-Jail* label correctly.

C Error Study

Although our method outperforms all baseline models, we still observe some failure cases. Table 6 gives a typical example of the wrong prediction of event *Transport* (*Trans* for short). For the query instance, the ground truth event trigger is “pouring out”. The word “pouring” should be labeled as *B-Trans* and the *out* should be labeled as *I-Trans*. However, our model only detects “pouring” with *B-Trans* while missing “out”. From the support set, we find that all support instances of this event type only contain the one-word trigger without *I-Trans* label tokens, resulting in that the prototype of *I-Trans* is zero vector. As a result, the emission score for the label *I-Trans* of each query token is calculated as zero and the transition scores based on the prototypes are also affected. Therefore, our model is not able to detect the *I-Trans* label correctly in this case. In the future, we will further study to

solve the missing *I* label problem.

D Analyses about Various Dataset Split

Model	R1	R2	R3	R4	R5
PA-CRF	59.0	33.4	53.1	42.4	48.0
DMBPN	44.9	31.1	40.8	32.6	27.9

Table 7: Performance of our PA-CRF and DMBPN in various split FewEvent dataset in the 5-Way-5-Shot scenario. F1 scores (10^{-2}) are reported.

Since Deng et al. (2020) do not public their split train/dev/test set of FewEvent dataset, to compare our PA-CRF with DMBPN (Deng et al., 2020), we re-split the FewEvent randomly in the same split ratio as the Deng et al. (2020) (80 event types for training set, 10 event types for dev set and the rest 10 event types for test set) and evaluate the DBMPN performance on our split test set. However, in our experiments, the performance of DMBPN is lower than the original paper. We assume that the different data split may influence the model performance badly. To validate our assumption, we re-split the FewEvent dataset for five random seeds and conduct more experiments on these various split train/dev/test set. The results are reported in Table 7. From Table 7, it can be observed that: (1) Data split does influence the model performance significantly indeed. In these five different split train/dev/test set, the performance of PA-CRF varies from 59.0% to 33.4% with a huge range. Similarly, DMBPN also varies from 44.9% to 27.9%, owning a huge gap about 20%. It demonstrates that for the FewEvent dataset, different split could cause huge fluctuation of the model performance. Therefore, our PA-CRF including baselines performs lower than those Deng et al. (2020) reported due to the different data split. (2) PA-CRF outperforms DMBPN in all five random split settings, which powerfully proves the robustness of PA-CRF over the identify-then-classify paradigm.

LUX (Linguistic aspects Under eXamination): Discourse Analysis for Automatic Fake News Classification

Abstract

The democratization/decentralization of both the production and consumption of information has resulted in a subjective and often misleading depiction of facts known as Fake News - a phenomenon that is effectively shaping the perception of reality for many individuals. Manual fact-checking is time-consuming and cannot scale and although automatic fact-checking, vis a vis machine learning holds promise, it is significantly hindered by a deficit of suitable training data. We present both a novel dataset, VERITAS(VERIfying Textual Aspects), a collection of fact-checked claims, containing their original documents and LUX(Language Under eXamination), a text classifier that makes use of an extensive linguistic analysis to infer the likelihood of the input being a piece of fake-news.

1 Introduction

Often defined as the intentional or unintentional spread of false information (K et al., 2019), Fake News has found fertile ground in the actual scenario of ever-growing data consumption and generation, where factors like news source decentralization, citizen journalism, democratization of media and astroturfing[1] (Lee, 2010) make the task of manually checking and correcting disinformation across the internet impractical if not infeasible, (Shao et al., 2016) despite the significant efforts of Fact-Checking Agencies - organised groups of journalists that manually identify and investigate rumours conveyed by Fake-news articles.

Consequently, it is imperative that we develop an efficient and reliable way to account for the veracity of what is produced and spread as information; this process is known as automatic fact-checking. (Hassan et al., 2015)

Although the there has been significant research effort to tackle the task of automatic fact-checking (Azevedo, 2018), the deficit of datasets containing organic news articles - in their entirety - which have been manually labeled with respect to their veracity is a common obstacle for the development of supervised classification models. The absence of such datasets makes researchers rely on other approaches, e.g., stance determination (Popat et al., 2017), knowledge base matching (Wu et al., 2014), trust assessment of sources (Balakrishnan and Kambhampati, 2011), data structuring (Conroy et al., 2015), network pattern analysis (Shao et al., 2016), etc.

In this work we present the challenges faced in the process of developing a language model enriched by discourse features for fake-news detection, along with experimental results. The contributions of this work are mainly two: the dataset creation process, described in Section 2 and the introduction of the text classification model, - LUX(Language Under eXamination), in Section 3. Section 4 brings a comprehensive evaluation of both VERITAS and LUX, while also featuring an ablation analysis of the latter.

2 Datasets for Fake News Classification

2.1 Available Corpora on Fake News

The deficit of suitable corpora for the intended approach is the main influence behind the creation of the VERITAS Dataset, and by consequence, the VERITAS Annotator. Below we present a list of datasets commonly used in related tasks. Note that although the following are considered valuable resources for many related tasks, none of them include all of the three most important characteristics required for a content based supervised classifier which are i) a significant volume of entries, ii) gold standard labels and iii) the entire fake news articles

---

[1] Astroturfing is the practice of masking the sponsors of a message or organization to make it appear as though it originates from and is supported by grassroots participants.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 41–56
August 1–6, 2021.

(i.e., the origin).

Emergent16 a collection of 300 rumours and 2,595 associated news articles - a counterpart to 'origin' in the VERITAS Dataset. Each claim's veracity is estimated by journalists after they have judged that enough evidence has been collected (Ferreira and Vlachos, 2016). Besides the claim labeling, each associated article is summarized into a headline and also labelled according to its stance towards the claim. Given the fixed structured of the website we were able to obtain valid labeled examples using a scraper.[2] Unfortunately they sum up to less than 100 usable claim-origin pairs (discussed in subsection 2.3).

LIAR17 includes around 13K human-labeled short statements which are rated by the fact-checking website PolitiFact into: "pants on fire", "false", "barely true", "half true", "mostly true", or "true" (Wang, 2017). The domain-restricted data as well as the reduced length of text that can be retrieved from this corpus makes it unsuitable for generic domain linguistic fake news detection.

FakeNewsNet18 is a data repository containing a collection of around 22K real and fake news obtained from Politifact and GossipCop[3] fact-checking websites. Each row contains an ID, URL, title, and a list of tweets that shared the URL. It also includes linguistic, visual, social, and spatiotemporal context regarding the articles. This repository could still be used for supervised learning models if it were not for the fact that it does not provide sufficiently long texts to be used by a classifier based on linguistic aspects. For the same reason, **CREDBANK** (Mitra and Gilbert, 2015) and **PHEME** (Derczynski and Bontcheva, 2014) are also unsuitable for the authors' use case. Those three datasets focus on network indicators (e.g. number of retweets, sharing patterns, etc.) of fake news, instead of its contents. CREDBANK is a crowd sourced corpus of "more than 60 million tweets grouped into 1,049 real-world events, each annotated by 30 human annotators", while PHEME includes 4,842 tweets, in the form of 330 threads, related to 9 events.

FEVER18 (Thorne et al., 2018) created FEVER, a set of more than 185K claims by modifying sentences from a collection of 50K Wikipedia articles. Annotators were tasked with annotating other sentences from the same article in respect to their stance towards the modified sentence. The corpus is the largest to our knowledge, but since it is synthetically created and focused on a sentence-level stance classification approach, it is unlikely to perform efficiently on heterogeneous web documents as a fake news classifier.

Snopes19 (Hanselowski et al., 2019) provides a large collection of more than 16 thousand manually annotated text snippets extracted from 6,422 `snopes.com` articles. Unfortunately, less than half of those snippets present a stance (agreeing or disagreeing) towards the fact-checked claim. Also, the annotated snippets are, by definition, only a portion of the original article. Nevertheless, an origin identification process could generate a significant amount of valid examples from this data.

Due to space restrictions, we cannot provide a detailed description of the following list of datasets, although is important to include them: **BuzzFeed16** (Potthast et al., 2018), **Kaggle**[4] and **NELA17** (Horne et al., 2018).

2.2 The VERITAS Dataset

The VERITAS Dataset is, to our knowledge, the most complete data collection of manually annotated claims in regards to their veracity. It is the only dataset to contain not only the mentioned veracity labels but also the document (in its entirety) from which the checked claim originated. VERITAS has been developed in a two step process: **1)** Fact-Checking articles scraping and **2)** Claim Origin Identification.

Step 1: Scraping FCAs As the cost for manually checking a large number of disputed claims is extensive, both in time and money, we have started the dataset creation process by scraping articles from fact-checking agencies and consequently trusting the work made by their journalists that undertake the processes of: 1)selecting controversial

---

[2] While web scraping can be done manually by a software user, the term typically refers to automated processes implemented using a bot or web crawler.

[3] `https://www.gossipcop.com`

[4] `https://www.kaggle.com/mrisdal/fake-news/data`

claims, 2)leveraging web documents that either support or deny those statements to 3) finally come to a veracity verdict. In simple terms, a Fact-Checking Article (FCA) is a narrative of this investigative process.

For each scraped FCA, we create an entry in the dataset and extract a number of attributes, most importantly: the claim, the veracity label, and the list of hyperlinks to the mentioned web documents, which we call *Origin Candidates*, since they will be the subject of the Origin Identification process. The code used to scrap the pages is openly available[5].

Step 2: Claim Origin Identification One of the most important steps of the dataset creation pipeline was a task we defined as "origin identification". In short, after three automatic ways of identifying the article in which a fact-checked claim originated were carried out and yielded non-satisfactory results, it was decided that a manual annotation process would be used to select the correct entries from the totality of the dataset. An annotation tool[6] was developed in order to make the task easier and faster. This annotation process not only provided a large and complete version of the dataset, but also leaves a possibility for an automation of the origin identification process as a future improvement of the project.

The final structure of each entry contains the following fields: Fact-Checking Article URL, Checked Claim, Claim Label, Tags, FCA date, Origin URL, Origin Domain, Origin Body, Origin Title, Origin Summary, Origin Keywords, Origin Date and Origin Author. Given the limited space, a more in-depth description of each field is not provided but can be found within the supplementary material (appendix 1) and also along an extensive description of the origin annotation process in (Azevedo and Moustafa, 2019). The past versions of the dataset are also openly available[7]

2.3 Consolidation of VERITAS Dataset

A consolidation of the VERITAS dataset followed the large annotation process over the scraped FCA pages that augmented both the quantity of annotated origins (1032 consolidated origins from more than 10k annotations) and the quality of the annotations, measured by Krippendorff's Alpha[8], reaching a substantial score of 0.6014. This consolidation generated the fourth version of the dataset, here addressed as V4.

Given the constant structure of `Emergent.info` articles, we have also incorporated its few valid claims, i.e., the ones with "true" or "false" verdict, and their respective sources.

Although the majority of origins obtained from Emergent were linked to "true" claims, when aggregated to the consolidated origins from VERITAS v4.0, the data collection showed a false/true class imbalance ratio of ≈ 1.44. Therefore, in order to quickly obtain "true" labeled news articles to balance the scraped Dataset, reporting articles were scraped and automatically labeled as "true" and composed a **separated** dataset where their headlines are used for the claim field. The sources of those articles were selected according to studies determining the least biased[9] and/or most trusted[10] news outlets in the U.S..

We are aware that the label assumption of those articles is far from ideal. Notwithstanding, it offers another **option** of palliative solution for the label unbalance issue and yielded positive results in similar works (Horne and Adali, 2017; Ireland, 2018). It should, however, be tested with caution and compared with other - also sub-optimal - methods, i.e., discarding "false" entries and/or implementing class weights on the model training. Both the collection of reporting articles and the emergent articles are provided **separately** so they can be optionally disregarded and eventually substituted by gold-standard data. Table 1 provides additional details about each subset.

Since the improvement of incorporating the entries from emergent was still to be evaluated by the proposed classifier, two different sample sets from the trusted sources were created, to balance both the v4.0 dataset by itself (V4+T1), as well as the concatenation of VERITAS and emergent (V4+EM+T2). The evaluation results will be presented at Section 4, as they are also the evaluation for the linguistic model. By comparing both balanced sets we can gain a better understanding of the

quality of the data obtained from emergent, keeping in mind that the difference in volume of entries would still affect the performance.

3 LUX - Language Under eXamination

The core contribution of this work is the investigation of the usage of linguistic aspects as discriminative features in a text classification model that should determine whether the given article is fake or not. We call this classifier LUX, short for Language Under eXamination.

Previous work investigated the use of such linguistic aspects as features for similar tasks such as deception detection (Reichel and Lendvai, 2016; Zhou et al., 2004), document clustering (Yu and Hatzivassiloglou, 2003a), text classification (Louis and Nenkova, 2011; Biyani et al., 2016) among others. Related works make use of few (mainly one) of those aspects and the majority of them report an improvement of their results by doing so.

Here we present a set of linguistic aspects that were shown to be correlated to deception. For each of these aspects, we present their contextual definition, along with a short literature review and a description of the methods we use to evaluate its presence or absence in a given piece of text. The objective is to build LUX (Language Under eXamination), a Fake News Classifier, effectively using these linguistic aspects to estimate the likelihood of an article containing fake news. Here, we present the results obtained with two baseline language models (BERT[11] (Devlin et al., 2018) and Word2Vec (W2V) (Mikolov et al., 2013)) towards building this classifier.

We are aware of an imbued redundancy that our features might present, since the aspects analyzed by the different approaches, in some cases, overlap with each other, but expect that the eventual bias this redundancy might add to the model can be overcome with the implementations of techniques such as LDA (Linear Discriminant Analysis) or PCA (principal component analysis).

3.1 Linguistic Aspects

Subjectivity Louis and Nenkova (Louis and Nenkova, 2011) observed that general sentences tend to be more subjective. Some of the shallow features that are correlated to the subjectivity level of a sentence are also used in their model, for example, punctuation marks, average number of characters and average number of words.

Pattern[12], a python library for text analysis, states in its section about subjectivity: “Written texts can be broadly categorized into two types: facts and opinions.” Based on a lexicon of adjectives produced for product review analysis, pattern.en provides a function that maps the subjectivity score of a sentence to a range between 0 and 1 depending on the number of adjectives it contains. It also provides implementations of measuring functions for mood and polarity.

Riloff et Wiebe (Riloff et al., 2003) presents a methodology for the creation of the MPQA Subjectivity Lexicon. In summary, the authors: 1) use an automatic subjectivity classifier to label data while also 2) identifying patterns present in the sentences labeled as subjective and 3) use the learned patterns to improve the classification model(1) and iterate between the three steps, making bootstrapping possible. The MPQA Lexicon is also used for us to measure the subjectivity of a given text. Based on the lexicon, (Wilson et al., 2005) also created OpinionFinder, a Subjectivity Classifier.

Another interesting method was presented by (Yu and Hatzivassiloglou, 2003a), where a Naive Bayes classifier is trained over a Wall Street Journal dataset containing two classes: Subjective (every article with type Editorial or Letter to Editor) and Objective (Business or

---

[11] Bidirectional Encoder Representations from Transformers

[12] https://pypi.org/project/Pattern/

News). By analysing low level features on the texts, the NB classifier achieved a 0.91 recall and 0.86 precision on the binary classification task.

In order to measure the subjectivity of a text, two values are calculated. Both are a sum of each word's subjectivity score normalized by the length of the document (in words) but use as reference different lexicons: the TextBlob[13] (a python library based on Pattern[12]) lexicon and the MPQA lexicon, described above.

Specificity Zhou et al. (Yu and Hatzivassiloglou, 2003b) uses specificity and measures it by words depicting the following aspects: perceptual information (sounds, smells, physical sensations and visual details) and spatio-temporal. (Fuller et al., 2009) measure bi-logarithmic type-token ratio (LogTTR) for evaluating specificity.

(Li and Nenkova, 2015) introduced Speciteller, a python framework for fast and accurate prediction of sentence specificity, which was enhanced and presented by (Ko et al., 2019). It introduces a new algorithm that adjust its weights to the training set, making it applicable to any domain, out-of-the-box. Speciteller is a machine learning classifier that uses as input a combination of:

Shallow features extracted from the text Number of words, number of symbols, average number of characters per word, number of stop-words, explicit discourse connectives (Prasad et al., 2008). From lexicons (General Inquirer (Stone et al., 1962), MRC (Wilson, 1988) and MPQA) other features like sentiment, subjectivity, polarity, familiarity, concreteness, imageability and meaningfulness are also evaluated.

Non-sparse features Brown clusters (Brown et al., 1992) are used to classify words into 100 groups and a vector of corresponding cardinality is used to keep track of the frequency of each class in the input text. Speciteller also uses averaged Word embeddings to represent a sentence embedding. These also are 100-dimensional vectors provided by (Turian et al., 2010).

The ablation results show that Speciteller contributes significantly to the LUX classifier and suggest that the framework could be even more impactful if contemporary word embedding generation techniques were to be used.

Complexity (Biyani et al., 2016) focused on the detection of click-baits (that can be seen as a subcategory of fake news) and reported that features used to measure the formality of a text were the most correlated to click bait articles. Using a slang lexicon and a list of bad words, as well as several readability scores, they obtained a reasonable F-1 score of 74,9.

A 1999 paper by (Heylighen and Dewaele, 1999) presents a famous metric for Formality evaluation, named the F-measure (not to be confused with the F1 score). (Pavlick and Tetreault, 2016) present a statistical model for predicting formality, but do not provide access to the model's code.

Another famous work on the formality area is Coh-Metrix (Graesser et al., 2014), but the only access to its implementation is through a simple HTML portal, so we have discarded this option.

Fortunately, a python library[14] provides several readability measuring tools, including known metrics as the Flesch-Kinkaid (Kincaid et al., 1975) and Coleman-Liau (Coleman and Liau, 1975), LIX (Björnsson, 1968) and RIX, which were also used by (Biyani et al., 2016). Those last two metrics are simple but effective, being the first one (LIX) calculated as $W/S + C/W * 100$ where W is the number of words in a text, S is the number of sentences and C is the number of *complex words* (words with more than 6 letters). The RIX metric is a simpler and graded version of LIX and is calculated as C/S.

Another python library[15], initially developed for the AFEL project (d'Aquin et al., 2018), provides more measuring tools for semantic complexity analyzer. The library starts by identifying the entities present in the input text and the relations between them in order to represent it as a knowledge graph which

---

[13] `https://textblob.readthedocs.io/en/dev/`

[14] `https://pypi.org/project/readability/`

[15] `https://github.com/afel-project/pySemanticComplexity/blob/master/pysemcom.py`

is then used to extract metrics as number of nodes, radius, assortativity[16] and other graph properties.

Both *readability* and *pySemCom* libraries are used by us to implement the highest amount of unique metrics for Complexity, Formality and Readability.

Uncertainty According to (Szarvas et al., 2012), "Uncertainty can be interpreted as lack of information: The receiver of the information cannot be certain about some pieces of information".

Rubin (Rubin et al., 2006) provides a solid survey on Certainty Identification. Building on that, (Vincze, 2015) elaborates on the same subject and achieves great results (Vincze et al., 2008) on the CoNLL Shared Task 10, that aimed for the classification of uncertain texts from the BioScope corpus. The approach was implemented very conveniently as a python library for Uncertainty detection, that is used by us for uncertainty measurement. The classifier is a simple model trained on a corpus of words that were assigned a binary label regarding their certainty. The model only requires the input text to be P.O.S-tagged in order to resolve syntactic ambiguity.

(Reichel and Lendvai, 2016) tried to identify hoax-resolving tweets by using the ratio between four data augmented lexicons (knowledge, report, belief, and doubt) as features, along with low-level syntactic features, not achieving good results.

Loughran and McDonald Sentiment Word Lists (Loughran and McDonald, 2011) and MPQA (Deng and Wiebe, 2015) are Uncertainty Lexicons that are leveraged by us for the evaluation of this aspect. A simple average of uncertain words over the number of words of the input text is used in our model.

Affect (Pang and Lee, 2008) is an extensive review of the literature on sentiment analysis and opinion mining that encompasses the field of linguistic aspect evaluation, which this work is focused on.

(Whissell, 2004) provides the Dictionary of Affect in Language, which includes people's mean ratings for the Pleasantness, Activation, and Imagery of close to 9,000 words. The dictionary is a lexicon with ratings representing the two main dimensions of emotional space, valence and arousal, along with another rating for people's assessment of imageability, i.e., how easily it is to form a mental picture of a word.

A better definition of Affect in the context of deception detection is necessary in order to decide which resource is more appropriate for the aspect evaluation, for now we are going to let the experiments evaluations indicate what is the most appropriate way of measuring affect for our task.

(Li and Nenkova, 2015) mention the MRC Psycholinguistic Database (Wilson, 1988) has words annotated w.r.t imageability among other aspects, while VADER (Valence Aware Dictionary and sEntiment Reasoner) (Hutto and Gilbert, 2014) is a lexicon and rule-based sentiment analysis tool that is specifically attuned to social media. Thus, it seems to be quite appropriate for us.

For this aspect we make use of two different sentiment classifiers: VADER and Pattern/TextBlob[13], already mentioned on the Subjectivity section. From each one of the two classifiers we obtain three metrics: the sum of all the positive scores, the sum of all negative scores and the total sum of scores, all averaged respectively by the number of words with positive score, words with negative score and total number of words in the input text. By using these metrics we ensure that statistics as variance and range of emotion within the text is passed to the LUX classifier.

Verbal Immediacy (Mehrabian and Wiener, 1966) first defined Immediacy as a linguistic property that refers to the degree to which a source associates himself/herself with the topics of a message; that is, "immediacy is the degree to which a source approaches or avoids a topic". Based on that definition, (Zhou et al., 2004) measured it by analysing spatial and temporal terms, passive voice ratio, self reference manner and group reference manner, among others. Different works relate the non-immediacy to the presence of deception in text since these try to disassociate oneself

---

[16] `https://en.wikipedia.org/wiki/Assortativity`

from one's communication.

Negative affect and passive voice are some indicators of non-immediacy. Since the first is already addressed by us, we will be using a ratio between passive sentences over the total number of sentences to determine how passive is the text. In this context, a sentence is deemed passive, if it contains a "BE" verb followed by some other, non-BE verb, except for a gerund.

Diversity / Quantity / Pausality Those are syntactic features and some of the previous defined ones already make use of one or more ways of measuring them. For example, the diversity measurement is used to evaluate a sentence's Complexity. Still, there are many different ways to measure diversity and since we intend to remove the redundancy of the features anyways, we will measure it with many different formulas.

In a 2013 article, (Jarvis, 2013) proposed that the six properties of lexical diversity should be measured by Variability, Volume, Evenness, Rarity, Dispersion and Disparity. Using a python library[17], we measure some of those metrics, namely different types of type-token ratio (TTR), vocd (McCarthy and Jarvis, 2007) and measure of textual lexical diversity (MTLD) (McCarthy, 2005).

Other simple aspects are also taken into account, as the overall quantity of words in absolute number and by P.O.S.-tag as well as the pausality, measured by the ratio between punctuation marks and number of sentences.

4 Evaluation and results

In simple terms LUX is a binary model for classifying general text into fake news / real news and it was originally proposed as a way to evaluate the efficiency of the above mentioned linguistic features. Aiming for generality, this model takes a text document (that could be a long article or a simple headline) as sole input and outputs the probabilities of it being fake or not, based on its psycho-linguistic profile and contextual representation. For the latter, different types of text encodings were tested and it became clear that the usage of fixed-size BERT document embeddings outperformed Word2Vec, which was tested on RNN, LSTM (Hochreiter and Schmidhuber, 1997) and Bi-LSTM (Schuster and Paliwal, 1997), with the latter having the best results, but still inferior to BERT.

After performing a grid search with different optimizers, activation functions, learning rates, training epochs and fully connected layer(FLC) dimensions, the initial model was decided to be composed of a simple ReLu[18] activated 64-dimensional FLC with a dropout of 30% attached to the final layer, of dimensionality 2 where a softmax filter would represent the false and true labels probabilities. Adam (Kingma and Ba, 2014) was the best performing optimizer and a combination of $\alpha = 0.001$ over 100 training epochs generally yielded the best results. Figure 1 brings an outline of the model.

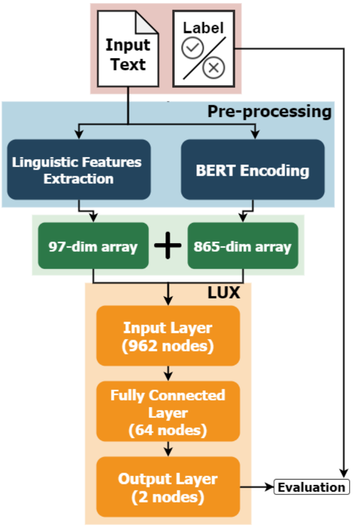

Figure 1: Outline of LUX classifier

All the reported values in Table 2 for Accuracy and F1 score come from a 9-fold training over the data. The results for the two best baseline models are also included, namely the same model using only the BERT document embeddings and only the w2v embeddings over a simple Bi-LSTM with 128 dimensions on the recurrent layer.

Since the data from FEVER18 (Thorne et al., 2018) and Snopes19 (Hanselowski et al., 2019) is composed of short statements a comparative analysis is also presented alongside a V4+EM+T2 run using only the claims as input text, instead of the larger body texts.

The final input for each article is a an ensemble of a document embedding generated by BERT

LUX	V4+EM+T2#	0.7723	0.708

**:Only the embeddings were used as input, these results serve as baselines to analyse the improvement added by LUX's linguistic features*
#:A version of V4+EM+T2 using the claim (and not the origin body) as input for comparison with other datasets focused on small texts.

trained on the BERT-Large uncased corpus[19] and the 97 linguistic features described in the previous section. A version of the code repository is available at `https://github.com/lucas0/Lux`.

Given the initial results, the robustness added from the a different source, i.e. emergent, with the benefit from balancing classes using the trusted news (T2) yielded the best results. Consequently, it was decided this was the selected subset for the linguistic features ablation analysis.

4.1 Ablation

Table 3 presents the three most impactful positive and negative features, i.e. features that, when removed, most decrease or most increase the accuracy of the model, respectively. Those are all results using as base the best model run, i.e., LUX model over the V4+EM+T2 data, depicted in Table 2. A longer table containing the results for the full ablation analysis can be found within the supplementary material (appendix 2).

Positive Features(PF): When individually removed, each of the 97 features of the model, 50 have report a decreased accuracy of the model by an average of 0.056%, where 21 'contribute' with more than the average of all the positive features and only 10 features decrease more than 1% accuracy when absent. All three top PF fall into the Quantity group, as P.O.S.-tag counts, while most of the most sophisticated, i.e. higher semantic level, make to the top 10. Besides the ones featured(pun intended) in the table, the top 10 also comprises, unordered: Pausability, Coleman-Liau informality score, specificity, measure of lexical textual diversity(MTLD), and three features from the semantic complexity evaluator (Venant and d'Aquin, 2019): assortativity, average number of in-links, and the density. In short, those features are metrics from a graph generated from entities identified in the text, when matched against DBpedia knowledge graph. They refer to, respectively, the similarity of connections with respect to the vertice the number of edges a vertex has to other vertices; the number of links that go from entities of the global DBPedia to the identified entities; and the density of a graph stresses how much nodes are connected to each other.

Negative Features(NF): As expected, the negative features account for the other 47 features. On average, each negative feature increases the accuracy of the model by 0.6% when removed individually. From those, 17 have a better-than-average impact. Avoiding the risk of removing important features from the model and given the high number of negative features, we mention the 9 features that, when **not** considered, improved LUX's accuracy by more than 1%, but focus the discussion on the top 3. Our results point to the number of VBD (verbs, in the past tense form) in the input text as being the third least important feature of the model, while the top two NF are metrics from the same complexity evaluation approach mentioned above. They are nbTypesStd and diameter of nodes, meaning respectively: the standard deviation on the number of different link types per node and the "spreadness"(sic.) of concepts, i.e., the more unrelated and specific concepts we have, the higher the diameter will be. The other six NF improved the accuracy of the model in more than 1% when removed are: the number of words P.O.S.-tagged as PDT (predeterminer), two readability metrics (Dale–Chall and Flesch Reading Ease) and three other features from PySemCom: number of entities, entities density in the text, standard deviation over the number of in-links.

Table 3: Ablation Results

Feat.Idx	Feature	Avg. Acc	≈Removal Impact
	Most Positive Features		
55	‘CD’	0.7864	-1.8%
74	‘RBR’	0.7871	-1.7%
71	‘PRP’	0.7904	-1.4%
	Most Negative Features		
17	diameter	0.8215	+1.6%
23	nbTypesStd	0.8208	+1.5%
81	‘VBD’	0.8201	+1.5%

5 Conclusion and Future Work

This work has done the following two significant contributions: i)the consolidation of the VERITAS Dataset, which is unique due its provision of organic origins for each given claim in the collection, which has, in turn, been manually verified by FCAs. Given the completeness of the released data, it can be an useful resource for a number of related tasks, namely: Document Retrieval, Stance Detection and Claim Validation. As a second contribution, we have confirmed the hypothesis that the inclusion of linguistic metrics as model features allows for a better text classification performance, at least in the target task of identifying fake-news.

After having set up an initial version of the classifier, named LUX, we could demonstrate an improvement from its first evaluation by increasing the quality and quantity of the training data, as well removing the most negative features from the model. The final LUX version performs better than both tested baselines. When used to evaluate the quality of datasets, LUX yields better scores when trained with VERITAS, than when compared with two other fake-news datasets, FEVER18 and Snopes19.

Future work would involve the development of an automatic origin identification step for the VERITAS dataset would allow for a much larger version of it, which in turn could further enhance the classification model (LUX). If this step is achieved, a bootstrapping loop for claim veracity checking with origin identification would be complete, and both the inclusion of new entries to the data collection as well as the further training of classification model could be fully automated, having as their only bottleneck, the permanent scraping of manually fact-checked claims, which is already an automatic process.

Another enhancement being added to this work is the output and analysis of BERT attention weights (Vaswani et al., 2017) for both explainability and interpretability of the model. (Yin et al., 2016; Rush et al., 2015)

Increasing the size of the VERITAS dataset could also be achieved by leveraging the work done by (Hanselowski et al., 2019) and identifying as the origins of a claim, the website containing the snippets annotated as ’supportive’ of the claim. This task is currently ongoing.

6 Appendix

6.1 Description of VERITAS fields

Fact-Checking Article URL The article where the fact-checker journalist analyses the claim, its source(s), characteristics, possible counter arguments, etc.

Checked Claim The main affirmation being verified in the article.

Claim Label The verdict, along with the source document of a fact candidate compose the input/outcome pairs of the dataset to be used in our classification model. In other applications or tasks it might not even be necessary.

We assign the gold-standard status to this annotation, given that each one of those checked documents was manually investigated by one or more fact-checking journalists, before coming to a verdict regarding its veracity, and thus, are as trustworthy as the journalists and correspondent fact-checking agencies themselves.

Different FCAs use different labels, e.g.'mostly-true', 'mixture', 'unproven', etc. consequently there is a need for normalization or removal of the ones that cannot be directly mapped into "true" nor "false".

Tags The set of tags used by the journalist that wrote the fact-checking article. These are mainly used for navigation within the website but could be used for clustering of the dataset and retrieval of other claims regarding the same topic.

FCA Date The date the claim was checked by one of the fact-checking agencies.

Origin URL The URL of the web document that originated the claim, i.e. its origin. Here, origin is defined as a source that directly supports the claim.

Note that an origin does not have to be the very first article that stated the claim and that there could be multiple origins for a single claim.

Origin Domain The origin URL domain. This can have great impacts in results of a neural network classifier's accuracy, or even in the weighting of a simpler classifier method. Examples of using the URL domain as a feature for it's content veracity are not new. (Nakashole and Mitchell, 2014; Balakrishnan and Kambhampati, 2011)

Origin Body The whole text extracted from the origin URL. Which method is used to obtain the Origin Body is the main difference across the versions, as discussed above.

Origin Title The title of the origin page. This is another possibly useful feature for related tasks or extra features for our classifier. (Popat et al., 2017)

Since the title and the checked claim have similar lengths, using this attribute instead of the whole origin text would have probably yielded better results on the stance classification ranking.

Origin Summary Besides being faster than the previously used crawling methods, the current version of the crawler[5] also generates a summary of the origin. This could be a valuable piece of information but would demand checking whether it is a valid depiction of the content of the origin.

Origin Keywords Similar to the Tags of the fact-checking article with the difference that these are obtained by the great article curator newspaper3k[20]. This could also be used as a feature for the Origin Identification Classifier (see on Future Work section).

Origin Date The date at which the origin article was published.

Origin Author The author of the origin article.

Diagnosing Transformers in Task-Oriented Semantic Parsing

Shrey Desai **Ahmed Aly**
Facebook
{shreyd, ahhegazy}@fb.com

Abstract

Modern task-oriented semantic parsing approaches typically use seq2seq transformers to map textual utterances to semantic frames comprised of intents and slots. While these models are empirically strong, their specific strengths and weaknesses have largely remained unexplored. In this work, we study BART (Lewis et al., 2020) and XLM-R (Conneau et al., 2020), two state-of-the-art parsers, across both monolingual and multilingual settings. Our experiments yield several key results: transformer-based parsers struggle not only with disambiguating intents/slots, but surprisingly also with producing syntactically-valid frames. Though pre-training imbues transformers with syntactic inductive biases, we find the ambiguity of copying utterance spans into frames often leads to tree invalidity, indicating span extraction is a major bottleneck for current parsers. However, as a silver lining, we show transformer-based parsers give sufficient indicators for whether a frame is likely to be correct or incorrect, making them easier to deploy in production settings.

1 Introduction

Task-oriented semantic parsing—mapping textual utterances to semantic frames—is a critical component of modern conversational AI systems (Gupta et al., 2018; Aghajanyan et al., 2020). Recent methodology casts parsing as transduction, using seq2seq pre-trained transformers to produce linearized parse trees (Aghajanyan et al., 2020; Chen et al., 2020; Li et al., 2021); here, each frame token is either *copied* from the utterance or *generated* from an ontology. Compared to explicit grammar-based approaches (Gupta et al., 2018), this plug-and-play of transformers simplifies the learning objective and scales to multilingual settings, but the lack of provenance makes it challenging to understand model behavior "under the hood."

In this work, we investigate the strengths and weaknesses of transformer-based semantic parsers and provide modeling directions based on data-driven insights. Specifically, we study BART (Lewis et al., 2020) and XLM-R (Conneau et al., 2020), two state-of-the-art conversational semantic parsers, on both monolingual (TOP/TOPv2; (Gupta et al., 2018; Chen et al., 2020)) and multilingual (MTOP; (Li et al., 2021)) datasets. The compositionality of utterances in these datasets provide a strong testbed for resolving both complex syntactic structure and semantic ambiguity, mirroring the types of challenges our parsers are likely to encounter in practice.

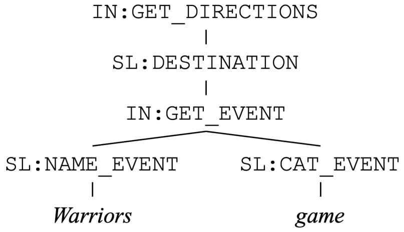

Figure 1: Example decoupled semantic frame representation (Aghajanyan et al., 2020) for the utterance *Directions to the Warriors game*.

We design our experiments around three main questions. First, broadly speaking, what types of errors do transformer-based parsers make? We begin by annotating 500+ predicted frames across 6 languages and categorize them with fine-grained types. We find transformer-based parsers struggle not only with *classification* (i.e., disambiguating intents/slots) but also *planning* (i.e., switching between copying/generating). Planning errors are more egregious: misplacing close brackets, for example, can violate tree constraints, rendering the entire frame unusable.

Next, we investigate transformer-based parsers' abilities to generate syntactically-valid trees. Specifically, are planning mistakes caused by general uncertainty, or worse, a pathology of seq2seq learning? To address this, we devise an oracle set-

ting where a model conditions on partially gold information (either utterance spans or syntactic structure) and predicts the remaining parts of the frame. Surprisingly, we find conditioning on gold spans—not gold structures—results in near-perfect trees at most depths, pointing towards span extraction as a major bottleneck for current parsers.

Finally, though transformer-based parsers are susceptible to error, ideally, we should be able to proactively diagnose mistakes. Using features from model generations (e.g., confidence), can we intrinsically judge if a sequence is correct or incorrect? Encouragingly, we show that a confidence estimation system combining a transformer-based parser and feature-based classifier can detect *correct* frames with 90%+ F1, indicating usability in production settings.

2 Experimental Setup

We conduct experiments on the following task-oriented semantic parsing datasets: (1) **TOP:** parallel corpus consisting of English utterances and corresponding semantic frames (Gupta et al., 2018); (2) **TOPv2:** monolingual extension of TOP to 6 domains (Chen et al., 2020); (3) **MTOP:** multilingual extension of TOP spanning English, Spanish, French, German, Hindi, and Thai (Li et al., 2021). Table 1 shows train, dev, and test splits for the datasets.

Each dataset sample consists of a textual utterance x and (linearized) semantic frame y. Here, frames are in decoupled form (Aghajanyan et al., 2020), as each token is derived either from *copying* from the utterance or *generating* from the ontology (see Figure 1). Following prior work, we fine-tune seq2seq transformers to maximize the log likelihood of the gold frame token at each timestep: $\sum_{(x,y)} \sum_t \log P(y_t|y_{<t}, x; \theta)$.

Table 4: Hyperparameters for fine-tuning models on TOP, TOPv2, and MTOP.

On TOP/TOPv2, we fine-tune BART (Lewis et al., 2020), a seq2seq transformer pre-trained with a denoising autoencoder objective on monolingual corpora, and on MTOP, we fine-tune XLM-R (Conneau et al., 2020) (equipped with a randomly-initialized decoder), a transformer encoder pre-trained with a masked language modeling objective on multilingual corpora. For XLM-R, specifically, we attach a randomly-initialized decoder (see Table 2). Table 3 shows model performance as judged by exact match. Hyperparameters for all models are listed in Table 4.

3 Error Analysis

In this section, we seek to better understand the types of errors transformer-based parsers make across both monolingual and multilingual settings.

3.1 Error Types

To standardize our analysis, we categorize model errors under the following types: **intent** (incorrect intent prediction), **slot** (incorrect slot prediction), **out-of-domain** (incorrect out-of-domain intent prediction), **mode** (confusion between copying an utterance token or generating an ontology token), and **leaf** (incorrect span in a frame leaf slot). In addition, we report the syntactic **validity** of parse trees separately, though we note mode errors typically result in invalid constructions.

	Exact Match			Tree Validity		
d	TOP	TOPv2	MTOP	TOP	TOPv2	MTOP
1	78.03	86.58	84.75	98.65	94.57	91.23
2	92.30	90.67	85.73	96.97	96.82	93.80
3	90.94	88.50	74.56	97.10	96.35	90.85
4	88.24	86.32	64.53	95.93	95.47	85.73
5	83.39	83.63	44.29	94.29	94.85	69.55
6	83.06	84.54	44.44	94.00	94.45	62.50

Table 5: Benchmarks of BART and XLM-R on TOP/TOPv2 and MTOP, respectively, according to exact match and tree validity at increasing tree depths (d).

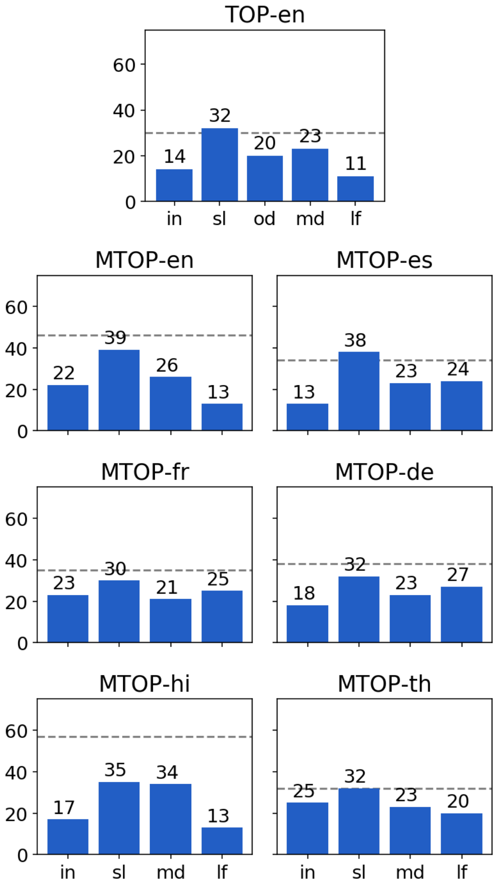

Figure 2: Distribution of errors across TOP and MTOP categorized by intent (in), slot (sl), out-of-domain (od), mode (md), and leaf (lf). Dashed lines indicate the percentage of trees which are syntactically valid.

One complicating factor is that a predicted sequence may potentially contain several errors, and because decoding is conducted autoregressively, a given error may be influenced by earlier errors (if any such exist). Therefore, to reduce the number of confounding variables, we only consider settings where an incorrect prediction has gold history $\mathrm{argmax}_{y_i} P(y_i|y^*_{<t}, x) \neq y^*_i$; put another way, we only count the *first* error in a sequence.

Using the framework discussed above, we annotate 700 errors across BART and XLM-R on TOP and MTOP, respectively; 100 errors are from TOP and 6×100 errors are from MTOP (100 per language).

3.2 Results

Table 5 benchmarks overall model performance and Figure 2 categorizes errors with fine-grained types; from these results, we draw the following conclusions:

Transformer-based parsers typically struggle with both classification and planning. In the seq2seq formulation, models must jointly *classify* (i.e., provide intent and slot labels) and *plan* (i.e., switch between copying and generating) when producing a semantic frame. Our results show intent/slot and mode errors, which generally fall under the theme of classification and planning, respectively, account for nearly 70-80% of errors. A key observation, however, is that classification and planning error statistics are relatively consistent across languages, suggesting our models may not need language-specific fine-tuning to address these particular errors.

Nearly 40% of incorrectly predicted frames are syntactically invalid. Surprisingly, a large percentage of incorrectly predicted frames violate tree constraints; for linearized frames, this implies the number of open brackets (`[in` or `[sl`) do not match the number of close brackets (`]`). Though well-formedness *is* correlated with depth, we see tree validity (1) is not substantially improved by increasing the number of monolingual samples (TOP → TOPv2) and (2) drops off quite rapidly for multilingual samples (TOP/TOPv2 → MTOP).

Span extraction is more challenging in multilingual settings. Leaf errors in English `(TOP|MTOP)-en` are typically twice as lower compared to those in non-English languages `MTOP-(es|fr|de|hi|th)`. Upon closer inspection, we find most leaf errors in English are relatively benign; the model may drop a preposition when copying a span (e.g., *Monday* as opposed to *on Monday*). However, for languages beyond English, extracted spans in leaf slots typically consist of hallucinated or duplicated subwords, which are much more serious in nature. Finally, though languages with non-projective structures (e.g., German) can populate leaf slots with non-contiguous spans, we noticed errors on these types of samples were infrequent.

Out-of-domain detection is also a significant source of error. TOP, in particular, mixes the canonical semantic parsing task with out-of-domain detection by assigning such utterances the frame `[in:unsupported ]`.[1] Though well-motivated, roughly 20% of errors are related to incorrect out-of-domain predictions, suggesting our models have not precisely learned the boundary between in-domain and out-of-domain utterances. If high detection accuracy is preferred, multi-tasking parsers in this fashion may not be an effective use of parameters (assuming more data is not available); instead, out-of-domain detection can be conducted independently with alternate methodology (Gangal et al., 2019).

4 Syntactic Structure

Our case study above demonstrates transformer-based parsers can produce syntactically-invalid frames at a high rate. These structural errors are more serious than disambiguation errors since they render the frame unusable, potentially causing cascading failures in a task-oriented dialog system. Therefore, in this section, we dive deeper into why tree constraints are not satisfied and question the possibility of achieving perfect tree validity.

While transduction models do not explicitly impose tree constraints, there is precedent that strong neural representations do implicitly model tree structures; recent studies demonstrate large-scale pre-training, in particular, imbues strong notions of syntax (Goldberg, 2019; Jawahar et al., 2019; Tenney et al., 2019). Taking these results together, we hypothesize that transformer representations may be "good enough", but instead there exist ambiguous aspects of our task-oriented semantic parsing task which cause tree invalidity.

Previously, we saw transformer-based semantic parsers largely struggled with classification- and planning-related errors. Therefore, the question we pose is: if we resolve these ambiguities by creating oracle models, can we achieve perfect tree validity? This setup also enables us to gain a deeper understand of the upper-bound performance of transformer-based semantic parsers, even as their representations get stronger.

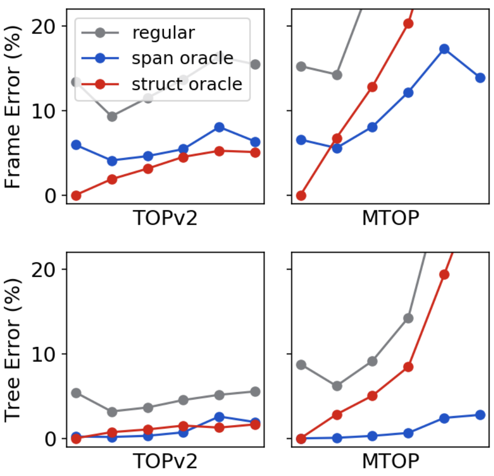

Figure 3: Exact match (EM) and tree validity (TV) error (%) of the regular, span oracle, and structure oracle models on TOPv2 and MTOP. Dots from left → right indicate increasing frame compositionality (the graph depths of 1 → 6).

Oracle Models. Because classification and planning target inherently different phenomena, creating an oracle that simultaneously makes both less ambiguous is challenging. Instead, we experiment with two separate oracles—**span oracle** and **structure oracle** models for classification and planning, respectively—which map an utterance x along with a "partially gold" snippet z to generate the frame y, inducing the objective $\sum_{(x,y,z)} \sum_t \log P(y_t|y_{<t}, x, z; \theta)$.

For example, given an utterance x *Where can I see fireworks tonight?* and frame y `[in [sl` *fireworks* `[sl` *tonight* `] ]`, the span oracle model defines z as `[span1]` *fireworks* `[span2]` *tonight* and the structure oracle model defines z as `[in [sl [span1] [sl [span2] ] ]`.[2] Here, providing z as input helps the model learn $y \setminus z$; span oracle models optimize for correct structure and structure oracle models optimize for correct spans. Table 6 shows example source and target pairs for the regular, span oracle, and structure oracle models.

Results. Figure 3 shows the oracle model results; we measure both exact match and tree validity error. **A key phenomenon we observe is that conditioning on gold spans results in near-zero tree validity error at most depths.** Surprisingly, we see conditioning on gold structures (to stress, the *exact* syntactic structure) never consistently results in well-formed trees, especially as the depth in-

---

[1] There also exist more fine-grained out-of-domain categories, such as `[in:unsupported-event ]`.

[2] Fine-grained intent/slot labels are omitted for visual clarity, but are included during model training.

model type	utterance x (+ snippet z)	frame y
regular	Where can I see fireworks tonight?	`[in [sl` fireworks `[sl` tonight `] ]`
span oracle	+ `[span1]` fireworks `[span2]` tonight	
struct oracle	+ `[in [sl [span1] [sl [span2] ] ]`	

Table 6: Example source and target pairs for oracle experiments. The span oracle specifies the gold spans while the struct oracle specifies the gold structure. Note that `[in` and `[sl` are used for brevity.

creases. Structure oracle models still suffer from mode errors during generation: augmenting a leaf span with an extra word instead of placing a close bracket, for example, is a typical mistake. Furthermore, we see this problem is magnified in MTOP, which connects to the notion that span extraction tends to be difficult in multilingual settings.

Our experiments suggest seq2seq transformer-based parsers *can* achieve near-perfect tree validity—even at large depths—provided that span extraction is precise. Currently, however, this is a major source of ambiguity our parsers are not well-equipped to handle, especially when scaling to languages beyond English.

5 Confidence Estimation

Despite the criticism we have presented of state-of-the-art, transformer-based conversational semantic parsers, these models do demonstrate strong performance over prior baselines, and correctly parse a vast majority of samples. A property that can make these models easier to deploy in practice is if they "know what they don't know" (Desai and Durrett, 2020); besides interpretability, this is particularly useful for identifying and correcting errors in tail scenarios via active learning (Dredze and Crammer, 2008; Duong et al., 2018; Sen and Yilmaz, 2020). We frame this problem as confidence estimation (Blatz et al., 2004): given an utterance x, predicted frame y', and gold frame y, we seek to learn a binary classifier which uses target-side features $f(y')$ to estimate $P(y' = y) = \text{sigmoid}(w^\top f(y'))$.

To make our approach as generalizable as possible, we constrain $f(y')$ to be as model-agnostic and recall-oriented as possible. We select the following features: (1) **length:** $|y'|$; (2) **validity:** $\max(0, \sum_i \mathbb{1}[y'_i \in V^+] - \mathbb{1}[y'_i \in V^+])$ where V^+ and V^- are the set of open and close brackets, respectively; and (3) **confidence:** $\frac{1}{|y'|}\sum_i P(y'_t|y'_{<t}, x)$. Using our best transformer-based parsers, we obtain predictions on a held-out set D_{dev} and test set D_{test}. Then, we train and test a SVM on D_{dev} and D_{test}, respectively, using the features defined above.

	TOPv2			MTOP		
	P	R	F1	P	R	F1
SVM	97.2	85.7	91.2	95.0	85.2	89.8
–length	**97.7**	84.8	90.8	**95.1**	84.7	89.6
–validity	97.0	82.6	89.2	94.9	80.5	87.1
–confidence	91.6	**98.8**	**95.1**	85.3	**95.8**	**90.2**

Table 7: Precision (P), recall (R), and F1 of the SVM-based confidence estimator. –x indicates an ablation of feature x (i.e., it is omitted during learning).

In addition to the standard hinge loss, we also add a class imbalance penalty as positive examples are typically 5-8× as prevalent depending on the dataset. We chiefly evaluate the binary classifier's ability to identify semantic frames which are correct (i.e., the positive class). From an active learning standpoint, getting positive samples wrong is more serious than getting negative samples wrong; annotation resources are best directed towards boundary or incorrect predictions.

Table 7 shows the performance and ablations of our confidence estimator. **In both monolingual and multilingual settings, using transformer-based features, we can detect *correct* semantic frames with 90%+ F1.** In particular, we see length and validity largely capture the space of correct frames (recall) and confidence effectively distinguishes between correct and incorrect frames (precision). Practitioners may select an SVM variant depending on whether precision or recall is preferred.

6 Conclusion

In this work, we assess the strengths and weaknesses of seq2seq transformers for task-oriented semantic parsing. These models "know what they don't know", making them easier to depoy in practice, but cannot perfectly model compositional utterances, as indicated by the challenges of span extraction. We believe that modeling efforts in this direction—as opposed to simply annotating more data—can improve parsers substantially.

Abstract

Change captioning is to describe the difference in a pair of images with a natural language sentence. In this task, the distractors, such as the illumination or viewpoint change, bring the huge challenges about learning the difference representation. In this paper, we propose a semantic relation-aware difference representation learning network to explicitly learn the difference representation in the existence of distractors. Specifically, we introduce a self-semantic relation embedding block to explore the underlying changed objects and design a cross-semantic relation measuring block to localize the real change and learn the discriminative difference representation. Besides, relying on the POS of words, we devise an attention-based visual switch to dynamically use visual information for caption generation. Extensive experiments show that our method achieves the state-of-the-art performances on CLEVR-Change and Spot-the-Diff datasets [1].

1 Introduction

Change Captioning aims to describe a semantic change between a pair of "before" and "after" images, which has many practical applications such as facility monitoring (Sakurada and Okatani, 2015), medical imaging (Patriarche and Erickson, 2004), and aerial photography (Gueguen and Hamid, 2015).

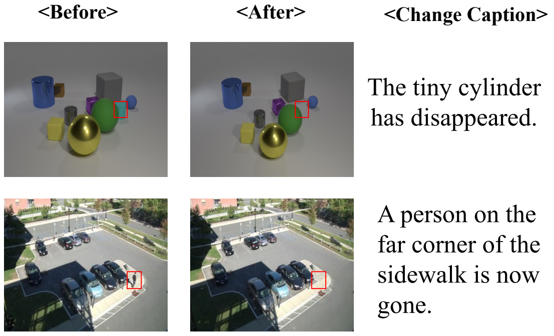

Figure 1: Two examples of change captioning with and without a viewpoint change.

The previous work (Jhamtani and Berg-Kirkpatrick, 2018) introduced this task with an ideal assumption that there is a semantic change between a completely-aligned image pair. However, there is always illumination change in a dynamic world, and same or similar scenes are prone to shoot under different viewpoints. Compared to semantic changes, both illumination and viewpoint changes are irrelevant distractors, so realistic change captioning requires a model: 1) distinguishing semantic changes (e.g., an object has moved) from distractors (e.g., a viewpoint change) and 2) conveying the detected change in a logically and grammatically accurate sentence. To this end, recent works (Park et al., 2019; Shi et al., 2020) focused on addressing change captioning in the presence of distractors.

Despite the progress, there are still two limitations for their approaches. First, the semantic difference was modeled only relying on the semantic features of objects, while ignoring their self-semantic relations. Hence, the feature difference is hard to capture the tiny change. As shown in Figure 1, compared with many unchanged objects, the dropped object is tiny and easy to ignore. Differently, if one of the objects has changed, especially number or position change (*e.g.*, "add", "drop", or "move"), the semantic relations surrounding it would change as well, which would be beneficial to explore the underlying objects that have changed. Second, due to the existing of irrelevant distractors, the model would capture the semantic difference

with noises and thus learn a wrong difference representation. However, both distractors are irrelevant to the semantics of image contents. Therefore, the cross-semantic relation between the captured semantic difference and the image pair is beneficial to judge whether the semantic change has actually happened, and further learn the difference representation in the "before" and "after" images.

Besides, during caption generation, previous works exploited visual information to generate each word, which is unnecessary or even misleading (Lu et al., 2017; Song et al., 2017). As words with different part-of-speech (POS) information not only play different grammatical roles in a sentence (Wang et al., 2019), but also have different relationships with the visual information in an image. As shown in the first example of Figure 1, some words (e.g., "tiny", "cylinder" and "disappeared") belong to adjective, noun and verb words, which denote the size, category, and state of the visual object, while the word (i.e.,"the") is a determiner word which does not have corresponding canonical visual signals. Thus, it is useful to introduce the POS of words for switching visual information during change caption generation.

In this paper, we propose a Semantic Relation-aware Difference Representation Learning (SRDRL) network to localize the semantic change in the presence of distractors, and introduce an Attention-based Visual Switch (AVS) to dynamically decide when to use visual information during change caption generation. Specifically, first, a Self-Semantic Relation Embedding block (SSRE) builds semantic relations of objects for each image in the "before"/"after" pair via the self-attention mechanism. The built relations are embedded into image features for computing a relation-embedded feature difference. Second, a Cross-Semantic Relation Measuring block (CSRM) leverages the obtained difference to query the underlying "candidate change" in the each image. Further, CSRM uses the difference to generate an attention gate measuring its cross-semantic relations with respect to each image. Subsequently, the attention gate is applied to the candidate change to distinguish semantic change from the viewpoint/illumination change. Third, the change localizer is introduced to learn the accurate difference representation in the image pair under the guidance of a prior knowledge (the above distinguished information).

Finally, according to POS information of words, an Attention-based Visual Switch (AVS) is devised and incorporated into the caption generator to dynamically control visual information when predicting the next word. Extensive experiments show that our approach outperforms the state-of-the-art change captioning models with a large margin.

In summary, the contributions of this work have threefold: (1) We propose SRDRL that explicitly learns the semantic difference representation in the image pair by embedding self-semantic relations into object features of each image and further measuring the cross-semantic relations between the image pair and their difference. (2) Both SSRE and CSRM blocks are designed to help the change localizer to accurately focus on the changed objects. (3) An AVS is customized to dynamically utilize visual information for caption generation based on the POS information of words.

2 Related Work

Different from conventional image (Liu et al., 2020, 2019; Li et al., 2020; Yan et al., 2019, 2020a, 2021) or video captioning (Deng et al., 2021; Zhang et al., 2017; Tu et al., 2017, 2020; Yan et al., 2020b), change captioning addresses two-image captioning, especially to describe their difference. Jhamtani *et al.* (Jhamtani and Berg-Kirkpatrick, 2018) is the first work for change captioning. However, it is built upon an ideal situation by assuming there are no distractors (illumination/viewpoint change) between a pair of images. To make this task more close to our dynamic world, Park *et al.* and Shi *et al.* (Park et al., 2019; Shi et al., 2020) both aimed to address change captioning in the existence of distractors. On one hand, Park *et al.* directly concatenated the coarse feature difference with the image pair to operate spatial attention to localize the change. However, due to the existing of distractors, when the captured feature difference is not what the model really expects, the spatial attention module could be misled to give fallacious results. On the other hand, Shi *et al.* first exploited a cross-attention mechanism to search the most similar patches between the image pair and they are regarded as the unchanged representation. Then, they subtracted them from the original image to get the difference representation. However, as our aforementioned, the changed object is tiny and easy to ignore, so it is insufficient to capture the difference representation only at feature level.

Different from the above state-of-the-art meth-

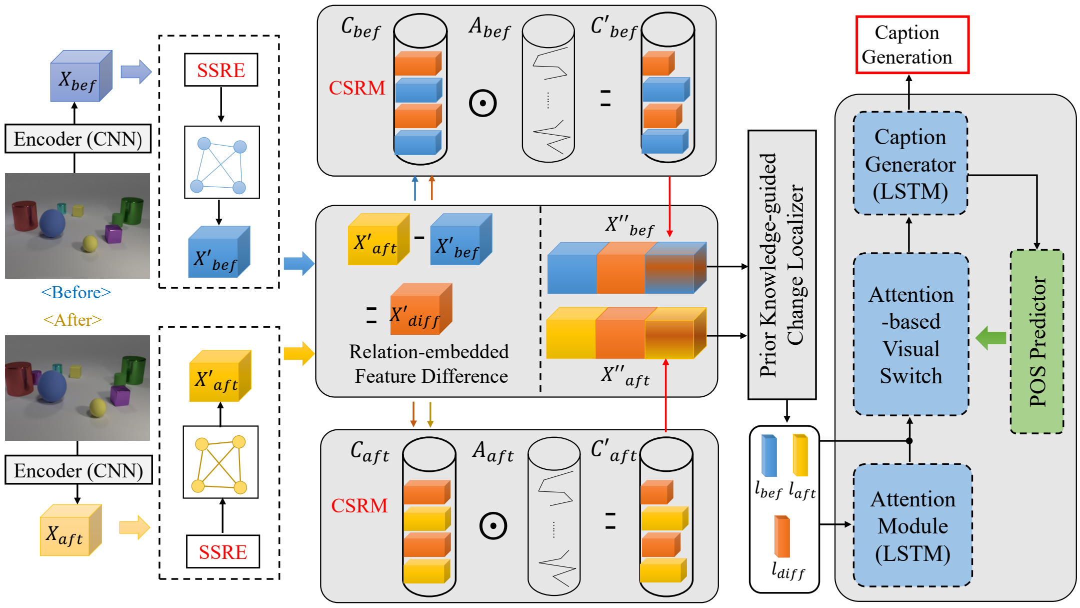

Figure 2: The architecture of the proposed semantic relation-aware difference representation learning (SRDRL) network and an attention-based visual switch (AVS). The SRDRL consists of a self-semantic relation embedding block (SSRE), a cross-semantic relation measuring block (CSRM) and a prior knowledge-guided change localizer. The AVS is incorporated into the caption generator and guided by a POS predictor.

ods, we first use SSRE to improve the fine-grained representation ability of object features by embedding the self-semantic relations among them. Then, we exploit CSRM to distinguish the actual semantic change from irrelevant distractors via measuring cross-semantic relations between the captured candidate difference and the original images. Finally, we use POS information to devise an attention-based visual switch that dynamically determines not only when to use visual information, but also which to use (*e.g.*, "before" and "after"). Compared to the aforementioned methods, our method not only can learn discriminative difference representation, but also can describe it using an accurate natural language sentence.

3 Methodology

We present a semantic relation-aware difference representation learning (SRDRL) network for change localization and devise an attention-based Visual Switch (AVS) under the guidance of POS information for caption generation. When a pair of "before" and "after" images are given (denoted as I_{bef} and I_{aft}), our SRDRL first detects *what* (position, number, attribute, or nothing) has changed in a scene and further decides *where* to localize on both I_{bef} and I_{aft}. Then, during caption generation, the AVS is able to dynamically decide *when* to use visual information and *which* to use (*e.g.*, "before" and "after").

3.1 Semantic Relation-aware Difference Representation Learning Network

3.1.1 Self-Semantic Relation Embedding

Formally, given a pair of I_{bef} and I_{aft}, we first use pre-trained CNN model to extract object-level features and denote them as X_{bef} and X_{aft}, where $X_i \in \mathbb{R}^{C\times H\times W}$; C, H, W indicate the number of channels, height, and width. However, These original object features are independent, and there exist semantic relations among them (Huang et al., 2020; Wu et al., 2019; Yin et al., 2020). Inspired by the self-attention (Vaswani et al., 2017) using in machine translation, the self-semantic relation embedding block (SSRE) relies on it to implicitly model the semantic relations among objects in each image. Specifically, we first reshape X_i to $X_i \in \mathbb{R}^{N\times C}$ $(N = HW)$, where $i \in (bef, aft)$. Then, given (*key*, *value*), SSRE exploits the scaled dot-product attention on queries Q by:

$$SSRE(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V. \quad (1)$$

In our case, the queries, keys and values are all projections of the object features of X_i:

$$(Q, K, V) = \left(X_i W^Q, X_i W^K, X_i W^V\right). \quad (2)$$

Though the SSRE, the semantic relations are embedded in the original object features; both X_{bef} and X_{aft} can be updated to X'_{bef} and X'_{aft}. Finally, we subtract X'_{bef} from X'_{aft} to capture the semantic difference X'_{diff} in the both object feature and relation aspects.

3.1.2 Cross-Semantic Relation Measuring

Due to the existing of distractors, the resulting X'_{diff} would include some irrelevant information, which would be noises for the accurate difference representation learning on both X'_{bef} and X'_{aft}. Thus, we propose a cross-semantic relation measuring block (CSRM) to distinguish the semantic change from the irrelevant illumination or viewpoint change by measuring the cross-semantic relation between the X'_{diff} and X'_{bef} (X'_{aft}). Concretely, the CSRM utilizes the X'_{diff} to first query the possible “candidate change” C_{bef} on the X'_{bef}, and then generates an “attention gate” A_{bef} measuring its semantic relations with respect to X'_{bef}. These are defined by using two separate non-linear transformations:

$$\begin{aligned} C_{bef} &= \phi\left(X'_{diff}W_q^i + X'_{bef}W_v^i + b^i\right), \\ A_{bef} &= \sigma\left(X'_{diff}W_q^g + X'_{bef}W_v^g + b^g\right), \end{aligned} \tag{3}$$

where $W_q^i, W_v^i, W_q^g, W_v^g \in \mathbb{R}^{C\times C}, b^i, b^g \in \mathbb{R}^C$, and C is the dimension of X'_{diff} and X'_{bef} ; σ and ϕ denote the sigmoid and tanh function. The value in the “attention gate” indicates the semantic relevance between the “candidate change” and the “before”. Thus, the more information in the “candidate change” passes through the “attention gate”, the more X'_{diff} is relevant to X'_{bef}.

Next, the CSRM applies the A_{bef} to the C_{bef} to filter all the underlying change information and focus on only the information about semantic change via element-wise multiplication:

$$C'_{bef} = A_{bef} \odot C_{bef}. \tag{4}$$

Besides, the information about semantic change C'_{aft} is computed via the similar operation between the X'_{diff} and X'_{aft} :

$$\begin{aligned} C_{aft} &= \phi\left(X'_{diff}U_q^i + X'_{aft}U_v^i + z^i\right), \\ A_{aft} &= \sigma\left(X'_{diff}U_q^g + X'_{aft}U_v^g + z^g\right), \\ C'_{aft} &= A_{aft} \odot C_{aft}. \end{aligned} \tag{5}$$

3.1.3 Prior Knowledge-guided Change Localizer

After obtaining the C'_{bef} and C'_{aft}, we use them as the prior knowledge to guide the change localizer to learn the difference representation. Specifically, the change localizer first predicts two separate attention maps under the guidance of C'_{bef} and C'_{aft}, respectively:

$$\begin{aligned} X''_{\text{bef}} &= [X'_{\text{bef}}\,; X'_{\text{diff}}\,; C'_{\text{bef}}\,], \\ a_{\text{bef}} &= \sigma\left(\text{conv}_2\left(\text{ReLU}\left(\text{conv}_1\left(X''_{\text{bef}}\right)\right)\right)\right), \\ X''_{\text{aft}} &= [X'_{\text{aft}}\,; X'_{\text{diff}}\,; C'_{\text{aft}}\,], \\ a_{\text{aft}} &= \sigma\left(\text{conv}_2\left(\text{ReLU}\left(\text{conv}_1\left(X''_{\text{aft}}\right)\right)\right)\right), \end{aligned} \tag{6}$$

where $[;]$, conv, and σ indicate concatenation, convolutional layer, and element-wise sigmoid, respectively. After that, the difference representation features l_{bef} and l_{aft} are attended to by applying a_{bef} and a_{aft} to the input image features X'_{bef} and X'_{aft} :

$$\begin{aligned} l_{\text{bef}} &= \textstyle\sum_{H,W} a_{\text{bef}} \odot X'_{\text{bef}}, l_{\text{bef}} \in \mathbb{R}^C, \\ l_{\text{aft}} &= \textstyle\sum_{H,W} a_{\text{aft}} \odot X'_{\text{aft}}, l_{\text{aft}} \in \mathbb{R}^C. \end{aligned} \tag{7}$$

3.2 Change Caption Generation

3.2.1 POS Predictor

Inspired by POS used in machine translation (Yin et al., 2019), we dynamically predict POS tags [1] of target words based on the previous hidden states $h_c^{(t-1)}$ of the caption generator. The predicted tags help the captioning model use visual information in a dynamic way.

Specifically, at time t, $h_c^{(t-1)}$ is first fed into a single hidden layer with the ReLU activation function:

$$d_t^p = \text{ReLU}\left(W_p^{(1)}h_c^{(t-1)} + b_p^{(1)}\right), \tag{8}$$

where $W_p^{(1)} \in \mathbb{R}^{M\times M}$ and $b_p^{(1)} \in \mathbb{R}^M$, and M is the dimension of the hidden state in caption generator. Then, a POS tag probability is predicted by a linear transformation with a softmax function:

$$w_t^p = \text{softmax}\left(W_p^{(2)}d_t^p + b_p^{(2)}\right), \tag{9}$$

where $W_p^{(2)} \in \mathbb{R}^{M\times n}$ and $b_p^{(2)} \in \mathbb{R}^n$, and n is the number of POS tag. After obtaining w_t^p, we represent the POS tag of the target word w_t using a semantic representation p_t:

$$p_t = E_p w_t^p, \tag{10}$$

where $E_p \in \mathbb{R}^{n\times N}$ is a POS embedding matrix and N is the dimension of the POS representation.

---

[1] The POS tags of words in ground truth are processed by Stanford Log-linear Part-Of-Speech Tagger (Toutanova et al., 2003).

3.2.2 Attention-based Visual Switch

Visual Attention. We first use a visual attention module to select a candidate feature from l_{bef}, l_{aft}, or l_{diff} (l_{aft} - l_{bef}), which could be relevant to the target word:

$$l_{\text{dyn}}^{(t)} = \sum_i \alpha_i^{(t)} l_i, \tag{11}$$

where $i \in$ (bef, diff, aft). $\alpha_i^{(t)}$ are current visual attention weights and they are computed by an attention LSTM$_a$:

$$\begin{aligned} v &= \operatorname{ReLU}\left(W_{d_1}\left[l_{\text{bef}} ; l_{\text{diff}} ; l_{\text{aft}}\right]+b_{d_1}\right) \\ u^{(t)} &= \left[v; h_c^{(t-1)}\right] \\ h_a^{(t)} &= \operatorname{LSTM}_a\left(h_a^{(t)} \mid u^{(t)}, h_a^{(0:t-1)}\right) \\ \alpha_i^{(t)} &\sim \operatorname{Softmax}\left(W_{d_2} h_a^{(t)}+b_{d_2}\right) \end{aligned} \tag{12}$$

where W_{d_1}, b_{d_1}, W_{d_2}, and b_{d_2} are learnable parameters. $h_a^{(*)}$ and $h_c^{(*)}$ are hidden states of the attention module LSTM$_a$ and the caption generator LSTM$_c$, respectively.

Visual Switch. Then, we exploit a visual switch to decide whether to rely on visual information to predict the next word based on the predicted POS information p_t. At time step t, the visual switch β_t is defined as:

$$\begin{aligned} m_t &= \left[p_t; h_c^{t-1}; l_{dyn}^{(t)}\right], \\ \beta_t &= \sigma(W_{s2}(\operatorname{ReLU}(W_{s1} m_t))), \end{aligned} \tag{13}$$

where σ is the sigmoid function and W_{s*} are the learnable parameters. The range of β_t is [0,1] and the value of it indicates how much visual information to use when predicting the target word. Then, we apply this switch to attended visual feature $l_{\text{dyn}}^{(t)}$ to control the use of visual information:

$$L_{dyn}^{(t)} = \beta_t \odot l_{dyn}^{(t)}. \tag{14}$$

3.2.3 Caption generator

After the proper visual information is obtained, we use it and the previous word w_{t-1} (ground-truth word during training, predicted word during inference) to the caption generator LSTM$_c$ to predict a series of distributions over the next word:

$$\begin{aligned} c^{(t)} &= \left[E\left[w_{t-1}\right]; L_{\text{dyn}}^{(t)}\right], \\ h_c^{(t)} &= \operatorname{LSTM}_c\left(h_c^{(t)} \mid c^{(t)}, h_c^{(0:t-1)}\right), \\ w_t &\sim \operatorname{Softmax}\left(W_c h_c^{(t)}+b_c\right), \end{aligned} \tag{15}$$

where E is a word embedding matrix; W_c and b_c are learnable parameters.

3.3 Joint Training

We jointly train the POS predictor and the caption generator end-to-end by maximizing the likelihood of the observed POS and word sequence. For the POS predictor, given the target ground-truth POS tags $(w_1^p, \ldots, w_m^p)$, we minimize its negative log-likelihood loss:

$$L_{pos}(\theta_p) = -\sum_{t=1}^{m} \log p\left(w_t^p \mid w_{<t}^p; \theta_p\right), \tag{16}$$

where θ_p are the parameters of the POS predictor and m is the length of the POS tag.

For the caption generator, given the target ground-truth caption words $(w_1^c, \ldots, w_m^c)$, we minimize its negative log-likelihood loss:

$$L_{cap}(\theta_c) = -\sum_{t=1}^{m} \log p\left(w_t^c \mid w_{<t}^c; \theta_c\right), \tag{17}$$

where θ_c are the parameters of the caption generator and m is the length of the caption. Thus, the final loss function is optimized as follows:

$$L(\theta) = L_{pos} + L_{cap} \tag{18}$$

4 Experiments

4.1 Datasets

CLEVR-Change. This dataset (Park et al., 2019) is a large scale dataset with a set of basic geometry objects, which consists of 79,606 image pairs and 493,735 captions. The change types consist of five cases, *i.e.*, "Color", "Texture", "Add", "Drop", and ''Move". We use the official split with image pairs of 67,660 for training, 3, 976 for validation and 7,970 for testing.

Spot-the-Diff. This dataset (Jhamtani and Berg-Kirkpatrick, 2018) contains 13,192 real image pairs which are well aligned image pairs, with one or more changes between the images (but no distractors). Similar to (Park et al., 2019), we only evaluate our model in a single change setting and split it into training, validation, and test sets with a ratio of 8:1:1.

4.2 Evaluation Metrics

We use five standard metrics to evaluate the quality of generated sentences, *i.e.*, BLEU-4 (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), ROUGE-L (Lin, 2004), CIDEr (Vedantam et al., 2015) and SPICE (Anderson et al., 2016). We get all the results in this paper according to the Microsoft COCO evaluation server (Chen et al., 2015).

Table 1: Ablation studies on CLEVR-Change in terms of total performance, where B-4, M, R, C, and S are short for BLEU-4, METEOR, ROUGE-L, CIDEr, and SPICE, respectively.

	Total				
Method	BLEU-4	METEOR	ROUGE-L	CIDEr	SPICE
Baseline	53.1	37.3	70.6	115.6	31.2

SRDRL+AVS	**52.7**	**36.4**	**69.7**	**114.2**	**30.8**	**62.2**	51.3	76.9	**117.0**	**34.9**

4.3 Implementation Details

To extract image features, we use ResNet-101 (He et al., 2016) pre-trained on the Imagenet dataset (Russakovsky et al., 2015). We use features from the convolutional layer with dimensionality of 1024 × 14 × 14. The hidden size is set to 512 and the number of attention heads in SSRE is set to 4. The words are represented by trainable 300D word embedding features. POS tags are divided into 16 categories. In the training phase, on CLEVR-Change and Spot-the-Diff, we respectively set the mini-batch size as 128 and 96. We use Adam optimizer (Kingma and Ba, 2014) with the learning rate of 1×10^{-3} and 5×10^{-4}, respectively. At inference, greedy decoding strategy is used to generate target captions. Both training and inference are implemented with PyTorch (Paszke et al., 2019) on a TITAN Xp GPU.

4.4 Ablation studies

In order to figure out the contribution of each module, we carry out the following ablation studies on CLEVR-Change: (1) Baseline which is based on DDUA (Park et al., 2019); (2) SSRE which only embeds the self-semantic relations of objects into their representations; (3) CSRM which only measures the cross-semantic relations between the captured candidate difference and the original images, and the learned discriminative difference representation is used as a prior knowledge to guide the change localizer; (4) SRDRL which is the combination of (2) and (3); (5) AVS which only relies on the POS information to determine when to use visual information and which of them should be used; (6) SRDRL+AVS which is the combination of (4) and (5).

The Evaluation on Total Performance. We frist study the total performance of each block of the proposed method under the whole dataset, including scene change and none-scene change. Experimental results are shown in Table 1. We can observe that each module of the proposed method improves the total performance of the baseline. Moreover, the best performance is achieved when putting them together, which indicates each block not only plays its unique role, but also can be a supplementary role for the others. This global statistical performance validates the generalization ability of the proposed method, that is, it not only can explicitly judge whether there is a semantic change between a pair of unaligned images, but also can describe the change using an accurate sentence.

The Evaluation on Scene Change and None-scene Change. The experimental results are shown

Table 3: Comparing with state-of-the-art methods on CLEVR-Change in Total Performance. RL is short for reinforcement learning training strategies.

		Total				
Method	RL	B-4	M	R	C	S
Capt-Dual (Park et al., 2019)	×	43.5	32.7	-	108.5	23.4
DDUA (Park et al., 2019)	×	47.3	33.9	-	112.3	24.5
M-VAM (Shi et al., 2020)	×	50.3	37.0	69.7	114.9	30.5
M-VAM+RAF (Shi et al., 2020)	✓	51.3	37.8	70.4	115.8	30.7
SRDRL+AVS	×	**54.9**	**40.2**	**73.3**	**122.2**	**32.9**

Table 4: Comparing with state-of-the-art methods on CLEVR-Change in terms of two settings.

		Scene Change				None-scene Change			
Method	RL	B-4	M	C	S	B-4	M	C	S
Capt-Dual (Park et al., 2019)	×	38.5	28.5	89.8	18.2	56.3	44.0	108.9	28.7
DDUA (Park et al., 2019)	×	42.9	29.7	94.6	19.9	59.8	45.2	110.8	29.1
M-VAM+RAF (Shi et al., 2020)	✓	-	-	-	-	-	**66.4**	**122.6**	33.4
SRDRL+AVS	×	**52.7**	**36.4**	**114.2**	**30.8**	**62.2**	51.3	117.0	**34.9**

in Table 2, in terms of scene change, we can observe that 1) SSRE, CSRM and AVS all achieve improvements over the baseline; 2) compared with SSRE, the improvement is relatively small when respectively using CSRM and AVS; 3) better performances are achieved when using two kinds of combinations (SRDRL and SRDRL+AVS). These indicate 1) the effectiveness of our proposed SRDRL and its single block, as well as the AVS; 2) the priority of this task is to capture the semantic difference in the image pair. The reason is that only if the semantic difference is captured sufficiently, can the following specific change localization and caption generation do well on itself part.

Besides, we can observe that although each single block can improve the baseline in the case of scene change, but they are worse than the baseline in one or more metrics in the case of none-scene change. Our conjecture is that the robustness of single block is relatively weak, so it would sometimes misidentify the illumination or viewpoint change as the actual semantic change. When observing the performance of two kinds of combinations (SRDRL and SRDRL+AVS), both of them improve the baseline in all metrics, which indicates the robustness of our overall model is strong.

4.5 Performance Comparison

4.5.1 Results on CLEVR-Change

In this dataset, we compare with four state-of-the-art methods, Capt-Dual (Park et al., 2019), DUDA (Park et al., 2019), M-VAM (Shi et al., 2020) and M-VAM+RAF (Shi et al., 2020), in four dimensions: 1) the total performance of scene change and none-scene change; 2) only scene change; 3) only none-scene change; 4) specific type of scene change. The comparison results are shown in Table 3, Table 4, and Table 5, respectively.

From Table 3, in terms of total performance, we can clearly observe that our method achieves significant improvements over them in all evaluation metrics, in particular with an increase of 34.3% and 7.2% in SPICE, respectively. From Table 4, under two kinds of settings, we can observe that our method outperforms DDUA with a large margin. Furthermore, since the M-VAM+RAF did not report the results on scene change, we only compare with them in the setting of none-change. We can observe that it outperforms us in METEOR and CIDEr. This superiority could derive from the reinforcement learning strategy. However, this strategy will remarkably increase training time and computation complexity. Moreover, as reported in Table 3, our total performance is much better than them, which is evaluated under the both scene change and none-scene change. Hence, compared to them, our method is more robust due to the discriminative difference representation learning.

Table 5 is the detailed breakdown of the evaluation based on five change types: "Color" (C), "Texture" (T), "Add" (A), "Drop" (D), and "Move" (M). Specifically, compare to all SOTA methods,

SRDRL+AVS	×	**13.0**	31.0	35.3	**18.0**

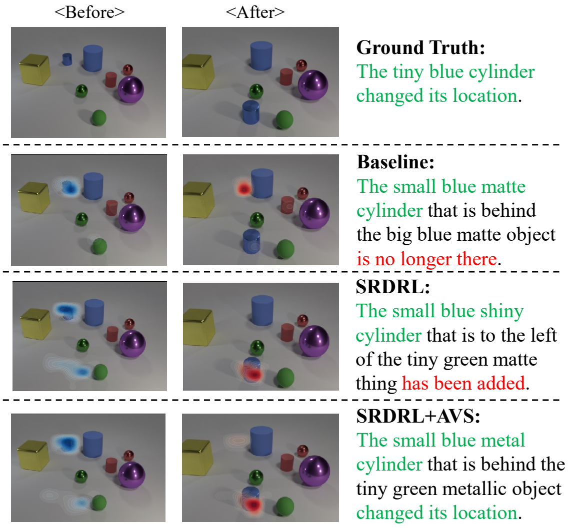

Figure 3: A comparative example about "Move" case from the test set of CLEVR-Change, which involves the caption generated by the baseline, SRDRL, and SRDRL+AVS. We visualize the localization results on "before" (blue) and "after" (red).

our method significantly raises the CIDEr scores in "Color" and "Texture" types, which indicates our method can better distinguish the attribute change of objects from an illumination change. Besides, for the number or position change of objects ("Add", "Drop", and "Move"), our method all outperforms them in most of metrics. Especially for SPICE, compared to them, our method has 64.9% and 12.9% improvements for "Move" case, respectively, which also shows our method can better localize the object movement from the viewpoint change. In particular, the most challenging change types are "Texture" and "Move" in this dataset, because they are most often confused with the illumination or viewpoint changes (Park et al., 2019). The relative experiments show that our method is more robust than SOTAs, and this benefits from the fact that the CSRM block helps attend to the actually semantic change by measuring the cross-semantic relations of the image pair and their difference.

4.5.2 Results on Spot-the-Diff

To validate the generalization ability of the proposed method, we conduct the experiments on a recent published Spot-the-Diff dataset, where the image pairs are mostly well aligned and their is no viewpoint change. We compare with eight SOTA methods and most of them cannot consider handling viewpoint changes: DDLA (Jhamtani and Berg-Kirkpatrick, 2018), DDUA (Park et al., 2019), SDCM (Oluwasanmi et al., 2019a), FCC (Oluwasanmi et al., 2019b), static rel-att / dynamic rel-att (Tan et al., 2019), and M-VAM / M-VAM+RAF (Shi et al., 2020).

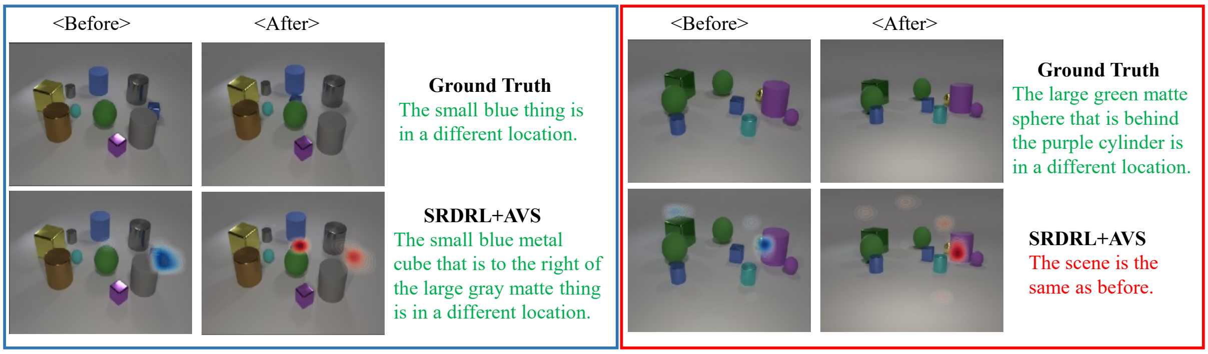

Figure 4: Qualitative examples of SRDRL+AVS. The left is a successful case that SRDRL+AVS localizes the accurate changed object and generates a correct sentence to describe the change. The right is a failure case that a slight movement of the object is not detected.

The results are reported in Table 6. We can observe that our method achieves the best performance in terms of METEOR and SPICE. Especially for SPICE which is recently designed for evaluating the image captioning task, our method achives 28.6% and 5.3% improvements over the current SOTA method M-VAM and M-VAM+RAF. Hence, compared to the above methods, the generated captions by our method are more in line with standards of human caption evaluation. This superiority results from that the SSRE block can capture the relation-embedded feature difference so as to better explore those tiny changed objects.

4.6 Qualitative Analysis

Figure 3 shows a comparative example about "Move" from the CLEVR-Change dataset, which includes the change captions generated by humans, baseline, SRDRL, and SRDRL+AVS. We also visualize the results of change detection. The baseline is implemented based on DDUA (Park et al., 2019). We can clearly observe that it localizes a wrong region on the "after" and thus misidentifies "Move" as "Drop". By contrast, both proposed methods (SRDRL and SRDRL+AVS) can accurately localize the moved object on both "before" and "after" images, which validates the effectiveness of the proposed SRDRL. Moreover, it is interesting to note that, for the proposed methods, although the results of change localization are accurate, only using SRDRL generates a wrong caption, which indicates the POS tags of target words indeed guide and regularize the change caption generation.

Figure 4 illustrates two examples with viewpoint changes on CLEVR-Change dataset. The left example is a success in which SRDRL+AVA can distinguish the small blue changed cube from the irrelevant viewpoint change. This benefits from that SRDRL can learn discriminative difference representation and overcome viewpoint changes. The right example shows a failure, where SRDRL+AVA judges there is no difference. Our conjecture is that the movement of this sphere is very slight and thus confused with the viewpoint change. Hence, we will improve our method to learn more fine-grained difference representation in the future work.

5 Conclusion

In this paper, we propose a semantic relation-aware difference representation learning network (SRDRL) and attention-based visual switch (AVS) to address change captioning in the presence of distractors, where SRDRL can explicitly learn the difference representation in the image pair and AVS can aid the caption generator to convey the localized change in a logically and grammatically accurate sentence. Extensive experiments conducted on both CLEVR-Change and Spot-the-Diff datasets show that the proposed method achieves state-of-the-art results.

Abstract

It is evident that deep text classification models trained on human data could be biased. In particular, they produce biased outcomes for texts that explicitly include identity terms of certain demographic groups. We refer to this type of bias as explicit bias, which has been extensively studied. However, deep text classification models can also produce biased outcomes for texts written by authors of certain demographic groups. We refer to such bias as implicit bias, of which we still have a rather limited understanding. In this paper, we first demonstrate that implicit bias exists in different text classification tasks for different demographic groups. Then, we build a learning-based interpretation method to deepen our knowledge of implicit bias. Specifically, we verify that classifiers learn to make predictions based on language features that are related to the demographic attributes of the authors. Next, we propose a framework **Debiased-TC** to train deep text classifiers to make predictions on the right features and consequently mitigate implicit bias. We conduct extensive experiments on three real-world datasets. The results show that the text classification models trained under our proposed framework outperform traditional models significantly in terms of fairness, and also slightly in terms of classification performance.

1 Introduction

Many recent studies have suggested that machine learning algorithms can learn social prejudices from data produced by humans, and thereby show systemic bias in performance towards specific demographic groups or individuals (Mehrabi et al., 2019; Blodgett et al., 2020; Shah et al., 2020). As one machine learning application, text classification has been proven to be discriminatory towards certain groups of people (Dixon et al., 2018; Borkan et al., 2019). Text classification applications such as sentiment analysis and hate speech detection are common and widely used in our daily lives. If a biased hate speech detection model is deployed by a social media service provider to filter users' comments, the comments related to different demographic groups can have uneven chances to be recognized and removed. Such a case will cause unfairness and bring in negative experiences to users. Thus, it is highly desired to mitigate the bias in text classification.

The majority of existing studies on bias and fairness in text classification have mainly focused on the bias towards the individuals mentioned in the text content. For example, in (Dixon et al., 2018; Park et al., 2018; Zhang et al., 2020), it is investigated how text classification models perform unfairly on texts containing demographic identity terms such as "gay" and "muslim". In such scenarios, the demographic attributes of the individuals subject to bias explicitly exist in the text. In this work, we refer to this kind of bias as **explicit bias**. Bias in texts, however, can be reflected more subtly and insidiously. While a text may not contain any reference to a specific group or individual, the content can somehow be revealing of the demographic information of the author. As shown in (Coulmas, 2013; Preoţiuc-Pietro and Ungar, 2018), the language style (e.g., wordings and tone) of a text can be highly correlated with its author's demographic attributes (e.g., age, gender, and race). We find that a text classifier can learn to associate the content with demographic information and consequently make unfair decisions towards certain groups. We refer to such bias as **implicit bias**. Table 1 demonstrates an example of implicit bias. There are two short texts where the first text is written by a white American and the second one is written by an African American. The task is to predict the sentiment of a text by a convolutional

Table 1: An illustrative example on the implicit bias of a CNN text classification model.

Author	Text	Label	Prediction
White American	Can't wait to visit your new home. Yes, I going to be a great guest!	positive	positive
African American	Can't wait to visit your new home. Yup , I goin to be a great guest!	positive	negative

neural network (CNN) model. Words with a red background indicate those with the salient predictive capability by the model where the darker the color, the more salient the words. The words "yup" and "goin" in the second text are commonly used by African Americans (Liu et al., 2020a) and are irrelevant to the sentiment. However, the CNN model has hinted at them and consequently has predicted a positive text to be negative.

In this work, we aim to understand and mitigate implicit bias in deep text classification models. One key source of bias is the imbalance of training data (Dixon et al., 2018; Park et al., 2018). Thus, existing debiasing methods mainly focus on balancing the training data, such as adding new training data (Dixon et al., 2018) and augmenting data based on identity-term swap (Park et al., 2018). However, these methods cannot be directly applied to mitigate implicit bias. Obtaining new texts from authors of various demographic groups is very expensive. It requires heavy human labor. Meanwhile, given that there is no explicit demographic information in texts, identity-term swap data augmentation is not applicable. Thus, we propose to enhance deep text classification models to mitigate implicit bias in the training process. To achieve this goal, we face tremendous challenges. First, to mitigate the implicit bias, we have to understand how deep models behave. For example, how they correlate implicit features in text with demographic attributes and how the models make biased predictions. Second, we need to design new mechanisms to take advantage of our understandings to mitigate the implicit bias in deep text classifiers.

To address the above challenges, in this paper, we first propose an interpretation method, which sheds light on the formation mechanism of implicit bias in deep text classification models. We show that the implicit bias is caused by the fact that the models make predictions based on incorrect language features in texts. Second, based on this finding, we propose a novel framework **Debiased-TC** (Debiased Text Classification) to mitigate the implicit bias of deep text classifiers. More specifically, we equip the deep classifiers with an additional saliency selection layer that first determines the correct language features which the model should base on to make predictions. We also propose an optimization method to train the classifiers with the saliency selection layer. Note that both our proposed interpretation method and the learning framework are model-agnostic, which means that they can be applied to any deep text classifier. We evaluate the framework with two popular deep text classification models across various text classification tasks on three public datasets. The experimental results demonstrate that our method significantly mitigates the implicit bias in the classification models while maintaining or even improving their prediction performance.

2 Preliminary Study

In this section, we perform a preliminary study to validate the existence of implicit bias in deep text classification models. We first introduce the data and text classification tasks, and then present the empirical results.

2.1 Data and Tasks

In the preliminary study, we investigate different text classification tasks and various demographic groups to validate the implicit bias. We use three datasets, including the DIAL and PAN16 datasets processed by (Elazar and Goldberg, 2018) and the Multilingual Twitter Corpus (MTC) introduced in (Huang et al., 2020).

The DIAL dataset contains dialectal texts collected from Twitter. Each tweet's text is associated with the *race* of the author as the demographic attribute, denoted as "white" or "black", respectively. This dataset is annotated for two classification tasks: sentiment analysis and mention detection. The sentiment analysis task aims to categorize a text as "happy" or "sad". The mention detection task tries to determine whether a tweet mentions another user, which can also be viewed as distinguishing conversational tweets from non-conversational ones.

The PAN16 dataset consists of tweets. For each tweet, *age* and *gender* of its author have been manually labelled. The demographic attribute age has two categories of "18-34" and "≥ 35", and gender has “male” and “female”. Also, this dataset is annotated for the mention detection task as described above.

The MTC dataset contains multilingual tweets for the hate speech detection task. Each tweet is annotated as “hate speech” or “non hate speech” and associated with four author’s demographic attributes: race, gender, age, and country. We only use the English corpus with the attribute *race*. In this dataset, the attribute race has two categories, i.e., “white” and “nonwhite”.

More information about these three datasets, including their statistical information, annotation process, and the links to downloadable versions of the data can be found in Appendix A.

2.2 Empirical study

In this subsection, we aim to empirically study if text classification models make the predictions dependent on the demographic attributes of the authors of the texts. The explicit bias in text classification tasks stems from the imbalance of training data (Dixon et al., 2018; Park et al., 2018). For example, when there are more negative examples from one group in the training data, the model learns to correlate that group with the negative label, which results in bias. Inspired by this observation, to validate the existence of implicit bias, we investigate if the imbalance of training data in terms of demographic attributes of the authors can lead to biased predictions. To answer this question, we consider the following setting: (1) the training data has an equal number of positive and negative examples; and (2) positive and negative examples in the training data are imbalanced among different groups of the authors according to their demographic attributes. Intuitively, if the predictions are independent of the demographic attributes of authors, the model should still perform similarly for different groups.

For each task and demographic attribute of authors, we consider two labels (i.e., positive and negative) and two demographic groups (i.e., Group I and Group II). For each dataset, we follow the aforementioned setting to build a training set. We make the training set overall balanced in terms of the labels and demographic groups. That is, we set the overall ratio of positive and negative examples as 1:1, and the overall ratio of examples from Group I and Group II as 1:1 as well. Meanwhile, we make the data in each group imbalanced. In particular, for Group I, we set the ratio of its positive and negative examples to 4:1, while the ratio is automatically set to 1:4 for Group II. We name the proportion of positive and negative samples in Group I as the “balance rate”. We train a CNN text classifier as a representative model on the training set and evaluate it on the test set. We use the false positive/negative rates (Dixon et al., 2018) and the demographic parity rate (a.k.a., positive outcome rate, the probability of the model predicting a positive outcome for one group) (Dwork et al., 2012; Kusner et al., 2017) to evaluate the fairness of the classification models.

The results are shown in Table 2. For the demographic attribute race, Group I/Group II stands for white/black in the DIAL dataset, and white/nonwhite in the MTC dataset. For gender and age, Group I/Group II stands for male/female and age ranges (18-34)/($\geq$35), respectively. From the table, we observe that in terms of different tasks and demographic attributes of authors, the model shows significant bias with the same pattern. For all cases, the demographic group with more positive examples (Group I) always gets a higher false positive rate, a lower false negative rate, and a higher demographic parity rate than the other group. This demonstrates that imbalanced data can cause implicit bias, and the predictions are not independent of the demographic attributes of authors. Since the text itself doesn’t explicitly contain any demographic information, the model could learn to recognize the demographic attributes of authors based on implicit features such as language styles and associate them with a biased outcome. Next, we will understand one formation of implicit bias and then propose Debiased-TC to mitigate it.

3 Understanding Implicit Bias

In this section, we aim to understand the possible underlying formation mechanism of implicit bias. Our intuition is – when a training set for sentiment analysis has more positive examples from white authors and more negative examples from black authors, a classification model trained on such a dataset may learn a “shortcut” (Mahabadi et al., 2020) to indiscriminately associates the language style features of white people with the positive sentiment and those of black people with the negative sentiment. In other words, the model does not use the correct language features (e.g., emotional words) to make the prediction. Thus, we attempt

Table 2: Preliminary study.

Dataset	Task	Demo	False Positive (%)		False Negative (%)		Demographic Parity (%)	
			Group I	Group II	Group I	Group II	Group I	Group II
DIAL	Sentiment	Race	46.97	23.38	21.29	62.75	62.84	30.32
	Mention	Race	48.72	15.99	17.32	34.90	65.70	40.55
PAN16	Mention	Gender	23.90	12.30	13.06	23.01	55.42	44.64
	Mention	Age	24.91	9.88	16.48	26.43	54.22	41.72
MTC	Hate Speech	Race	80.33	1.77	12.13	49.35	84.10	26.21

to examine the following hypothesis: *A deep text classification model presents implicit bias since it makes predictions based on language features that should be irrelevant to the classification task but are correlated with a certain demographic group of authors.* To verify this hypothesis, we first propose an interpretation method to detect the salient words a text classification model relies on to make the prediction. The interpretation model enables us to check the overlapping between the salient words and the words related to the authors' demographic attributes. Consequently, it allows us to understand the relationship between such overlapping and the model's implicit bias.

3.1 An Interpretation Method

We follow the idea of the learning-based interpretation method L2X (Chen et al., 2018) to train an explainer to interpret a given model. The reasons for choosing L2X are – 1) as a learning-based explainer, it learns to globally explain the behavior of a model, instead of explaining a single instance at one time; and 2) the explainer has the potential to be integrated into our debiasing framework to mitigate implicit bias in an end-to-end manner, which will be introduced in Section 4.

A binary text classification model $\mathcal{M} : X \rightarrow Y$ maps an input text $X = (x_1, x_2, \ldots, x_n)$ to a label $Y \in \{0, 1\}$. For a certain model $\mathcal{M}$, we seek to specify the contribution of each word in X for $\mathcal{M}$ to make the prediction Y. The contributions can be denoted as a saliency distribution $S = (s_1, s_2, \ldots, s_n)$, where s_i is the saliency score of the word x_i, and $\sum_{i=1}^{n} s_i = 1$. Given a model $\mathcal{M}$, we train an explainer $\mathcal{E}^{\mathcal{M}} : X \rightarrow S$ to estimate the saliency distribution S of an input text X.

The explainer is trained by maximizing $I(X_S, Y)$, the mutual information (Cover, 1999) between the response variable Y and the selected feature X_S of X under saliency distribution S. The selected feature $X_S = X \odot S = (s_1 \cdot x_1, s_2 \cdot x_2, \ldots, s_n \cdot x_n)$ [1] is calculated as the element-wise product between X and S. In our implementation, we parametrize the explainer by a bi-directional recurrent neural network (RNN) followed by a linear layer and a Softmax layer. More details about the optimization of the explainer can be found in Appendix B.

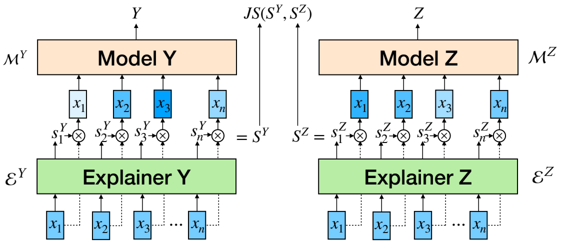

Figure 1: An illustration of the bias interpretation model.

3.2 Saliency Correlation Measurement

In this work, we assume that the text classification task is totally independent of the demographic attribute of the author of the text. In other words, language features that reflect the author's demographic information should not be taken as evidence for the main task. Thus, we propose to understand the implicit bias of a deep text classification model by examining the overlapping between salient words for the main task and the words correlated with the demographic attribute.

With the interpretation model, we can estimate the saliency distributions of the input words for the classification task and the demographic attribute prediction task, respectively, and then check their overlapping. As shown in Figure 1, we train two models $\mathcal{M}^Y$ and $\mathcal{M}^Z$ with the same architecture for the former and the latter tasks, respectively. Then, two corresponding explainers $\mathcal{E}^Y$ and $\mathcal{E}^Z$ are trained for them. Thus, given an input text X, two explainers can estimate the saliency distributions S^Y and S^Z on two tasks, respectively. We use the Jensen-Shannon (JS) divergence $JS(S^Y || S^Z)$ to measure the overlap between language features that

---

[1] Without confusion, we use x_i to denote both a word and its word embedding vector.

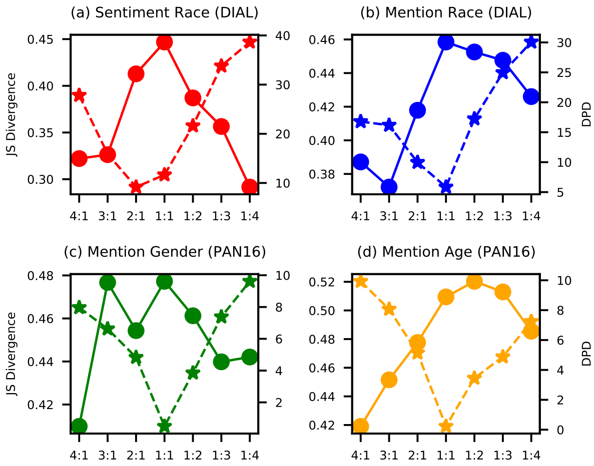

Figure 2: The average JS divergence (solid lines) and DPD (dash lines) vs. the balance rate. The x-axis indicates the balance rate of the training set. The y-axis on the left hand indicates the average JS divergence, and the y-axis on the right hand is the DPD.

these two tasks relying on to make the predictions on Y and Z.

3.3 Empirical Analysis

In this subsection, we present the experiments to verify our hypothesis on the formulation of implicit bias. Following the experimental settings in Section 2.2, we vary the "balance rate" of the training data and then observe how the saliency correlation changes. We use CNN text classifiers (see Appendix C for details) for both $\mathcal{M}^Y$ and $\mathcal{M}^Z$. In Figure 2, we show how the average JS divergence and the demographic parity difference (DPD) vary with the changes of the balance rate. DPD is the absolute value of the difference between the demographic parity rates for the two groups. We only report the results for DIAL and PAN16 datasets and DPD as the fairness metric since we achieved similar results for other settings. For each task and each demographic attribute, the DPD is small when the training data are balanced and becomes large when the data are imbalanced. However, the JS divergence is large for balanced data while small for imbalanced data. A larger DPD indicates stronger implicit bias and a smaller JS divergence stands for a stronger overlap between the saliency distributions for the two tasks. Thus, these observations suggest that when the training data are imbalanced, the text classifiers tend to use language features related to the demographic attribute of authors to make the prediction.

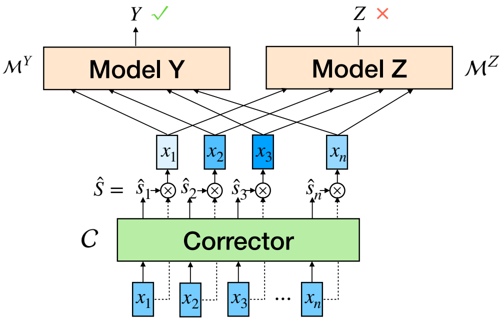

Figure 3: An illustration of the bias mitigation model.

4 The Bias Mitigation Framework

In the previous section, we showed that a model with implicit bias tends to utilize features related to the demographic attribute of authors to make the prediction, especially when training data is imbalanced in terms of the demographic attribute of authors. One potential solution is to balance the training data by augmenting more examples from underrepresented groups. However, collecting new data from authors of different demographics is expensive. Thus, to mitigate the implicit bias, we propose a novel framework **Debiased-TC**. Our proposed approach can mitigate implicit bias by automatically correcting their selection of input features. In this section, we will introduce the proposed framework with the corresponding optimization method.

4.1 Debiased Text Classification Model

An illustration of Debiased-TC is shown in Figure 3. Similar to the explainer in the interpretation model, we equip the base model $\mathcal{M}^Y$ with a corrector layer $\mathcal{C}$ after the input layer. The corrector $\mathcal{C} : X \rightarrow S$ learns to correct the model's feature selection. It first maps an input text $X = (x_1, x_2, \ldots, x_n)$ to a saliency distribution $S = (s_1, s_2, \ldots, s_n)$, which is expected to give high scores to words related to the main tasks and low scores to words related to demographic attributes of authors. Then, it assigns weights to the input features with the saliency scores by calculating $X_S = X \odot S$, which is fed into the classification model $\mathcal{M}^Y$ for prediction.

To train a corrector to achieve the expected goal, we adopt the idea of adversarial training. More specifically, in addition to the main classifier $\mathcal{M}^Y$, we introduce an adversarial classifier $\mathcal{M}^Z$, which takes X_S as the input and predicts the demographic attribute Z. During the adversarial training, the corrector attempts to help $\mathcal{M}^Y$ make correct predictions while preventing $\mathcal{M}^Z$ from predicting demographic attributes. To make this feasible, we use the gradient reversal technique (Ganin and Lempitsky, 2015), where we add a gradient-reversal layer between the weighted inputs X_S and the adversarial classifier $\mathcal{M}^Z$. The gradient-reversal layer has no effect on its downstream components (i.e., the adversarial classifier $\mathcal{M}^Z$). However, during backpropagation, the gradients that pass down through this layer to its upstream components (i.e., the corrector $\mathcal{C}$) are getting reversed. As a result, the corrector $\mathcal{C}$ receives opposite gradients from $\mathcal{M}^Z$. The outputs of the $\mathcal{M}^Y$ and $\mathcal{M}^Z$ are used as signals to train the corrector such that it can upweight the words correlated with the main task label Y and downweight the words correlated with the demographic attribute Z. We set the adversarial classifier $\mathcal{M}^Z$ with the same architecture as the main classifier $\mathcal{M}^Y$. The corrector $\mathcal{C}$ has the same architecture as the explainer introduced in Section 3.

4.2 An Optimization Method for Debiased-TC

In this subsection, we discuss the optimization method for the proposed framework. We denote the parameters of $\mathcal{M}^Y$, $\mathcal{M}^Z$ and $\mathcal{C}$ as $\mathbf{W}^Y$, $\mathbf{W}^Z$ and $\mathbf{\Theta}$, respectively. The optimization task is to jointly optimize the parameters of the classifiers, i.e., $\mathbf{W}^Y$ and $\mathbf{W}^Z$, and the parameters of the corrector, i.e., $\mathbf{\Theta}$. We can view the optimization as an architecture search problem. Since our debiasing framework is end-to-end and differentiable, we develop an optimization method for our framework based on the differentiable architecture search (DARTS) technique (Liu et al., 2018). We update $\mathcal{M}^Y$, $\mathcal{M}^Z$ by optimizing the training losses L^Y_{train} and L^Z_{train} on the training set and update $\mathbf{\Theta}$ by optimizing the validation loss L_{val} on the validation set through gradient descent. We denote the cross-entropy losses for $\mathcal{M}^Y$ and $\mathcal{M}^Z$ as L^Y and L^Z, respectively. L^Y_{train} and L^Z_{train} indicate the cross-entropy losses L^Y and L^Z on the training set. L_{val} denotes the combined loss of the two cross-entropy losses $L = L^Y + L^Z$ on the validation set.

The goal of optimizing the corrector is to find optimal parameters $\mathbf{\Theta}^*$ that minimizes the validation loss $L_{val}(\mathbf{W}^{Y*}, \mathbf{W}^{Z*}, \mathbf{\Theta})$, where the optimal parameters $\mathbf{W}^{Y*}$ and $\mathbf{W}^{Z*}$ are obtained by minimizing the training losses as follows.

$$\mathbf{W}^{Y*} = \arg\min_{\mathbf{W}^Y} L^Y_{train}(\mathbf{W}^Y, \mathbf{\Theta}^*)$$
$$\mathbf{W}^{Z*} = \arg\min_{\mathbf{W}^Z} L^Z_{train}(\mathbf{W}^Z, \mathbf{\Theta}^*)$$

The above goal forms a bi-level optimization problem (Maclaurin et al., 2015; Pham et al., 2018), where $\mathbf{\Theta}$ is the upper-level variable and $\mathbf{W}^Y$ and $\mathbf{W}^Z$ are the lower-level variables:

$$\begin{aligned}&\min_{\mathbf{\Theta}} L_{val}\big(\mathbf{W}^{Y*}(\mathbf{\Theta}), \mathbf{W}^{Z*}(\mathbf{\Theta}), \mathbf{\Theta}\big)\\ &s.t.\ \mathbf{W}^{Y*}(\mathbf{\Theta}) = \arg\min_{\mathbf{W}^Y} L^Y_{train}(\mathbf{W}^Y, \mathbf{\Theta}^*)\\ &\qquad \mathbf{W}^{Z*}(\mathbf{\Theta}) = \arg\min_{\mathbf{W}^Z} L^Z_{train}(\mathbf{W}^Z, \mathbf{\Theta}^*)\end{aligned}$$

Optimizing $\mathbf{\Theta}$ is time-consuming due to the expensive inner optimization of $\mathbf{W}^Y$ and $\mathbf{W}^Z$. Therefore, we leverage the approximation scheme as DARTS:

$$\begin{aligned}&\nabla_{\mathbf{\Theta}} L_{val}\big(\mathbf{W}^{Y*}(\mathbf{\Theta}), \mathbf{W}^{Z*}(\mathbf{\Theta}), \mathbf{\Theta}\big)\\ \approx\ &\nabla_{\mathbf{\Theta}} L_{val}\big(\mathbf{W}^Y - \xi\nabla_{\mathbf{W}^Y} L^Y_{train}(\mathbf{W}^Y, \mathbf{\Theta}),\\ &\qquad \mathbf{W}^Z - \xi\nabla_{\mathbf{W}^Z} L^Z_{train}(\mathbf{W}^Z, \mathbf{\Theta}), \mathbf{\Theta}\big)\end{aligned}$$

where ξ is the learning rate for updating $\mathbf{W}^Y$ and $\mathbf{W}^Z$. The approximation scheme estimates $\mathbf{W}^{Y*}(\mathbf{\Theta})$ and $\mathbf{W}^{Z*}(\mathbf{\Theta})$ by updating $\mathbf{W}^Y$ and $\mathbf{W}^Z$ for a single training step, which avoids the total optimization $\mathbf{W}^*(\mathbf{\Theta}) = \arg\min_{\mathbf{W}} L_{train}(\mathbf{W}, \mathbf{\Theta}^*)$ to the convergence. In our implementation, we apply first-order approximation with $\xi = 0$, which can even lead to more speed-up. Also, in our specific experiments, since the amount of validation data is limited, we build an augmented validation dataset $\mathcal{V}' = \mathcal{V} \cup \mathcal{T}$ combining the original validation set $\mathcal{V}$ with the training set $\mathcal{T}$ for optimizing Θ.

We present our DARTS-based optimization algorithm in Algorithm 1. In each iteration, we first update the corrector's parameters based on the augmented validation set $\mathcal{V}'$ (lines 2-3). Then, we collect a new mini-batch of training data (line 4). We generate the saliency scores $S = (s_1, s_2, \ldots, s_n)$ for the training examples via the corrector with its current parameters (line 5). Next, we make predictions via the classifiers with their current parameters and X_S (line 6). Eventually, we update the parameters of the classifiers (line 7).

5 Experiment

In this section, we conduct experiments to evaluate our proposed debiasing framework. Through the

experiments, we try to answer two questions: 1) Does our framework effectively mitigate the implicit bias in various deep text classification models? and 2) Does our framework maintain the performance of the original models (without debasing) while reducing the bias?

5.1 Baselines

In our experiments, we compare our proposed debiasing framework with two baselines. Since there is no established method for mitigating implicit bias, we adopt two debiasing methods designed for traditional explicit bias and adapt them for implicit bias.

Data Augmentation* (Data Aug) (Dixon et al., 2018). We manually balance the training data of two demographic groups by adding sufficient negative examples for Group I and positive examples for Group II. As a result, the ratio of positive and negative training examples for both groups is 1:1. As discussed in the introduction, obtaining additional labeled data from specific authors is very expensive. In this work, we seek to develop a bias mitigation methodology without extra data. *Since Data Aug introduces more training data, it's not fair to directly compare it with other debiasing methods that only utilize original training data (including our method). We include Data Aug as a special baseline for reference.*

Instance Weighting (Ins Weigh) (Zhang et al., 2020). We re-weight each training instance with a numerical weight $\frac{P(Y)}{P(Y|Z)}$ based on the label distribution for each demographic group to mitigate explicit bias. In this method, a random forest classifier is built to estimate the conditional distribution $P(Y|Z)$ and the marginal distribution $P(Y)$ is manually calculated.

5.2 Experimental Settings

We conduct our experiments for implicit bias mitigation on two representative base models: **CNN** (Kim, 2014) and **RNN** (Chung et al., 2014). We use the same datasets with manually designed proportions, as described in Section 2.2. The details of the base models, as well as the implementation details of the experiments, can be found in Appendix C.

5.3 Performance Comparison

We train the base models with our proposed debiasing framework as well as the baseline debiasing methods. We report the performance on the test set in terms of fairness and classification performance.

Fairness Evaluation. Table 3 shows the results for fairness evaluation metrics: false positive equality difference (FPED), false negative equality difference (FNED), and DPD. FPED/FNED indicates the absolute value of the difference between the false positive/negative rates of the two groups. We make the following observations. First, the base models attain high FPED, FNED, and DPD, which indicates the existence of significant implicit bias towards the authors of the texts. Ins Weigh seems ineffective in mitigating implicit bias since it only achieved comparable fairness scores with the base models. Note that not every example that belongs to a certain group necessarily results in bias towards that group. Thus, assigning a uniform weight for all examples with the same label Y and demographic attribute Z is not a proper way to reduce implicit bias. Third, both Data Aug and Debiased-TC can mitigate the implicit bias by achieving lower equality and demographic parity differences. However, compared to Data Aug, Debiased-TC has two advantages. First, Data Aug needs to add more training data while Debiased-TC does not. Debiased-TC can locate the main source of implicit bias by analyzing how it forms in a deep text classification model. Due to the proposed corrector model, it can make a classification model focus on the relevant features for predictions and discard the features that may lead to implicit bias. Second, Debiased-TC is more stable than Data Aug. For the sentiment classification task with race as the demographic

attribute, the CNN and RNN classifiers trained on augmented data still result in high FPED and DPD scores. This suggests that balancing the training data cannot always mitigate implicit bias. In fact, only training examples with demographic language features can contribute to the implicit bias. Since some texts in the training set do not contain any language features belonging to a demographic group, they do not help balance the data.

Text Classification Performance Evaluation. The prediction performance of the text classification models trained under various debiasing methods is shown in Table 4, where we report the accuracy and F1 scores. First, it is not surprising to see that Data Aug achieves the best performances, since the data augmentation technique introduces more training data. It's not fair to directly compare it with other debiasing methods that only utilize original training data. Second, in most cases, our method achieves comparable or even better performance than the original base models. As we verified before, the implicit bias of a text classification model is caused by the fact that it learns a wrong correlation between labels and demographic language features. Debiased-TC corrects the model's selection of language features for predictions and thereby improves its performance on the classification task.

In conclusion, our proposed debiasing framework significantly mitigates the implicit bias, while maintaining or even slightly improving the classification performance.

6 Related Work

Fairness in Machine Learning. With the wide spread of the machine learning (ML) applications in our daily lives, bias and fairness issues in them are drawing increasing attention from the community. Researches are conducted to detect and mitigate the bias in ML models on various tasks. Specifically, studies investigate how algorithms can be biased in classification (Kamiran and Calders, 2009; Chouldechova, 2017), regression (Berk et al., 2017; Agarwal et al., 2019), and clustering tasks (Backurs et al., 2019; Chen et al., 2019). In the domain of computer vision, researchers show that ML-based face recognition (Buolamwini and Gebru, 2018) and object detection (Ryu et al., 2017) models perform unfairly for different demographic groups. Besides, a lot of works examine the bias in language related tasks, including word embedding (Bolukbasi et al., 2016), coreference resolution (Zhao et al., 2018), machine translation (Prates et al., 2019) and dialogue generation (Liu et al., 2020a,b), etc. Moreover, some recent studies also explore the relationship between the fairness of an ML model and its other properties, such as robustness (Xu et al., 2020; Nanda et al., 2021) and privacy (Cummings et al., 2019).

Fairness in Text Classification. In this work, we focus on the fairness issues in the text classification task. In this task, Dixon et al. (2018)

demonstrate that the source of unintended bias in models is the imbalance of training data, and they provide a debiasing method, which introduces new data to balance the training data. In (Park et al., 2018), gender bias is measured on abusive language detection models, and the effects of different pretrained word embeddings and model architectures are analyzed. By considering the various ways that a classifier's score distribution can vary across designated groups, a suite of threshold-agnostic metrics is introduced in (Borkan et al., 2019), which provides a nuanced view of unintended bias. Furthermore, the work (Zhang et al., 2020) proposes to debias text classification models using instance weighting, i.e., different weights are assigned to the training samples involving different demographic groups. The works discussed above focus on explicit bias, where the demographic attributes are explicitly expressed in the text. However, works studying implicit bias are rather limited. Huang et al. (2020) introduce the first multilingual hate speech dataset with inferred author demographic attributes. Through experiments on this dataset, they show that popular text classifiers can learn the bias towards the demographic attribute of the author. But this work doesn't discuss how the bias is produced, and no debiasing method is provided.

7 Conclusion

In this paper, we demonstrate that a text classifier with implicit bias makes predictions based on language features correlated with demographic groups of authors, and propose a novel learning framework Debiased-TC to mitigate such implicit bias. The experimental results show that Debiased-TC significantly mitigates implicit bias, and maintains or even improves the text classification performance of the original models. In the future, we will investigate implicit bias in other NLP applications.

A Details of the Datasets

In this section, we describe the statistical information and the annotation process of the three datasets DIAL, PAN16, and MTC used in our experiments. The datasets DIAL and PAN16 can be downloaded from the link [2]. The dataset MTC can be downloaded from the link [3].

A.1 Data Statistics

The statistics of the datasets DIAL, PAN16, and MTC are shown in Table 5. In the table, the "task" section shows the text classification tasks included in a dataset. "Sentiment" is short for sentiment analysis. "Mention" is short for mention detection. "Hate Speech" is short for hate speech detection. "Demog." indicates the demographic attribute of the tweet authors collected in a dataset. The "Size" section shows the total number of instances in a dataset. Each instance is a tweet text. The "Avg.Len." section shows the average number of words in one instance in a dataset.

Table 5: Statistics of the datasets.

Dataset	Task	Demog.	Size	Avg.Len.
DIAL	Sentiment	Race	317,151	11.20
	Mention	Race	400,000	10.56
PAN16	Mention	Gender	175,871	14.64
	Mention	Age	175,471	14.55
MTC	Hate Speech	Race	47,627	19.60

A.2 Data Annotation

The DIAL dataset is annotated based on the dialectal tweet corpus (Blodgett et al., 2016), which contains 59.2 million tweets from 2.8 million users. The race attribute is annotated by an automated probabilistic inference method based on the geolocation information of the user and the tweet text. Given that geolocation information (residence) is highly associated with the race of a user, the model can make accurate predictions. To further ensure the accuracy, DIAL only keeps annotations with confidence above 80%.

---

[2] `https://github.com/yanaiela/demog-text-removal`

[3] `https://github.com/xiaoleihuang/Multilingual_Fairness_LREC`

The PAN16 dataset (Rangel et al., 2016) contain 436 Twitter users, each of which has up to 1,000 tweets. The age and gender of the users are manually annotated by referring to their LinkedIn profiles. Specifically, annotators judge the gender based on the user's name and profile photo. The age is inferred based on the user's birth date or degree starting date.

The MTC dataset (Huang et al., 2020) is annotated based on 7 published Twitter hate speech datasets in five languages. The dataset contains user demographic information such as race, gender, age, and country. We only focus on the English corpus and the attribute race in our experiments. The race of a user is inferred by the computer vision API, Face++[4], based on the profile photo.

B Optimization of the Explainer

We train the explainer $\mathcal{E}$ by maximizing the mutual information between the response variable Y and the selected features X_S. The optimization problem can be formulated as:

$$\begin{aligned} \max_{\mathcal{E}} \quad & I(X_S; Y) \\ \text{s.t.} \quad & S \sim P_{\mathcal{E}}(S|X) \end{aligned} \tag{1}$$

where

$$\begin{aligned} I(X_S, Y) &= \mathbb{E}\Big[\log \frac{P(X_S, Y)}{P(X_S)P(Y)}\Big] \\ &= \mathbb{E}\Big[\log \frac{P_{\mathcal{M}}(Y|X_S)}{P(Y)}\Big] \\ &\propto \mathbb{E}\Big[\log P_{\mathcal{M}}(Y|X_S)\Big] \\ &= \mathbb{E}_X \mathbb{E}_{S|X} \mathbb{E}_{Y|X_S}\Big[\log P_{\mathcal{M}}(Y|X_S)\Big] \end{aligned}$$

Solving the optimization problem in Eq. (1) is equivalent to finding an explainer $\mathcal{E}$ satisfying the following:

$$\max_{\mathcal{E}} P_{\mathcal{M}}(Y|X_S) \quad \text{s.t.} \qquad S \sim P_{\mathcal{E}}(S|X).$$

Hence, we train the explainer $\mathcal{E}$ by optimizing $P_{\mathcal{M}}(Y|X_S)$ with the parameters of the classification model $\mathcal{M}$ fixed. In our implementation, we adopt the cross-entropy loss for training, as we do when we train the classification model $\mathcal{M}$.

C Implementation Details

C.1 Details of Base Models

In the base model CNN, we use 100 filters with three different kernel sizes (3, 4, and 5) in the convolution layer, where we use a Rectified Linear Unit (ReLU) as the non-linear activation function. Each obtained feature map is processed by a max-pooling layer. Then, the features are concatenated and fed into a linear prediction layer to get the final predictions. A dropout with a rate of 0.3 is applied before the linear prediction layer.

For the base model RNN, we use a one-layer unidirectional RNN with Gated Recurrent Units (GRU). The hidden size is set to 300. The last hidden state of the RNN is fed into a linear prediction layer to get the final predictions. We apply a dropout with a rate of 0.2 before the linear prediction layer.

C.2 Details of Experimental Settings

For the text classifiers, we use randomly initialized word embeddings with a size of 300. All the models are trained by an Adam optimizer (Kingma and Ba, 2015) with an initial learning rate of 0.001. We apply gradient clipping with a clip-value of 0.25 to prevent the exploding gradient problem. The batch size is set to 64. For the base model and the baseline methods, when the prediction accuracy of the validation data doesn't improve for 5 consecutive epochs, the training is terminated, and we pick the model with the best performance on the validation set. Our model utilizes the validation data for training. To avoid it overfitting the validation data, we don't select the model based on its performance on the validation set. Instead, we train the model for a fixed number of epochs (5 epochs, the same for all the three datasets) and evaluate the obtained model.

Abstract

Which type of information affects the existing neural relation extraction (RE) models to make correct decisions is an important question. In this paper, we observe that entity type and trigger are the most indicative information for RE in each instance. Moreover, these indicative clues are always constrained to co-occur with specific relations at the corpus level. Motivated by this, we propose a novel RAtionale Graph (RAG) to organize such co-occurrence constraints among entity types, triggers and relations in a holistic graph view. By introducing two subtasks of entity type prediction and trigger labeling, we build the connection between each instance and RAG, and then leverage relevant global co-occurrence knowledge stored in the graph to improve the performance of neural RE models. Extensive experimental results indicate that our method outperforms strong baselines significantly and achieves state-of-the-art performance on the document-level and sentence-level RE benchmarks.

1 Introduction

Relation extraction (RE), which aims to identify the semantic relation between two entities in plain text, is one of the fundamental tasks in information extraction (IE). In the deep learning era, many approaches are proposed including models based on attention mechanism (Lin et al., 2016; Zhang et al., 2017), graph neural networks (Zhang et al., 2018; Guo et al., 2019), and pre-trained language models (Joshi et al., 2020; Yu et al., 2020).

While these neural RE models have achieved the latest state-of-the-art results, little is known about which type of information affects the models to make decisions. Recently, an empirical study shows that the understanding of two main information sources, entity type, and textual context, is necessary and effective for training a RE model (Peng et al., 2020). Entity type, is always an important side information for RE (Liu et al., 2014; Vashishth et al., 2018). In the textual context, some words play an indicative role in relation expression. Yu et al. (2020) initially annotated the minimal contiguous indicative word span and named them *trigger*. For example, in Figure 1, when we notice that both the subject and object entities are `person`, as well as the trigger `children` appears in the context, our immediate reaction is that they probably hold a parent-child relation, then we make a further judgment by reading the complete text.

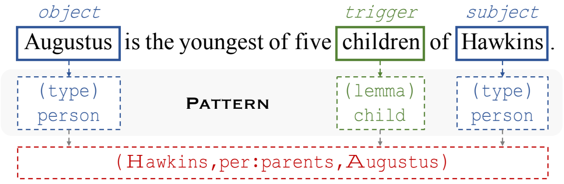

Figure 1: Illustration of the decision-making process in RE, where patterns are the most indicative information.

What is the support behind such rapid and accurate decision-making of human beings? In RE, if we look at the entire corpus from a global view, we can find a common phenomenon that one certain entity type or trigger is constrained to co-occur with specific relations. Taking entity type as an example, two entities of type `person` can only participate in person-related relations (e.g., `per:parents`, `per:siblings`). Such global co-occurrence induced by multiple seen instances serves as the crucial prior knowledge in the process of human cognition (Chater et al., 2006), and can naturally form a bipartite graph, in which the nodes on two sides are entity types and relations respectively. Similarly, the same logic can also go for triggers.

Inspired by the above observation, in this paper, we propose a RAtionale Graph (RAG) to organize the global co-occurrence statistics aggregated from

---

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 86–95
August 1–6, 2021. ©2021 Association for Computational Linguistics

the corpus. Specifically, nodes in the graph are constructed based on the relations and patterns[1]. There are totally four types of directed edges that exist between different types of nodes. For example, the edge between a trigger node and a relation node depicts the co-occurrence probability of a text expressing the relation when the trigger appears in the text. This probabilistic knowledge, together with the involved nodes, is collectively referred to as *rationale*. In the end, RAG is excepted to present a holistic view of all patterns and relations, and then facilitate the relation prediction.

Now we incorporate RAG with neural networks to improve the RE performance. Given an instance with a text and two entities, we first predict the entity type and label the trigger, then establish the link between the input instance with the known patterns in RAG, and finally enhance the instance representation with the attended relation node features in the graph. Meanwhile, we introduce the gate mechanism and graph neural networks (GNNs) to perform the information propagation from the input instance to relation nodes. Hence, this workflow makes full use of all aforementioned rationale knowledge to guide the processing of new instances by linking them to each seen pattern stored in the graph, like humans recognizing new things by intuitively associating with the knowledge they have memorized. In the training phase, the model learns simultaneously (1) the relation along with (2) the entity type and trigger for each instance. This means that we care about not only the final relation label (*what*), but also the intermediate results, i.e., whether the entity type and trigger are correctly predicted (*why*). By doing so, we can retrieve the relevant global pattern knowledge from the graph with the predicted trigger and entity types, during testing.

To evaluate our approach, we first conduct experiments on the document-level RE task DialogRE (Yu et al., 2020). Experimental results show the benefits of the proposed method, leading to state-of-the-art performance. An exciting discovery is that our method is very effective in small-scale annotation scenes, using only half (with 2,584 positive instances) of the pattern-annotated instances results in a comparable performance as using all conventional annotated instances. To further validate this advantage, we manually annotate 20% (with 2,585 positive instances) patterns of the sentence-level RE benchmark TACRED (Zhang et al., 2017), and empirically demonstrate similar experimental conclusions with DialogRE.

2 Related Work

Extracting relational facts between entities from text is an essential and classical problem in natural language processing. The popular research methods have gone through the iteration from pattern-based methods (Mooney, 1999; Chang and Lui, 2001) to feature-based methods (Kambhatla, 2004; Zhou et al., 2005), and then to neural-based methods (Zeng et al., 2014; Zhang et al., 2017). Nowadays, most state-of-the-art work develops powerful neural models based on pre-trained language models or graph neural networks (Soares et al., 2019; Zhang et al., 2019; Guo et al., 2019). All the time, there are two main consensuses in the community: when extracting a relation, entity types are important side indicators, which are often used to enhance the input or output layer (Vashishth et al., 2018; Kuang et al., 2020). On the other hand, not all the words in the text are beneficial to RE. Thus there are also efforts focusing on the heuristic or implicit selection of the key clues related to relation expression (Zhang et al., 2018; Yu et al., 2019), and Yu et al. (2020) is the first work to annotate such clue words in texts and name them trigger.

However, most previous studies are only based on local features, in other words, models are trained on individual instance, limiting the ability to capture the connection between textual indicative information and relations globally. Conversely, Su et al. (2018) emphasized the importance of the global view, and embed the textual relations with global statistics to combat the wrong labeling problem of distant supervision. Wang et al. (2020) proposed an interpretable network embedding model based on a corpus-level entity graph to rationalize medical relation prediction. Unfortunately, their methods are not suitable for the supervised RE task in the general domain. The most related work, (Zhang et al., 2020), collected a global type-relation mapping as prior knowledge to guide the optimization with knowledge distillation. One major difference is that we systematically consider both entity type and textual trigger to collect all indicative knowledge in a holistic view. Another unique aspect of this work is that we perform the prediction of entity type and trigger as two subtasks, while previous studies only focus on the final relation labels.

---

[1] For the sake of generality, we refer to the *entity type* and *trigger* as *pattern* in the remaining of this paper.

3 Rationale Graph (RAG)

Different from existing work only using raw text for RE, we assume the global co-occurrence statistics among relations, triggers, and entity types is given, which are pre-construed based on the whole corpus, and denoted as a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where each vertex $v \in \mathcal{V}$ refers the *relation*, *trigger*, or *entity type pair* extracted from the corpus and each edge $e \in \mathcal{E}$ is associated with the global co-occurrence count for the connected nodes. Inspired by Zhang et al. (2020), we organize the global co-occurrence count between two kinds of nodes as bipartite rationale mapping and pack all bipartite mappings together to obtain a rationale graph (RAG). Figure 2 shows the schematic diagram for clarity.

3.1 Bipartite Rationale Mapping

Here we take *type* (short for *entity type pair*) and *relation* as an example to describe the construction process of bipartite rationale mapping. Specifically, for instance with a text x and two entities (s, o), we combine two entity types to achieve a *pattern* p. From this step, we obtain the pattern set $\mathcal{T} = \{t_i\}$ and formulate a support set $\mathcal{S}(t_i)$ for each t_i, in which the support set $\mathcal{S}(t_i)$ contains all instances with pattern t_i. Besides, we also collect a set of relations $\mathcal{R} = \{r_j\}$, and the support set $\mathcal{S}(r_j)$ denoting the set of instances holding relation r_j. The co-occurrence number of pattern t_i and relation r_j is defined as $w_{ij} = |\mathcal{S}(t_i) \cap \mathcal{S}(r_j)|$. In other word, every instance (x, s, o) with pattern t_i and relation r_j is counted as a co-occurrence of t_i and r_j.

However, it is inappropriate to take the raw co-occurrence count as mapping weight directly. The relation distribution in reality typically has a power-law tail (Zhang et al., 2017), meaning that the count spans several orders of magnitude in different relations. To meet this challenge, for each pattern, we normalize its co-occurrence count to form a valid probability distribution over relations. In the end, the bipartite mapping $\mathcal{M}_{tp2re}$ is constructed, with one node set being the types, the other being the relations, and the weighted edges $\bar{w}_{ij} = p(r_j|t_i) = w_{ij}/\sum_{j'} w_{ij'}$ representing the normalized global co-occurrence probability.

3.2 Graph Construction

Considering that trigger and type are two kinds of information sources for RE (Peng et al., 2020), we first introduce the bipartite rationale mapping from type to relation $\mathcal{M}_{tp2re}$ and the mapping from trigger to relation $\mathcal{M}_{tg2re}$ in RAG. In this way, we assume that the graph reflects the prior probability of relation when some indicative information appears in the text. Furthermore, triggers are actually relations in the form of natural language (Hu et al., 2020) and entity types are tightly bound to certain trigger words within the context (Lin et al., 2020). In other words, type and trigger are mutually related and restricted. Therefore, we introduce a set of bidirectional mapping, that is, from type to trigger $\mathcal{M}_{tp2tg}$ and from trigger to type $\mathcal{M}_{tg2tp}$. Finally, we place four kinds of edges in the graph: $\mathcal{E} \leftarrow \{\mathcal{M}_{tp2re}, \mathcal{M}_{tg2re}, \mathcal{M}_{tp2tg}, \mathcal{M}_{tg2tp}\}^2$.

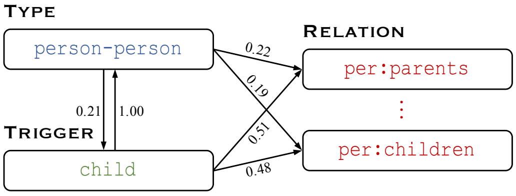

Figure 2: Schematic diagram of RAG, in which edges are weighted by normalized co-occurrence statistics.

4 Relation Extraction with RAG

In this section, we exemplify how to incorporate existing RE models with RAG. Given a text, a subject entity, and an object entity, the model aims to identify the semantic relationship between these two entities with the aid of RAG. Moreover, we also require the model to predict entity type pair and label trigger (if possible) as two auxiliary subtasks. For the example in Figure 3, we build a unified model that not only accurately predicts the relation `per:parents`, but also provides meaningful rationales on how the prediction is made: the subject and object entities are both `person`, and the key clue `children` appears in the context.

4.1 Encoding Module

We utilize BERT (Devlin et al., 2019) as the feature encoder to extract token representations due to its effectiveness in representation learning. Theoretically, the encoding module can be easily replaced by other advanced models. The encoder receives a BERT-style packed sequence and outputs a context representation matrix $\mathbf{H} \in \mathbb{R}^{n \times d}$ with an overall vector $\mathbf{h}_{cls} \in \mathbb{R}^d$ (the representation of the [CLS] token in BERT), where d is the vector dimension

---

[2] In view of the diversity of natural language, we use spaCy (`https://spacy.io/`) to perform lemmatization on triggers, before putting them into RAG as vertexes.

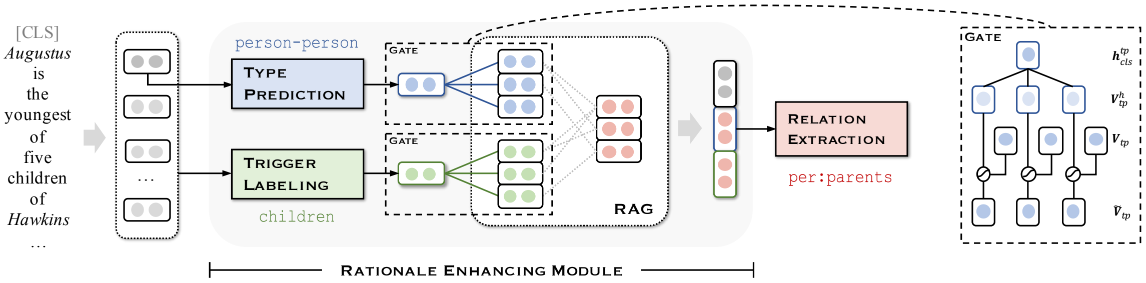

Figure 3: The overall architecture of the proposed model. Rationale enhancing module is the core component in our approach, which enhances the instance representation by retrieving pertinent rationales stored in RAG.

of the last layer of BERT. Typically, existing BERT-based RE solutions first concatenate target entities with the text or mark them in the input sequence with special tokens, and then directly take $\mathbf{h}_{cls}$ as the input of final classification module (Joshi et al., 2020; Yu et al., 2020).

4.2 Rationale Enhancing Module

The rationale enhancing module consists of two enhancing branches and one rationale integration unit. In each branch, we first predict pattern (type or trigger) for the input instance and then calculate the *pattern probability* that the instance belongs to each pattern in RAG. The integration unit aims to collect rationale enhancing features for final relation extraction based on the pattern probability and the rationale in the graph.

4.2.1 Type Enhancing Branch

In this branch, we predict the types of subject and object entities at the same time. Similar to RE, type prediction is regarded as a closed-world classification problem, and the class space is all seen entity type pairs, that is, all type nodes in RAG. Following the classification paradigm of BERT (Devlin et al., 2019), we project the overall vector $\mathbf{h}_{cls}$ into a new space for type prediction:

$$\begin{aligned}\mathbf{h}_{cls}^{tp} &= \texttt{tanh}(\texttt{MLP}_{\{d,d\}}(\mathbf{h}_{cls})),\\ \mathbf{p}_{tp} &= \texttt{SoftMax}\left(\texttt{MLP}_{\{d,n_{tp}\}}(\mathbf{h}_{cls}^{tp})\right).\end{aligned} \tag{1}$$

Here $\texttt{MLP}_{d,n_{tp}}(\cdot)$ denotes a multi-layer perceptron module with input dimension d and output dimension n_{tp}, $\mathbf{p}_{tp} \in \mathbb{R}^{n_{tp}}$ is the type probability that the given instance belongs to each type pair, where n_{tp} is the number of all known type pairs.

4.2.2 Trigger Enhancing Branch

Different from the prediction of entity type, triggers are flexible and can be any word or phrase in the text. We formulate the trigger recognition task as a labeling problem with two label sequences.

Given the representation matrix $\mathbf{H}$ output from BERT, the model predicts two probabilities of each token being the start index and end index of a trigger, respectively. To handle the instances without clear trigger (about half of them), we concatenate $\mathbf{H}$ with $\mathbf{h}_{cls}$ to form $\bar{\mathbf{H}} = [\mathbf{H}; \mathbf{h}_{cls}]$, and set the boundary index pointing to the [CLS] token. These two probability distributions over the entire sequence $\mathbf{p}_{sta}, \mathbf{p}_{end} \in \mathbb{R}^{(n+1)}$ can be obtained by

$$\begin{aligned}\mathbf{p}_{sta} &= \texttt{SoftMax}\left(\texttt{MLP}_{\{d,1\}}(\bar{\mathbf{H}})\right),\\ \mathbf{p}_{end} &= \texttt{SoftMax}\left(\texttt{MLP}_{\{d,1\}}(\bar{\mathbf{H}})\right).\end{aligned} \tag{2}$$

To align the labeling result with the triggers in RAG, we first weight each token in $\bar{\mathbf{H}}$ based on the two index probabilities and get the representation of predicted trigger $\mathbf{h}_{pre}^{tg} \in \mathbb{R}^{d}$, then calculate and normalize the similarity between $\mathbf{h}_{pre}^{tg}$ and all known triggers $\mathbf{V}_{tg} \in \mathbb{R}^{n_{tg} \times d}$:

$$\begin{aligned}\mathbf{h}_{pre}^{tg} &= \frac{1}{2}\left(\mathbf{p}_{sta} + \mathbf{p}_{end}\right)\bar{\mathbf{H}},\\ \mathbf{p}_{tg} &= \texttt{SoftMax}\left(\texttt{sim}(\mathbf{h}_{pre}^{tg}, \mathbf{V}_{tg})\right),\end{aligned} \tag{3}$$

where $\mathbf{p}_{tg} \in \mathbb{R}^{n_{tg}}$ is the probability of the given instance corresponding to each known trigger, n_{tg} is the number of all triggers, and $\texttt{sim}(\cdot)$ is a similarity function as follows:

$$\begin{aligned}\texttt{sim}(\mathbf{h}_{pre}^{tg}, \mathbf{v}_{tg}^{i}) = &\texttt{MLP}_{\{4d,1\}}([\mathbf{h}_{pre}^{tg}; \mathbf{v}_{tg}^{i};\\ &\mathbf{h}_{pre}^{tg} - \mathbf{v}_{tg}^{i}; \mathbf{h}_{pre}^{tg} \circ \mathbf{v}_{tg}^{i}]),\end{aligned} \tag{4}$$

where $\mathbf{v}_{tg}^{i} \in \mathbb{R}^{d}$ is the i-th trigger in $\mathbf{V}_{tg}$ and $\circ$ denotes element-wise product. In that case, even if we run into a new trigger that we have never seen before, we can also estimate the correlation between the new trigger and the known triggers via semantic similarity, and then absorb more global statistics from similar triggers. It provides the possibility for the rationale enhancing on trigger branch.

4.2.3 Rationale Integration

For each type node in RAG, we update its embedding with the instance type feature $\mathbf{h}_{cls}^{tp}$. It is intuitive that the higher the probability of an instance to a type, the more its contribution to the updating process of that type. Specifically, we first compute the update representation for each type node based on the pattern probability $\mathbf{p}_{tp}$, and then aggregate information on the text side $\mathbf{V}_{tp}^{h} \in \mathbb{R}^{n_{tp} \times d}$ and graph side $\mathbf{V}_{tp} \in \mathbb{R}^{n_{tp} \times d}$ via a gate mechanism:

$$\begin{aligned} \mathbf{V}_{tp}^{h} &= \mathbf{p}_{tp}^{\top} \mathbf{h}_{cls}^{tp}, \\ \delta_{tp} &= \texttt{Sigmoid}\left(\texttt{MLP}_{\{2d,1\}}([\mathbf{V}_{tp}; \mathbf{V}_{tp}^{h}])\right), \\ \tilde{\mathbf{V}}_{tp} &= (1-\delta_{tp}) \circ \mathbf{V}_{tp} + \delta_{tp} \circ \mathbf{V}_{tp}^{h}. \end{aligned} \tag{5}$$

Similarly, we perform the same computation on the trigger branch to reconstruct the trigger node embeddings in RAG and result in $\tilde{\mathbf{V}}_{tg} \in \mathbb{R}^{n_{tg} \times d}$.

Next, we execute GNNs-based algorithm on the RAG to update the representation of relation nodes. R-GCN (Schlichtkrull et al., 2018) is chosen as the message propagation strategy here because RAG is naturally a heterogeneous graph:

$$\bar{\mathbf{V}}_{tp}, \bar{\mathbf{V}}_{tg}, \bar{\mathbf{V}}_{re} = \texttt{R-GCN}\left(\tilde{\mathbf{V}}_{tp}, \tilde{\mathbf{V}}_{tg}, \mathbf{V}_{re}\right). \tag{6}$$

After that, for the type enhancing branch, we first calculate the *mapping probability* of an instance to each relation based on the type probability $\mathbf{p}_{tp}$ and corresponding bipartite rationale mapping $\mathbf{M}_{tp2re} \in \mathbb{R}^{n_{tp} \times n_{re}}$ (i.e., the edge weight $\mathcal{M}_{tp2re}$), and then weight the updated relation embeddings based on the mapping probability to obtain type enhancing vector $\mathbf{h}_{tp} \in \mathbb{R}^{d}$. Meanwhile, similar operations are performed in the trigger branch:

$$\begin{aligned} \mathbf{h}_{tp} &= \mathbf{p}_{tp} \mathbf{M}_{tp2re} \bar{\mathbf{V}}_{re}, \\ \mathbf{h}_{tg} &= \mathbf{p}_{tg} \mathbf{M}_{tg2re} \bar{\mathbf{V}}_{re}. \end{aligned} \tag{7}$$

4.3 Classification Module

The output module combines the overall vector and two enhancing features to get final representation, which is fed into a multi-layer perceptron followed by a softmax function for relation classification:

$$\begin{aligned} \mathbf{h}_{re} &= [\mathbf{h}_{cls}; \mathbf{h}_{tp}; \mathbf{h}_{tg}], \\ \mathbf{p}_{re} &= \texttt{SoftMax}\left(\texttt{MLP}_{\{3d,n_{re}\}}(\mathbf{h}_{re})\right). \end{aligned} \tag{8}$$

4.4 Training Objectives

Recall that there are totally three tasks in our model, including relation extraction, type prediction, and trigger (start and end indexes) labeling, which are all reduced to the classification problem. In optimization, we train the model end-to-end in a multi-task manner here, and adopt cross-entropy as the loss function for each task:

$$\mathcal{L}_{task} = \texttt{CrossEntropy}(\mathbf{y}_{task}, \mathbf{p}_{task}), \tag{9}$$

where $\mathbf{y}_{task}$ denotes the ground truth, represented by one-hot vector, $\mathbf{p}_{task \in \{re,tp,sta,end\}}$ is the estimated probability for each class.

Towards learning to perceive the strong signal that a known trigger exactly in the text, we utilize contrastive loss (Hadsell et al., 2006). The intuition is that the trigger in text h_{pre}^{tg} and the matched trigger in RAG v_{tg}^{mat} should have similar representations (i.e., have a small distance in vector space, d). For the mismatched trigger, we expect a margin m between their embeddings. The contrastive loss of trigger matching is as follows, where $\mathbb{1}_{mat}$ is 1 if a trigger is originally in the text and 0 if it is not:

$$\begin{aligned} d &= ||\mathbf{h}_{pre}^{tg} - \mathbf{v}_{tg}^{mat}||_2, \\ \mathcal{L}_{mat} &= (1-\mathbb{1}_{mat})(\max\{0, m-d\})^2 \\ &\quad + (\mathbb{1}_{mat})(d)^2 . \end{aligned} \tag{10}$$

The joint loss of trigger labeling is thus

$$\mathcal{L}_{tg} = \mathcal{L}_{sta} + \mathcal{L}_{end} + \mathcal{L}_{mat}. \tag{11}$$

Finally, the losses from the main RE task and two subtasks are aggregated to form the training objective, with two weight factors λ_{tp} and λ_{tg}:

$$\mathcal{L} = \mathcal{L}_{re} + \lambda_{tp}\mathcal{L}_{tp} + \lambda_{tg}\mathcal{L}_{tg}. \tag{12}$$

Extension. Here, we introduce a simple extension to simultaneously make full use of all data with relation label and any number of data with pattern annotation. Specifically, when there are intact pattern annotations for an instance, we set $\mathbb{1}_{ext}$ to 1 and calculate the losses of type prediction and trigger labeling. Otherwise, we do not calculate them and set $\mathbb{1}_{ext}$ to 0. In this way, the training objective (Equation 12) is modified as follow,

$$\mathcal{L}^{'} = \mathcal{L}_{re} + \mathbb{1}_{ext}(\lambda_{tp}\mathcal{L}_{tp} + \lambda_{tg}\mathcal{L}_{tg}). \tag{13}$$

5 Experiments

We name our proposed model RARE[3], which can be adopted to both document-level and sentence-level RE tasks. Due to the differences in data formats, applicable baseline models, and the custom

Table 1: Main results on the document-level RE (DialogRE) task, σ denotes the standard deviation computed from five independent runs of each model. † marks the results we reproduce based on the official released code.

in handling entities, we conduct two sets of experiments, comparing RARE to their respective state-of-the-art models on the two tasks. In the experiment, we take *bert-base-uncased* as backbone encoder to verify the effectiveness of RARE and perform further analysis. Besides, we reproduce TypeKD (Zhang et al., 2020) as an extra baseline, which is a recent work using global statistics between entity types and relations in RE.

Implementation Details. We follow the same input format and hyper-parameter settings as in baselines for fair composition. Besides, the layer number of RAG is set to 2 (chosen from $\{1, 2, 3\}$), the match margin in $\mathcal{L}_{mat}$ is set to 0.1 (chosen from $\{1, 0.1, 0.01\}$) for the two sets of experiments. We tune the loss weights λ_{tp} and λ_{tg} with grid search (chosen from $[0.01, 0.05]$ in steps of 0.01) and set λ_{tp} to 0.01 and λ_{tg} to 0.03. For the nodes in RAG, we regard entity types, triggers, and relations as plain text, then employ the encoding module to achieve their initial embeddings. All the hyper-parameters are tuned based on dev set.

Evaluation Metrics. Following popular choices and previous work, we use F1/F1c scores as evaluation metrics in the document-level RE task (i.e., DialogRE), where F1c is computed by only taking in the early part of a dialogue as input, instead of the entire dialogue. In the sentence-level RE task (i.e., TACRED/V), we report micro-averaged Precision, Recall, and F1 scores.

5.1 Document-Level Relation Extraction

DialogRE (Yu et al., 2020) is a human-annotated document-level RE dataset constructed from the transcripts of an American television situation comedy *Friends*. It is also the first RE dataset with both entity type and trigger annotation.

	P	R	F1
Type Prediction	79.3	77.4	78.3
Trigger Labeling	51.5	54.2	52.7

Table 2: Performance of two subtasks on DialogRE.

5.1.1 Experimental Setup

We employ BERT and BERTs (Yu et al., 2020) as the encoding module of RARE in this task. BERTs is a speaker-aware version of BERT, achieving the best performance on the dataset. For the completeness of experiments, we include all official baselines: Majority strategy and CNN/LSTM/BiLSTM-based models (Yu et al., 2020).

5.1.2 Results and Analysis

Main Results. Comparing the performance of different models in Table 1, the first conclusion we draw is that RARE$_{BERTs}$ outperforms all baseline models in all evaluation matrices, which demonstrates the effectiveness of our rationale enhanced approach, as well as the motivation of using global pattern co-occurrence statistics to boost the performance of RE models. Secondly, RARE$_{BERTs}$ improves by a relative margin against RARE$_{BERT}$. It is strong evidence that RARE is flexible enough to adapt to various encoders. Thus, we have reason to believe that a more powerful encoding module could bring further performance gain for RARE. Lastly, TypeKD-based models have a similar trend, but their performance is relatively worse than models based on RARE, which shows that trigger and type are two non-overlapping information sources, and only considering one of them is not enough to capture complete indicative knowledge.

We report the performance of RARE$_{BERTs}$ on the two subtasks in Table 2. From the results, we find

	Dev F1
RARE$_{BERT}$	64.6
w/o Rationale graph	62.3
w/o Type enhancing branch	62.8
w/o Trigger enhancing branch	63.3
w/o Trigger matching loss	64.0
w/o Probabilistic edge weights	63.7
w/o Gate mechanism & GNNs	63.5

Table 3: Ablation study on DialogRE dev set.

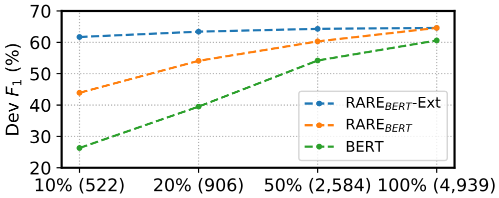

Figure 4: Performance of models on DialogRE dev set with partial training data. The positive instance number with pattern annotation is shown in brackets.

that type prediction is relatively simpler than trigger labeling. We explain that the entity type is a kind of shallow linguistic feature, while the labeling trigger requires a full understanding of context semantics. We also notice that trigger labeling performance is even worse than that of RE, since about half of the positive instances have no explicit trigger (Yu et al., 2020), meaning that the recognition of trigger faces a more serious data imbalance problem than RE. Overall, there is still a long way to improve the performance of these two subtasks, which can be left as a possible future direction.

Ablation Study. To investigate the effectiveness of each module in RARE, we conduct an ablation study on the DialogRE dev set. From the ablations in Table 3, we observe that: (1) Rationale graph is a necessary component that contributes 2.3% F1. The performance superiority of this ablation over BERT also shows that the two auxiliary subtasks of type prediction and trigger labeling are beneficial to RE. (2) Without the type or trigger enhancing branch, the performance degradation suggests that both type and trigger are necessary for our RARE. (3) The ablation of removing the trigger matching loss hurts the final result by 0.6% F1, which justifies the design philosophy of entrusting the model with the ability to perceive whether the trigger is exactly in text. (4) We also try to remove the probabilistic edge weights in RAG to make it degenerate into a standard heterogeneous graph. In that case, the performance drops by 0.9% F1. We think that such probabilistic weights are capable of carrying more global information than one-hot constraints. (5) The information propagation (i.e., gate mechanism and GNNs) brings the improvement of 1.1% F1, which provides a channel to integrate the features of input instance in the output layer.

Labor-Efficiency Study. Considering that most RE datasets have no trigger annotation, we seek to study the cost-effectiveness of adding patterns as additional annotation in this experiment. Accordingly, we explore the performance of RARE$_{BERT}$ and BERT for various fractions of training data. From Figure 4, we can see that RARE$_{BERT}$ with pattern annotations delivers competitive or even better performance as BERT with twice the traditional training data. The drastic performance gain justifies the slightly additional cost incurred in annotating patterns. Furthermore, we also introduce RARE-Ext, the extension of RARE, to fully use the partial data with pattern annotations and the remaining data with only relation labels in training, which provides a plug-and-play manner to utilize pattern annotations. The results show that with the increase of annotations, the performance improvement becomes less significant. When using 50% (with 2,584 positive instances) pattern annotations, the performance of the model is comparable to that of 100% annotations.

5.2 Sentence-Level Relation Extraction

In this section, we evaluate RARE on the sentence-level RE task with two datasets TACRED (Zhang et al., 2017) and TACREV (Alt et al., 2020). TACRED is the most widely used sentence-level RE dataset that constructed from *New York Times*. The recent TACREV (a.k.a TACRED-Revised) dataset has the same training set as TACRED, which corrects the wrong labels in the dev and test sets.

5.2.1 Experimental Setup

To our knowledge, SpanBERT (Joshi et al., 2020) is the best performance model without external knowledge in TACRED. We employ it as another encoder (besides BERT) for RARE. For completeness, we also include two official baselines, LSTM and PA-LSTM (Zhang et al., 2017), as well as two recent graph-based models, AG-GCN (Guo et al., 2019) and LST-AGCN (Sun et al., 2020), here.

Different from DialogRE, TACRED/V annotates only entity types. Inspired by the results of the label-efficiency study on DialogRE, we annotate

Model	TACRED			TACREV		
	P	R	F1	P	R	F1
LSTM (Zhang et al., 2017)	65.7	59.9	62.7	71.5	69.7	70.6
PA-LSTM (Zhang et al., 2017)	65.7	64.5	65.1	74.5	74.1	74.3
AG-GCN (Guo et al., 2019)	73.1	60.9	68.2	77.7	73.4	75.5
LST-AGCN (Sun et al., 2020)	-	-	68.8	-	-	-
BERT (Devlin et al., 2019)‡	67.2	69.3	68.2	76.0	75.6	75.1

RARE$_{BERT}$-Ext (ours)*	71.4	68.1	**69.8**	78.6	76.2	**77.4**
SpanBERT (Joshi et al., 2020)	70.8	70.9	70.8	75.7	80.7	78.0
TypeKD$_{SpanBERT}$ (Zhang et al., 2020)†	71.7	70.4	**71.0**	79.8	78.3	78.8
RARE$_{SpanBERT}$-Ext (ours)*	72.5	69.3	70.8	80.1	78.0	**79.0**

Table 4: Main results on the sentence-level RE (TACRED/V) task. ‡ marks the results we reproduce based on the repository released by (Joshi et al., 2020). We implement RARE-Ext with 20% extra annotations ($\star$).

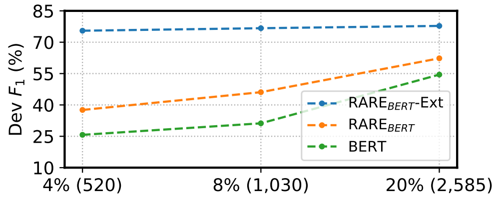

Figure 5: Performance of models on TACREV dev set with partial training data.

triggers for 2,585 positive instances, which accounts for about 20% of all positive instances in the training set of TACRED/V, to verify whether RARE could maintain such excellent lab efficient performance on sentence-level RE task. We repeat our experiments for five random seed initializations, and the results are statistically significant with a p-value of less than 0.05.

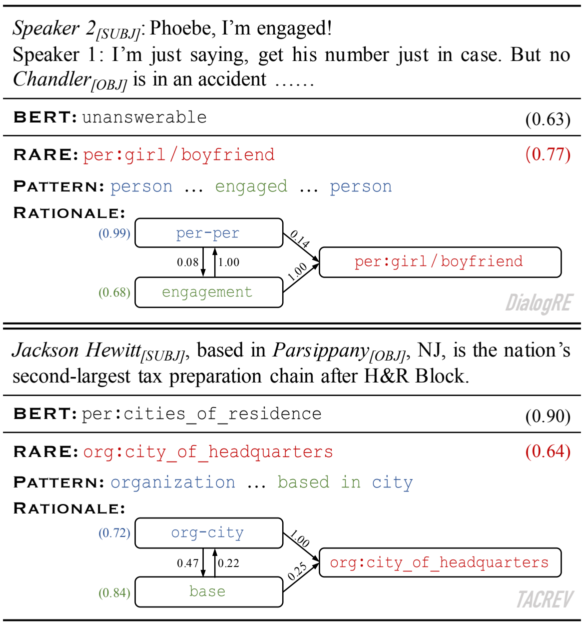
5.2.2 Results and Analysis

Main Results. With 20% pattern annotations, we compare RARE-Ext against several representative baselines and summarize the results in Table 4. Similar observations hold that RARE is capable of achieving superior performances with advanced encoding modules. Moreover, RARE-Ext achieves or even surpasses the performance of TypeKD that using 100% type annotations. Although sometimes RARE does not make significant improvements on TACRED, it outperforms the baselines in TACREV and leads to state-of-the-art performances, which is a more accurate evaluation set. Overall, the performance gain of RARE on this task is not as amazing as the document-level task. We analyze that because the sentence is much shorter than the document, and involves fewer relations, BERT-based models are sufficient in capturing the key semantic clue for decision-making, thus the benefits of global knowledge are slightly limited.

Labor-Efficiency Study. Following the approximate number of positive instances in DialogRE, we split the pattern-annotated data to perform the labor-efficiency study on TACREV (see Figure 5). The results indicate that when both using partial data, RARE$_{BERT}$ consistently outperforms BERT. It enlightens us to fully exploit the potential knowledge of the dataset, including local annotation and global statistics, to improve the performance of RE, especially under a low-resource scenario. The considerable progress of RARE$_{BERT}$-Ext demonstrates that RARE is able to improve RE by annotating patterns on any part of an existing dataset. Considering the differences between DialogRE and TACREV (e.g., relation number, domain and style, the ratio of positive and negative instances), it is under investigation whether further improvements could be made by increasing annotations on TACREV, and we leave it as future work.

5.3 Case Study

In Figure 6, we select two representative cases to demonstrate the working principle of RARE. The first case is a short snippet from a DialogRE document, in which two entities are scattered in different sentences, and the context semantics is complex and changeable, BERT fails to capture the relation between them. Conversely, RARE predicts the trigger `engaged` and aligns it with the known trigger `engagement`, and then highlights the strong signal to identify the relation correctly. In the second case, which is from TACREV, BERT mistakenly regards `Jackson Hewitt` as a person, leading to a wrong answer of person-related relation. With the help of type prediction and the global type-relation



Speaker 2$_{[SUBJ]}$: Phoebe, I'm engaged!
Speaker 1: I'm just saying, get his number just in case. But no *Chandler*$_{[OBJ]}$ is in an accident ……

BERT: `unanswerable` (0.63)

RARE: `per:girl/boyfriend` (0.77)

PATTERN: `person … engaged … person`

RATIONALE:

Jackson Hewitt$_{[SUBJ]}$, based in *Parsippany*$_{[OBJ]}$, NJ, is the nation's second-largest tax preparation chain after H&R Block.

BERT: `per:cities_of_residence` (0.90)

RARE: `org:city_of_headquarters` (0.64)

PATTERN: `organization … based in city`

RATIONALE:

Figure 6: Internal principles of RARE. The number in bracket refers the probabilities predicted by model.

constraints in RAG, RARE could avoid this error and make the right decision.

6 Conclusion

In this paper, we propose a novel rationale graph to organize the global co-occurrence statistics among entity types, triggers, and relations. By introducing the two subtasks of entity type prediction and trigger labeling, we build the connection between input instance and the known patterns in rationale graph, which provides the model with the possibility to benefit from the global co-occurrence knowledge stored in the graph, so as to improve the performance of RE. Experimental results on two public datasets prove the effectiveness of our method. We also highlight two directions for future work: the first is to improve the performance of two subtasks, especially trigger labeling, the other is to adopt the proposed approach in more RE scenarios.

Abstract

This work studies the long-standing problems of model capacity and negative interference in multilingual neural machine translation (MNMT). We use network pruning techniques and observe that pruning 50-70% of the parameters from a trained MNMT model results only in a 0.29-1.98 drop in the BLEU score. Suggesting that there exist large redundancies in MNMT models. These observations motivate us to use the redundant parameters and counter the interference problem efficiently. We propose a novel adaptation strategy, where we iteratively prune and retrain the redundant parameters of an MNMT to improve bilingual representations while retaining the multilinguality. Negative interference severely affects high resource languages, and our method alleviates it without any additional adapter modules. Hence, we call it parameter-free adaptation strategy, paving way for the efficient adaptation of MNMT. We demonstrate the effectiveness of our method on a 9 language MNMT trained on TED talks, and report an average improvement of +1.36 on high resource pairs. Code will be released here.

1 Introduction

Multilingual neural machine translation(MNMT) has seen various advances in recent years (Dong et al., 2015; Firat et al., 2016; Zoph et al., 2016; Tan et al., 2019; Aharoni et al., 2019; Arivazhagan et al., 2019). However, the core principle behind the effectiveness in terms of modelling multiple languages remains the same, i.e., sharing all the model parameters between all the languages (Johnson et al., 2017). Although highly scalable and effective, the performance on high resource languages decreases as more low resource languages are added in the model; this is called negative interference. To overcome this, recent works (Bapna and Firat, 2019; Philip et al., 2020; Zhang et al., 2020) proposed language-specific adapter modules, which provide extra parameters to learn language specific representations, and overcomes the effect of negative interference caused by a high degree of parameter sharing.

In this paper, we propose an alternative to adapter modules. Instead of adding more parameters, we show that the Transformer (Vaswani et al., 2017) has enough capacity to model multiple languages and overcome negative interference effectively. Inspired by the work of Mallya and Lazebnik (2018), we apply iterative pruning to free up the redundant parameters from an MNMT, and retrain them to learn language specific representations. We start with a trained MNMT model, and prune a fraction of the model parameters, we freeze the surviving parameters and retrain the free ones on a bilingual dataset. This process is iteratively applied for each bilingual pair to get bilingual masks over all the model parameters, as illustrated in figure 1. We show that using only a fraction of redundant parameters, significantly improves the performance on high resource languages. Also, we retain the multilinguality and the zero-shot translation ability after adaptation. By demonstrating the effectiveness of this approach, we open a potential research direction towards parameter-free adaptation in MNMT.

2 Related Work

Adding multiple tasks to a single network: Due to the over-parameterized nature of deep neural networks, prior works (Kirkpatrick et al., 2017; Lee et al., 2017; Li and Hoiem, 2017; Triki et al., 2017) aimed at developing methods to learn multiple tasks while avoiding catastrophic forgetting. Mallya and Lazebnik (2018) proposed an iterative pruning approach to free up parameters for adding new tasks and retain the previously trained parameters at the same time. Inspired by the concept,

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 96–102
August 1–6, 2021.

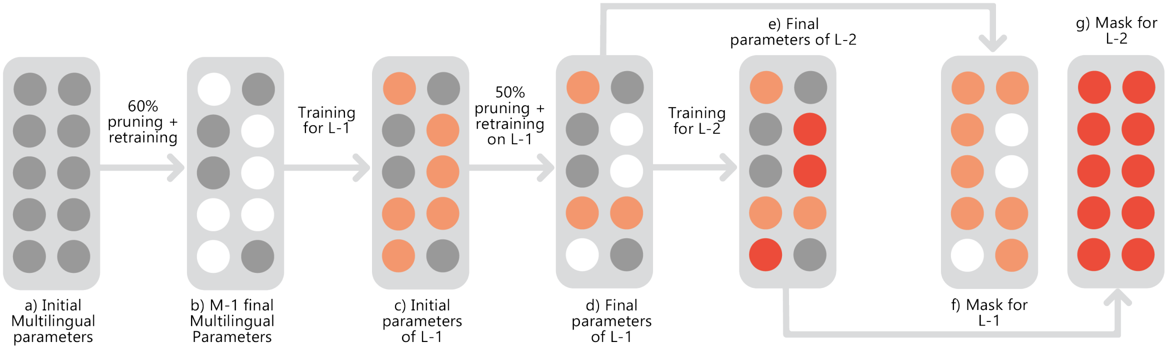

Figure 1: (Better seen in colour.) Illustration of the evolution of model parameters. (a) shows the multilingual parameters in grey. Through 60% pruning and retraining, we arrive at (b), here white represents the free weights with value=0. The surviving weights in grey will be fixed for the rest of the method. Now, we train the free parameters on the first bilingual pair (L-1) and arrive at (c), which represents the initial parameters of L-1 in orange, and share weights with the previously trained multilingual parameters in grey. Again, with 50% pruning and retraining on the current L-1 specific weights in orange, we get the final parameters for L-1 shown in (d) and extract the final mask for L-1 in (f). We repeat the same procedure for all the bilingual pairs and extract the masks for each pair.

we show that an MNMT Transformer model can be heavily pruned and the freed up parameters can be retrained to improve bilingual performance, while retaining the multilinguality.

Adapting multilingual model to a new language pair and domain adaptation: Prior works on adaptation (Neubig and Hu, 2018; Variš and Bojar, 2019; Stickland et al., 2020; Escolano et al., 2020; Akella et al., 2020; Bapna and Firat, 2019; Philip et al., 2020; Zhang et al., 2020) aims at improving language specific performance by either fine-tuning the same MNMT model or adding language specific modules. While being effective, these methods either lose their multilinguality or introduce additional parameters. Sharing the same objective, we propose a method to adapt an MNMT, without adding language-specific modules, while retaining the multilinguality at the same time. Another line of work (Thompson et al., 2018; Wuebker et al., 2018), proposed training of subnetworks and freezing the rest for domain adaptation.

3 Method

The central idea of our method is to use magnitude pruning to free up parameters in the model and learn bilingual specific representations. Figure 1 depicts the evolution of model weights during the training procedure, with (a) representing the initial multilingual weights in grey. We prune away a fraction of parameters using the one-shot magnitude pruning technique (Han et al., 2015), which results in a compressed multilingual representation. We further train the survived multilingual weights for a few more epochs on the multilingual dataset to compensate for extreme pruning, now the multilingual parameters will remain fixed. Then, we use the free parameters to learn the first language-specific representations. We select the first bilingual dataset and train the free parameters. Next we again prune a fraction of weights from the current bilingual parameters only, to accommodate more bilingual representations. We repeat the same procedure for all the existing bilingual pairs. A point to note is that during a forward pass data flows through all the shared and specific weights, while during the backward pass only the current bilingual-specific parameters get updated. Hence, the accuracy is retained for all the previously trained bilingual pairs and it enables a high degree of sharing and specificity at the same time.

Pruning Approach: We perform magnitude pruning (Han et al., 2015) over the weights of all layers. For simplicity, we do not use the more sophisticated pruning methods (Frankle and Carbin, 2019; Michel et al., 2019; Voita et al., 2019). We do not perform pruning over biases and layer normalization parameters, since they correspond to less than 1% of the total parameters, which is insignificant. Also, we do not prune the embeddings, as they are data specific parameters. All are kept fixed after training the multilingual model.

Inference: After finishing the training for each bilingual pair, we get the final mask over all the parameters of the model. Values of the mask range from $1 \rightarrow N$, where N is the total number of bilingual pairs. Each model parameter is masked according to the bilingual pair of interest. To predict a translation for the t^{th} pair, all the parameters learned for languages $1 \rightarrow t$ will be used, as shown in figure 1(f) and (g).

4 Experiments

4.1 Datasets

We use the TED talks (Qi et al., 2018) in all our experiments, and all the numbers are BLEU (Papineni et al., 2002) scores over the test set[1]. Here we have chosen to train on 8 English centring language pairs[2] en-xx covering a spectrum of sizes from high resource *Ar (Arabic)*, 214K to low resource *Be (Belarusian)*, 4.5K.

4.2 Training

Architecture: We use Transformer architecture (Vaswani et al., 2017), implemented in `fairseq` (Ott et al., 2019), which was modified to include the pruning and masking modules. We train a joint BPE model (Sennrich et al., 2016) on all languages to the vocabulary size of 40K. The Transformer (Vaswani et al., 2017) architecture used in this work[3] has 8 attention heads, 6 encoder and decoder layers, an embedding size of 512, and a feed-forward dimension of 2048. We set the dropout to 0.3.

MNMT Training: We train a standard MNMT model following similar settings as Johnson et al. (2017). A single many-to-many model is trained on all the English-centric data, using a source-side control token to indicate the target language. We use Adam (Kingma and Ba, 2015) with an inverse square root schedule, with 4500 warm-up updates and a maximum learning rate of 0.0003. We set the maximum batch size per GPU to 3050 tokens and train on 4 GPUs. Like Arivazhagan et al. (2019), to avoid the size imbalance, we use the temperature-based sampling strategy with $T = 5$. The MNMT is trained for 40 epochs over 8 English-centric language pairs, i.e., 16 directions. As shown in table 1, we train a strong parent MNMT baseline.

Pruning MNMT: We prune 50% of parameters from a fully converged MNMT model, and retrain the surviving parameters on the same multilingual dataset for ten more epochs, to compensate for the lost parameters.

Adapting MNMT to bilingual specific representations: After pruning the MNMT model, we select each bi-direction datasets (en-xx and xx-en) in the descending order of dataset sizes. We use the original source side control token, reset the learning rate scheduler and train all the free parameters for 20 epochs. Then, we prune 75% of parameters from the current bilingual specific parameters and retrain for ten more epochs to compensate for heavy pruning.

Pruning ratios are decided based on the trade off between the accuracy lost and the space left to adapt all the languages. We prune 50-70% of parameters from the parent MNMT and observe that it leads to a drop of 0.29-1.98 Bleu score. Therefore, we select 50% to be the first pruning ratio, and is kept constant in all the experiments. The second pruning ratio is kept 75% such that the last language pairs get at least 2-5% of parameters. More variations in the second pruning ratio is demonstrated in section 5.4.

5 Results and Discussions

5.1 Overcoming interference for high resource pairs:

In table 1, we present a comparative study of a high resource language scenario, severely affected by negative interference. Adapted MNMT outperforms the parent MNMT on all the 8 directions, with an average improvement of +1.40 on xx-en, and +1.32 on en-xx directions, and closes the gap with high performing bilingual baselines.

Analysing model capacity and negative interference: Now, we expound on the problems of model capacity and interference. As shown in table 1, pruning 50% of parameters from the parent MNMT model leads to an average loss of just 0.29 BLEU points. This observation confirms, that there exists large redundancies even in a 9-language MNMT model. The drop in the performance of an MNMT over its counterpart bilingual models is loosely associated with the lack of capacity. As can be seen in figure 2, by using only a fraction of parameters for each bilingual pair, we can significantly improve the performance over the parent MNMT. Our results demonstrate the ability of parameter-free adaptation to fight negative interference, and improve the performance of severely affected high resource language pairs.

	Adapted MNMT	32.68	38.41	38.31	41.04	16.72	27.63	25.76	35.76

Table 1: BLEU scores of our models on the TED test sets compared to the literature, (1) - Bilingual baselines. (2) - Multilingual models scores. Here Aharoni et al. (2019) and Philip et al. (2020) are trained on 59 and 20 languages respectively. Parent MNMT is our multilingual model trained till convergence on 9 languages. 50% pruned MNMT is the compressed parent MNMT. Adapted MNMT is the proposed model.

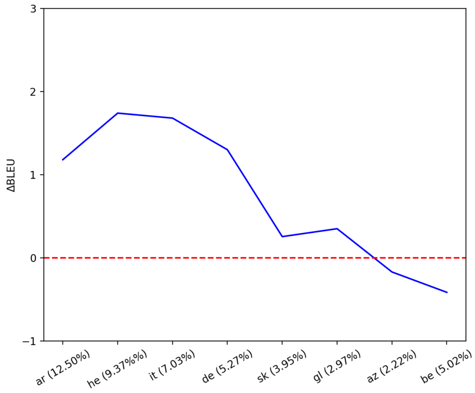

Figure 2: Absolute difference in the BLEU scores, with the parent MNMT, for 8 bilingual pairs. Each bilingual pair is the average over both the English-centric directions. The languages are arranged in the exact order of the training sequence. Numbers on the x-axis are percentages of the bilingual specific parameters used.

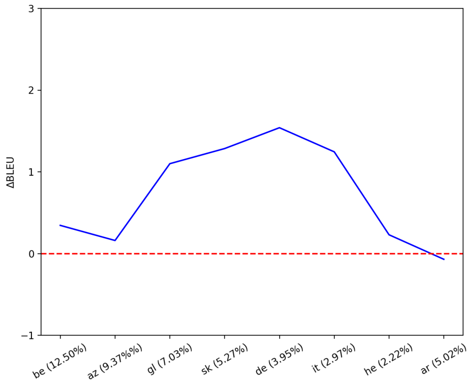

Figure 3: Same as figure 2, trained in the reverse order

5.2 Analysing differences in the adaptation of high and low resource pairs:

To understand the impact of parameter-free adaptation on both the high and low resource language pairs in an unbiased setting. We train two models in opposite orders of adding bilingual pairs. First, we train in the order of high to low resource languages (Ar to Be). Second, we train in the order of low to high resource languages (Be to Ar). Now, we assign the same proportion of parameters, to the high and low resource languages (Ar, He) in case 1, and (Be, Az) in case 2 respectively. As evident from figure 2 and 3, the improvements in Ar and He in case 1 is significantly more, than the improvement in Be and Az in case 2. This observation agrees with the fact that negative interference severely affects the high resource languages in an MNMT, and it needs adaptation to be improved. But, the performance of low resource languages in an MNMT, is already near saturation due to the positive transfer from high resource languages. Hence, to extract the most out of parameter-free adaptation, it is better to prune and retrain the network in the order of high to low resource languages. This assigns high proportion of parameters to high resource pairs, to effectively overcome negative interference.

5.3 Zero-shot Translation:

Zero-shot translation in the context of MNMT, refers to inference between pairs that are not seen directly during the training phase xx-xx. We show that we retain this important ability in our adapted MNMT. Adapted MNMT consists of 50% pruned MNMT weights and 50% language specific weights. The pruned MNMT weights are used to evaluate on zero-shot pairs, just like a traditional MNMT by appending the source side language control token

		xx→ *en*				*en*→ *xx*			
		Ar	*He*	*It*	*De*	*Ar*	*He*	*It*	*De*
(Bilingual)	Full-FT	33.89	39.66	41.64	40.00	17.38	27.50	36.72	29.87
(Multilingual)	Ar only	33.01	-	-	-	16.80	-	-	-
	Ar-He	33.21	38.26	-	-	16.72	25.52	-	-
	Ar-He-It	32.99	38.45	41.03	-	16.61	26.00	35.56 -	
	Ar-He-It-De	32.68	38.43	41.14	38.39	16.72	25.89	36.08	27.25

Table 2: Full-FT represents the bilingual models derived from finetuning the full parent MNMT. Rest are the adapted MNMTs adapted over 50% free parameters of the pruned MNMT. 1) Ar only with 50% parameters, 2) Ar, He with 25% each, 3) Ar, He, It with 16.6% each, and 4) Ar, He, It, De with 12.5% each.

Johnson et al. (2017). As shown in figure 4, adapted MNMT performs as good as the parent MNMT on all the 56, xx-xx directions even with only 50% of the total parameters.

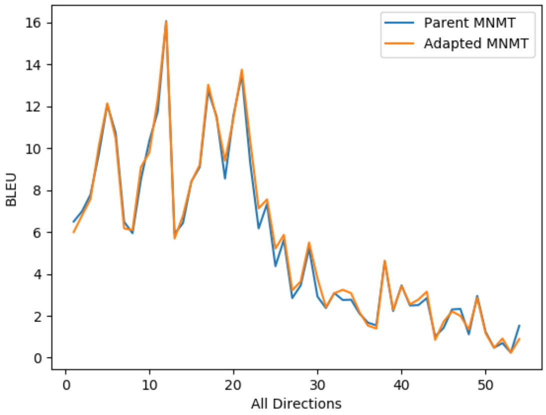

Figure 4: Absolute BLEU scores for the parent and the adapted MNMT on all the 56 zero-shot xx-xx pairs arranged from high to low resource.

5.4 Adapting to a subset of languages and retaining the multilinguality:

Due to limited and fixed number of parameters, we cannot adapt to arbitrary number of languages. However, this framework allows high flexibility in adapting the parent MNMT to only the languages of interest, while retaining the multilinguality simultaneously. We adapt the parent MNMT to four models: 1) Ar, 2) Ar, He, 3) Ar, He, It and, 4) Ar, He, It, De. This way, we can assign all the free parameters to only the languages of interest and increase their capacities. The first pruning ratio is set to 50% for all four models. The second pruning ratio is set such that each language receives equal proportion of parameters. From the results in table 2, we observe that assigning more parameters improve the performance marginally. The four adapted MNMTs have similar performances, even with a significant difference in the proportion of parameters assigned for each language. The 4^{th} model, with only 12.5% parameters reserved for Ar, performs competitively with the 1^{st} model with 50% parameters for Ar. This implies, that a small fraction of parameters can effectively overcome negative interference, hence allowing space to adapt to multiple languages. To infer on the remaining languages which are not adapted, we can use 50% pruned MNMT weights, as done for zero-shot translation in the previous section, hence retaining the multilinguality.

In table 2, we also compare the results of the four adapted MNMTs, with naive finetuning of the full parent MNMT to bilingual pairs (Full-FT). The difference between naive finetuning and the proposed adaptation approach is that the former uses all the 100% of model parameters and the embeddings to adapt to a single bilingual pair, thus the multilinguality is lost. While in our approach, the pruned MNMT weights and the embeddings are fixed, and we only retrain the free parameters very efficiently, allowing to adapt to multiple languages. As can be seen in table 2, adapted MNMTs perform competitively with Full-FT while retaining the multilinguality.

6 Conclusion

We investigate the problems of model capacity and negative interference in multilingual neural machine translation. We show that even a 9 language MNMT has a large proportion of redundant parameters, which are efficiently retrained to overcome interference. We propose a parameter-free adaptation strategy. Where, we use iterative pruning and retraining to improve bilingual representations, without any additional parameters. We hope that our work will attract more attention to practical and efficient ways of adapting an MNMT.

Abstract

Recently, deep neural networks (DNNs) have achieved great success in semantically challenging NLP tasks, yet it remains unclear whether DNN models can capture *compositional* meanings, those aspects of meaning that have been long studied in formal semantics. To investigate this issue, we propose a Systematic Generalization testbed based on Natural language Semantics (SyGNS), whose challenge is to map natural language sentences to multiple forms of scoped meaning representations, designed to account for various semantic phenomena. Using SyGNS, we test whether neural networks can systematically parse sentences involving novel combinations of logical expressions such as quantifiers and negation. Experiments show that Transformer and GRU models can generalize to unseen combinations of quantifiers, negations, and modifiers that are similar to given training instances in form, but not to the others. We also find that the generalization performance to unseen combinations is better when the form of meaning representations is simpler. The data and code for SyGNS are publicly available at `https://github.com/verypluming/SyGNS`.

1 Introduction

Deep neural networks (DNNs) have shown impressive performance in various language understanding tasks (Wang et al., 2019a,b, i.a.), including semantically challenging tasks such as Natural Language Inference (NLI; Dagan et al., 2013; Bowman et al., 2015). However, a number of studies to probe DNN models with various NLI datasets (Naik et al., 2018; Dasgupta et al., 2018; Yanaka et al., 2019; Kim et al., 2019; Richardson et al., 2020; Saha et al., 2020; Geiger et al., 2020) have reported that current DNN models have some limitations to generalize to diverse semantic phenomena, and it is still not clear whether DNN models obtain the ability to capture *compositional* aspects of meaning in natural language.

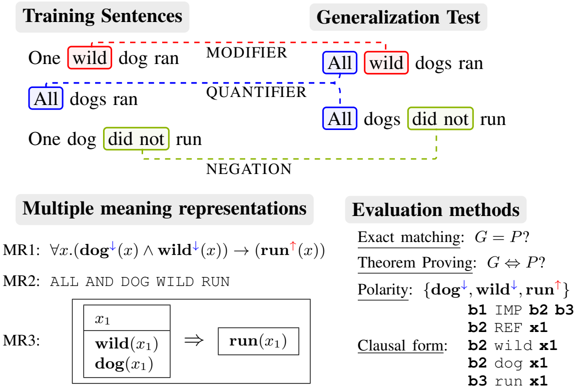

Figure 1: Illustration of our evaluation protocol using SyGNS. The goal is to map English sentences to meaning representations. The generalization test evaluates novel combinations of operations (modifier, quantifier, negation) in the training set. We use multiple meaning representations and evaluation methods.

There are two issues to consider here. First, recent analyses (Talmor and Berant, 2019; Liu et al., 2019; McCoy et al., 2019) have pointed out that the standard paradigm for evaluation, where a test set is drawn from the same distribution as the training set, does not always indicate that the model has obtained the intended generalization ability for language understanding. Second, the NLI task of predicting the relationship between a premise sentence and an associated hypothesis without asking their semantic interpretation tends to be *black-box*, in that it is often difficult to isolate the reasons why models make incorrect predictions (Bos, 2008).

To address these issues, we propose SyGNS (pronounced as *signs*), a Systematic Generalization testbed based on Natural language Semantics. The goal is to map English sentences to various meaning representations, so it can be taken as a sequence-to-sequence semantic parsing task.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 103–119
August 1–6, 2021. ©2021 Association for Computational Linguistics

Figure 1 illustrates our evaluation protocol using SyGNS. To address the first issue above, we probe the generalization capability of DNN models on two out-of-distribution tests: *systematicity* (Section 3.1) and *productivity* (Section 3.2), two concepts treated as hallmarks of human cognitive capacities in cognitive sciences (Fodor and Pylyshyn, 1988; Calvo and Symons, 2014). We use a train-test split controlled by each target concept and train models with a minimally sized training set (Basic set) involving primitive patterns composed of semantic phenomena such as quantifiers, modifiers, and negation. If a model learns different properties of each semantic phenomenon from the Basic set, it should be able to parse a sentence with novel combination patterns. Otherwise, a model has to memorize an exponential number of combinations of linguistic expressions.

To address the second issue, we use multiple forms of meaning representations developed in formal semantics (Montague, 1973; Heim and Kratzer, 1998; Jacobson, 2014) and their respective evaluation methods. We use three *scoped* meaning representation forms, each of which preserves the same semantic information (Section 3.3). In formal semantics, it is generally assumed that scoped meaning representations are standard forms for handling diverse semantic phenomena such as quantification and negation. Scoped meaning representations also enable us to evaluate the compositional generalization ability of the models to capture semantic phenomena in a more fine-grained way. By decomposing an output meaning representation into constituents (e.g., words) in accordance with its structure, we can compute the matching ratio between the output representation and the gold standard representation. Evaluating the models on multiple meaning representation forms also allows us to explore whether the performance depends on the complexity of the representation forms.

This paper provides three main contributions. First, we develop the SyGNS testbed to test model ability to systematically transform sentences involving linguistic phenomena into multiple forms of scoped meaning representations. The data and code for SyGNS are publicly available at `https://github.com/verypluming/SyGNS`. Second, we use SyGNS to analyze the systematic generalization capacity of two standard DNN models: Gated Recurrent Unit (GRU) and Transformer. Experiments show that these models can generalize to unseen combinations of quantifiers, negations, and modifiers to some extent. However, the generalization ability is limited to the combinations whose forms are similar to those of the training instances. In addition, the models struggle with parsing sentences involving nested clauses. We also show that the extent of generalization depends on the choice of primitive patterns and representation forms.

2 Related Work

The question of whether neural networks obtain the systematic generalization capacity has long been discussed (Fodor and Pylyshyn, 1988; Marcus, 2003; Baroni, 2020). Recently, empirical studies using NLI tasks have revisited this question, showing that current models learn undesired biases (Glockner et al., 2018; Poliak et al., 2018; Tsuchiya, 2018; Geva et al., 2019; Liu et al., 2019) and heuristics (McCoy et al., 2019), and fail to consistently learn various inference types (Rozen et al., 2019; Nie et al., 2019; Yanaka et al., 2019; Richardson et al., 2020; Joshi et al., 2020). In particular, previous works (Goodwin et al., 2020; Yanaka et al., 2020; Geiger et al., 2020; Yanaka et al., 2021) have examined whether models learn the systematicity of NLI on monotonicity and veridicality. While this line of work has shown certain limitations of model generalization capacity, it is often difficult to figure out why the NLI model fails and how to improve it, partly because NLI tasks depend on multiple factors, including semantic interpretation of target phenomena and acquisition of background knowledge. By focusing on semantic parsing rather than NLI, one can probe to what extent models systematically interpret the meaning of sentences according to their structures and the meanings of their constituents.

Meanwhile, datasets for analysing the compositional generalization ability of DNN models in semantic parsing have been proposed, including SCAN (Lake and Baroni, 2017; Baroni, 2020), CLUTRR (Sinha et al., 2019), and CFQ (Keysers et al., 2020). For example, the SCAN task is to investigate whether models trained with a set of primitive instructions (e.g., *jump* → `JUMP`) and modifiers (e.g., *walk twice* → `WALK WALK`) generalize to new combinations of primitives (e.g., *jump twice* → `JUMP JUMP`). However, these datasets deal with artificial languages, where the variation of linguistic expressions is limited, so it is not clear to what extent the models systematically interpret various semantic phenomena in natural language, such as quantification and negation.

Regarding the generalization capacity of DNN models in natural language, previous studies have focused on syntactic and morphological generalization capacities such as subject-verb agreement tasks (Linzen et al., 2016; Gulordava et al., 2018; Marvin and Linzen, 2018, i.a.). Perhaps closest to our work is the COGS task (Kim and Linzen, 2020) for probing the generalization capacity of semantic parsing in a synthetic natural language fragment. For instance, the task is to see whether models trained to parse sentences where some lexical items only appear in subject position (e.g., *John ate the meat*) can generalize to structurally related sentences where these items appear in object position (e.g., *The kid liked John*). In contrast to this work, our focus is more on semantic parsing of sentences with logical and semantic phenomena that require scoped meaning representations. Our study also improves previous work on the compositional generalization capacity in semantic parsing in that we compare three types of meaning representations and evaluate them at multiple levels, including logical entailment, polarity assignment, and partial clause matching (Section 3.3).

3 Overview of SyGNS

We use two evaluation concepts to assess the systematic capability of models: systematicity (Section 3.1) and productivity (Section 3.2). In evaluating these two concepts, we use synthesized pairs of sentences and their meaning representations to control a train-test split (Section 3.4). The main idea is to analyze models trained with a minimum size of a training set (Basic set) involving primitive patterns composed of various semantic phenomena; if a model systematically learns primitive combination patterns in the Basic set, it should parse a new sentence with different combination patterns. We target three types of scoped meaning representations and use their respective evaluation methods, according to the function and structure of each representation form (Section 3.3).

3.1 Systematicity

Pattern		Sentence
		Train
Primitive quantifier		**One** tiger ran
Basic 1	EXI	**A** tiger ran
	NUM	**Two** tigers ran
	UNI	**Every** tiger ran
Basic 2	ADJ	**One** *small* tiger ran
	ADV	**One** tiger ran *quickly*
	CON	**One** tiger ran *or came*
		Test
EXI+ADJ		**A** *small* tiger ran
NUM+ADV		**Two** tigers ran *quickly*
UNI+CON		**Every** tiger ran *or came*

Table 1: Training and test instances for systematicity.

Table 1 illustrates how we test systematicity, i.e., the capacity to interpret novel combinations of primitive semantic phenomena. We generate Basic set 1 by combining various quantifiers with sentences without modifiers. We also generate Basic set 2 by setting an arbitrary quantifier (e.g., *one*) to a primitive quantifier and combining it with various types of modifiers. We then evaluate whether models trained with Basic sets 1 and 2 can parse sentences involving unseen combinations of quantifiers and modifiers. We also test the combination of quantifiers and negation in the same manner; the detail is given in Appendix D.

To provide a controlled setup, we use three quantifier types: existential quantifiers (EXI), numerals (NUM), and universal quantifiers (UNI). Each type has two patterns: *one* and *a* for EXI, *two* and *three* for NUM, and *all* and *every* for UNI. We consider three settings where the primitive quantifier is set to the type EXI, NUM, or UNI.

For modifiers, we distinguish three types — adjectives (ADJ), adverbs (ADV), and logical connectives (CON; conjunction *and*, disjunction *or*) — and ten patterns for each. Note that each modifier type differs in its position; an adjective appears inside a noun phrase (e.g., one *small* tiger), while an adverb (e.g., *quickly*) and a coordinated phrase with a logical connective (e.g., *or came*) appears at the end of a sentence. Although Table 1 only shows the pattern generated by the primitive quantifier *one* and the noun *tiger*, the noun can be replaced with ten other nouns (e.g., *dog*, *cat*, etc.) in each setting. See Appendix A for more details on the fragment of English considered here.

3.2 Productivity

Productivity refers to the capacity to interpret an indefinite number of sentences with recursive operations. To test productivity, we use embedded relative clauses, which interact with quantifiers to gen-

Pattern		Sentence
Train (Basic 1: depth 0, Basic 2: depth 1)		
Basic 1	NON	Two dogs loved Ann
Basic 2	PER	Bob liked a bear [that chased all polite cats]
	CEN	Two dogs [that all cats kicked] loved Ann
Test (examples: depth 2)		
PER+PER		Bob liked a bear [that chased all polite cats [that loves Ann]]
PER+CEN		Two dogs [that a bear [that chased all polite cats] kicked] loved Ann

Table 2: Training and test instances for productivity.

erate logically complex sentences. Table 2 shows examples. We provide two Basic sets; Basic set 1 consists of sentences without embedded clauses (NON) and Basic set 2 consists of sentences with a single embedded clause, which we call sentences with depth one. We then test whether models trained with Basic sets 1 and 2 can parse a sentence involving deeper embedded clauses, i.e., sentences whose depth is two or more. As Table 2 shows, we consider both peripheral-embedding (PER) and center-embedding (CEN) clauses.

3.3 Meaning representation and evaluation

Overview To evaluate generalization capacity in semantic parsing at multiple levels, we use three types of scoped meaning representations: (i) First-Order Logic (FOL) formulas, (ii) Discourse Representation Structures (DRSs; Kamp and Reyle, 1993), and (iii) Variable-Free (VF) formulas (Baader et al., 2003; Prat-Hartmann and Moss, 2009). DRSs can be converted to *clausal forms* (van Noord et al., 2018a) for evaluation. For instance, the sentence (1) is mapped to the FOL formula in (2), the DRS in (3a), its clausal form in (3b), and the VF formula in (4).

(1) One white dog did not run.

(2) $\exists x_1.(\mathbf{white}(x_1) \wedge \mathbf{dog}(x_1) \wedge \neg\mathbf{run}(x_1))$

(3) a. $\begin{array}{|l|} \hline x_1 \\ \hline \mathbf{white}(x_1) \\ \mathbf{dog}(x_1) \\ \neg\ \boxed{\mathbf{run}(x_1)} \\ \hline \end{array}$

b. **b1** REF **x1**
b1 white **x1**
b1 dog **x1**
b1 NOT **b2**
b2 run **x1**

(4) EXIST AND WHITE DOG NOT RUN

Using these multiple forms enables us to analyze whether the difficulty in semantic generalization depends on the format of meaning representations.

Previous studies for probing generalization capacity in semantic parsing (e.g., Lake and Baroni, 2017; Sinha et al., 2019; Keysers et al., 2020; Kim and Linzen, 2020) use a fixed type of meaning representation, with its evaluation method limited to the exact-match percentage, where an output is considered correct only if it exactly matches the gold standard. However, this does not properly assess whether models capture the structure and function of meaning representation. First, exact matching does not directly take into account whether two meanings are logically equivalent (Blackburn and Bos, 2005): for instance, schematically two formulas $A \wedge B$ and $B \wedge A$ are different in form but have the same meaning. Relatedly, scoped meaning representations for natural languages can be made complex by including parentheses and variable renaming mechanism (the so-called α-conversion in λ-calculus). For instance, we want to identify two formulas which only differ in variable naming, e.g., $\exists x_1.F(x_1)$ and $\exists x_2.F(x_2)$. It is desirable to compare exact matching with alternative evaluation methods, and to consider alternative meaning representations that avoid these problems. Having this background in mind, below we will describe each type of meaning representation in detail.

FOL formula FOL formulas are standard forms in formal and computational semantics (Blackburn and Bos, 2005; Jurafsky and Martin, 2009), where content words such as nouns and verbs are represented as predicates, and function words such as quantifiers, negation, and connectives are represented as logical operators with scope relations (cf. the example in (2)). To address the issue on evaluation, we consider two ways of evaluating FOL formulas in addition to exact matching: (i) automated theorem proving (ATP) and (ii) monotonicity-based polarity assignment.

First, FOL formulas can be evaluated by checking the logical entailment relationships that directly consider whether two formulas are logically equivalent. Thus we evaluate predicted FOL formulas by using ATP. We check whether a gold formula G entails prediction P and vice versa, using an off-the-shelf FOL theorem prover[1]. To see the logical relationship between G and P, we measure the accuracy for unidirectional and bidirectional

---

[1] We use a state-of-the-art FOL prover Vampire available at `https://github.com/vprover/vampire`

One dog$^{\uparrow}$ ran$^{\uparrow}$:	$\exists x.(\mathbf{dog}^{\uparrow}(x) \wedge \mathbf{run}^{\uparrow}(x))$
All dogs$^{\downarrow}$ ran$^{\uparrow}$:	$\forall x.(\mathbf{dog}^{\downarrow}(x) \rightarrow \mathbf{run}^{\uparrow}(x))$
All dogs$^{\downarrow}$ did not run$^{\downarrow}$:	$\forall x.(\mathbf{dog}^{\downarrow}(x) \rightarrow \neg\mathbf{run}^{\downarrow}(x))$

Table 3: Examples of monotonicity-based polarity assignments for FOL formulas.

entailment: $G \Rightarrow P$, $G \Leftarrow P$, and $G \Leftrightarrow P$.

Second, the polarity of each content word appearing in a sentence can be extracted from the FOL formula using its monotonicity property (van Benthem, 1986; MacCartney and Manning, 2007). This enables us to analyze whether models can correctly capture entailment relations triggered by quantifier and negation scopes. Table 3 shows some examples of monotonicity-based polarity assignments. For example, existential quantifiers such as *one* are upward monotone (shown as ↑) with respect to the subject NP and the VP, because they can be substituted with their hypernyms (e.g., *One dog ran* ⇒ *One animal moved*). These polarities can be extracted from the FOL formula because $\exists$ and $\wedge$ are upward monotone operators in FOL. Universal quantifiers such as *all* are downward monotone (shown as ↓) with respect to the subject NP and upward monotone with respect to the VP. Expressions in downward monotone position can be substituted with their hyponymous expressions (e.g., *All dogs ran* ⇒ *All white dogs ran*). The polarity can be reversed by embedding another downward entailing context like negation, so the polarity of *run* in the third case in Table 3 is flipped to downward monotone.[2] For evaluation based on monotonicity, we extract a polarity for each content word in a gold formula and a prediction and calculate the F-score for each monotonicity direction (upward and downward).

DRS A DRS is a form of scoped meaning representations proposed in Discourse Representation Theory, a well-studied formalism in formal semantics (Kamp and Reyle, 1993; Asher, 1993; Muskens, 1996). By translating a box notation as in (3a) to the clausal form as in (3b), one can evaluate DRSs by COUNTER[3], which is a standard tool for evaluating neural DRS parsers (Liu et al., 2018; van Noord et al., 2018b). COUNTER searches for the best variable mapping between predicted DRS clauses and gold DRS clauses and calculates an F-score over matching clause, which is similar to SMATCH (Cai and Knight, 2013), an evaluation metric designed for Abstract Meaning Representation (AMR; Banarescu et al., 2013). COUNTER alleviates the process of variable renaming and correctly evaluates the cases where the order of clauses is different from that of gold answers.

VF formula FOL formulas in our fragment have logically equivalent forms in a variable-free format, which does not contain parentheses nor variables as in the example (4). Our format is similar to a variable-free form in Description Logic (Baader et al., 2003) and Natural Logic (Prat-Hartmann and Moss, 2009). VF formulas alleviate the problem of parentheses and variable renaming, while preserving semantic information (cf. Wang et al., 2017). Due to the equivalence with FOL formulas, it is possible to extract polarities from VF formulas. See Appendix A for more examples of VF formulas.

3.4 Data generation

To provide synthesized data, we generate sentences using a context-free grammar (CFG) associated with semantic composition rules in the standard λ-calculus (see Appendix A for details). Each sentence is mapped to an FOL formula and VF formula by using the semantic composition rules specified in the CFG. DRSs are converted from the generated FOL formulas using the standard mapping (Kamp and Reyle, 1993). To generate controlled fragments for each train-test split, the CFG rules automatically annotate the types of semantic phenomena involved in sentences generated. We annotate seven types: the positions of quantifiers (subject or object), negation, adjectives, adverbs, conjunction, disjunction, and embedded clause types (peripheral or center embedding).

To test systematicity, we generate sentences using the CFG, randomly select 50,000 examples, and then split them into 12,000 training examples and 38,000 test examples according to a primitive quantifier. To test productivity, we apply up to four recursive rules and randomly select 20,000 examples for each depth.

4 Experiments and Analysis

Using SyGNS, we test the performance of Gated Recurrent Unit (GRU; Cho et al., 2014) and Transformer (Vaswani et al., 2017) in an encoder-decoder setup. These are widely used models

---

[2] We follow the surface order of NPs and take it that the subject NP always take scope over the VP.

to perform well on hierarchical generalization tasks (McCoy et al., 2018; Russin et al., 2020).

4.1 Experimental setup

In all experiments, we trained each model for 25 epochs with early stopping (patience = 3). We performed five runs and reported their average accuracies. The input sentence is represented as a sequence of words, using spaces as a separator. The maximum input and output sequence length is set to the length of a sequence with maximum depths of embedded clauses. We set the dropout probability to 0.1 on the output and used a batch size of 128 and an embedding size of 256. Since incorporating pre-training would make it hard to distinguish whether the models’ ability to perform semantic parsing comes from training data or from pre-training data, we did not use any pre-training.

For the GRU, we used a single-layer encoder-decoder with global attention and a dot-product score function. Since a previous work (Kim and Linzen, 2020) reported that unidirectional models are more robust regarding sentence structures than bi-directional models, we selected a unidirectional GRU encoder. For the Transformer, we used a three-layer encoder-decoder, a model size of 512, and a hidden size of 256. The number of model parameters was 10M, respectively. See Appendix B for additional training details.

4.2 Results on systematicity

Generalization on quantifiers Table 4 shows the accuracy by quantifier type. When the existential quantifier *one* was the primitive quantifier, the accuracy on the problems involving existential quantifiers, which have the same type as the primitive quantifier, was nearly perfect. Similarly, when the universal quantifier *every* was the primitive quantifier, the accuracy on the problems involving universal quantifiers was much better than that on the problems involving other quantifier types. These results indicate that models can easily generalize to problems involving quantifiers of the same type as the primitive quantifier, while the models struggle with generalizing to the others. We also experimented with larger models and observed the same trend (see Appendix C). The extent of generalization varies according to the primitive quantifier type and meaning representation forms. For example, when the primitive quantifier is the numeral expression *two*, models generalize to problems of VF formulas involving universal quantifiers. This can be explained by the fact that VF formulas involving universal quantifiers like (5b) have a similar form to those involving numerals as in (6b), whereas FOL formulas involving universal quantifiers have a different form from those involving numerals as in (5c) and (6c).

(5) a. All small cats chased Bob
    b. `ALL AND CAT SMALL EXIST BOB CHASE`
    c. $\forall x_1.(\mathbf{cat}(x_1) \wedge \mathbf{small}(x_1) \rightarrow \exists x_2.(\mathbf{bob}(x_2) \wedge \mathbf{chase}(x_1, x_2)))$

(6) a. Two small cats chased Bob
    b. `TWO AND CAT SMALL EXIST BOB CHASE`
    c. $\exists x_1.(\mathbf{two}(x_1) \wedge \mathbf{cat}(x_1) \wedge \mathbf{small}(x_1) \wedge \exists x_2.(\mathbf{bob}(x_2) \wedge \mathbf{chase}(x_1, x_2)))$

We also check the performance when three quantifiers *one*, *two*, and *every* are set as primitive quantifiers. This setting is easier than that for the systematicity in Table 1, since the models are exposed to combination patterns of all the quantifier types and all the modifier types. In this setting, the models achieved almost perfect performance on the test set involving non-primitive quantifiers (*a*, *three*, *all*).

Generalization on modifiers Table 5 shows the accuracy by modifier type where *one* is set to the primitive quantifier (see Appendix C for the results where other quantifier types are set to the primitive quantifier). No matter which quantifier is set as the primitive quantifier, the accuracy for problems involving logical connectives or adverbs is better than those involving adjectives. As in (8), an adjective is placed between a quantifier and a noun, so the position of the noun *dog* with respect to the quantifier *every* in the test set changes from the example in the training (Basic) set in (7). In contrast, adverbs and logical connectives are placed at the end of a sentence, so the position of the noun does not change from the training set, as in (9). This suggests that models can more easily generalize in problems involving unseen combinations of quantifiers and modifiers where the position of the noun is the same between the training and test sets.

(7) Every dog ran   Train (Basic set)
(8) Every large dog ran   Test (ADJ)
(9) Every dog ran and cried   Test (CON)

Table 5 also shows that the accuracy is nearly the same regardless of the existence of negation. Basic set contains examples involving negation, and this indicates that the existence of complex phenomena like negation does not affect generalization performance of models on modifiers so long as such phenomena are included in the training set.

Meaning representation comparison Comparing forms of meaning representations, accuracy by exact matching is highest in the order of VF formulas, DRS clausal forms, and FOL formulas. This indicates that models can more easily generalize to unseen combinations where the form of meaning representation is simpler; VF formulas do not contain parentheses nor variables, DRS clausal forms contain variables but not parentheses, and FOL formulas contain both parentheses and variables.

4.3 Model comparison

Regarding the generalization capacity of models for decoding meaning representations, the left two figures in Figure 2 show learning curves on FOL prediction tasks by quantifier type. While GRU achieved perfect performance on the same quantifier type as the primitive quantifier, where the number of training data is 2,500, Transformer achieved the same performance when the number of training data is 8,000. The right two figures in Figure 2 show learning curves by modifier type. The GRU accuracy is unstable even when the number of training examples is maximal. In contrast, the Transformer accuracy is stable when the number of training data exceeds 8,000. These results indicate that GRU generalizes to unseen combinations of quantifiers and modifiers with a smaller training set than can Transformer, while the Transformer performance is more stable than that of GRU.

ATP-based evaluation Table 6 shows the ATP-based evaluation results on FOL formulas. For combinations involving numerals, both GRU and Transformer achieve high accuracies for $G \Rightarrow P$ entailments but low accuracies for $G \Leftarrow P$ entailments. Since both models fail to output the formulas corresponding to modifiers, they fail to prove $G \Leftarrow P$ entailments. Regarding combinations involving universal quantifiers, the GRU accuracy for both $G \Rightarrow P$ and $G \Leftarrow P$ entailments is low, and the Transformer accuracy for $G \Leftarrow P$ entailments is much higher than that for $G \Rightarrow P$ entailments. As indicated by examples shown in Table 7,

Test	GRU		Transformer	
	Up	Down	Up	Down
EXI	99.9	100.0	100.0	100.0
NUM	84.8	96.8	88.1	97.5
UNI	90.9	40.7	94.9	73.4

Table 8: Monotonicity-based evaluation results on FOL (primitive quantifier: *one*). "Up" and "Down" columns show upward and downward accuracy, respectively.

GRU tends to fail to output the formula for a modifier, e.g., $\mathbf{wild}(x)$ in this case, while Transformer fails to correctly output the position of the implication ($\rightarrow$). The ATP-based evaluation results reflect such differences between error trends of models in problems involving different forms of quantifiers.

Monotonicity-based evaluation Table 8 shows accuracies for the monotonicity-based polarity assignment evaluation on FOL formulas. The accuracies were higher than those using exact matching (cf. Table 4). Monotonicity-based evaluation captures the polarities assigned to content words even for the problems that exact-matching judges as incorrect because of the differences in form. Table 7 shows examples of predicted polarity assignments. Here both models predicted correct polarities for three content words, $\mathbf{cat}^{\downarrow}$, $\mathbf{escape}^{\uparrow}$, $\mathbf{run}^{\uparrow}$. Exact-matching cannot take into account such partial matching. The downward monotone accuracies for problems involving universal quantifiers are low (40.7 and 73.4 in Table 8). In Table 7, both models failed to predict the downward monotonicity of $\mathbf{wild}^{\downarrow}$. The results indicate that both models struggle with capturing the scope of universal quantifiers. Appendix C shows the evaluation results on the polarities of VF formulas.

4.4 Results on productivity

Table 9 shows very low generalization accuracy for both GRU and Transformer at unseen depths. Although the evaluation results using COUNTER on DRS prediction tasks is much higher than those by exact matching, this is due to the fact that COUNTER uses partial matching; both models tended to correctly predict the clauses in the subject NP that are positioned at the beginning of the

sentence (see Appendix E for details).

We checked whether models can generalize to unseen combinations involving embedded clauses when the models are exposed to a part of training instances at each depth. We provide Basic set 1 involving non-embedding patterns like (10), where **Q** can be replaced with any quantifier. This Basic set 1 exposes models to all quantifier patterns. We also expose models to Basic set 2 involving three primitive quantifiers (*one*, *two*, and *every*) at each embedding depth, like (11) and (12). We provide around 2,000 training instances at each depth. We then test models on a test set involving the other quantifiers (*a*, *three*, and *all*) at each embedding depth, like (13) and (14). If models can distinguish quantifier types during training, they can correctly compose meaning representations involving different combinations of multiple quantifiers. Note that this setting is easier than that for productivity in Table 2, in that models are exposed to some instances at each depth.

(10) **Q** dog(s) liked Bob

(11) **One** dog liked Bob [that loved **two** rats]

(12) **One** dog liked Bob [that loved **two** rats [that knew **every** pig]]

(13) **A** dog liked Bob [that loved **three** rats]

(14) **A** dog liked Bob [that loved **three** rats [that knew **all** pigs]]

Table 10 shows that both models partially generalize to the cases where the depth is 1 or 2. However, both models fail to generalize to the cases where the depth is 3 or more. This suggests that even if models are trained with some instances at each depth, the models fail to learn distinctions between different quantifier types and struggle with parsing sentences whose embedding depth is 3 or more.

5 Conclusion

We have introduced an analysis method using SyGNS, a testbed for diagnosing the systematic generalization capability of DNN models in semantic parsing. We found that GRU and Transformer generalized to unseen combinations of semantic phenomena whose meaning representations are similar in forms to those in a training set, while the models struggle with generalizing to the others. In addition, these models failed to generalize to cases involving nested clauses. Our analyses using multiple meaning representation and evaluation methods also revealed detailed behaviors of models. We believe that SyGNS serves as an effective testbed for investigating the ability to capture compositional meanings in natural language.

A Data generation details

Table 12 shows a set of context-free grammar rules and semantic composition rules we use to generate a fragment of English annotated with meaning representations in the SyGNS dataset. Each grammar rule is associated with two kinds of semantic composition rules formulated in λ-calculus. One is for deriving first-order logic (FOL) formulas, and the other is for deriving variable-free (VF) formulas. For FOL, semantic composition runs in the standard Montagovian fashion where all NPs (including proper nouns) are treated as generalized quantifiers (Heim and Kratzer, 1998; Jacobson, 2014). From FOL formulas, we can extract the *polarity* of each content word using the monotonicity calculus (Van Eijck, 2005). Table 13 shows some examples of polarized FOL formulas. The derivation of VF formulas runs in two steps. To begin with, a sentence is mapped to a variable-free form by semantic composition rules. For instance, the sentence *a small dog did not swim* is mapped to a variable-free formula `EXIST(AND(SMALL,DOG),NOT(SWIM))` by the rules in Table 12. Second, since this form is in prefix notation, all brackets can be eliminated without causing ambiguity. This produces the resulting VF formula `EXIST AND SMALL DOG NOT SWIM`. Some other examples are shown in Table 13. DRSs are converted from FOL formulas in the standard way (Kamp and Reyle, 1993).

B Training details

We implemented the GRU model and the Transformer model using PyTorch. Both models were optimized using Adam (Kingma and Ba, 2015) at an initial learning rate of 0.0005. The hyperparameters (batch size, learning rate, number of epochs, hidden units, and dropout probability) were tuned by random search. In all experiments, we trained models on eight NVIDIA DGX-1 Tesla V100 GPUs. The runtime for training each model was about 1-4 hours, depending on the size of the training set. The order of training instances was shuffled for each model. We used 10% of the training set for a validation set.

C Detailed evaluation results

Effect of Model Size The results we report are from a model with 10M parameters. How does the number of parameters affect the systematic generalization performance of models? Table 11 shows the performance of three models of varying size (large: 27M, medium: 10M, small: 4M). The number of parameters did not have a large impact on the generalization performance; all runs of the models achieved higher than 90% accuracy on the validation set and the test set involving quantifiers of the same type as the primitive quantifier, while they did not work well on the test set involving the other types of quantifiers.

Test	GRU			Transformer		
	4M	10M	27M	4M	10M	27M
Exi	96.8	99.9	97.1	99.9	99.8	99.3
Num	7.1	11.5	10.4	12.3	12.2	12.4
Uni	6.0	4.9	2.9	7.8	5.9	7.9
Valid	97.2	99.9	97.6	100.0	99.8	97.2

Table 11: The effect of model size on generalization performance (primitive quantifier: existential quantifier *one*, representation form: FOL).

Modifier type Table 14 shows all evaluation results by modifier types where *two* or *every* is set to the primitive quantifier. Regardless of primitive quantifier type, accuracies for problems involving logical connectives or adverbs were better than those for problems involving adjectives.

Monotonicity Table 15 shows all evaluation results of predicted FOL formulas and VF formulas based on monotonicity. We evaluate the precision, recall, and F-score for each monotonicity direction (upward and downward). Regardless of meaning representation forms, downward monotone accuracy on problems involving universal quantifiers is low. This indicates that both models struggle with learning the scope of universal quantifiers.

D Evaluation on systematicity of quantifiers and negation

We also analyze whether models can generalize to unseen combinations of quantifiers and negation. Here, we generate Basic set 1 by setting an arbitrary quantifier to a primitive quantifier and combining it with negation. As in (15b), we fix the primitive quantifier to the existential quantifier *one* and generate the negated sentence *One tiger did not run*. Next, as in (16a) and (16b), we generate Basic set 2 by combining a primitive term (e.g., *tiger*) with various quantifiers. If a model has the ability to systematically understand primitive combinations in Basic set, it can represent a new mean-

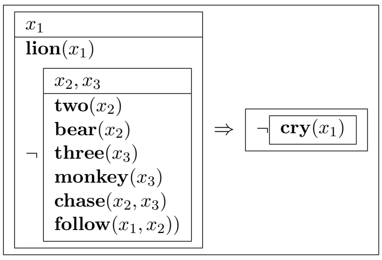
b. **Two** tigers *did not* run

Table 16 shows the accuracy on combinations of quantifiers and negations by quantifier type. Similar to the results with unseen combinations of quantifiers and modifiers, models can easily generalize to problems involving quantifiers of the same type as the primitive quantifier. Table 17 shows the accuracy on combinations of quantifiers and negations by modifier types. Similar to the results in Table 14, the accuracies on problems involving logical connectives or adverbs were slightly better than those on problems involving adjectives.

E Error analysis of predicted DRSs

In the productivity experiments, the evaluation results using COUNTER on DRS prediction tasks are much higher than those by exact matching. Table 18 shows an example of predicted DRSs for the sentence *all lions that did not follow two bears that chased three monkeys did not cry*. This sentence contains embedded clauses with depth two, having the following gold DRS:



Both GRU and Transformer tend to correctly predict some of the clauses for content words, implication, and negation that appear at the beginning of the input sentence, while they fail to capture long-distance dependencies between subject nouns and verbs (e.g., *all lions ... did not cry*). Also, COUNTER correctly evaluates the cases where the order of clauses is different from that of gold answers.

Fully Non-autoregressive Neural Machine Translation: Tricks of the Trade

Abstract

Fully non-autoregressive neural machine translation (NAT) simultaneously predicts tokens with single forward of neural networks, which significantly reduces the inference latency at the expense of quality drop compared to the Transformer baseline. In this work, we target on closing the performance gap while maintaining the latency advantage. We first inspect the fundamental issues of fully NAT models, and adopt *dependency reduction* in the learning space of output tokens as the primary guidance. Then, we revisit methods in four different aspects that have been proven effective for improving NAT models, and carefully combine these techniques with necessary modifications. Our extensive experiments on three translation benchmarks show that the proposed system achieves the state-of-the-art results for fully NAT models, and obtains comparable performance with the autoregressive and iterative NAT systems. For instance, one of the proposed models achieves **27.49** BLEU points on WMT14 En-De with **16.5**× speed-up compared to similar sized autoregressive baseline under the same inference condition. The implementation of our model is available here[1].

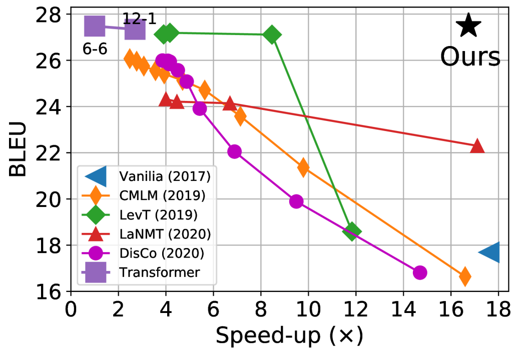

Figure 1: The translation quality v.s. inference speed-up on WMT'14 En→De test set. The upper right corner achieves the best trade-off.

1 Introduction

State-of-the-art neural machine translation (NMT) systems are based on autoregressive models (Bahdanau et al., 2015; Vaswani et al., 2017) where each generation step depends on the previously generated tokens. This sequential nature inevitably leads to inherent latency at inference time. On the other hand, non-autoregressive neural machine translation models (NAT, Gu et al., 2018a) attempt to generate output sequences in parallel to speed-up the decoding process. The incorrect independence assumption nevertheless prevents NAT models to properly learn the dependency between target tokens in real data distribution, resulting in poorer performance compared to autoregressive (AT) models. One popular solution to improve the NAT translation accuracy is to sacrifice the speed-up by incorporating an iterative refinement process, through which the model explicitly learns the conditional distribution over partially observed reference tokens (Ghazvininejad et al., 2019; Gu et al., 2019). However, recent studies (Kasai et al., 2020b) indicated that iterative NAT models seem to lose the speed advantage compared to AT models with careful tuning of the layer allocation. For instance, an AT model with *deep encoder and shallow decoder* obtains similar latency as iterative NAT models without hurting the translation accuracy.

Therefore, how to build a competitive fully NAT model without iterative refinements calls for more exploration. Several works (Ghazvininejad et al., 2020a; Saharia et al., 2020; Qian et al., 2020) have recently been proposed to improve the training of NAT, though the performance gap compared to the iterative ones remains. In this work, we first ar-

gue that the key to successfully training a fully NAT model is to perform *dependency reduction* in the learning space of output tokens (§ 2) from all aspects. With this guidance, we revisit various methods which are able to reduce the dependencies among target tokens as much as possible including four different perspectives, i.e., training corpus (§ 3.1), model architecture (§ 3.2), training objective (§ 3.3) and learning strategy (§ 3.4). The performance gap can not be near closed unless we combine these techniques' advantages.

We validate the proposed fully NAT model on standard translation benchmarks including 5 translation directions where our system achieves new state-of-the-art results for fully NAT models on all directions. We also demonstrate the quality-speed trade-off comparing with AT and recent iterative NAT models in Figure 1. Moreover, compared to the Transformer baseline, our model achieves **16.5**× inference speed-up under the same software/hardware conditions while maintaining comparable translation quality.

2 Motivation

Given an input sequence $\boldsymbol{x} = x_1 \dots x_{T'}$, an autoregressive model (Bahdanau et al., 2015; Vaswani et al., 2017) predicts the target $\boldsymbol{y} = y_1 \dots y_T$ sequentially based on the conditional distribution $p(y_t|y_{<t}, x_{1:T'}; \theta)$, which tends to suffer from high latency in generation especially for long sequences. In contrast, non-autoregressive machine translation (NAT, Gu et al., 2018a), proposed for speeding-up the inference by generating all the tokens in parallel, has recently been on trend due to its nature of parallelizable on devices such as GPUs and TPUs. A typical NAT system assumes a conditional independence in the output token space, that is

$$\log p_\theta(\boldsymbol{y}|\boldsymbol{x}) = \sum_{t=1}^{T} \log p_\theta(y_t|x_{1:T'}) \qquad (1)$$

where θ is the parameters of the model. Typically, NAT models are modeled with Transformer without causal attention map in the decoder side. As noted in Gu et al. (2018a), the independence assumption, however, generally does not hold in real data distribution for sequence generation tasks such as machine translation (Ren et al., 2020), where the failure of capturing such dependency between target tokens leads to a serious performance degradation in NAT. This is a fairly understandable but fundamental issue of NAT modeling which can be easily shown with a toy example in Figure 2. Given a simple corpus with only two examples: *AB* and *BA*, each of which has 50% chances to appear. It is designed to represent the dependency that symbol *A* and *B* should co-occur. Although such simple distribution can be instantly captured by any autoregressive model, learning the vanilla NAT model with maximum likelihood estimation (MLE, Eq. (1)) assigns probability mess to incorrect outputs (*AA*, *BB*) even these samples never appear during training. In practice, the dependency in real translation corpus is much more complicated. As shown in Figure 1, despite the inference speed-up, the vanilla NAT leads to a quality drop over **10** BLEU points.

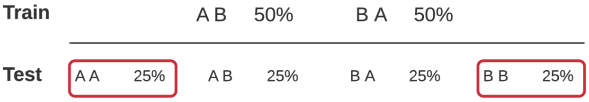

Figure 2: Toy example shows that NAT fails to learn when dependency exists in output space.

To ease the modeling difficulty, recent state-of-the-art NAT systems (Lee et al., 2018; Stern et al., 2019; Ghazvininejad et al., 2019; Gu et al., 2019; Kasai et al., 2020a; Shu et al., 2020; Saharia et al., 2020) trade accuracy with latency by incorporating iterative refinement in non-autoregressive prediction. For instance, Gu et al. (2019) learns to translate by editing (deletion, insertion) on previously generated sequence iteratively. Although iterative NAT models have already achieved comparable or even better performance than the autoregressive counterpart, Kasai et al. (2020b) showed AT models with a deep encoder and a shallow decoder can readily outperform strong iterative models with similar latency, indicating that the latency advantage of iterative NAT has been overestimated.

By contrast, while maintaining a clear speed advantage, fully NAT system – model makes parallel predictions with single neural network forward – still lags behind in translation quality and has not been fully explored in literature (Libovický and Helcl, 2018; Li et al., 2018; Sun et al., 2019; Ma et al., 2019; Ghazvininejad et al., 2020a). This motivates us in this work to investigate various approaches to push the limits of learning a fully NAT model towards autoregressive models regardless of the architecture choices (Kasai et al., 2020b).

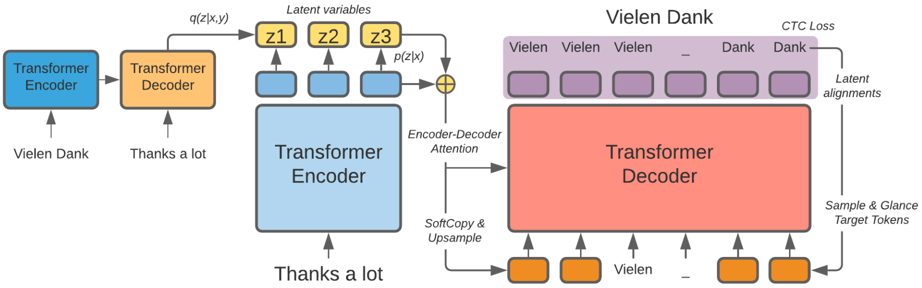

Figure 3: The overall framework of our fully NAT model.

3 Methods

In this section, we discuss several essential ingredients to train a fully NAT model. As discussed in § 2, we argue that the guiding principle of designing any NAT models is to perform *dependency reduction* as much as possible in the output space so that it can be captured by the NAT model. For example, iterative-based models (Ghazvininejad et al., 2019) explicitly reduce the dependencies between output tokens by learning the conditional distribution over the observed reference tokens. The overall framework of training our fully NAT system is presented in Figure 3. We also summarize the pros/cons for each proposed method in Table 1 for reference.

3.1 Data: Knowledge Distillation

The most effective *dependency reduction* technique is knowledge distillation (KD) (Hinton et al., 2015; Kim and Rush, 2016) which is firstly proposed to improve NAT in Gu et al. (2018a) and has been widely employed for all subsequent NAT models. The original target samples are replaced with sentences generated from a pre-trained autoregressive model. As analyzed in Zhou et al. (2020), KD is able to simplify the training data where the generated targets have less noise and are aligned to the inputs more deterministically. Also, it showed that the capacity of the teacher model should be constrained to match the desired NAT model to avoid further degradation, especially for weak NAT students without iterative refinement.

3.2 Model: Latent Variables

Different from iterative NAT, *dependency reduction* can be done with (nearly) zero additional cost at inference by adding latent variables to the model. In such case, output tokens $y_{1:T}$ are modeled conditionally independent over the latent variables z which are predicted from the prior distribution:

$$\log p_\theta(\boldsymbol{y}|\boldsymbol{x}) = \log \int_{\boldsymbol{z}} p_\theta(\boldsymbol{z}|\boldsymbol{x}) p_\theta(\boldsymbol{y}|\boldsymbol{z}, \boldsymbol{x}) d\boldsymbol{z} \quad (2)$$

z can be either extracted by a fixed external library (e.g. fertility in Gu et al. (2018a)), or jointly optimized with the NAT model using variational autoencoders (VAEs) (Kaiser et al., 2018; Shu et al., 2020) or normalizing flow (Ma et al., 2019).

In this work, we followed the formulation proposed in Shu et al. (2020) where continuous latent variables $\boldsymbol{z} \in \mathbb{R}^{T' \times D}$ are modeled as spherical Gaussian at the encoder output of each position. Like typical VAEs (Kingma and Welling, 2013), the model is trained by maximizing the evidence lower-bound (ELBO) with a posterior network q_ϕ:

$$\underbrace{\mathop{\mathbb{E}}_{\boldsymbol{z}\sim q_\phi} \left[\log p_\theta(\boldsymbol{y}|\boldsymbol{z}, \boldsymbol{x})\right]}_{\text{likelihood}} - \mathcal{D}_{\mathrm{KL}}(q_\phi(\boldsymbol{z}|\boldsymbol{x}, \boldsymbol{y}) \| p_\theta(\boldsymbol{z}|\boldsymbol{x})) \quad (3)$$

where $\mathcal{D}_{\mathrm{KL}}$ is the Kullback–Leibler divergence between the prior and posterior. In this work, we use a Transformer to encode $q_\phi(\boldsymbol{z}|\boldsymbol{x}, \boldsymbol{y})$. Only the embedding layers are shared between θ and ϕ

3.3 Loss Function: Latent Alignments

Standard NMT models are trained with the cross entropy (CE) loss which compares the model's output with target tokens at each corresponded position. However, as NAT ignores the dependency in the output space, it is almost impossible for such models to model token offset accurately. For instance, while with little effect to the meaning, simply changing "*Vielen Dank !*" to "*, Vielen Dank*" causes a huge penalty for fully NAT models.

To ease such limitation, recent works proposed to consider the latent alignments between the target positions, and optimize (Ghazvininejad et al.,

Methods	Distillation	Latent Variables	Latent Alignments	Glancing Targets
What it can do?	simplifying the training data	model any types of dependency in theory	handling token shifts in the output space	ease the difficulty of learning hard examples
What it cannot?	uncertainty exists in the teacher model	constrained by the modeling power of the used latent variables	unable to model non-monotonic dependency, e.g. reordering	training / testing phase mismatch
Potential issues	sub-optimal due to the teacher's capacity	difficult to train; posterior collapse	decoder inputs must be longer than targets	difficult to find the optimal masking ratio

Table 1: Comparison between the proposed techniques for improving fully NAT models.

2020a), or marginalize all alignments (Libovický and Helcl, 2018; Saharia et al., 2020). As a special form of latent variables in loss computation, latent alignments can be easily computed through dynamic programming. The dependency is reduced because the NAT model is able to freely choose the best prediction regardless of the target offsets. In this work, we put our primary focus on Connectionist Temporal Classification (CTC) (Graves et al., 2006) as the latent alignments, considering its superior performance and the flexibility of variable length prediction. Formally, CTC is capable of efficiently finding all valid aligned sequences $\boldsymbol{a}$ which the target $\boldsymbol{y}$ can be recovered from, and marginalize log-likelihood:

$$\log p_\theta(\boldsymbol{y}|\boldsymbol{x}) = \log \sum_{\boldsymbol{a}\in\Gamma(\boldsymbol{y})} p_\theta(\boldsymbol{a}|\boldsymbol{x}) \tag{4}$$

where $\Gamma^{-1}(\boldsymbol{a})$ is the collapse function that recovers the target sequence by collapsing consecutive repeated tokens, and then removing all blank tokens. Also, it is straightforward to apply the same CTC loss into the VAE models (§ 3.2) by replacing the likelihood term in Eq (3) with the CTC loss. Because of the strong assumptions of monotonic alignment, it is impossible to reduce all dependencies between target tokens in real distribution.

3.4 Learning: Glancing Targets

Ghazvininejad et al. (2019) showed that it improved test time performance by glancing the reference tokens when training NAT models. That is, instead of $\log p_\theta(\boldsymbol{y}|\boldsymbol{x})$, we optimize $\log p_\theta(\boldsymbol{y}|\boldsymbol{m}\odot\boldsymbol{y},\boldsymbol{x}), \boldsymbol{m} \sim \gamma(l,\boldsymbol{y}), l \sim \mathcal{U}_{|\boldsymbol{y}|}$, where $\boldsymbol{m}$ is the mask, and γ is the sampling function given the number of masked tokens l. As mentioned earlier, we suspect such explicit modeling of the distribution conditional to unmasked tokens assists the *dependency reduction* in the output space.

Naively applying random masks for every training example may cause severe mismatch between training and testing. To migrate this, Qian et al. (2020) proposed GLAT – a curriculum learning strategy, in which the ratio of glanced target tokens is proportional to the translation error of the fully NAT model. More precisely, instead of sampling uniformly, we sample l by:

$$l \sim g(f_{\text{ratio}} \cdot \mathcal{D}(\hat{\boldsymbol{y}},\boldsymbol{y})) \tag{5}$$

where $\hat{\boldsymbol{y}} = \arg\max_{\boldsymbol{y}} \log p_\theta(\boldsymbol{y}|\boldsymbol{x})$, $\mathcal{D}$ is the discrepancy between the model prediction and the target sequence, e.g. Levenshtein distance (Levenshtein, 1966), and f_{ratio} is a hyperparameter to adjust the mask ratio. The original formulation (Qian et al., 2020) utilized a deterministic mapping (g), while we use a Poisson distribution to sample a wider range of lengths including "no glancing".

The original GLAT (Qian et al., 2020) assumes to work with golden length so that it can glance at the target by placing the target word embedding to the corresponded inputs, which is incompatible with CTC as we always require the inputs longer than the targets. To enable GLAT training, we glance at target tokens from the viterbi aligned tokens $\boldsymbol{a}^* = \arg\max_{\boldsymbol{a}\in\Gamma(\boldsymbol{y})} \log p_\theta(\boldsymbol{a}|\boldsymbol{x})$ which has the same length as the decoder inputs. Intuitively, a poorly trained model will glance at many target tokens. When the model becomes better and generates higher quality sequences, the number of masked words will be larger, which helps the model gradually learn generating the whole sentence.

4 Experiments

We perform extensive experiments on three challenging translation datasets by combining all mentioned techniques to check (1) whether the proposed aspects for *dependency reduction* are complementary; (2) how much we can minimize the gap between a fully non-autoregressive model with the autoregressive counterpart.

4.1 Experimental Setup

Dataset and Preprocessing We validate our proposed models on three standard translation benchmarks with variant sizes, i.e., WMT14 English (EN) ↔ German (DE) (4.0M pairs), WMT16 English (EN) ↔ Romanian (RO) (610k pairs) and WMT20 Japanese (JA) → English (EN) (13M pairs after filtering). For EN↔DE and EN↔RO, we apply the same prepossessing steps and learn subwords as mentioned in prior work (EN↔DE: Zhou et al., 2020, EN↔RO: Lee et al., 2018). For JA→EN, the original data (16M pairs) is first filtered with Bicleaner (Sánchez-Cartagena et al.)[2] and we apply SentencePiece (Kudo and Richardson, 2018) to generate 32,000 subwords.

Knowledge Distillation Following previous efforts, we also train the NAT models on distilled data generated from pre-trained transformer models (*base* for WMT14 EN↔DE and WMT16 EN↔RO and *big* for WMT20 JA→EN) using beam search with a beam size 5 and length penalty 1.0.

Decoding At inference time, the most straightforward way is to generate the sequence with the highest probability at each position. The outputs from the CTC-based NAT models require an additional collapse process Γ^{-1} which can be done instantly. A relatively more accurate method is to decode multiple sequences, and rescore them to obtain the best candidate in parallel, i.e. *noisy parallel decoding* (NPD, Gu et al., 2018a). Furthermore, CTC-based models are also capable of decoding sequences using beam-search (Libovický and Helcl, 2018), and optionally combined with n-gram language models (Heafield, 2011; Kasner et al., 2020). More precisely, we search in a beam to approximately find the optimal $\boldsymbol{y}^*$ that maximizes:

$$\log p_\theta(\boldsymbol{y}|\boldsymbol{x}) + \alpha \cdot \log p_{\text{LM}}(\boldsymbol{y}) + \beta \log |\boldsymbol{y}| \quad (6)$$

where α and β are hyperparameters for language model scores and word insertion bonus. In principle, it is no longer non-autoregressive as beam-search is a sequential process by nature. However, it does not contain any neural network computations and can be implemented efficiently in C++[3].

Baselines We adopt Transformer (AT) and existing NAT approaches (see Table 2) for comparison. For AT, except for the standard *base* and *big* architectures (Vaswani et al., 2017), we also compare with a *deep encoder, shallow decoder* Transformer suggested in Kasai et al. (2020b) that follows the model dimensions of *base* with 12 encoder layers and 1 decoder layer (i.e. *base* (12-1) for short).

Evaluation BLEU (Papineni et al., 2002) is used to evaluate the translation performance for all models. Following prior works, we compute tokenized BLEUs for EN↔DE and EN↔RO, while using SacreBLEU (Post, 2018) for JA→EN. In this work, we use three measures to fully investigate the translation latency of all the models:

- $\mathcal{L}_1^{\text{GPU}}$: translation latency by running the model with one sentence/batch on single GPU, aligning applications like instantaneous translation.
- $\mathcal{L}_1^{\text{CPU}}$: the same as $\mathcal{L}_1^{\text{GPU}}$ while running the model without GPU speed-up. Compared to $\mathcal{L}_1^{\text{GPU}}$, it is less friendly to NAT models that make use of parallelism, however, closer to real scenarios.
- $\mathcal{L}_{\text{max}}^{\text{GPU}}$: the same as $\mathcal{L}_1^{\text{GPU}}$ on GPU while running the model in a batch with as many sentences as possible. In this case, the hardware memory bandwidth are taken into account.

We measure the wall-clock time for translating the whole test set, and report the averaged time over sentences as the latency measure. For more implementation details, please refer to Appendix A.

4.2 Results

WMT'14 EN↔DE & WMT'16 EN↔RO We report the performance of our fully NAT model comparing with AT and existing NAT approaches (including both iterative and fully NAT models) in Table 2. Iterative NAT models with enough number of iterations generally outperform fully NAT baselines by a certain margin as they are able to recover the generation errors by explicitly modeling dependencies between (partially) generated tokens. However, the speed advantage is relatively small compared to AT *base* (12-1) which also achieves 2.5 times faster than the AT baseline.

Conversely, our fully NAT models are able to readily achieve over 16 times speed-up on EN→DE by restricting translation within a single iteration. Surprisingly, merely training NAT with KD and CTC loss already beats the state-of-the-art for single iteration NAT models across all four directions. Moreover, combining with either latent variables (VAE) or glancing targets (GLAT) further closes the performance gap or even outperforms the AT results on both language pairs. For example, our best

Table 2: Comparison between our models and existing methods. The speed-up is measured on WMT'14 En→De test set. All results reported standalone are without re-scoring. **Iter.** denotes the number of iterations at inference time, **Adv.** means adaptive, * denotes models trained with distillation from a *big* Transformer.

model achieves **27.49** BLEU on WMT14 EN-DE – almost identical to the AT performance (27.48) while **16.5** times faster in the inference time.

Table 2 also indicates the difficulties of learning NAT on each dataset. For instance, EN↔RO is relatively easier as "KD + CTC" is enough to close the performance gap. By contrast, applying VAE or GLAT helps to capture non-monotonic dependencies and improve by $0.5 \sim 1$ BLEU points on EN↔ED. For both datasets, we ONLY need a single greedy generation to achieve similar translation quality as AT beam-search results.

WMT'20 JA→EN In Table 3, we also present results for training the fully NAT model on a more challenging benchmark – WMT'20 JA→EN which is much larger (13M pairs) and noisier. In addition, JA is linguistically distinct from EN which makes it harder to learn mappings between them. Consequently, both AT (12-1) and our fully NAT models become less confident and tend to generate shorter translations (BP < 0.9), which in turn underperform the AT teacher even trained with KD.

Beam search & NPD Previous works (Gu et al., 2018a; Libovický and Helcl, 2018) find that NAT performance can be effectively improved by allowing advanced decoding methods, such as beam-search and re-ranking (NPD). To fully examine our proposed fully NAT model and demonstrate its extensibility with advanced decoding approaches, we further conduct experiments on WMT'20 JA→EN.

For CTC beam search, we use a fixed beam-size 20 while grid-search α, β (Eq.(6)) based on the performance on the validation set. The language model [4] is trained directly on the distilled target sentences to avoid introducing additional information. We explored both 3-gram and 4-gram LMs in our initial experiments, and found 4-gram worked slightly better with no effect on the infer-

Table 3: Performance comparison between fully NAT and AT models on WMT'20 JA→EN. Translation latency on both the GPU and CPUs are reported over the test set. The brevity penalty (BP) is also shown for reference.

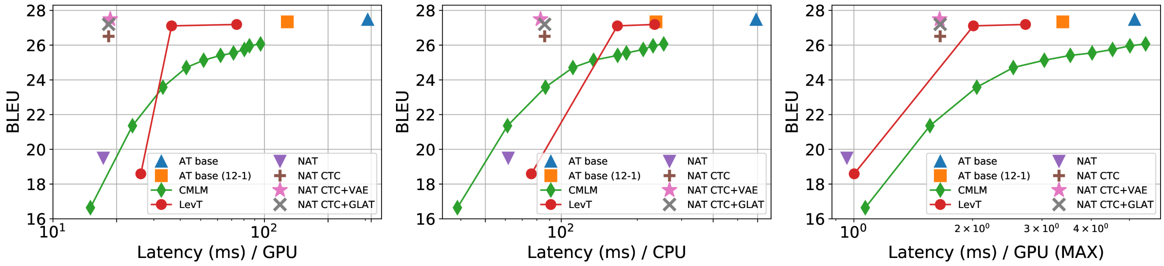

Figure 4: Quality v.s. Latency (the upper left corner achieves the best trade-off) for fully NAT models with other translation models (AT *base* and *base* 12-1 (Kasai et al., 2020b), CMLM (Ghazvininejad et al., 2019) and LevT (Gu et al., 2019)) on WMT'14 EN→DE. We evaluate latency in three setups (from left to right: $\mathcal{L}_1^{\text{GPU}}$, $\mathcal{L}_1^{\text{CPU}}$, $\mathcal{L}_{\text{max}}^{\text{GPU}}$) and show them in Logarithmic scale for better visualization.

ence speed. For noisy parallel decoding (NPD), we draw multiple z from the learned prior distribution with temperature 0.1, and use the teacher model to rerank the best z with the corresponded translation.

As shown in Table 3, with similar GPU latency ($\mathcal{L}_1^{\text{GPU}}$), beam search is much more effective than NPD with re-ranking, especially combined with a 4-gram LM where we achieve a BLEU score of 21.41, beating the teacher model with 11× speed-up. More importantly, by contributing the insertion bonus (3rd term in Eq (6)) with β in beam search, we have the explicit control to improve BP and output longer translations. Also, we gain another half point by combining NPD and beam search. To have a fair comparison, we also report latency on CPUs where it is limited to leverage parallelism of the device. The speed advantage drops rapidly for NAT models, especially for NAT with NPD, however, we still maintain around 100 ms latency via beam search – over 2× faster than the lightweight AT (12-1) systems with higher translation quality.

Quality v.s. Latency We perform a full investigation for the trade-off between translation quality and latency under three measures defined in § 4.1. The results are plotted in Figure 4. For fully NAT models, no beam search or NPD is considered. The latency is measured by $\mathcal{L}_1^{\text{GPU}}$, $\mathcal{L}_1^{\text{CPU}}$ and $\mathcal{L}_{\text{max}}^{\text{GPU}}$ so as to understand this trade-off in various scenarios. In all three setups, our fully NAT models obtain superior trade-off compared with AT and iterative NAT models. Iterative NAT models (LevT and CMLM) require multiple iterations to achieve reliable performance with the sacrifice of latency, especially under $\mathcal{L}_1^{\text{CPU}}$ and $\mathcal{L}_{\text{max}}^{\text{GPU}}$ where iterative NAT performs similarly or even worse than AT *base* (12-1), leaving fully NAT models a more suitable position in quality-latency trade-off.

Figure 4 also shows the speed advantage of fully NAT models shrinks in the setup of $\mathcal{L}_1^{\text{CPU}}$ and $\mathcal{L}_{\text{max}}^{\text{GPU}}$ where parallelism is constrained. Moreover, NAT models particularly those with CTC consume more computation and memory compared to AT models with a shallow decoder. For instance when calculating $\mathcal{L}_{\text{max}}^{\text{GPU}}$, we notice that the maximum allowed batch is 120K tokens for AT base (12-1), while we can only compute 15K tokens at a time for NAT with CTC due to the up-sampling step, even though the NAT models still win the wall-clock time. We

mark it as one limitation for future research.

4.3 Ablation Study

Impact of various techniques Our fully NAT models benefit from dependency reduction techniques in four aspects (data, model, loss function and learning), and we analyze their effects on translation accuracy through various combinations in Table 4. First of all, the combinations without KD have clear performance drop compared to those with KD, showing its vital importance in NAT training. For the loss function, although both AXE (Ghazvininejad et al., 2019) and CTC consider the latent alignments, the CTC-based model obtains much better accuracy due to its flexibility of output length. In all cases, incorporating latent variables also effectively improves the accuracy, especially for CTC without KD ($\sim$ 5 BLEU improvement). Because of the capability to reduce the mismatch between training and inference time, the model with GLAT is superior to those with randomly (RND) sampled masks. To conclude, we find that KD and CTC are necessary components for a robust fully NAT model. Adding either VAE or GLAT to them achieve similar improvements.

Distillation corpus We report the performance of models trained on real data and distilled data generated from AT *base* and *big* models in Table 5. For *base* models, both AT (12-1) and NAT achieve better accuracy with distillation, while AT benefits more by moving from *base* to *big* distilled data. On the contrary, the NAT model improves marginally indicating that in terms of the modeling capacity, our fully NAT model is still worse than AT model even with 1 decoder layer. It is not possible to further boost the NAT performance by simply switching the target to a better distillation corpus, which aligns the finding in Zhou et al. (2020). Nonetheless, we can increase the NAT capacity by learning in *big* size. As shown in Table 5, we can achieve superior accuracy compared to AT (12-1) with little effect on the translation latency ($\mathcal{L}_1^{\text{GPU}}$).

Models		Distillation *base*	Distillation *big*	BLEU	Speed-up

	big		✓	**27.89**	15.8×

Table 5: Performance comparison between AT and NAT models on the test set of WMT'14 EN→DE. The latency is measured one sentence per batch and compared with the Transformer *base*. For NAT model, we adopt CTC+VAE as the basic configuration.

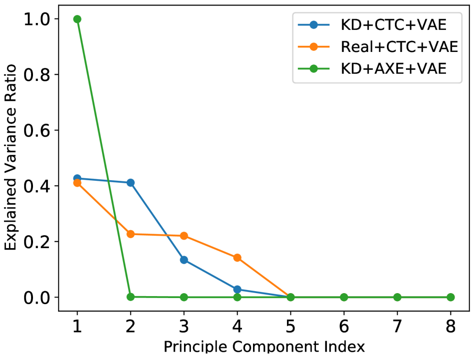

Figure 5: Principle component explained variance ratios of latent variables on WMT'14 EN→DE test set.

Effective Latent Dimensionality of Latent Variables To confirm the necessity of combining VAEs with CTC, We apply principal component analysis (PCA) (Wold et al., 1987) on the learned latent variables. More precisely, we extract the latent variables from the posterior of various models (see Table 4) on WMT'14 EN→DE test set. These main components' explained variance ratios, the percentage of variance that is attributed by each of the component, are shown in Figure 5.

First, we find that the number of effective latent dimensionality (capturing at least 95% of the total variance) is much lower than the number of latent dimensions (8 in our experiments), which indicates simply increasing the number of latent dimensions does not lead to better representations, and the ability to capture dependencies is limited. Therefore, VAEs need to be combined with other techniques e.g. KD, CTC to take effect. Also, compared to the AXE, the effective dimensionality of latent variables in CTC loss-based models is higher.

We include more analysis with qualitative examples in Appendix B.

5 Discussion and Future work

In this section, we go through the proposed four techniques again for fully NAT models. In spite of the success to close the gap with autoregressive models on certain benchmarks, we still see limitations when using non-autoregressive systems as mentioned in Table 1.

We and most of the prior research have repeatedly found that knowledge distillation (KD) is the indispensable *dependency reduction* components, especially for training fully NAT models. Nevertheless, we argue that due to the model agnostic property, KD may lose key information that is useful for the model to translate. Moreover, Anonymous (2021) pointed out KD does cause negative effects on lexical choice errors for low-frequency words in NAT models. Therefore, an alternative method that improves the training of NAT models over raw targets using such as GANs (Bińkowski et al., 2019) or domain specific discriminators (Donahue et al., 2020) might be the future direction.

Apart from KD, we also notice that the usage of CTC loss is another key component to boost the performance of fully NAT models across all datasets. As discussed in § 4.2, however, the need of up-sampling constrains the usage of our model on very long sequences or mobile devices with limited memory. In future work, it is possible to explore models to hierarchically up-sample the length with a dynamic ratio to optimize the memory usage.

Lastly, both experiments with VAE and GLAT prove that it is helpful but not enough to train NAT models with loss based on monotonic alignments (e.g. CTC) only. To work on difficult pairs such as JA-EN, it may be a better option to adopt stronger models to capture richer dependency information, such as normalizing flows (van den Oord et al., 2018; Ma et al., 2019) or non-parametric approaches (Gu et al., 2018b).

6 Related Work

Besides iterative NAT and fully NAT models, there are other works trying to improve the decoding speed of translation models from other aspects. One research line is to hybrid AT and NAT models. Wang et al. (2018) proposed a semi-autoregressive model which adopted non-autoregressive decoding locally but kept the autoregressive property in global. On the contrary, Kong et al. (2020); Huang et al. (2017) and Ran et al. (2020) introduced a local autoregressive NAT models which retained the non-autoregressive property in global.

Alternatively, there are also efforts improving the decoding speed of AT models directly. Model quantization and pruning have been widely studied as a way to improve the decoding speed (See et al., 2016; Junczys-Dowmunt et al., 2018; Aji and Heafield, 2020). Also, specialized light-weight AT model (e.g. replacing self-attention with SSRU) together with improved teacher-student training (Kim et al., 2019) are explored.

7 Conclusion

In this work, we aim to minimize the performance gap between fully NAT and AT models. We investigate *dependency reduction* methods from four perspectives and carefully unite them with necessary revisions. Experiments on three translation benchmarks demonstrate that the proposed fully NAT models achieve the SoTA performance. For future work, it is worth exploring simpler but more effective diagrams for learning NAT models. For instance, with the combination of CTC and more powerful latent variable models, it is possible to remove the necessity of knowledge distillation.

Appendix

A Implementation Details

Architecture We design our fully NAT model with the hyperparameters of the *base* Transformer: 8-512-2048 (Vaswani et al., 2017). For EN→DE experiments, we also implement the NAT model in *big* size: 8-1024-4096 for comparison.

VAEs For experiments using variational autoencoders (VAE), we use the last layer encoder hidden states to predict the mean and variance of the prior distribution. The latent dimension D is set to 8, and the predicted $\boldsymbol{z}$ are linearly projected and added on the encoder outputs. Following Shu et al. (2020), we use a 3 layer encoder-decoder as the posterior network, and apply freebits annealing (Chen et al., 2016) to avoid posterior collapse.

CTC By default, we upsample the length of decoder inputs $3\times$ as long as the source for CTC, while using the golden length for other objectives (CE and AXE). We also train an additional length predictor when CTC is not used. For both cases, we use *SoftCopy* (Wei et al., 2019) which interpolated the encoder outputs as the decoder inputs based on the relative distance of source and target positions.

GLAT The mask ratio, f_{ratio}, is 0.5 for GLAT training. The original GLAT (Qian et al., 2020) assumes to work with the golden length so that it can glance at the target by placing the target word embedding to a clear corresponded inputs. It is incompatible with CTC loss where we always need longer inputs than the targets. To enable GLAT learning, we glance at target tokens from the viterbi aligned tokens ($\boldsymbol{\alpha} = \arg\max_{\boldsymbol{\alpha}\in\beta(\boldsymbol{y})} p(\boldsymbol{\alpha}|\boldsymbol{x})$) which has the same length as the decoder inputs.

Training For both AT and NAT models, we set the dropout rate as 0.3 for EN↔DE and EN↔RO, and 0.1 for JA→EN. We apply weight decay 0.01 as well as label smoothing $\epsilon = 0.01$. All models are trained for 300K updates using Nvidia V100 GPUs with a batch size of approximately 128K tokens. We measure the validation BLEU scores for every 1000 updates, and average the last 5 checkpoints to obtain the final model.

Inference We measure the GPU latency by running the model on a single Nvidia V100 GPU, and CPU latency on Intel(R) Xeon(R) CPU E5-2698 v4 @ 2.20GHz with 80 cores. All models are implemented on `fairseq` (Ott et al., 2019).

λ	BLEU	$\mathcal{L}_1^{\text{GPU}}$	$\mathcal{L}_{\max}^{\text{GPU}}$	$\mathcal{L}_1^{\text{CPU}}$
1.5	26.16	17.9 ms	**0.95 ms**	**66.6 ms**
2.0	26.39	17.5 ms	1.03 ms	71.6 ms
2.5	**26.54**	17.6 ms	1.16 ms	76.9 ms
3.0	26.51	**17.0 ms**	1.32 ms	81.8 ms

Table 6: Performance comparison of different upsample ratios (λ) for CTC-based models on WMT'14 EN→DE test set. All models are trained on distilled data.

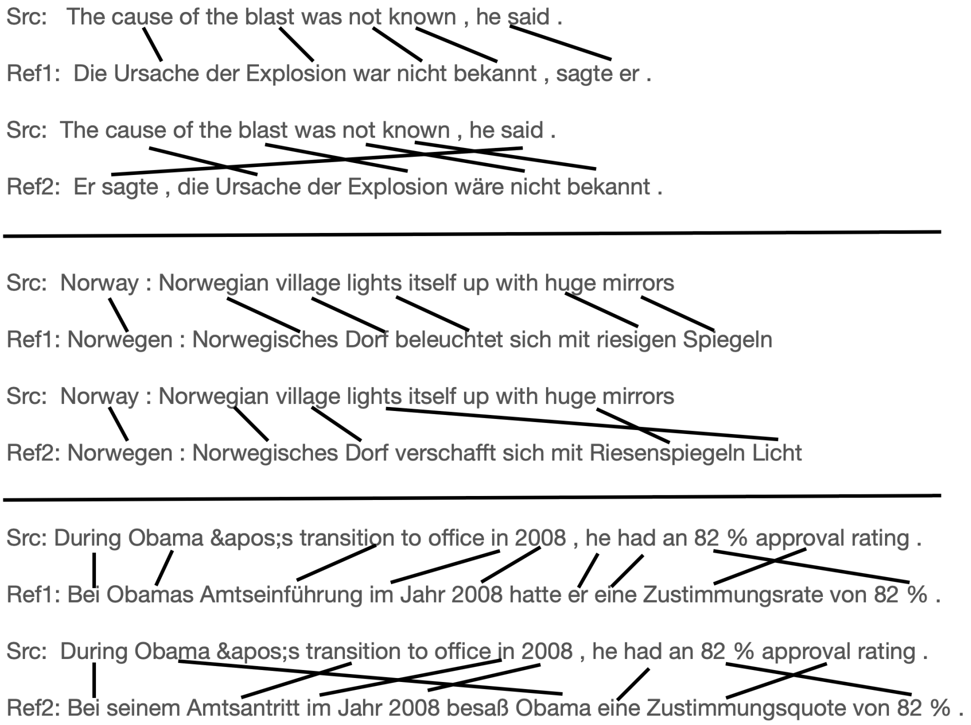
B More ablation study

Upsampling Ratio (λ) for CTC Loss To meet the length requirements in CTC loss, we upsample the encoder output by a factor of 3 in our experiments. We also explore other possible values and report the performance in Table 6. The higher upsampling ratio provides a larger alignment space, leading to better accuracy. Nevertheless, with a large enough sampling ratio, a further increase will not lead to the performance increase. Because of the high degree of parallelism, $\mathcal{L}_1^{\text{GPU}}$ speed is similar among these ratios. However, the model with a larger ratio has a clear latency drop on CPU or GPU with large batches.

Representation reordering in the latent space In our main experiments, VAEs has been proven to effectively improve the performance of NAT models. Here, we perform a qualitative study to show how VAEs helps NAT models.

Ott et al. (2018) collected additional reference translations for each source sentence in the WMT'14 En→De test set. We first choose three source sentences and show the alignments between them and two of their different translations in Figure 6. In each sample, it is clear to find that the word order of the first pair is more similar to the second one (e.g., in the second sample, the verb 'light' in the source sentence is translated to the end of the second reference sentence). However, given the monotonic alignment assumption, CTC is difficult to align sentence pairs with different word orders. Then, for each sample, we extract latent variables of both sentence pairs and align them by first computing the Euclidean distance between every position and then employing the linear sum assignment algorithm (LAP).

Regarding the first pair as the baseline, we find that the latent variable is able to adjust the word order according to the input sentence pair. For example, the alignment between latent variables of



Src: The cause of the blast was not known , he said .

Src: During Obama 's transition to office in 2008 , he had an 82 % approval rating .

Ref2: Bei seinem Amtsantritt im Jahr 2008 besaß Obama eine Zustimmungsquote von 82 % .

Figure 6: Alignments between source sentences and their different translations.

the second sample is shown as: 0-0, 1-1, 2-2, 3-3, 4-9, 5-5, 6-6,7-7, 8-8, 9-4, which shows that the latent representation of the 9th position in the second pair is aligned to the 5th position of the second pair. In another word, the latent representation of the word 'lights' is reordered to the last position in the second pair's latent variable, which corresponds to the word order difference in the second pair. Therefore, given various reference information, the latent variable makes the alignment between the source and target representation more monotonic. CTC can consequently benefit from it to learn a better NAT model.

Generate, Prune, Select: A Pipeline for Counterspeech Generation against Online Hate Speech

Wanzheng Zhu and **Suma Bhat**
University of Illinois at Urbana-Champaign, USA
`wz6@illinois.edu`, `spbhat2@illinois.edu`

Abstract

Warning: *this paper contains content that may be offensive or upsetting.*

Countermeasures to effectively fight the ever increasing hate speech online without blocking freedom of speech is of great social interest. Natural Language Generation (NLG), is uniquely capable of developing scalable solutions. However, off-the-shelf NLG methods are primarily sequence-to-sequence neural models and they are limited in that they generate commonplace, repetitive and safe responses regardless of the hate speech (e.g., "Please refrain from using such language.") or irrelevant responses, making them ineffective for de-escalating hateful conversations. In this paper, we design a three-module pipeline approach to effectively improve the *diversity* and *relevance*. Our proposed pipeline first generates various counterspeech candidates by a generative model to promote *diversity*, then filters the ungrammatical ones using a BERT model, and finally selects the most *relevant* counterspeech response using a novel retrieval-based method. Extensive Experiments on three representative datasets demonstrate the efficacy of our approach in generating diverse and relevant counterspeech.

1 Introduction

Hate speech is any form of expression through which speakers intend to vilify, humiliate, or incite hatred against a group or a class of persons on the basis of some characteristics, including race, religion, skin color, sexual identity, gender identity, ethnicity, disability, or national origin (Ward, 1997; Nockleby, 2000). Its ever-growing increase on the Internet makes it a problem of significant societal concern (Williams, 2019); effective countermeasures call for not blocking freedom of speech by means of censorship or active moderation (Gagliardone et al., 2015; Strossen, 2018). A very promising countermeasure is *counterspeech*—a response that provides non-negative feedback through fact-bound arguments and broader perspectives to mitigate hate speech and fostering a more harmonious conversation in social platforms (Schieb and Preuss, 2016; Munger, 2017; Mathew et al., 2018; Shin and Kim, 2018). Counterspeech as a measure to combat abusive language online is also promoted in active campaigns such as "Get The Trolls Out".[1]

Hate Speech:	I am done with Islam and isis. All Muslims should be sent to their homeland. Britain will be better without their violence and ideology.
Expert:	I agree that ISIS is an evil aberration, but to extend this to include up to 3 million people just in the UK is just plain silly.
Commonplace:	Hate speech is not tolerated. Please review our user policies. Thank you for your cooperation.
Not relevant:	Use of the r-word is unacceptable as it demeans and insults people with disabilities.

Table 1: An illustrative example of hate speech and counterspeech.

What makes an effective counterspeech? Informed by psychosocial and linguistic studies on counterspeech (Mathew et al., 2019b) and the large number of effective counterspeech examples created by crowdsourcing (Qian et al., 2019) and by experts (Chung et al., 2019), we identify that effective counterspeech should be **diverse** and **relevant** to the hate speech instance. *Diversity* is the requirement that a collection of counterspeech should not be largely commonplace, repetitive and safe responses without regard to the target or type of hate speech (e.g., "Please refrain from using such language."). *Relevance* refers to the property that counterspeech should directly address and target the central aspects of the hate speech, enabling

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 134–149
August 1–6, 2021. ©2021 Association for Computational Linguistics

coherent conversations rather than irrelevant or off-topic ones (e.g., the hate speech instance targets an ethnic group, while the counterspeech talks about people with disabilities). Comparative examples are shown in Table 1 where we list some counterspeech that lack diversity or relevance.

While NLG systems (in particular, sequence-to-sequence models) offer much promise for generating text at scale (Sutskever et al., 2014; Zhu et al., 2018; Lewis et al., 2020), the quality of the outputs is modest in the context of the requirements identified above. Indeed, Qian et al. (2019), the only existing quality work on counterspeech generation, has highlighted their limitations: the responses are largely commonplace and sometimes irrelevant. These limitations apply more broadly to general conversational language generation tasks, arising primarily due to the intrinsic end-to-end training nature of a single sequence-to-sequence architecture (Sordoni et al., 2015; Li et al., 2016; Serban et al., 2017; Jiang and de Rijke, 2018). Model refinements to account for these limitations have been addressed individually: improved diversity (Li et al., 2016; Xu et al., 2018) or improved relevance (Gao et al., 2019; Li et al., 2020). However, combining these improvements into a single model is not straightforward. Such is the goal of this paper.

We tackle the problem from an entirely novel angle by proposing a three-module pipeline approach, *Generate*, *Prune*, *Select* (denoted as "GPS") to ensure the generated sentences adhere to the required properties of diversity and relevance. First, the *Candidate Generation* module generates a large number of diverse response candidates using a generative model. As such, a large candidate pool is made available for selection, which accounts for improved diversity. Second, the *Candidate Pruning* module prunes the ungrammatical candidates from the candidate pool. Last, from the pruned counterspeech candidate pool, the *Response Selection* module selects the most relevant counterspeech for a given hate speech instance by a novel retrieval-based response selection method.

We demonstrate the efficacy of GPS, the first pipeline approach for counterspeech generation, by a systematic comparison with other competitive NLG approaches in generating *diverse* and *relevant* counterspeech. We derive new state-of-the-art results on three benchmark datasets by showing improved diversity and relevance using both automatic and human evaluations.

2 Proposed Model

We assume access to a corpus of labeled pairs of conversations $\mathcal{D} = \{(x_1, y_1), (x_2, y_2), ..., (x_n, y_n)\}$, where x_i is a hate speech and y_i is the appropriate counterspeech as decided by experts or by crowdsourcing. The goal is to learn a model that takes as input a hate speech x and outputs a counterspeech y. A motivating example is shown in Table 1. Most importantly, we aim at generating *diverse* and *relevant* counterspeech. We present an overview of the model in Figure 1 and describe each module in detail below.

2.1 Candidate Generation

The main goal of this module is to create a diverse candidate pool for counterspeech selection. We extract all available counterspeech instances $Y = [y_1, y_2, ..., y_n]$ from the training dataset and enlarge the counterspeech pool by a generative model.

Specifically, we utilize an RNN-based variational autoencoder (Bowman et al., 2016), that incorporates the global distributed latent representations of all sentences to generate candidates. Both the encoder and the decoder have two layers with 512 nodes each, and we use two highway network layers (Srivastava et al., 2015) to facilitate robust training. Like all other generative models, it aims to maximize the lower bound of the likelihood $\mathcal{L}$ of generating the training data Y,

$$\mathcal{L} = -KL(q_\theta(z|y) \,||\, p(z)) + \mathbb{E}_{q_\theta(z|y)}[\log p_\theta(y|z)]$$

where θ denotes all parameters of the generative model, z is a latent variable having a Gaussian distribution with a diagonal covariance matrix, p denotes the prior distribution, q denotes the posterior distribution, and KL denotes the KL-divergence (Kullback and Leibler, 1951). In the training process, we apply the KL annealing technique (Bowman et al., 2016) to prevent the undesirable stable equilibrium problem (i.e., the first term of the likelihood function $KL(q_\theta(z|y) || p(z))$ becomes zero). Upon the completion of the training, we generate candidates by simply decoding from noise ϵ sampled from a standard Gaussian distribution (i.e., $\epsilon \sim \mathcal{N}(0, 1)$).

As demonstrated by Bowman et al. (2016) (and as inferred from our own experiments described in Section 3), the generative model not only captures

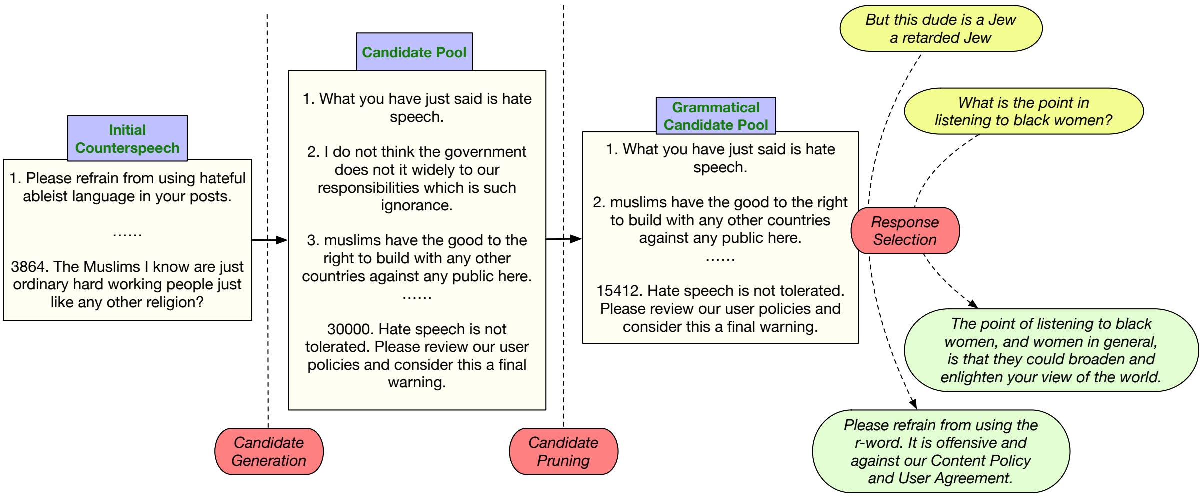

Figure 1: Overview of GPS. The red ovals correspond to the individual modules.

holistic properties of sentences such as style, topic, and high-level syntactic features, but also produces *diverse* candidates.

2.2 Candidate Pruning

Though candidates generated by such an RNN-based variational autoencoder are diverse, they are not always grammatical as pointed out by Bowman et al. (2016). Therefore, in this module, we prune the candidate list and retain only the grammatical ones. Toward this, we train a grammaticality classifier on the corpus of linguistic acceptability (CoLA) (Warstadt et al., 2018), a dataset with 10,657 English sentences labeled as grammatical or ungrammatical from linguistics publications. We select BERT (Devlin et al., 2019) as the classification model, and fine-tune it on the CoLA dataset. The choice of BERT is to best capture both the syntactic and the contextual information, and we select the 'bert-base-cased' model for its better computational efficiency.

2.3 Response Selection

We now have a collection of diverse and grammatical counterspeech responses. Finally, we aim to select the most *relevant* response to a given hate speech instance.

Taking into consideration the limited training instances that are realistically available (Chung et al., 2019; Qian et al., 2019), and inspired by the recent success of pretrained models (Devlin et al., 2019), we innovate on a pretrained response selection model for task-oriented dialogue systems (Henderson et al., 2019) and perform fine-tuning on our dataset. Henderson et al. (2019) proposed two response selection methods, but we find that neither of them is well-suited for our task.

1. *Train a response selection classifier with the negative sampling technique*: It relies on randomly drawing other candidates from the candidate pool as negative examples. However, in our task, one hate speech instance usually has multiple appropriate counterspeech instances. For example, given the hate speech in Table 1, there are many other instances that can work as quality counterspeech, such as "You cannot blame all people for the actions of a few. Banning something altogether will not solve anything." or "Does prohibition of anything ever work? I thought religious tolerance was one of our 'British values'?". Therefore, many wrongly chosen negative examples may negatively impact the inductive bias of the response selection classifier.

2. *Select by cosine similarity*: we point out that the embeddings of the input (hate speech) and the responses (counterspeech candidates) do not share the same latent vector space and therefore, the learned embeddings and their cosine similarities may not fully serve the purpose of relating the response to the input.

Therefore, instead of adopting the two available methods directly, we improve on the second one by fusing the latent spaces of the input and the responses, inspired by Gao et al. (2019). Specifically, we propose to learn a linear embedding mapping from the latent space of the responses to the latent space of the input, and then select the best response by cosine similarity. Mathematically, we use e_x to denote the input embedding and e_y to denote the response embedding. We aim to learn a linear mapping from e_y to e'_y, where $e'_y = (W + BI) \cdot e_y$, W and B are learnable parameters, and I is an identity matrix. We learn the mapping such that the sum of the cosine similarities between e_x and e'_y for the training data is maximized. By way of this transformation, e'_y now maps the vector space of the responses to that of the input, and thus allows the pretrained model to effectively utilize the discriminative power of the sentence embeddings. We empirically observe that the linear mapping works well and leave other advanced mapping techniques for future work.

3 Empirical Evaluation

In this section, we empirically evaluate the performance of our proposed approach and a set of baseline models.

3.1 Experimental Setup

Datasets: We use the benchmark datasets collected by Qian et al. (2019), which are fully-labeled hate speech intervention datasets collected from Reddit and Gab, comprising 5,257 and 14,614 hate speech instances respectively. We use the filtered conversation setting in Qian et al. (2019), which includes the posts labeled as hate speech only and discards other non-hateful conversations. Besides, we use the English language portion of the CONAN dataset (Chung et al., 2019), which contains counterspeech for 408 hate speech instances, written by experts trained on countering hatred. The Reddit, Gab and CONAN datasets have on average 2.66, 2.86 and 9.47 ground truth counterspeech for each hate speech respectively.

Training Data: Since each hate speech can have multiple ground truth counterspeech, we follow Qian et al. (2019) to dis-aggregate the counterspeech and construct a pair (hate speech, counterspeech) for each of the ground truth counterspeech in each dataset. Given a counterspeech dataset, we randomly choose 70% (hate speech, counterspeech) pairs for model training, 15% for cross validation and the rest 15% for testing.

Baselines: We compare our proposed approach with the following competitive baseline models:

1. Seq2Seq (Sutskever et al., 2014; Cho et al., 2014) is a widely used neural model for language generation. We use 2 bidirectional Gated Recurrent Unit (GRU) layers for the encoder and 2 GRU layers followed by a 3-layer neural network as the decoder.
2. Maximum Mutual Information (MMI) (Li et al., 2016) is a diversity-promoting approach for neural conversation models. We implement the MMI-bidi model (Li et al., 2016) and adopt incremental learning (Ranzato et al., 2016) to facilitate robust training.
3. SpaceFusion (Gao et al., 2019) optimizes both diversity and relevance by introducing a fused latent space, where the direction and distance from the predicted response vector roughly match the relevance and diversity, respectively. We align the direction parameter with the ground truth counterspeech. To better exercise the diversity power, we randomly choose the distance parameter at each time of generation.
4. BART (Lewis et al., 2020) is the state-of-the-art pre-trained sequence-to-sequence model for language generation. It has a standard Transformers-based neural machine translation architecture which can be seen as generalizing BERT (Devlin et al., 2019), GPT (Radford et al., 2018) and many pretraining schemes. We fine-tune the BART model on our training data.

We compare with Seq2Seq since they are initially proposed and used by Qian et al. (2019).[2] We select MMI, SpaceFusion and BART as baselines because they are the state-of-the-art models in promoting diversity, optimizing both diversity and relevance, and generating quality language respectively.

3.2 Evaluation

We evaluate all model outputs along three dimensions: diversity, relevance and language quality. *Diversity* refers to vocabulary richness, variety in expression and the extent to which the response is dissimilar from the rest in a generated collection of responses. *Relevance* captures the extent to which the counterspeech addresses the central aspect of the hateful message and makes a coherent conversation towards mitigating the hate speech. A low relevance score means that the counterspeech is irrelevant to the hate speech or off-topic (e.g., the hate speech talks about LGBTQ whereas the counterspeech is related to religious beliefs). *Language*

---

[2] We do not include the results of the variational auto-encoder model and the reinforcement learning model in Qian et al. (2019) for comparison as they has very similar performance as Seq2Seq. Readers are referred to Qian et al. (2019) for detailed performance.

Table 3: Human evaluation results. Div.: Diversity; Rel.: Relevance; LQ.: Language Quality.

quality measures whether the generated responses are grammatical, fluent and readable.

3.2.1 Automatic Evaluation

We evaluate *diversity* by distinct n-grams (**Dist-n**) (Li et al., 2016), Entropy (**Ent-n**) (Zhang et al., 2018) and **Self-BLEU** (Zhu et al., 2018). For *relevance*, we compare 1) the generated response with the ground truth counterspeech by **BLEU** (Papineni et al., 2002) and **ROUGE** (Lin and Hovy, 2003; Lin, 2004) for syntactic similarity, and by **MoverScore** (Zhao et al., 2019) and **BERTScore** (Zhang et al., 2020a) for semantic similarity; 2) the generated response with the hate speech by **BM25** (Manning et al., 2008), a relevance estimation function widely used in information retrieval. We adopt GRUEN (Zhu and Bhat, 2020) to evaluate the *language quality*. Note that larger scores indicate better quality, except for Self-BLEU.

3.2.2 Human Evaluation

Following Qian et al. (2019), we ask human annotators to perform "winner selection" instead of numeric ratings. We randomly sampled 100 hate speech instances from each dataset's test collection, and corresponding model-generated counterspeech outputs from Seq2Seq, MMI, BART, and our model.[3] Two human annotators (native English speakers and sensitive about hate speech online) were presented with one hate speech and the four generated outputs, and were asked to evaluate the outputs for relevance and language quality separately. As for diversity, the annotators were presented with 10 responses for each of the four models each time, and were asked to select the model with the best diversity. For each of the three dimensions, the *best* output received a 1 (ties were allowed, i.e., multiple outputs could receive a 1) and the rest received a 0.

3.3 Results

We obtain the results of our model (denoted as "GPS") by generating 30k, 30k, 40k candidates for the CONAN, Reddit and Gab datasets respectively.[4] After the Candidate Pruning module, we

---

[3] To save human annotation effort, we asked human raters to annotate only the best 4 models w.r.t. automatic metrics, and therefore leave SpaceFusion out of annotation.

[4] The number of generated candidates are selected based on the performance on the cross validation datasets.

Hate Speech	Generated Counterspeech by GPS
(a): All the Muslims should have been punished for yesterday, not only a few. Citizen will take action if the government does not do anything.	You cannot blame all people for actions of a few. Banning something altogether will not solve anything.
(b): The world would be a better place without Muslims. They are only killing and raping our children.	The world would actually be a very dark place without Muslims who contribute a lot to our society. What about our Muslim doctors, scientists, philanthropists, actors, job-creators?
(c): What is the point in listening to black women? They are all retarded.	The point of listening to black women, and women in general, is that they could broaden and enlighten your view of the world.

Table 4: Examples of the generated counterspeech

have 15.4k, 17.9k and 25.4k grammatical candidates for each dataset respectively.

The results by automatic metrics and human evaluation metrics are presented in Table 2 and Table 3 respectively. Overall, GPS has the best diversity with significant margins than the baselines. For relevance, GPS has slightly better performance for BLEU, ROUGE, MoverScore and BERTScore, while has much better performance on BM25. This implies the counterspeech generated by GPS are more related to the hate speech and therefore, make more coherent conversations. Examples of counterspeech generated by GPS are presented in Table 4. We find that GPS is able to generate diverse and relevant rather than merely commonplace responses, such as “Please refrain from using such language”. Comparative case studies for different baseline models are shown in Appendix A.4. Therefore, we conclude that GPS has the best diversity and relevance, compared to the baselines. Besides, GPS has comparable language quality with the best baseline model—BART.

Among these baselines, BART is the strongest one with much better relevance and language quality. Yet, BART still suffers from the diversity issue, as discussed in Section 4.3. SpaceFusion has very poor results overall, though a manual inspection of the latent space fusion visualization suggests otherwise. One explanation is that SpaceFusion, with substantially more parameters compared with the Seq2Seq model may not have had sufficient training instances for its optimal performance. In their own experiments, Gao et al. (2019), demonstrate that SpaceFusion worked well on two datasets with 0.2M and 7.3M conversations, which is at least one to two orders of magnitude larger than our dataset. If provided with more training data, SpaceFusion could possibly be a strong candidate too. In comparison, though BART is an even more complicated model with 139M parameters, it was pre-trained on the BooksCorpus dataset (Zhu et al., 2015) with over 7,000 unique unpublished books and has the fine-tunable property.

3.4 Ablation Study

We compare with the following ablations of GPS and show the results in Figure 2.

1. G-BART: instead of generating the candidates by the RNN-based variational autoencoder (Bowman et al., 2016), we generate the candidates by BART (Lewis et al., 2020).
2. P-no: we exclude the pruning module and make all generated candidates available for selection.
3. S-tfidf: we select the most relevant response by tf-idf on raw texts.
4. S-cos: we exclude the latent space fusion step and select the best response by the cosine similarity of the response embeddings and the hate speech embeddings (Henderson et al., 2019).
5. S-neg: we use the negative sampling technique to train a response selection classifier (Henderson et al., 2019).

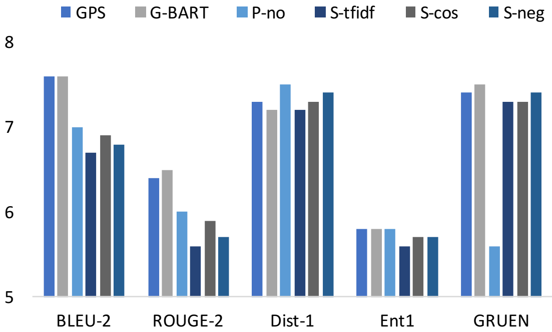

Figure 2: Ablation study. Plots show average results across all three datasets. We scale Dist-1 by 100 times and GRUEN by 10 times for better visualization.

G-BART has almost the same performance as GPS. Therefore, we select the RNN-based variational autoencoder for candidate generation for its better computational efficiency. Compared with the full model, though P-no has slightly better performance on diversity, it performs poorly on both relevance and language quality. Three ablation methods for response selection have similar performance. They have comparable performance to GPS on diversity and language quality, but worse results on relevance.

The ablation study demonstrates the significance of the Candidate Pruning module and our proposed Response Selection method. It also implies that diversity, language quality and relevance are improved by the Candidate Generation module, the Candidate Pruning module, and the Response Selection module respectively.

3.5 Generation *vs.* Selection

This section studies the relationship between the Candidate Generation module and the Response Selection module. The more candidates we generate, the more diversity the model gains potentially. However, one might think that the selection model may suffer from a very large candidate pool and result in poor relevance. Empirically as shown in Figure 3, we find that once the number of candidates generated has passed a threshold, the diversity (i.e., the blue line) almost converges. Besides, we also find the relevance is not compromised and relatively stable even with more candidates generated beyond the threshold. Therefore, we select the number of candidates at the "elbow" point based on the performance on the validation dataset, for efficient computations.

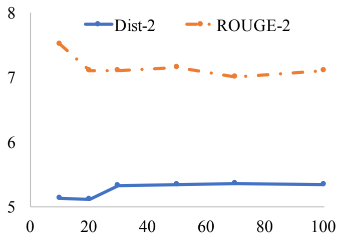

Figure 3: Dist-2 and ROUGE-2 *vs.* Number of candidates (in thousands) generated on the Reddit dataset. We scale Dist-2 by 10 times for better visualization.

3.6 Explicit Relevance (BM25) *vs.* Diversity

Based on the reasoning that models with better BM25 scores should specifically address the central aspect of hate speech and thus produce dissimilar responses for different hate speech, we hypothesize that models with better BM25 should generate more diverse responses. Therefore, we present scatter plots of BM25 and diversity scores for all five models (in Section 3.1) on all three datasets altogether in Figure 4, resulting 15 data points per subfigure. We find that BM25 and diversity have a reasonably strong correlation (Pearson's Correlation scores are 0.47 and -0.60 for Ent-1 and Self-BLEU-1 respectively).

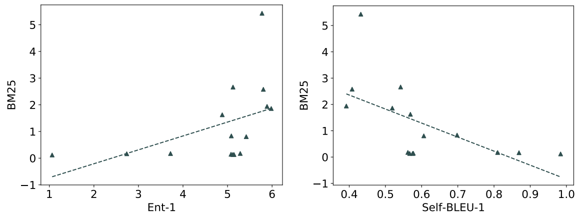

Figure 4: BM25 *vs.* Diversity. Each data point denotes a (diversity, BM25) pair for one model on one dataset, and the dotted lines indicate regression lines.

4 Related Work

We focus on three areas to the problem of hate speech and its countermeasures, i.e. (i) psychosocial analysis, (ii) automatic counterspeech generation, and more broadly, (iii) conversational language generation.

4.1 Psychosocial Analysis of Counterspeech

Effectiveness of Counterspeech: There is a significant research interest in understanding the effectiveness of counterspeech to fight hatred and de-escalate the conversation as evidenced by a growing number of recent studies (Schieb and Preuss, 2016; Munger, 2017; Mathew et al., 2018). Munger (2017) found that subjects who were educated by high-follower white males, significantly reduced their use of racist slurs on Twitter. Schieb and Preuss (2016) studied counterspeech on Facebook via a simulation, and concluded that counterspeech could have a considerable impact on a given audience, and the impact was a function of the proportion of hate speakers in the audience. In a subsequent study, Mathew et al. (2018) recorded the case of a user who, after seeing the counterspeech posted to her hateful messages on Twitter, openly apologized for her actions. Besides academia, some organizations are also set to promote countermeasures via campaigns such as the no hate speech movement[5] and the Facebook counterspeech campaign[6]. Therefore, Benesch (2014); Mathew et al. (2019b) suggest that counterspeech can be regarded as one of the most promising and "constitutionally preferred" approaches to hate speech. In addition, counterspeech could be likened to the effect of prosocial active bystanders in face-to-face bullying scenarios, where bystander intervention (speaking on behalf of the victim) has been found to successfully abate victimization most of the time (Oconnell et al., 1999; Craig et al., 2000).

Psychosocial and Linguistic Aspects: Besides the effectiveness of counterspeech, psychosocial and linguistic aspects of both counterspeech and hate speech have been actively studied by Mathew et al. (2019a); Siegel (2019); Schieb and Preuss (2016); Weingartner and Stahel (2019); Mathew et al. (2018). For instance, Mathew et al. (2019b) performed detailed psycholinguistic analysis on counterspeech, compared the effectiveness of different counterspeech strategies, and revealed some important insights, such as counterspeech comments receive much more "likes" on YouTube compared to the non-counterspeech comments, suggesting a communal empathy for the target of hate speech. Besides, Mathew et al. (2019b); Chung et al. (2019) studied different strategies (e.g., call for influential users) to produce effective counterspeech. Mathew et al. (2018) found that the hate tweets by verified accounts were much more viral as compared to tweets by non-verified accounts, by analyzing the hate speech and counterspeech accounts on Twitter. Mathew et al. (2019a) study how hate speech spreads in online social media. More recently, Sap et al. (2020) studied pragmatic formalisms to capture ways in which people express social biases and power differentials in language, permitting a broader computational framework for processing hate speech.

4.2 Counterspeech Generation

Though the effectiveness of counterspeech is well-motivated from both psychosocial and linguistic perspectives, limits to manual counterspeech generation at scale have prompted automatic generation of counterspeech, an area that has received little attention to date. The first key challenge in this direction is the creation of reliable counterspeech datasets of high quality. Mathew et al. (2019b) collected counterspeech from YouTube comments, but omit the hate speech associated with each counterspeech. Such a dataset may be good for psychosocial and linguistic analysis, but is not sufficient for training an NLG model. To enable model training, Qian et al. (2019) released two fully-labeled datasets collected from Reddit and Gab. Besides, Chung et al. (2019) collected a quality dataset where the counterspeech instances are written by trained experts and are meant to fight each hate speech and de-escalate a hateful situation. Recently, Tekiroglu et al. (2020) proposed an approach to collect counterspeech responses in a more effective manner, but have not yet released a quality dataset. In our work, we conduct the experiments on all the publicly available datasets (i.e., (Chung et al., 2019; Qian et al., 2019)) to date, to the best of our knowledge.

Research on NLG algorithms for counterspeech generation is still in its infancy. Qian et al. (2019) made the only initial attempt and proposed the use of three neural models to generate counterspeech. However, they only experimented with the most basic model architectures (e.g., Seq2Seq) to prove the feasibility of the task, and leave the performance improvement for future work. In our work, we extend their results by studying more advanced architectures, identifying principal dimensions of effective counterspeech, and proposing a novel pipeline to better solve the problem. To the best of our knowledge, this paper represents the first successful pipeline model for counterspeech generation.

From the technical perspective, our work shares some high-level similarities with Tekiroglu et al. (2020) since we both use generative models to generated candidates. However, we would like to highlight that our essential goals are different. Tekiroglu et al. (2020) aim to *collect quality data* by enabling language models and studying human annotation strategies, while we aim to *generate counterspeech* to a given hate speech.

4.3 Conversational Language Generation

Counterspeech generation is broadly related to conversational language generation, where most of the best performing approaches are based on neural models trained in a sequence-to-sequence manner (See et al., 2019a). Despite the good performance of these models, one of their widely acknowledged intrinsic drawbacks is the generation of safe and commonplace responses (Sordoni et al., 2015) due

---

[5] `https://www.nohatespeechmovement.org`

[6] `https://counterspeech.fb.com`

to improper objective function (Li et al., 2016), lack of model variability (Serban et al., 2017; Zhao et al., 2017), weak conditional signal (Tao et al., 2018), and model over-confidence (Jiang and de Rijke, 2018). Such tendency has prompted the study of methods that improve diversity and has resulted in a wide variety of solutions, such as optimizing a different loss function (Li et al., 2016; Zhang et al., 2018), varying the latent space (Shao et al., 2019; Gao et al., 2019), utilizing adversarial learning (Xu et al., 2018; Shetty et al., 2017; Shi et al., 2018), and leveraging non-conversational information (Wu et al., 2020; Su et al., 2020; Tu et al., 2019). Our work is different from all above in that we adopt a *pipeline* model which promotes diversity by generating a variety of candidates. As such, it does not have the aforementioned intrinsic drawback of a sequence-to-sequence model.

5 Conclusion and Future Work

We proposed a three-module pipeline — *Generate*, *Prune*, *Select* for counterspeech generation against online hate speech. Empirical evaluation on three datasets demonstrates that our model is effective in producing diverse and relevant counterspeech.

Future works could include the following two directions: 1) stylistic counterspeech generation: Mathew et al. (2019b) find that different counterspeech styles/strategies may be needed for different hate speech topics and therefore, it would be interesting to develop new techniques to generate the most effective style of counterspeech for each hate topic. We think this could be a natural extension to our proposed model, since we can utilize a style classifier in the Candidate Pruning module. 2) system deployment: studying the real social impacts of automatic counterspeech generation in reducing online hate speech via system deployment and the actual activity monitoring can directly inform research in this area.

Reproducibility: Our code is available at `https://github.com/WanzhengZhu/GPS`.

Acknowledgments

We thank the anonymous reviewers for comments on earlier drafts that significantly helped improve this manuscript. We thank Pooja Bhagchandani and Neha Prabhu for annotating the model outputs. This research was supported by the National Science Foundation award CNS-1720268.

Ethical Considerations

We recognize that studying counterspeech generation necessarily requires us to confront online content that may be offensive or disturbing. However, deliberate avoidance does not eliminate such problems (Sap et al., 2020). Since the effectiveness of counterspeech has already been widely studied in Section 4.1, our work makes a positive step towards automating the process, which could potentially educate hate speakers and mitigate hate speech online. Besides, the automation process could help reduce the amount of human work and therefore, potential harm to human moderators (Barrett, 2020; Zhu et al., 2021). In addition, the collective analysis over large corpora and counterspeech can also be insightful for educating people on reducing the usage of hate speech consciously or unconsciously in their language.

Risks in deployment: The deployment of counterspeech generation (e.g., (de los Riscos and DHaro, 2020)) should be done after paying attention to several ethical aspects some of which we list below.

- Social and racial bias (Sap et al., 2020): Does the model have any pragmatic implications which project unwanted social or racial biases and stereotypes onto online users?
- Fairness (Mitchell et al., 2019; Corbett-Davies et al., 2017): can the model ensure fairness for different demographic groups or speakers of different forms/dialects/vernaculars of English?
- Failure cases: are there any failure cases, which could further incite more aggressive hate speech? It is crucial to ensure that counterspeech deployment does not escalate a given hateful situation.
- Evaluation metrics (Corbett-Davies et al., 2017): the present study improves upon prior works by more comprehensive evaluations on diversity, relevance and language quality. However, there is a chance that the three criteria are sufficient for deployment in a realistic setting and there may be additional criteria associated with their effectiveness.
- Potential nefarious side effects and misuse potential (Lau et al., 2020): how to ensure that our model is not misused for other unwanted purposes?

Given the limited scope of the present study, we call for attention to these aspects by way of well-designed experiments before deploying counterspeech generation bots.

Regulatory standpoint on the present study: Institutional Review Board (IRB) gave us clear feedback on what is considered human research and thus subject to IRB review. Analyses relying on user-generated content do not constitute human-subject research, and are thus not the purview of the IRB, as long as 1) the data analyzed are posted on public fora and were not the result of direct interaction from the researchers with the people posting, 2) there are no private identifiers or personally identifiable information associated with the data, and 3) the research is not correlating different public sources of data to infer private data.[7] All of these conditions apply to the present study. Additionally, the hate speech and counterspeech instances were secondary data, previously collected by Qian et al. (2019); Chung et al. (2019) and the annotators in our study were evaluating the quality of the generated sentences only.

Risks in annotation: The data we use in this paper were posted on publicly accessible websites, and do not contain any personally identifiable information (i.e., no real names, email addresses, IP addresses, etc.). The annotators were undergraduate assistants in the lab receiving research credit for their annotation and were blind to the systems they were annotating. They were warned about the offensive content before they read the data, and were informed that they could quit the task at any time if they were uncomfortable with the content.

A Appendix

A.1 Selection of Automatic Metrics

A.1.1 Diversity

We measure distinct n-grams (Dist-n) (Li et al., 2016), Entropy (Ent-n) (Zhang et al., 2018) and Self-BLEU (Zhu et al., 2018) for diversity.

Dist-n reflects the vocabulary diversity by simply dividing the number of unique n-grams by the total number of n-grams of model output. One limitation of Dist-n is that it fails to accommodate the frequency difference of n-grams. To accommodate the frequency difference of n-grams, we also use the Entropy metric (Zhang et al., 2018), which reflects how evenly the empirical n-gram distribution is.

Though Dist-n and Ent-n evaluate the vocabulary diversity well, they fail to evaluate the inter-response diversity. For instance, they favor responses with diverse n-grams even when they are highly similar with the rest of the responses. Therefore, to accommodate such inter-response diversity, we resort to use Self-BLEU (Zhu et al., 2018) to evaluate how one response resembles the rest in a generated collection of responses. Self-BLEU regards one generated sentence as the hypothesis and the other generated sentences as the reference, and calculates the BLEU score for every generated sentence. Therefore, the smaller the Self-BLEU, the better the diversity.

A.1.2 Relevance

Most existing works measure relevance *implicitly* by BLEU and ROUGE, a set of metrics evaluating syntactic similarity between the ground truth and the generated output. They assume that the ground truth is highly relevant to the conversational input (i.e., it refers to the hate speech in our task) and therefore, the "closer" the generated output is to the ground truth, the more relevant the output is to the hate speech instance.

Explicit relevance evaluation (i.e., relatedness between the conversational input and the generated output) has been studied in only a few existing works. For instance, See et al. (2019b) and Zhang et al. (2020b) ask human annotators to evaluate relevance explicitly. Li et al. (2020) propose to use HIT-Q and HIT-R, two hit rate based metrics which require hand-crafted rules. For automatic metrics, Gao et al. (2019) propose to use "Precision" to measure relevance. However, we consider "Precision" inappropriate in our problem setting, because it only measures the relationship between the generated output and the ground truth, but not the relationship between the generated output and the conversational input.

Since there is no consensus on which automatic metric best serves the purpose of explicit relevance, we select BM25 (Manning et al., 2008) — a relevance estimation function widely used in information retrieval. Besides, we follow existing works to evaluate implicit relevance by measuring BLEU and ROUGE for syntactic similarity, and MoverScore and BERTScore for semantic similarity.

A.1.3 Language Quality

GRUEN (Zhu and Bhat, 2020) is the only existing open-source unsupervised metric that measures the language quality of generated text. It requires no reference to compare with and has been shown to correlate well with human annotations on a variety of language generation tasks.

A.2 Relevance and Diversity *vs.* Number of Epochs

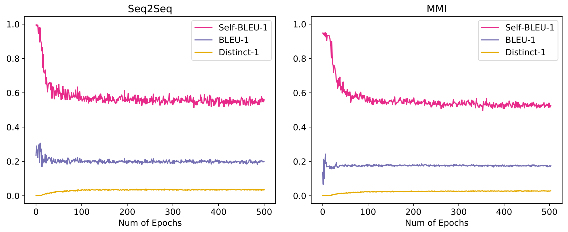

Figure 5: Effects of number of epochs for the Seq2Seq and MMI models on the Gab dataset.

In order to see how the robustness of baseline neural models changes with the number of epochs, we plot relevance and diversity measured by automatic metrics against the number of epochs for Seq2Seq and MMI in Figure 5. For each sub-figure, the middle line indicates relevance while the other two lines indicate diversity.

We note that the diversity increases with the number of epochs, until converges at about 100 epochs. Surprisingly, the relevance has a spike in the initial few training epochs and then converges to a lower score at about 50 epochs. We inspected the results where the spike occurs and observed that the model learns to produce only a few general repetitive counterspeech (e.g., "Hi there, please refrain from using derogatory comments in the thread. They are hurtful and unwanted. If you continue, Admin will be alerted.") to all hate speech. Such general responses, though result in high relevance scores (e.g., BLEU and ROUGE), are not yet effective due to the lack of diversity. With more training epochs, the models learn to produce more diverse responses at the cost of reduced BLEU and ROUGE.

Note that all results in this paper (e.g., Table 2) are reported when both relevance and diversity stabilize (i.e., 100 epochs of training). Qian et al. (2019) report higher BLEU and ROUGE scores than our results in Table 2 for the Seq2Seq model and we suspect that their reported results were obtained with only a few epochs of training.

A.3 Efficiency Comparison

We implemented all models in Python 3.7 and conducted all the experiments on a computer with twenty 2.9 GHz Intel Core i7 CPUs and one GeForce GTX 1080 Ti GPU. We report the average training time on three datasets. Seq2seq: 4.2 hours; MMI: 7.8 hours; BART: 7.1 hours; SpaceFusion: 16.2 hours (running on the CPUs only); GPS: 4.0 hours. We observe that our model requires lower or similar training cost, compared to the baselines.

A.4 Case Study

Table 5 presents case studies on the generated response for different models. In cases (a) and (b), both BART and our model make reasonable responses, whereas Seq2Seq and MMI produce only nonsense. In cases (c)-(e), Seq2Seq, MMI and BART generate general and safe responses while our model directly targets the bad words (e.g., "twat", "fairy gay faggot") in the hate speech, and even shows understanding and kind warnings to the hate speaker in case (c). Therefore, our model may make the hate speaker feel their voices have been heard and is considered closer to human-like moderators. Moreover, we find BART sometimes identifies wrong hate words (In case (d), the hate word is "twat" while BART refers to "troll" in the response. In case (e), the hate word is "fairy gay faggot" while BART refers to "kike".). The incorrect referral could potentially make the hate speakers irritated and become even more offensive.

A.5 Examples of Annotations

Table 6 presents human annotation guidelines and examples on the three dimensions. The inter-annotator reliability scores are 0.50, 0.46, 0.36 for diversity, relevance and language quality respectively.

Hate Speech	What is the point in listening to Muslim women? They are all retarded.
Seq2Seq	“So is thinly veiled Muslim Muslim women , the , population , perhaps we go to”
MMI	“That is influential figures of Baroness Sayeeda Warsi , Malala Yousafzai- I Harvard Fellow Hayfa Al-Kaylani ? Should I list some more brilliantly smart Muslim women ?”
BART	And when CVs submitted under a non Muslim name are 3 times more likely to get an interview than those with a Muslim name attached, the problem very clearly lies with those employers who discriminate against Muslim women who do not want to work with them and instead discriminate against those who do.
GPS	The point of listening to Muslim women, and women in general, is that they could broaden and enlighten your view of the world.

(a) Islamophobia

Hate Speech	All the Muslims should have been punished for yesterday, not only a few. Citizen will take action if the government does not do anything.
Seq2Seq	Are you suggesting that the government deports the good in the countries.
MMI	I am not think the government ’s Witness , I is not think that they are not.
BART	What happened to the good old British values of stuff like ‘tolerance’ and ‘respect for the rule of law’ - what you are suggesting sounds like mob rule, vigilante action and people running around with burning torches? If you really care about stopping crime, I think you should focus your energy on campaigning against it, not using it to support your anti-Muslim rhetoric.
GPS	You cannot blame all people for actions of a few. Banning something altogether will not solve anything.

(b) Islamophobia

Hate Speech	I WILL NOT support this one. Not interested in a SJW nigger loving virtue signaler. Will oppose her to all my friends and elected officials.
Seq2Seq	It does n’t make sense to hate an entire race or group of people based on the actions of a few people .
MMI	We does n’t make sense to hate an entire race or religion based on the actions of a few people .
BART	Whoa there, Racist views are hurtful and derogatory. Please be considerate of others when posting. Please refrain from using this type of language. Thank you and have a great day, thank you. (bloody lot of you) (n-word)
GPS	I understand you don’t care for her, but using words like that will only turn people against you, not her.

(c) Derogatory Language

Hate Speech	delusional twat
Seq2Seq	Use of the r-word is unacceptable in discourse as it demeans and insults people with mental disabilities .
MMI	We can make the same point more effectively without the use of hateful terminology .
BART	Use of the slur here is unacceptable in our discourse as it demeans and insults women, and is hurtful and offensive to the mentally disabled and their families.“Troll” is an offensive term. is an ethnic slur, please use better word choices.
GPS	Please refrain using the word twat.

(d) Derogatory Language

Hate Speech	A political homo? I am not listening to a fairy gay faggot for anyone. Thank you very much.
Seq2Seq	Stop using hateful language regarding sexual orientation.
MMI	Please refrain from using hateful words in your posts . It ! It adds nothing of value to the discussion .
BART	Use of the slurs and rank hatred here is unacceptable in our discourse as it demeans and insults and alienates others. “faggot” and “kike” are hate speech and are offensive and should be avoided. the word faggot is wrong.
GPS	Attacking someone’s sexuality (“fairy gay faggot”) to express your disagreement with someone’s politics is not acceptable in this forum.

(e) Derogatory Language

Table 5: Examples of the generated counterspeech.

Hate Speech	What is the point in listening to Muslim women? They are all retarded.
System A	“So is thinly veiled Muslim Muslim women , the , population , perhaps we go to”
System B	“That is influential figures of Baroness Sayeeda Warsi , Malala Yousafzai- I Harvard Fellow Hayfa Al-Kaylani ? Should I list some more brilliantly smart Muslim women ?”
System C	And when CVs submitted under a non Muslim name are 3 times more likely to get an interview than those with a Muslim name attached, the problem very clearly lies with those employers who discriminate against Muslim women who do not want to work with them and instead discriminate against those who do.
System D	The point of listening to Muslim women, and women in general, is that they could broaden and enlighten your view of the world.

Question 1:	Which system-generated counterspeech is most relevant to the hate speech? A relevant counterspeech should address the central aspect of the hateful message and make a coherent conversation.
Question 2:	Which system-generated counterspeech is most grammaticality correct, readable and fluent?

(a) Evaluation on relevance and language quality

System A	1. ”Using “c–ts” to refer to women is offensive, unnecessary and should be avoided.
	2. Using the foul language will make people more appropriate words.
	......
	10. Using the word “retards” is offensive to the mentally disabled. its a direct attack to their disability.
System B	1. “Ret–ds” as used here may offend the mentally disabled and their families; it should be avoided as it adds nothing of substance.
	2. Please don’t use the r-word in your posts. It doesn’t help to the discussion in this thread.
	......
	10. Please do not use derogatory language for women.
System C	1. Please refrain from using hateful and ableist language in your posts. It adds nothing to your argument or the discussion in this thread. Please refrain in the future if you would like to keep your account active. Thank you, and have a nice day!
	2. Please refrain from using hateful ableist language in your posts. It adds nothing productive to the conversation or the sub. Please refrain from it in the future if you would like to keep your account active. “Retard” is a hateful word that is used to demean people who struggle with intellectual disability.
	......
	10. Using the word “cunts” is a direct attack against a person based on their gender. Its offensive, unnecessary and should be avoided. “B–ch” and “c–t” are hateful terms used to demeans women in a hateful manner.
System D	1. Feminists are just human beings fighting for their human rights. Please refrain from using the term in a negative context.
	2. I don’t think that you should be spending so much energy defending your right to violence.
	......
	10. Right. I cannot stand this either. As a woman I’m annoyed when female characters are forced into the story.

Question 3:	Which system has the most diversified counterspeech in terms of vocabulary richness, variety in expression and inter-response diversity?

(b) Evaluation on diversity. The hate speech are not shown to the annotators.

Table 6: Examples of Annotation. We randomize the system outputs to avoid annotators’ selection preferences.

REPT: Bridging Language Models and Machine Reading Comprehension via Retrieval-Based Pre-training

Abstract

Pre-trained Language Models (PLMs) have achieved great success on Machine Reading Comprehension (MRC) over the past few years. Although the general language representation learned from large-scale corpora does benefit MRC, the poor support in evidence extraction which requires reasoning across multiple sentences hinders PLMs from further advancing MRC. To bridge the gap between general PLMs and MRC, we present REPT, a REtrieval-based Pre-Training approach. In particular, we introduce two self-supervised tasks to strengthen evidence extraction during pre-training, which is further inherited by downstream MRC tasks through the consistent retrieval operation and model architecture. To evaluate our proposed method, we conduct extensive experiments on five MRC datasets that require collecting evidence from and reasoning across multiple sentences. Experimental results demonstrate the effectiveness of our pre-training approach. Moreover, further analysis shows that our approach is able to enhance the capacity of evidence extraction without explicit supervision.

1 Introduction

Machine Reading Comprehension (MRC) is an important task to evaluate the machine understanding of natural language. Given a set of documents and a question (with possible options), an MRC system is required to provide the correct answer by either retrieving a meaningful span (Rajpurkar et al., 2018a) or selecting the correct option from a few candidates (Lai et al., 2017; Sun et al., 2019; Guo et al., 2019, 2021). Recently, with the development of self-supervised learning, the pre-trained language models (Devlin et al., 2019; Yang et al., 2019b) fine-tuned on several machine reading comprehension benchmarks (Reddy et al., 2019; Kwiatkowski et al., 2019) have achieved superior performance. The dominant reason lies in the strong and general contextual representation learned from large-scale natural language corpora. Nevertheless, PLMs focus more on the general language representation and semantics to benefit various downstream tasks, while MRC demands the capability of extracting evidence across one or multiple documents and performing reasoning over the collected clues (Fang et al., 2020; Yang et al., 2018). Put it differently, there exists an obvious gap, indicating an insufficient exploitation of PLMs over MRC.

Some efforts have been made to bridge the gap between PLMs and downstream tasks, which can be roughly divided into two categories: knowledge enhancement and task-oriented pre-training (Qiu et al., 2020). The former introduces commonsense or world knowledge into the pre-training (Zhang et al., 2019; Sun et al., 2020; Varkel and Globerson, 2020; Ye et al., 2020) or fine-tuning (Yang et al., 2019a) for better performance over knowledge-driven tasks. And the latter includes some delicately designed pre-training tasks, e.g., the contrastive approach of learning discourse knowledge towards textual entailment task (Iter et al., 2020). Although these approaches have achieved some improvements on certain tasks, few of them are specifically designed for evidence extraction, which is indeed indispensable to MRC.

In fact, equipping PLMs with the capability of evidence extraction in MRC is challenging due to the following two factors. 1) The process of collecting clues from a document is difficult to be integrated into PLMs without designing specific model architectures or pre-training tasks (Qiu et al., 2020; Zhao et al., 2020). And 2) large-scale pre-training process would make PLMs overfit to pre-

Query

1. History The Mentally Retarded Children's Society of SA Inc. was established in 1950 by a group of parents who wanted [MASK A] employment and accommodation opportunities for their children within the local community at a time when institutionalised [MASK B] in Adelaide was their only alternative.
2. Today [MASK C] provides assisted employment, assisted accommodation and respite services to people with intellectual disabilities.

Passage

3. The society's aims were to seek education or training facilities for people with intellectual disabilities to establish sheltered workshops and to establish residential hostels.
4. A number of sheltered workshops were established and in 1980, the name was changed to the Aboriginal word Orana which means Welcome.
5. Orana's current and previous clients include Mitsubishi Motors Clipsal RAA Elders Limited and Billycart Kids.
6. Orana was one of the first disability service organisations to achieve Quality Accreditation.
7. After the unveiling of the Australian Government's Commonwealth Home Support Programme CHSP and seeing it as a natural step of progression Orana now provides quality tailored aged care at home.
8. The well resourced organization delivers help across a range of areas helping the elderly remain where they want to be in the comfort of their own home during their later years.

Input Order: 1 2 3 4 5 6 7 8

Original Order: 1 3 4 2 5 6 7 8

Recovery:

1. [MASK A] -> education
2. [MASK B] -> care
3. [MASK C] -> Orana

Figure 1: A running example obtained from our method. The query sentences are extracted from the original document with some crucial information being randomly masked, i.e., the sentence 1 and 2. The model is required to predict the preceding and following sentence for each query in the original document and recover the masked clues, i.e., infer the original order from input order and fill the [MASK] with the initial token. The phrases in boxes are the possible clues for recovering the masked tokens and the correct order.

training tasks (Chung et al., 2021; Tamkin et al., 2020). In other words, it is difficult to take full advantage of the pre-training merits if the training objectives of pre-training and downstream MRC are greatly separated.

To deal with the aforementioned challenges, we propose a novel retrieval-based pre-training approach, REPT, to bridge the gap between PLMs and MRC. Firstly, to unify the training objective, we design a novel pre-training task, namely Surrounding Sentences Prediction (SSP), as illustrated in Figure 1. Given a document, several sentences will be firstly selected as queries, and the others are jointly treated as a passage[1]. Thereafter, for each query, the model should predict its preceding and following sentences in the original document by collecting clues from each sentence, which is compatible with evidence extraction in MRC tasks. It is worth emphasizing that, the repeated occurrence of entities or nouns across different sentences often lead to information short-cut (Lee et al., 2020), from which the order of sentences can be easily recovered. In view of this, we propose to mask such explicit clues. As a result, the model is enforced to infer the correct positions of queries by gathering evidence with the incomplete information. Secondly, to preserve the effectiveness of contextual representation, the masked clues are also required to be recovered through retrieving relevant information from other parts of the document, which is implemented via our Retrieval based Masked Language Modeling (RMLM) task.

In this way, the pre-training stage can be properly aligned with MRC: 1) the training objectives are connected through the introduction of the two pre-training tasks, which will be inherited by downstream MRC tasks through consistent retrieval operation. And 2) the capability of evidence extraction from documents or sentences is enhanced during pre-training, and will be smoothly transferred to MRC. Our contributions in this paper are summarized as follows:

1. We present REPT, a novel pre-training approach, to bridge the gap between PLMs and MRC through retrieval-based pre-training.

2. We design two self-supervised pre-training tasks, i.e., SSP and RMLM, to augment PLMs with the ability of evidence extraction with the help of retrieval operation and eliminating information short-cut, which can be smoothly transferred to downstream MRC tasks.

3. We evaluate our method over five reading comprehension benchmarks of two different task forms: Multiple Choice QA (MCQA) and Span Extraction (SE). The substantial improvements over strong baselines demonstrate the effectiveness of our pre-training approach. We conduct an empirical study to verify that our method are able to enhance evidence extraction as expected.

2 Related Work

MRC has received increasing attention in recent years. Many challenging benchmarks have been established to examine various forms of reasoning abilities, e.g., multi-hop (Yang et al., 2018), discrete (Dua et al., 2019), and logic reasoning (Yu et al., 2020). To solve the problem, a typical design is to gather possible clues through entity linking

---

[1] We use *passage* here to keep consistent with MRC tasks. And *document* refers to the combination of queries and *passage*.

(Zhao et al., 2020) or self-constructed graph (Fang et al., 2020; Ran et al., 2019), and then perform multi-step reasoning. It is worth noting that, gathering clues is vital but challenging, especially for long document understanding. Some efforts have been dedicated to improving evidence extraction via direct (Wang et al., 2018) or distant supervision (Niu et al., 2020).

Generally, the fine-tuned PLMs (Devlin et al., 2019; Yang et al., 2019b) can obtain superior performance in MRC due to their strong and general language representation. However, there still exist some gaps between PLMs and various downstream tasks, since certain abilities required by the downstream tasks cannot be learned through the existing pre-training tasks (Qiu et al., 2020). In order to take full advantage of PLMs, a few studies attempt to align the pre-training and fine-tuning stages. For example, Tamborrino et al. (2020) reformulated the commonsense question answering task as scoring via leveraging the predicted probabilities for Masked Language Modeling (MLM) in RoBERTa (Liu et al., 2019). With the help of the commonsense learned through MLM, the method achieves comparable results with supervised approaches in zero-shot setting, indicating that bridging the gap between these two stages yields considerable improvement. Chung et al. (2021) tried to address the overfitting problem during pre-training through decoupling input and output embedding weights and enlarging the embedding size during decoding. The resultant model is therefore more transferable across tasks and languages.

In addition, some task-oriented pre-training methods have also been developed. For instance, Wang et al. (2020) proposed a novel pre-training method for sentence representation learning, where the masked tokens in a sentence are forced to be recovered from other sentences through sentence-level attention. Based on this, the attention weights can be directly fine-tuned to rank the candidates in answer selection or information retrieval. Lee et al. (2019) tried to learn the dense document representation for information retrieval by minimizing the distance between the representation of an query sentence and its context. Guu et al. (2020) designed an augmented MLM tasks to jointly train a neural retriever and a language model for Open-domain QA. Different from these methods ranking the documents for open-domain QA, our approach focuses on enhancing the ability of evidence extraction in MRC, where the MLM based task by it alone is insufficient.

3 Method

In this section, we present the details of the proposed method, REPT. We firstly describe the data pre-processing part (§3.1), and then illustrate the two pre-training tasks, i.e., SSP and RMLM (§3.3) and the training objectives (§3.4). Finally, we detail how to fine-tune our pre-trained model for downstream tasks through retrieval-based evidence extraction (§3.5).

3.1 Data Pre-processing

For pre-training, we use the English Wikipedia[2] as our training data. We divide each Wikipedia article into segments, each containing up to 500 tokens[3] without overlapping. We treat each segment as a document and split it into several sentences[4].

In order to increase the difficulty and efficiency of pre-training, for each document, we select 30% of the most important sentences as queries and the rest in their original order as a passage. Specifically, the importance of each sentence in a document is measured through the summation of the importance of entities and nouns it contains, which is further defined as the number of sentences an entity/noun occurs. Hereafter, masking is introduced to entities and nouns in queries according to pre-defined ratios to eliminate information short-cut. More details about the masking strategy are described in Appendix A and an example after pre-processing can be found in Figure 1.

3.2 Task Definition

We treat a document as a sequence of n sequential sentences with m tokens. Supposing that there are t sentences selected as queries following §3.1, the rearranged sequence is defined as $\mathcal{S} = [\mathbf{s}^1, \mathbf{s}^2, \cdots, \mathbf{s}^t, \cdots, \mathbf{s}^n]$, and the index of queries is $\mathcal{Q} = \{1, 2, \cdots, t\}$. Besides, we define a mapping function r to map the rearranged sentences to their original position. Taking Figure 1 as an example, the mapping $r(\mathbf{s}^1) = 1,\ r(\mathbf{s}^2) = 4,\ r(\mathbf{s}^3) = 2$ and $(\mathbf{s}^4) = 3$ indicates that the original order is $\{\mathbf{s}^1, \mathbf{s}^3, \mathbf{s}^4, \mathbf{s}^2, \cdots\}$.

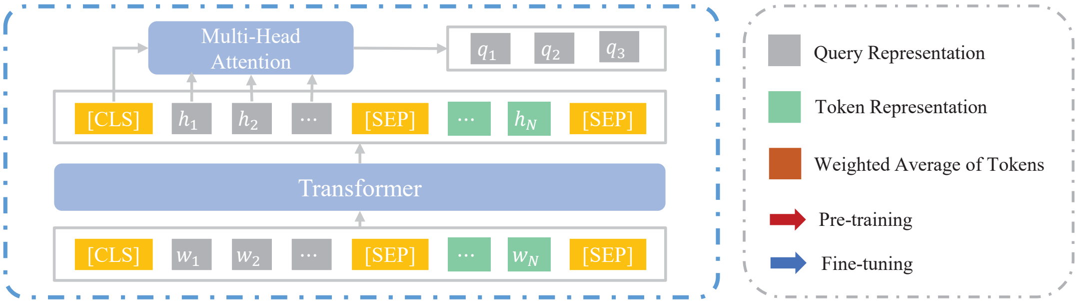
Taking $\mathcal{S}$ as input, the Surrounding Sentences Prediction task should predict the correct sentence

---

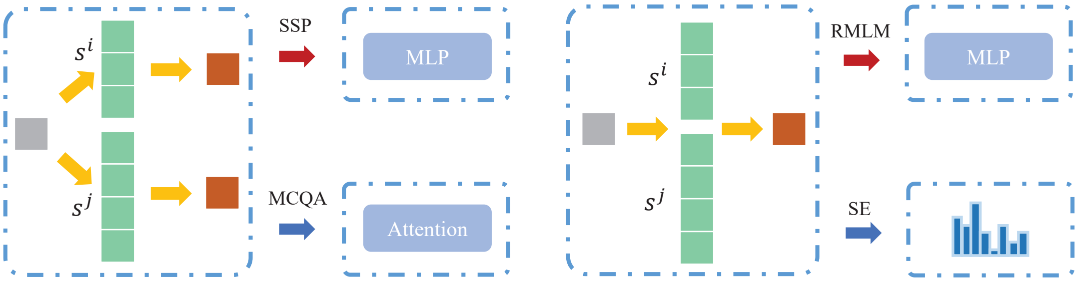
[2] We use the 2020/05/01 dump.

[3] The tokenized sub-words following BERT and RoBERTa.

[4] Any sentence with less than five tokens is concatenated to its previous one.



a) Encoder



b) Sentence-Level Retrieval for SSP and MCQA

c) Document-Level Retrieval for RMLM, ODQA and Span Extraction (SE)

Figure 2: Framework of our model. a) Encoder composed of a pre-trained Transformer encoder and a query generator based on multi-head attention. b) The attention-based sentence-level retrieval for evidence extraction for each sentence, which will be further adopted by SSP during pre-training and MCQA during fine-tuning. c) The attention-based document-level retrieval for evidence extraction among the input sequence, which is employed for RMLM. For SE, the similarity function is directly fine-tuned.

index a and b for each query $\mathbf{s}^q$ with $q \in \mathcal{Q}$[5]:

$$\begin{cases} r(\mathbf{s}^a) = r(\mathbf{s}^q) - 1, \\ r(\mathbf{s}^b) = r(\mathbf{s}^q) + 1. \end{cases} \tag{1}$$

As for the Retrieval based Masked Language Modeling (RMLM) task, the model should recover all the masked tokens in each query $\mathbf{s}^q$.

3.3 Model

First of all, we leverage a pre-trained Transformer (Vaswani et al., 2017), such as BERT, as our encoder to obtain the contextual representation of sentences. The output of Transformer is formulated as:

$$\mathbf{H} = [\mathbf{h}_{\text{cls}}, \cdots, \mathbf{h}_m, \mathbf{h}_{\text{sep}}] = \text{Encoder}(\tilde{\mathcal{S}}), \tag{2}$$

where $\mathbf{H} \in \mathbb{R}^{d \times (m+3)}$, and d is the hidden size. For a better illustration, we will use $\mathbf{H}^i$ to represent the hidden state matrix of tokens that belong to sentence $\mathbf{s}^i$, such that:

$$\mathbf{H} = [\mathbf{H}^1, \mathbf{H}^2, \cdots, \mathbf{H}^n], \ \mathbf{H}^i \in \mathbb{R}^{d \times l_i},$$

where l_i is the length of sentence $\mathbf{s}^i$ and $m = \sum_i l_i$. Since the process for each query is exactly the same, we use $q \in \mathcal{Q}$ as a representative to introduce the calculation with respect to each query below.

3.3.1 Query Representation

In order to gather potential clues from a document or sentences, we adopt the multi-head attention mechanism proposed by (Vaswani et al., 2017) to obtain the sentence-level representation for each query. Formally, the attention mechanism is defined as $\text{MHA}(\mathbf{Q}, \mathbf{K}, \mathbf{V})$, where $\mathbf{Q}, \mathbf{K}, \mathbf{V}$ are query, key and value matrices, respectively. To consider the global information, we leverage $\mathbf{h}_{\text{cls}}$ as the query vector, and $\mathbf{H}^q$ as $\mathbf{K}$ and $\mathbf{V}$:

$$\mathbf{v}_0^{q\top} = \text{MHA}(\mathbf{h}_{\text{cls}}^\top, \mathbf{H}^q, \mathbf{H}^q). \tag{3}$$

During pre-training, we reuse the layer defined by Equation 3 with $\mathbf{Q} = \mathbf{v}_0^q$ and $\mathbf{K} = \mathbf{V} = \mathbf{H}^q$, to generate the task-specific query representation $\mathbf{v}^q$, which is designed to alleviate the overfitting problem (He et al., 2021).

3.3.2 Surrounding Sentence Prediction

To enhance the capability of pre-trained models for evidence extraction, we have carefully designed the SSP task, where the model should predict the preceding and following sentences for a given query by extracting the relevant evidence from each sentence. Consequently, we introduce a retrieval operation, which is implemented via a single-head attention

---

[5] Specifically, for $r(\mathbf{s}^q) = 1$ or $r(\mathbf{s}^q) = n$, the corresponding prediction task is removed since its preceding or following sentence does not exist.

mechanism[6]:

$$\mathbf{u}_q^{i\top} = \mathrm{Att}(\mathbf{v}^{q\top}, \mathbf{H}^i, \mathbf{H}^i), \tag{4}$$

where $\mathbf{u}_q^i$ is the representation of sentence s^i, highlighting the evidence information pertaining to query s^q. Finally, the score of each sentence in the document with regard to s^q is obtained through:

$$\mathbf{o}_q^i = \mathbf{W}_2(\tanh(\mathbf{W}_1\mathbf{u}_q^i + \mathbf{b}_1)) + \mathbf{b}_2. \tag{5}$$

3.3.3 Retrieval based MLM

Since the masking noise introduced when constructing queries could also bring inconsistency between pre-training and fine-tuning, we further designed a retrieval based MLM task to alleviate this problem. In the RMLM task, the model should predict the masked entities or nouns through retrieving relevant information from a document. More specifically, the query-aware evidence representation of the input sequence is obtained via:

$$\mathbf{g}^{q\top} = \mathrm{Att}(\mathbf{v}^{q\top}, \mathbf{H}, \mathbf{H}). \tag{6}$$

Denoting the index of a masked token in query s^q as z, the representation of the masked token s_z^q used for recovering is:

$$\tilde{\mathbf{h}}_z^q = f(\mathbf{h}_z, \mathbf{g}^q), \tag{7}$$

where the function $f(\cdot,\cdot)$ is implemented as a normalized 2-layer feed-forward network, and the details are illustrated in Appendix B.2.

3.4 Optimization

As the definition in Equation 1, given a and b as the index of the original preceding and following sentences of the query s^q in $\mathcal{S}$, the corresponding probabilities for surrounding sentences are formulated as:

$$\begin{cases} p_{\mathrm{ssp}}(a|q,\mathcal{S}) = \dfrac{\exp(\mathbf{o}_q^a)}{\sum_{j=1, j\notin\{b,q\}}^{n} \exp(\mathbf{o}_q^j)}, \\ p_{\mathrm{ssp}}(b|q,\mathcal{S}) = \dfrac{\exp(\mathbf{o}_q^b)}{\sum_{j=1, j\notin\{a,q\}}^{n} \exp(\mathbf{o}_q^j)}. \end{cases} \tag{8}$$

The objective of SSP is subsequently defined as:

$$\mathcal{L}_{\mathrm{ssp}} = \mathbb{E}(-\frac{1}{|\mathcal{Q}|}\sum_q \big(\log p_{\mathrm{ssp}}(a|q,\mathcal{S}) + \log p_{\mathrm{ssp}}(b|q,\mathcal{S})\big)). \tag{9}$$

As for RMLM, supposing the index set of masked tokens in query $\mathbf{s}^q$ is $\mathcal{Z}^q$, and the set of corresponding original tokens is $\mathcal{X}^q$, the probability for recovering a masked token is:

$$p_{\mathrm{rmlm}}(x_z|z,q,\mathcal{S}) = \frac{\exp(\mathrm{e}(x_z)^\top \tilde{\mathbf{h}}_z^q)}{\sum_{x'} \exp(\mathrm{e}(x')^\top \tilde{\mathbf{h}}_z^q)}, \tag{10}$$

where $z \in \mathcal{Z}^q, x_z \in \mathcal{X}^q$, x' is a token in vocabulary, and $\mathrm{e}(x)$ denotes the word embedding of x. Then the objective of RMLM is:

$$\mathcal{L}_{\mathrm{rmlm}} = \mathbb{E}(-\frac{\sum_q \sum_z \log p_{\mathrm{pmlm}}(x_z|z,q,\mathcal{S})}{\sum_q |\mathcal{Z}^q|}). \tag{11}$$

During pre-training, the model tries to optimize the two objectives jointly:

$$\mathcal{L} = \mathcal{L}_{\mathrm{ssp}} + \mathcal{L}_{\mathrm{rmlm}}. \tag{12}$$

3.5 Fine-tuning

During fine-tuning, the input contains a query sentence and a passage. For multiple choice QA tasks, we concatenate a question with an option to form a question-option pair and use it as a whole query. In this section, we use $q = 0$ to represent the index of the query and the sentences of passage are kept in their original order. The input sequence can be thus denoted as:

$$\mathcal{S} = [s^q, s^1, s^2, \cdots, s^n].$$

To inherit the evidence extraction ability augmented during pre-training, we incorporate the same retrieval operation into fine-tuning to collect clues from the passage. Firstly, we reuse the attention mechanism defined in Equation 3 to obtain the query representation $\mathbf{v}^q$. As for the evidence extraction process, we formulate it differently for Multiple Choice QA and Span Extraction.

3.5.1 Multiple Choice QA

Similar to Equation 4, we adopt an attention mechanism, whereby the query-aware sentence representation $\mathbf{u}_q^i$ is obtained via gathering evidence from each sentence:

$$\mathbf{u}_q^{i\top} = \mathrm{Att}(\mathbf{v}^{q\top}, \mathbf{H}^i, \mathbf{H}^i),\ i \neq q. \tag{13}$$

And the final passage representation highlighting the evidence can be obtained via the sentence-level evidence extraction:

$$\mathbf{v}^p = \mathrm{Att}(\mathbf{v}^{q\top}, \mathbf{U}, \mathbf{U}), \tag{14}$$

---

[6] The details are illustrated in Appendix B.1.

where $\mathbf{U} = [\mathbf{u}_q^1, \cdots, \mathbf{u}_q^n]$ and $\mathbf{U} \in \mathbb{R}^{d \times n}$. Finally, we represent the probability of each option c using both the query $\mathbf{v}^q$ and the passage $\mathbf{v}^p$:

$$p_c^{\text{mc}} \propto \exp(\mathbf{W}_6(\tanh(\mathbf{W}_5[\mathbf{v}^q; \mathbf{v}^p] + \mathbf{b}_5)) + \mathbf{b}_6). \tag{15}$$

Specifically, for Multi-RC, since the number of correct answer options for each question is uncertain, the task is often treated as a binary classification problem for each option. As a result, we adopt a MLP to get the probability of whether an option c is correct:

$$p_c^{\text{mc}} = \sigma(\mathbf{W}_8(\tanh(\mathbf{W}_7[\mathbf{v}^q; \mathbf{v}^p] + \mathbf{b}_7)) + \mathbf{b}_8), \tag{16}$$

where σ is the sigmoid function.

3.5.2 Span Extraction

Since answer spans are often consistent with corresponding evidences, we directly leverage the query to extract relevant spans. The probability of selecting start position s and end position e of an answer span is given by:

$$\begin{cases} p_s^{\text{span}} \propto \exp(\mathbf{v}^{q\top} \mathbf{W}_9 \mathbf{h}_s), \\ p_e^{\text{span}} \propto \exp(\mathbf{v}^{q\top} \mathbf{W}_{10} \mathbf{h}_e). \end{cases} \tag{17}$$

4 Experiment

4.1 Dataset

4.1.1 Multiple Choice Question Answering

DREAM (Sun et al., 2019) contains 10,197 multiple choice questions for 6,444 dialogues collected from English Examinations designed by human experts, in which 85% of the questions require reasoning across multiple sentences, and 34% of the questions also involve commonsense knowledge.

RACE (Lai et al., 2017) is a large-scale reading comprehension dataset collected from English Examinations and created by domain experts to test students' reading comprehension skills. It has a wide variety of question types, e.g., summarization, inference, deduction and context matching, and requires complex reasoning techniques.

Multi-RC (Khashabi et al., 2018) is a dataset of short paragraphs and multi-sentence questions. The number of correct answer options for each question is not pre-specified and the correct answer(s) is not required to be a span in the text. Moreover, the dataset provides annotated evidence sentence.

ReClor (Yu et al., 2020) is extracted from logical reasoning questions of standardized graduate admission examinations. Existing studies show that the state-of-the-art models perform poorly on ReClor, indicating the deficiency of logical reasoning ability of current PLMs.

4.1.2 Span Extraction

Hotpot QA (Yang et al., 2018) is a question answering dataset involving natural and multi-hop questions. The challenge contains two settings, the distractor setting and the full-wiki setting. In this paper, we focused on the full-wiki setting, where the system should retrieve the relevant paragraphs from Wikipedia and then predict the answer.

SQuAD2.0 (Rajpurkar et al., 2018b) is reading comprehension dataset, consisting of questions posed by crowdworkers on a set of Wikipedia articles, where the answer to every question is a segment of text, or span, from the corresponding reading passage, or the question might be unanswerable.

4.2 Implementation Detail

We leave the details about the implementation and pre-training corpora in Appendix A due to the limitation of space.

4.3 Baseline

Since our method is used for further pre-training, we mainly compared our model with BERT/RoBERTa and their variants. For Hotpot QA, we integrated our models into an open-sourced and well-accepted system (Asai et al., 2020) and evaluated the performance. The details of baselines are summarized as follows:

4.3.1 Multiple Choice QA

BERT is the BERT-base model with 2-layer MLP as the task-specific module.

BERT-Q & **RoBERTa-Q** refer to the designed but not further trained models, which include an extra multi-head attention for generating query representation via Equation 3, and our retrieval operation for evidence extraction as in §3.5.1 and §3.5.2.

BERT-Q w. R/S & **RoBERTa-Q w. R/S** refer to the designed models further trained with our proposed SSP and RMLM tasks (denoted as **S** and **R**, respectively).

BERT-Q w. R & **BERT-Q w. S** refer to the models further trained with only one pre-training task, RMLM or SSP.

BERT-Q w. M & **BERT w. M** refer to the models further trained with MLM. For fair comparison, we

Model / Dataset	RACE Dev Acc.	 Test Acc.	DREAM Dev Acc.	 Test Acc.	ReClor Dev Acc.	 Test Acc.	Multi-RC Dev EM	 $\mathrm{F1}_a$	 $\mathrm{F1}_m$
BERT-base†	–	65.0	63.4	63.2	**54.6**	47.3	–	–	–

Table 1: Results on multiple choice question answering tasks. ($\mathrm{F1}_a$: F1 score on all answer-options; $\mathrm{F1}_m$: macro-average F1 score of all questions.) We ran all experiments using **four** different random seeds with the same hyper-parameters, and report the average performance, except for ReClor and Multi-RC. For ReClor, we submitted the best model on the development set to the leaderboard to get the results on the test set. For MultiRC, we merely reported the performance on development set since the test set is unavailable. †: The results are reported by the leaderboard.

further train BERT with the same Wikipedia corpus for equivalent steps.

4.3.2 Hotpot QA

For hotpot QA, we constructed the system based on Graph-based Recurrent Retriever (Asai et al., 2020), which includes a retriever and a reader based on BERT. We simply replaced the reader with our models and evaluated their performance in comparison with several published strong baselines on the leaderboard[7].

5 Results and Analyses

5.1 Results for Multiple Choice QA

Table 1 shows the results of the baselines and our method on multiple choice question answering.

From Table 1, we can observe that: 1) Compared with BERT-Q and BERT, our method significantly improves the performance over all the datasets, which validates the effectiveness of our proposed pre-training method. 2) As for the model structure, BERT-Q obtains similar or worse results compared with BERT, which suggests that the retrieval operation can hardly improve the performance without specialised pre-training. 3) Taking the rows of BERT, BERT-Q, BERT w. M, BERT-Q w. M for comparison, the models with further pre-training using MLM achieve similar or slightly higher performance. The results show that further training BERT using MLM and the same corpus can only achieve very limited improvements. 4) Regarding the two pre-training tasks, BERT-Q w. R/S leads to similar performance on the development sets compared with BERT-Q w. S, but a much higher accuracy on the test sets, which suggests RMLM can help to maintain the effectiveness of contextual language representation. However, there is a significant degradation over all datasets for BERT-Q w. R. The main reason is possibly because the model cannot tolerate the sentence shuffling noise, which may lead to the discrepancy between pre-training and MRC, and thus need to be alleviated through SSP. And 5) considering the experiments over RoBERTa-based models, RoBERTa-Q w. R/S outperforms RoBERTa-Q and RoBERTa-base with considerable improvements over Multi-RC and the test set of DREAM, which also indicates that our method can benefit stronger PLMs.

5.2 Performance on Span Extraction QA

The results of span extraction on Hotpot QA are shown in Table 2. We constructed the system using the Graph Recurrent Retriever (GRR) proposed by Asai et al. (2020) and different readers. As shown in the table, GRR + BERT-Q w. R/S outpeforms GRR + BERT-base by more than 2.5% absolute points on both EM and F1. And GRR + RoBERTa-Q w. R/S also achieves a significant improvement over GRR + RoBERTa-base. During the test stage, our best system, GRR + RoBERTa-Q w. R/S performs better than the strong baselines and get closer to GRR + BERT-wwm-large. The above results strongly demonstrate the effectiveness of our pre-

Table 3: Results of our method and other baselines on the dev set of SQuAD2.0.

training method on the task requiring multi-hop evidence extraction and reasoning.

Besides, we also conducted experiments on the most common benchmark, SQuAD2.0. The results on development set shown in Table 3 have also verified the effectiveness of our proposed pre-training method.

5.3 Evaluation of Evidence Extraction

To evaluate the performance of our method for evidence extraction in the setting of implicit supervision (with only answers), we ranked sentences in a passage using their attention weights obtained in Equation 4 and chose those sentences with higher weights as the evidences.

As shown in Table 4, the models with our proposed pre-training tasks obtain considerable improvements on the precision and recall of evidence extraction, which verifies that our pre-training method is able to effectively equip PLMs with the capability for gathering evidence without explicit supervision. For a better illustration, we further provided two examples in Appendix C.

5.4 Effect of Different Masking Ratio During Pre-training

Table 5 shows the results of our model pre-trained with different masking ratios. Due to the small amount of entities contained in the document, we only consisdered the masking ratio of nouns as the variable. Formally, we considered three ratios: 30%, 60%, 90%, and an extra setting, where the entities and nouns are all kept and the RMLM task is also removed during pre-training.

Model	**P@1**	**R@1**	**P@2**	**R@2**
BERT-Q	21.83	9.66	20.24	17.73
BERT-Q w. R/S	**45.30**	**20.38**	**38.51**	**34.55**
RoBERTa-Q	28.25	12.45	26.93	23.74
RoBERTa-Q w. R/S	**35.34**	**15.76**	**30.33**	**26.85**

Table 4: Results of evidence extraction on the development set of Multi-RC.

Model/Dataset	RACE		Multi-RC		
	Dev	Test	Dev		
	Acc.	Acc.	EM	$\mathrm{F1}_a$	$\mathrm{F1}_m$
B.Q w.R/S (30%)	70.1	68.1	31.9	**73.8**	**76.3**
B.Q w.R/S (60%)	70.2	67.3	**32.0**	**73.8**	**76.3**
B.Q w.R/S (90%)	**70.4**	**68.2**	31.0	73.5	76.2
B.Q w.S (No Mask)	69.0	67.2	29.0	72.7	75.4

Table 5: Results on RACE and Multi-RC using models pre-trained with different mask ratios. *B.Q* means *BERT-Q*.

As shown in the table, with more possible clues being masked, the model tend to obtain better results on the downstream tasks. For example, BERT-Q w. R/S (90%) achieves the best accuracy on RACE, and BERT-Q w. R/S (60%) obtains the highest performance over Multi-RC. And all models that employ masking outperform BERT-Q w. S (no masking). The main reason can be that with more explicit information short-cut being eliminated, it is more difficult for models to collect potential clues, and PLMs are enhanced with stronger reasoning ability of evidence extraction. However, there also exists a trade-off: as higher masking ratio leads to more noise, it could worsen the mismatch between pre-training and fine-tuning, and cause performance degradation, e.g., BERT-Q w. R/S (90%) performs the worst on Multi-RC.

5.5 Performance in Low Resource Scenario

Figure 3 depicts the performance of BERT-Q w. R/S on the development and test set of RACE with limited training set. For each specific relative ratio, four reduced training sets are automatically generated using different random seeds and the corresponding accuracies are plotted on the figure. It is observed that with 70% training data, our model outperforms the baseline, BERT-Q, which was initialized using BERT and has not been further pre-

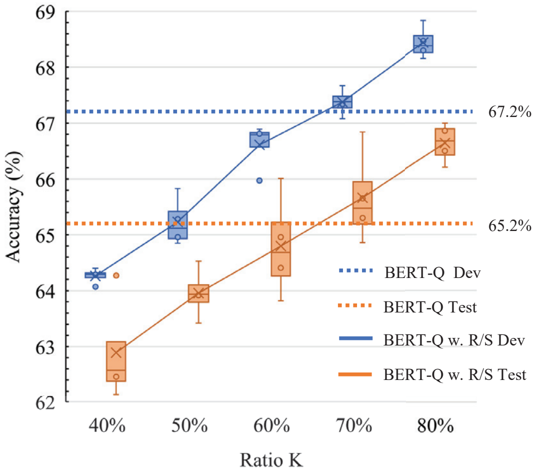

Figure 3: The accuracy of BERT-Q w. R/S on the development and test of RACE. The horizontal axis refers to the ratio K of training data compared to the original training set.

trained. The results indicate that our method can help to reduce the amount of annotated training data for downstream MRC tasks, which is especially useful in low resource scenarios.

6 Conclusion and Future Work

In this paper, we present a novel pre-training approach, REPT, to bridge the gap between pre-trained language models and machine reading comprehension through retrieval-based pre-training. Specifically, we design two retrieval-based pre-training tasks equipped with self-supervised learning, namely Surrounding Sentences Prediction (SSP) and Retreval based Masked Language Modeling (RMLM), to enhance PLMs with the capability of evidence extraction for MRC. The experiments over five different datasets validate the effectiveness of our proposed method. In the future, we plan to extend the proposed pre-training approach to the more challenging open-domain settings.

A Implementation Detail

We built our model on Huggingface's Pytorch transformer repository (Wolf et al., 2019), and used AdamW (Loshchilov and Hutter, 2019) as the optimizer. We used the pre-trained BERT-base-uncased and RoBERTa-base checkpoint to initialize our encoder, and performed pre-training using 16 P100 GPUs simultaneously. The pre-training processes last around 16 hours for BERT and 4 days for RoBERTa, which takes 20,000 steps and 80,000 steps with the batch size as 512, respectively. All hyper-parameters can be found in Table 6 for pre-training and Table 7 for fine-tuning.

During constructing the training sample for pre-training, we controlled the masking ratio for entity and noun in query. For BERT, we masked 90% entities and 30% nouns. For RoBERTa, we constructed two datasets, where the masking ratios for entity and noun are set to 90%, 30% and 90%, 90%, respectively. And we mixed the two for jointly training. We also explored the effect of different masking ratios and the analysis is detailed in §5.

As for the fine-tuning stage, for multiple choice QA, we ran all experiments using for different random seeds (i.e., 33, 42, 57 and 67) and reported the average performance, except for ReClor, in which we only submitted the results obtained from the model which performs the best on development set to the leaderboard because the limitation of submission times. For Hotpot QA, we mainly followed the hyper-parameters of Asai et al. (2020) and thus did not repeat the experiments using different random seeds. Due to the submission limitation, we only submitted our best model on the development set to the leaderboard and reported its performance on test set.

B The Details About Modeling

B.1 Single-head Attention

To reduce the extra parameters introduced, we define a single-head attention mechanism compared to the multi-head one. Given the query matrix $\mathbf{Q}$, key matrix $\mathbf{K}$ and value matrix $\mathbf{V}$, the simple attention mechanism is formualted as:

$$\mathrm{Att}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \mathrm{softmax}((\mathbf{Q}\mathbf{W} + \mathbf{b})^\top \mathbf{K})\mathbf{V},$$

where $\mathbf{W}$ and $\mathbf{b}$ is the learnable parameters.

B.2 Normalized Feed-forward Network

We adopt a 2-layer feed-forward network with GeLU activation (Hendrycks and Gimpel, 2016) and layer normalization (Ba et al., 2016) to predict the masked entities and nouns. Following SpanBERT (Joshi et al., 2020), the Equation 7 is decomposed as:

$$\begin{cases} \mathbf{h}_0 = [\mathbf{h}_z; \mathbf{g}^q], \\ \mathbf{h}_1 = \mathrm{LayerNorm}(\mathrm{GeLU}(\mathbf{W}_3\mathbf{h}_0 + \mathbf{b}_3)), \\ \tilde{\mathbf{h}}_z^q = \mathrm{LayerNorm}(\mathrm{GeLU}(\mathbf{W}_4\mathbf{h}_1 + \mathbf{b}_4)). \end{cases}$$

C Case Study About Evidence Extraction

In §5.3, the results show that our pre-training method can augment the ability to extract the correct evidence. To give an intuitive clarification over this, we select two cases shown in Figure 4. As we can see, BERT-Q w. R/S and RoBERTa-Q w. R/S can select the correct evidence sentences, while the baselines models attend to the wrong sentences. Besides, Figure 5 shows the attention maps of the two groups of comparison. It can be observed that our pre-training approach can help the model learn a uniform attention distribution over the possible evidence sentences.

D Analysis of Extra Parameters Introduced

For fair comparison, we try to introduce as few additional parameters as possible. Since the output layer is highly task-specific and the single head-attention defined in Appendix B.1 is simple, we main analyze the extra parameters introduced for query representation learning defined in §3.3.1. A single layer of Transformer comprises of a multi-head attention module and a feed-forward network. As a result, the multi-head attention module generating the query representation has introduced 2.8% extra parameters compared with a 12-layer Transformer without consideration to the parameters in embedding layer and layer normalization.

Case 1

Passage:

(0)A group of researchers at a remote jungle island outpost discover the natives are practicing voodoo and black magic. … (4)She returns years later as an adult with a group of mercenaries to attempt to uncover what happened to her parents. (5)Shortly after arriving at the island their boat's engine dies, stranding them. (6)Meanwhile elsewhere on the island a trio of hikers discover a cave, the same cave leading to the underground temple where the original curse was created. (7)After accidentally reviving the curse, the dead once again return to kill any who trespass on their island. (8)The mercenaries encounter their first zombie, who injures a member of the team. (9)Taking shelter in the remains of the old research facilities medical quarters they are soon joined by Chuck, the only surviving hiker. (10)Arming themselves with weapons left behind by the long dead research team, they make their stand as the dead once again rise. (11)One by one they are injured or killed, one of whom sacrifices himself to blow up the medical facility and his newly undead team members. (12)Jenny and Chuck flee, the only survivors remaining. (13)They stumble upon the cave once again, where the zombies appear and attack.

Question: Where did Chuck find weapons?

Option: From the previous research team.

Sentences Used: 9, 10.

BERT-Q: Answer: False Evidence: 0

BERT-Q w. R/S: Answer: True Evidence: 10, 9

Case 2

Passage:

(0)The film opens with Sunita, a medical student , and her friends working on a project about the human brain. (1)She wants to investigate the curious case of Sanjay Singhania, a notable city businessman, who is reported to have anterograde amnesia. (2)Her professor denies access to Sanjay's records as it is currently under criminal investigation. (3)Sunita, nonetheless, decides to investigate the matter herself. (4)Sanjay is introduced as he brutally murders a man. (5)He takes a Polaroid picture of the man, and writes on it ``done''. (6)It is revealed that Sanjay has anterograde amnesia where he loses his memory every 15 minutes. (7)Sanjay uses a system of photographs, notes, and tattoos on his body to recover his memory after each cycle. (8)It is revealed that Sanjay is ultimately out to avenge the death of his sweetheart Kalpana , and that he is systematically killing the people who were responsible for it. (9)His main target is ``Ghajini'', a notable social personality in the city. (10)Police Inspector Arjun Yadav, on the case of the serial murders, tracks Sanjay down to his flat and attacks and disables him. (11)Yadav finds two diaries where Sanjay has chronicled the events of 2005 and 2006. …

Question: Who denies Sunita access to Sanjay's records, who is reported to have anterograde amnesia, because they are under criminal investigation?

Option: Sunita's professor&Arjun Yadav.

Sentences Used: 1, 2.

Abstract

Event extraction (EE) is a crucial information extraction task that aims to extract event information in texts. Most existing methods assume that events appear in sentences without overlaps, which are not applicable to the complicated overlapping event extraction. This work systematically studies the realistic event overlapping problem, where a word may serve as triggers with several types or arguments with different roles. To tackle the above problem, we propose a novel joint learning framework with cascade decoding for overlapping event extraction, termed as CasEE. Particularly, CasEE sequentially performs type detection, trigger extraction and argument extraction, where the overlapped targets are extracted separately conditioned on the specific former prediction. All the subtasks are jointly learned in a framework to capture dependencies among the subtasks. The evaluation on a public event extraction benchmark FewFC demonstrates that CasEE[1] achieves significant improvements on overlapping event extraction over previous competitive methods.

1 Introduction

Event Extraction (EE) is an important yet challenging task in natural language understanding. Given a sentence, an event extraction system ought to identify event types, triggers and arguments appearing in the sentence. As an example, Figure 1(b) presents an event mention of type `Share Reduction`, triggered by "reduced". There are several arguments, such as "Fuda Industry" playing the `subject` role in the event.

However, events often appear in sentences complicatedly, where the triggers and arguments may have overlaps in a sentence. This paper focuses on a challenging and realistic problem in EE: *overlapping event extraction*. Generally, we categorize all the overlapping cases into three patterns: 1) A word may serve as triggers with different event types across several events. Figure 1(a) shows the token "acquired" triggers an `Investment` event and a `Share Transfer` event at the same time. 2) A word may serve as arguments with different roles across several events. Figure 1(a) shows "Shengyue Network" plays an `object` role in the `Investment` event and a `subject` role in the `Share Transfer` event. 3) A word may serve as arguments playing different roles in one event. Figure 1(b) shows that "Fuda Industry" plays a `subject` role and a `target` role in an event. For simplicity, we call pattern 1) as *overlapped trigger problem*, and both pattern 2) and 3) as *overlapped argument problem* in the following sections. There are about 13.5% / 21.7% sentences having overlapped trigger/argument problems in the Chinese financial event extraction dataset, FewFC (Zhou et al., 2021).

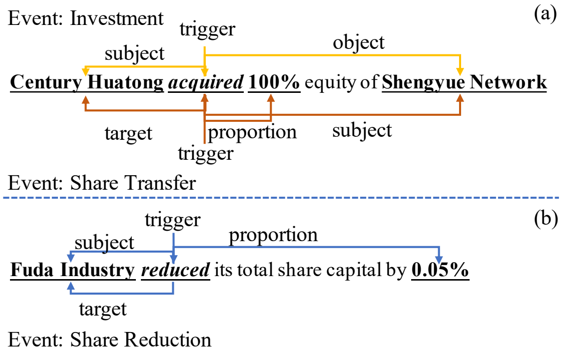

Figure 1: Examples of event overlapping problem: (a) Events with overlapped triggers and arguments; (b) An event with an overlapped argument in several roles.

Most existing EE studies assume that events appear in sentences without overlaps, which are not applicable to the complicated overlapping scenarios. Typically, current EE studies can be roughly

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 164–174
August 1–6, 2021.

categorized into two groups: 1) Traditional joint methods (Nguyen et al., 2016; Liu et al., 2018; Nguyen and Nguyen, 2019), which simultaneously extract triggers and arguments by a unified decoder labeling the sentence only once. However, they fail in extracting overlapped targets due to label conflicts, where a token may have several typed labels but only one label can be assigned. 2) Pipeline methods (Chen et al., 2015; Yang et al., 2019; Du and Cardie, 2020b), which sequentially extract triggers and arguments in separate stages. Yang et al. (2019) attempts to tackle the overlapped argument problem in the pipeline manner, but overlooks the overlapped trigger problem. Nevertheless, the pipeline methods neglect the feature-level dependencies between the trigger and arguments, and suffer from error propagation. In our knowledge, existing researches in EE neglect overlapping problems or only focus on one overlapping problem. Few researches simultaneously solve all the three mentioned overlapping patterns.

To address the above issues, we propose CasEE, a joint learning framework with Cascade decoding for overlapping Event Extraction. Specifically, CasEE realizes event extraction with a shared textual encoder and three decoders for type detection, trigger extraction and argument extraction. To extract overlapped targets across events, CasEE sequentially decodes the three subtasks, conducting trigger extraction and argument extraction according to the former predictions. Such a cascade decoding strategy extracts event elements according to the different conditions, so that the overlapped targets can be extracted in separate phases. A condition fusion function is designed to explicitly model the dependencies between adjacent subtasks. All the subtask decoders are jointly learned to further build connections among subtasks, which refines the shared textual encoder with feature-level interactions among downstream subtasks.

The contributions of this paper are three-fold:

(1) We systematically investigate the overlapping problems in EE, and categorize them into three patterns. To the best of our knowledge, this paper is among the first to simultaneously tackle all the three overlapping patterns.

(2) We propose CasEE, a novel joint learning framework with cascade decoding, to simultaneously solve all the three overlapping patterns.

(3) We conduct experiments on a public Chinese financial event extraction benchmark, FewFC. Experimental results reveal that CasEE achieves significant improvements on overlapping event extraction over existing competitive methods.

2 Related Work

Current EE research can be roughly categorized into two groups: 1) Traditional joint methods (Li et al., 2013; Nguyen et al., 2016; Nguyen and Nguyen, 2019; Liu et al., 2018; Sha et al., 2018) that perform trigger extraction and argument extraction simultaneously. They solve the task in a sequence labeling manner, and extract triggers and arguments by tagging the sentence only once. However, these methods fail in solving overlapping event extraction since the overlapping tokens would cause label conflicts when forced to have more than one label. 2) Pipeline methods (Chen et al., 2015; Yang et al., 2019; Wadden et al., 2019; Li et al., 2020; Du and Cardie, 2020b; Liu et al., 2020; Chen et al., 2020) that perform trigger extraction and argument extraction in separate stages. Though pipeline methods have the potential capacity to solve overlapping EE, they usually lack explicit dependencies between triggers and arguments, and suffer from error propagation. Among the researches, Yang et al. (2019) and Xu et al. (2020) solve the overlapped argument problem, but overlook the overlapped trigger problem, thus can not discern correct triggers for argument extraction. All the above methods can not simultaneously solve all the overlapping patterns in event extraction.

The overlapping problem has also been explored in other information extraction tasks outside event extraction. Luo and Zhao (2020) tackles nested named entity recognization with bipartite flat-graph networks. Zeng et al. (2018) tackles overlapped relational triple extraction by applying a sequence-to-sequence paradigm with a copy mechanism. Wei et al. (2020) and Yu et al. (2020) extract overlapped relational triples with a novel cascade tagging strategy, which inspire us to solve overlapping event extraction in the cascade decoding paradigm. Wang et al. (2020) further discusses the propagation error in cascade decoding. All the above researches are proposed for other tasks, which can not be directly transferred for overlapping event extraction due to the complicated event extraction definition.

3 Our Approach

Given an input sentence, the goal of EE is to identify triggers with their event types and arguments

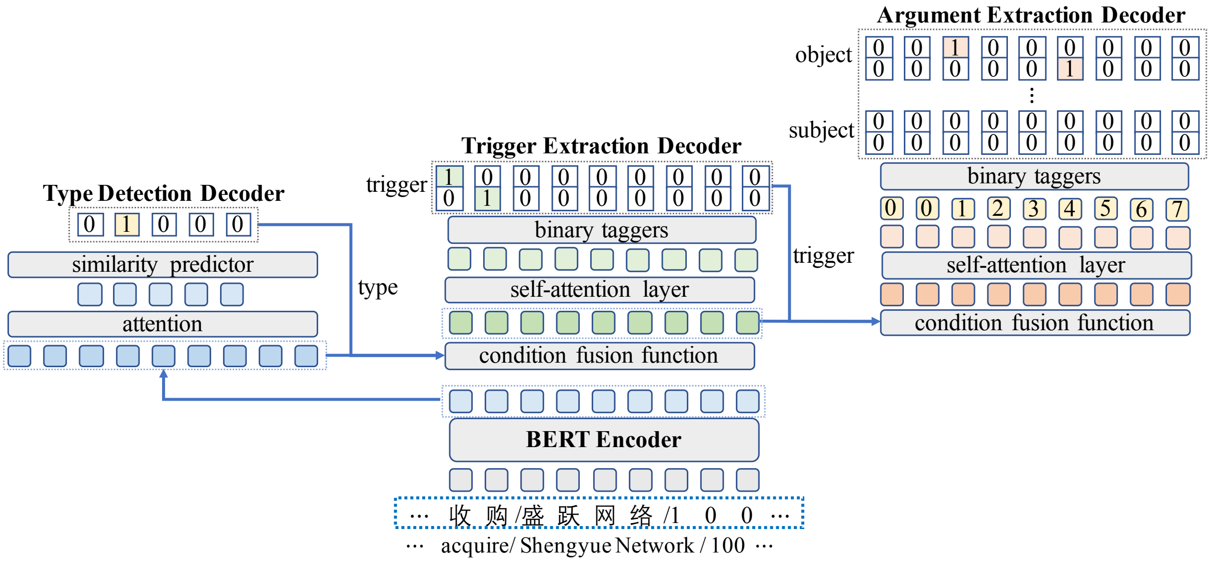

Figure 2: The overview of our proposed approach, CasEE, which contains a shared BERT encoder, a type detection decoder, a trigger extraction decoder and an argument extraction decoder.

with their corresponding roles, where triggers and arguments may overlap on some tokens. To tackle this problem, we propose a training objective at the event level. Formally, according to the pre-defined event schema, we have an event type set $\mathcal{C}$ and an argument role set $\mathcal{R}$. The overall goal is to predict all events in gold set $\mathcal{E}_x$ of the sentence x. We aim to maximize the joint likelihood of training data $\mathcal{D}$:

$$\prod_{x\in\mathcal{D}}\Big[\prod_{(c,t,a_r)\in\mathcal{E}_x} p((c,t,a_r))|x)\Big]$$

$$=\prod_{x\in\mathcal{D}}\Big[\prod_{c\in\mathcal{C}_x} p(c|x)\prod_{t\in\mathcal{T}_{x,c}} p(t|x,c)\prod_{a_r\in\mathcal{A}_{x,c,t}} p(a_r|x,c,t)\Big] \tag{1}$$

where $\mathcal{C}_x$ denotes the set of types occurring in x, $\mathcal{T}_{x,c}$ denotes the trigger set of type c, and $\mathcal{A}_{x,c,t}$ denotes the argument set of type c and trigger t. Note that each c is a type in $\mathcal{C}$, each t is a trigger word, and each $a_r \in \mathcal{A}_x$ is an argument word corresponding to its own role $r \in \mathcal{R}$. Eq. (1) exploits the fact of dependencies among the type, trigger and argument. Actually, it motivates us to learn a type detection decoder $p(c|x)$ to detect event types occurring in the sentence, a trigger extraction decoder $p(t|x,c)$ to extract triggers of type c, and an argument extraction decoder $p(a_r|x,c,t)$ to extract role-specific arguments with type c and trigger t.

Such a task decomposition solves all the event overlapping patterns claimed in the Introduction. Specifically, we first detect event types occurring in the sentence. When extracting triggers, we only predict the triggers with a specific type, thus the triggers overlapped across several events will be predicted in separate phases. Similarly, when extracting arguments, we predict the arguments with a specific type and trigger, thus the arguments overlapped across several events will also be predicted in separate phases. Since we adopt role-specific taggers in argument extraction, the overlapped arguments having several roles in an event can be predicted separately with specific taggers. All the predictions in type detection, trigger extraction and argument extraction form the final prediction.

Figure 2 demonstrates the details of CasEE. CasEE adopts a shared BERT encoder to capture textual features, and three decoders for type detection, trigger extraction and argument extraction. Since all subtasks are jointly learned in contrast to previous pipeline methods (Yang et al., 2019; Li et al., 2020), CasEE could capture feature-level dependencies among subtasks. For prediction, CasEE sequentially predicts event types, triggers and arguments in the cascade decoding process.

3.1 BERT Encoder

To capture the feature-level dependencies among subtasks, we share the textual representations of each sentence. As BERT has shown performance improvements across multiple NLP tasks, we adopt BERT (Devlin et al., 2019) as our textual encoder. BERT is a bi-directional language representation model based on transformer architecture (Vaswani et al., 2017), which generates textual representations conditioned on token context and remains rich textual information. Formally, the sentence with N tokens is denoted as $x = w_1, w_2, ..., w_N$. We input the tokens into BERT, and then obtain the hidden states $\mathbf{H} = \mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_N$ as the token representations for the following downstream subtasks.

3.2 Type Detection Decoder

Since we tackle the overlapped trigger problem by extracting triggers conditioned on the type predictions, we devise a type detection decoder to predict event types. Inspired by event detection without triggers (Liu et al., 2019), we adopt attention mechanism to detect event types, capturing the most relative context for each possible type. Specifically, we randomly initialize embedding matrix $\mathbf{C} \in \mathbb{R}^{|\mathcal{C}|\times d}$ as the type embeddings. We define a similarity function δ to measure the relevance between the candidate type $\mathbf{c} \in \mathbf{C}$ and each token representation $\mathbf{h}_i$. To fully capture the similarity information in different aspects, we achieve δ with an expressive learnable function. According to the relevance scores, we obtain the sentence representation $\mathbf{s}_c$ adaptive to the type. The details are as follows:

$$\delta(\mathbf{c}, \mathbf{h}_i) = \mathbf{v}^\intercal \tanh(\mathbf{W}[\mathbf{c}; \mathbf{h}_i; |\mathbf{c} - \mathbf{h}_i|; \mathbf{c} \odot \mathbf{h}_i])$$
$$\mathbf{s}_c = \sum_{i=1}^{N} \frac{\exp(\delta(\mathbf{c}, \mathbf{h}_i))}{\sum_{j=1}^{N} \exp(\delta(\mathbf{c}, \mathbf{h}_j))} \mathbf{h}_i \tag{2}$$

where $\mathbf{W} \in \mathbb{R}^{4d\times 4d}$ and $\mathbf{v} \in \mathbb{R}^{4d\times 1}$ are learnable parameters, $|\cdot|$ is an absolute value operator, $\odot$ is the element-wise production, and $[\cdot;\cdot]$ denotes the concatenation of representations.

Finally, we predict event types by measuring the similarity of the adaptive sentence representation $\mathbf{s}_c$ and the type embedding $\mathbf{c}$ with the same similarity function δ. Then, the predicted probability of each event type c occurring in the sentence is:

$$\hat{c} = p(c|x) = \sigma(\delta(\mathbf{c}, \mathbf{s}_c)) \tag{3}$$

where σ denotes sigmoid function. We select the event type with $\hat{c} > \xi_1$ as results, where $\xi_1 \in [0, 1]$ is a scalar threshold. All predicted types in sentence x form event type set $\mathcal{C}_x$. The decoder learnable parameter $\theta_{td} \triangleq \{\mathbf{W}, \mathbf{v}, \mathbf{C}\}$.

3.3 Trigger Extraction Decoder

To discern overlapped triggers with several types, we extract triggers conditioned on a specific type $c \in \mathcal{C}_x$. This decoder contains a condition fusion function, a self-attention layer, and a pair of binary taggers for triggers.

To model the conditional dependency between type detection and trigger extraction, we devise a condition fusion function ϕ to integrate condition information into textual representation. Specifically, we obtain the conditional token representation $\mathbf{g}_i^c$ by integrating the type embedding $\mathbf{c}$ into the token representation $\mathbf{h}_i$ as:

$$\mathbf{g}_i^c = \phi(\mathbf{c}, \mathbf{h}_i) \tag{4}$$

Actually, ϕ can be achieved by concatenation, addition operator or gate mechanism. To fully generate conditional representations in the statistical aspect, we introduce an effective and general mechanism, conditional layer normalization (CLN) (Su, 2019; Yu et al., 2021), to achieve ϕ. CLN is mostly based on the well-known layer normalization (Ba et al., 2016), but can dynamically generate gain γ and bias β based on the condition information. Given a condition embedding $\mathbf{c}$ and a token representation $\mathbf{h}_i$, CLN is formulated as:

$$\begin{aligned} \mathrm{CLN}(\mathbf{c}, \mathbf{h}_i) &= \gamma_c \odot (\frac{\mathbf{h}_i - \mu}{\sigma}) + \beta_c, \\ \gamma_c &= \mathbf{W}_\gamma \mathbf{c} + \mathbf{b}_\gamma, \beta_c = \mathbf{W}_\beta \mathbf{c} + \mathbf{b}_\beta \end{aligned} \tag{5}$$

where $\mu \in \mathbb{R}$ and $\sigma \in \mathbb{R}$ are the mean and standard variance taken across the elements of $\mathbf{h}_i$, and $\gamma_c \in \mathbb{R}^d$ and $\beta_c \in \mathbb{R}^d$ are the conditional gain and bias, respectively. In this way, the given condition representation is encoded into the gain and bias, and then integrated into contextual representations.

To further refine representations for trigger extraction, we adopt a self-attention layer over the conditional token representations. Formally, the refined token representations are derived as:

$$\mathbf{Z}^c = \mathrm{SelfAttention}(\mathbf{G}^c) \tag{6}$$

where $\mathbf{G}^c$ is the representation matrix composed of $\mathbf{g}_i^c$. For details of the self-attention layer, please refer to Vaswani et al. (2017).

To predict triggers, we devise a pair of binary taggers. For each token w_i, we predict whether it corresponds to a start or end position of a trigger as:

$$\begin{aligned} \hat{t}_i^{sc} &= p(t_s|w_i, c) = \sigma(\mathbf{w}_{t_s}^\intercal \mathbf{z}_i^c + b_{t_s}) \\ \hat{t}_i^{ec} &= p(t_e|w_i, c) = \sigma(\mathbf{w}_{t_e}^\intercal \mathbf{z}_i^c + b_{t_e}) \end{aligned} \tag{7}$$

where σ denotes sigmoid function, and $\mathbf{z}_i^c$ denotes the i-th token representation in $\mathbf{Z}^c$. We select tokens with $\hat{t}_i^{sc} > \xi_2$ as the start positions, and those with $\hat{t}_i^{ec} > \xi_3$ as end positions, where $\xi_2, \xi_3 \in [0, 1]$ are scalar thresholds. To obtain the trigger word t, we enumerate all the start positions and search the nearest following end position in the sentence, and the tokens between the start and end position form an entire trigger. In this way, the overlapped triggers can be extracted separately according to the type in separate phases. All the predicted trigger t of type c in sentence s forms the set $\mathcal{T}_{c,s}$. The decoder parameter θ_{te} includes all the parameters in the condition fusion function, the self-attention layer and the trigger taggers.

3.4 Argument Extraction Decoder

To tackle the overlapped argument problem, we extract role-specific arguments conditioned on both the specific event type $c \in \mathcal{C}_s$ and event trigger $t \in \mathcal{T}_{c,s}$. This decoder also contains a condition fusion function, a self-attention layer, and a group of role-specific binary tagger pairs for arguments.

We further integrate the trigger information into the typed textual representation $\mathbf{g}_i^c$ in Eq. (4) with function ϕ achieved by CLN. Here we take the average of the start and end position token representations of t as the trigger embedding. We also adopt a self-attention layer to derive the refined textual representations $\mathbf{Z}^{ct'}$. To be aware of the trigger position, we adopt the relative position embedding as used in Chen et al. (2015), which indicates the relative distance from current token to the trigger boundary token. Finally, the token representations $\mathbf{Z}^{ct}$ for argument extraction are derived as:

$$\mathbf{Z}^{ct} = [\mathbf{Z}^{ct'}; \mathbf{P}] \tag{8}$$

where $\mathbf{P} \in \mathbb{R}^{N \times d_p}$ is the relative position embeddings, d_p is the dimension, and $[\cdot;\cdot]$ denotes the concatenation of representations.

To predict arguments in roles, we devise a group of role-specific tagger pairs. For each token w_i, we predict whether it corresponds to a start or end position of an argument of the role $r \in \mathcal{R}$ as:

$$\begin{aligned} \hat{r}_i^{sct} &= p(a_r^s|w_i, c, t) = \mathrm{I}(r, c)\sigma(\mathbf{w}_{r_s}^{\intercal}\mathbf{z}_i^{ct} + b_{r_s}) \\ \hat{r}_i^{ect} &= p(a_r^e|w_i, c, t) = \mathrm{I}(r, c)\sigma(\mathbf{w}_{r_e}^{\intercal}\mathbf{z}_i^{ct} + b_{r_e}) \end{aligned} \tag{9}$$

where σ denotes sigmoid function, and $\mathbf{z}_i^{ct}$ denotes the i-th token representation in $\mathbf{Z}^{ct}$. Since not all roles belonging to the specific type c, we adopt an indicator function $\mathrm{I}(r, c)$ to indicate whether the role r belongs to the type c according to the pre-defined event scheme. To make the indicator function derivable, we parameterize $\mathrm{I}(r, c)$ to learn with the model parameters. Specifically, given the type embedding $\mathbf{c} \in \mathcal{C}$, we build the connection between the type and roles as:

$$\mathrm{I}(r, c) = \sigma(\mathbf{w}_r^{\intercal}\mathbf{c} + b_r) \tag{10}$$

where σ denotes sigmoid function, $\mathbf{w}_r, b_r$ are parameters associated with the role r. For each role r, we select tokens with $\hat{r}_i^{sct} > \xi_4$ as the start positions, and those with $\hat{r}_i^{ect} > \xi_5$ as end positions, where $\xi_4, \xi_5 \in [0, 1]$ are scalar thresholds. To obtain the argument word a with role r, we enumerate all the start positions and search the nearest following end position in the sentence, and the tokens between the start and end position form an entire argument. In this way, the overlapped arguments can be extracted separately according to the different types and triggers with role-specific taggers. All the predicted argument a_r with type c and trigger t in sentence x forms the set $\mathcal{A}_{t,c,x}$. The decoder parameter θ_{ae} includes the type embedding matrix $\mathbf{C}$, and all parameters in the condition fusion function, the self-attention layer and the argument taggers.

3.5 Model Training

To train the model, we take log of Eq (1), and the overall objective $\mathcal{J}(\Theta)$ is deployed as:

$$\begin{aligned} \sum_{x \in \mathcal{D}} \Big[\sum_{c \in \mathcal{C}_x} & \log p_{\theta_1}(c|x) + \\ & \sum_{t \in \mathcal{T}_{x,c}} \log p_{\theta_2}(t|x, c) + \sum_{a_r \in \mathcal{A}_{x,c,t}} \log p_{\theta_3}(a_r|x, c, t) \Big] \end{aligned} \tag{11}$$

where $\Theta \triangleq \{\theta_1, \theta_2, \theta_3\}$; $p_{\theta_1}(c|x)$, $p_{\theta_2}(t|x, c)$, and $p_{\theta_3}(a_r|x, c, t)$ for the subtasks are defined as:

$$\begin{aligned} p_{\theta_1}(c|x) &= (\hat{c})^{\bar{c}}(1 - \hat{c})^{(1-\bar{c})} \\ p_{\theta_2}(t|x, c) &= \prod_{z \in \{s,e\}} \prod_{i=1}^{N} (\hat{t}_i^{zc})^{\bar{t}_i^{zc}}(1 - \hat{t}_i^{zc})^{(1-\bar{t}_i^{zc})} \\ p_{\theta_3}(a_r|x, c, t) &= \prod_{r \in \mathcal{R}} \prod_{z \in \{s,e\}} \prod_{i=1}^{N} (\hat{r}_i^{zct})^{\bar{r}_i^{zct}}(1 - \hat{r}_i^{zct})^{(1-\bar{r}_i^{zct})} \end{aligned} \tag{12}$$

where $\hat{c}$, $\hat{t}_i^{sc}$, $\hat{t}_i^{ec}$, $\hat{r}_i^{sct}$, $\hat{r}_i^{ect}$ are the predicted probabilities in Eq (3), Eq (7), Eq (9), and $\bar{c}$, $\bar{t}_i^{sc}$, $\bar{t}_i^{ec}$, $\bar{r}_i^{sct}$, $\bar{r}_i^{ect}$ are the true $0/1$ labels of the training data, respectively. $\theta_1 \triangleq \{\theta_{bert}, \theta_{td}\}$, $\theta_2 \triangleq \{\theta_{bert}, \theta_{te}\}$, $\theta_3 \triangleq \{\theta_{bert}, \theta_{ae}\}$, where $\theta_{bert}, \theta_{td}, \theta_{te}, \theta_{ae}$ denote parameters in BERT, type detection, trigger extraction and argument extraction, respectively. We train the model by maximizing $\mathcal{J}(\Theta)$ through Adam stochastic gradient descent (Kingma and Ba, 2015) over the shuffled mini-batches.

	#Overlap	#Normal	#Sentence	#Event
Training	1,560	5,625	7,185	10,277
Validation	205	694	899	1,281
Testing	210	688	898	1,332
All	1,975	7,007	8,982	12,890

Table 1: Statistics of the dataset. Each column denotes the number of the sentences with overlapped elements, the sentences without overlapped elements, all the sentences and all the events.

4 Experiments

In this section, we conduct experiments to evaluate the performance of CasEE.

4.1 Dataset and Evaluation Metric

We conduct experiments[2] on a Chinese financial event extraction benchmark FewFC (Zhou et al., 2021). We split data with 8:1:1 for training/validation/testing. Table 1 shows more details.

For evaluation, we follow the traditional evaluation metrics (Chen et al., 2015; Du and Cardie, 2020b): 1) Trigger Identification (TI): A trigger is correctly identified if the predicted trigger span matches with a golden span; 2) Trigger Classification (TC): A trigger is correctly classified if it is correctly identified and assigned to the correct type; 3) Argument Identification (AI): An argument is correctly identified if its event type is correctly recognized and the predicted argument span matches with a golden span; 4) Argument Classification (AC): an argument is correctly classified if it is correctly identified and the predicted role matches with a golden role. We report Precision (P), Recall (R) and F measure (F1) for each of the four metrics.

4.2 Comparision Methods

Though various models have recently been developed for EE, few researches are investigated to solve overlapping event extraction. We attempt to develop the following baselines based on current solutions. For the realistic consideration, no candidate entities are previously known for EE.

Joint sequence labeling methods. This kind of method formulates event extraction into a sequence labeling task. **BERT-softmax** (Devlin et al., 2019) adopts BERT to learn textual representations and uses hidden states for classifying event triggers and arguments. **BERT-CRF** adopts conditional random field (CRF) to capture label dependencies, which is adopted in (Du and Cardie, 2020a) for document-level event extraction. **BERT-CRF-joint** borrows idea from joint extraction of entity and relation (Zheng et al., 2017), which adopts joint labels of the type and role as `B/I/O-type-role`. All the above methods can not solve the overlapping problem due to label conflicts.

Pipelined event extraction methods. This kind of method solves event extraction with a pipeline manner. **PLMEE** (Yang et al., 2019) solves overlapped argument problem by extracting role-specific arguments according to the trigger. Motivated by current Machine Reading Comprehension (MRC) based EE studies (Li et al., 2020; Du and Cardie, 2020b; Liu et al., 2020; Chen et al., 2020), we train multiple MRC BERTs for overlapping event extraction. We extend MQAEE (Li et al., 2020) for multi-span extraction and re-assemble the following methods[3] to consider conditions in EE: 1) The method first predicts types, and then predicts overlapped triggers/arguments according to the type, termed as **MQAEE-1**. 2) The method first predicts overlapped triggers with types, and then predicts overlapped arguments according to the typed triggers, termed as **MQAEE-2**. 3) The method sequentially predicts types, predicts overlapped triggers according to the type, and predicts overlapped arguments according to the type and trigger, termed as **MQAEE-3**. All the above pipeline methods could solve (or partly solve) overlapping event extraction.

4.3 Implementation Details

We adopt source code for PLMEE with its best hyper-parameters reported in the original literature. To achieve other baselines, we implement the code based on the Transformers library (Wolf et al., 2020). For all the methods, we adopt Chinese BERT-Base model[4] as the textual encoder, which has 12 layers, 768 hidden units and 12 attention heads. We use the same value for the common hyper-parameters among the methods, including the optimizer, learning rate, batch size and epoch. For all the hyper-parameters, we adopt grid search

---

[2] Though ACE 2005 dataset is usually used to evaluate traditional EE models, we observe that it contains a low proportion of sentences with overlapped argument problem (nearly 10% reported in Yang et al. (2019)), and doesn't exist sentences with overlapped trigger problem.

[3] For more details, please refer to the Appendix B.

Table 2: Results of event extraction on FewFC dataset, where TI, TC, AI, AC denote trigger identification, trigger classification, argument identification and argument classification, respectively.

strategy. We train all the methods with an Adam weight decay optimizer. The initial learning rate is tuned in $[1e^{-5}, 5e^{-5}]$ for BERT parameters and $[1e^{-4}, 3e^{-4}]$ for other parameters. The warming up proportion for learning rate is 10%, and the max training epoch is set to 20. The batch size is set to 8. For CasEE, the dimension d_p of the relative position embedding is tuned in $\{16, 32, 64\}$. To avoid overfitting, we apply dropout to BERT hidden states with the rate tuned in $[0, 1]$. Besides, the thresholds $\xi_1, \xi_2, \xi_3, \xi_4, \xi_5$ for prediction are tuned in $[0, 1]$. We select the best model leading to the highest performance on the validation data. The optimal hyper-parameter settings are tuned by grid search, listed in the Appendix A.

4.4 Main Results

The performance of all methods on the FewFC dataset is shown in 2. The table reveals that:

(1) Compared to the joint sequence labeling methods, CasEE achieves better performance on the F1 score. Specifically, CasEE achieves improvements of 4.5% over BERT-CRF and 4.3% over BERT-CRF-joint on F1 score of AC, respectively. Besides, CasEE produces higher results on the recall of the evaluation metrics, since the sequence labeling methods have label conflicts that only one label can be predicted for those multi-label tokens. The results demonstrate the effectiveness of CasEE on overlapping event extraction.

(2) Compared to the pipeline methods, our method also outperforms them on the F1 score. The results show that CasEE achieves 3.1% and 2.6% improvements on F1 score of TC and AC over PLMEE, indicating the importance of solving the overlapped trigger problem in EE. Though the MRC based baselines can extract the overlapped triggers and arguments, CasEE still achieves better performance. Specifically, CasEE improves by a relative margin of 4.1% against the strong baseline MQAEE-2. The reason may be that CasEE jointly learns textual representations for subtasks, building helpful interactions and connections among the subtasks. The results demonstrate the superiority of CasEE over the above pipeline baselines.

Variants	TI (%)	TC (%)	AI (%)	AC (%)
BERT-softmax	76.5	49.0	56.1	53.5

4.5 Analysis on Overlap/Normal Data

To further understand the performance in testing, we divide the original test data into two groups: the sentences with overlapped elements and the sentences without overlapped elements.

Variants	P (%)	R (%)	F1 (%)
MaxP	88.1	89.2	88.5
MeanP	88.3	89.8	88.6
CLS	**88.9**	88.7	88.5
CasEE	87.5	**91.9**	**89.2**

Table 5: Results of type detection decoder variants. The evaluation metric is precision, recall and F1 score in macro average of type classification.

Variants	P (%)	R (%)	F1 (%)
w/o self-attention	89.2	88.1	88.6
w/o condition	86.5	87.6	87.0
repl. concatenation	89.3	87.7	88.5
repl. addition	**90.4**	88.8	89.6
repl. gate mechanism	90.2	88.2	89.1
CasEE	90.1	**90.2**	**90.1**

Table 6: Results of trigger extraction decoder variants. The evaluation metric is precision, recall and F1 score on TC metric with oracle results of type detection.

Performance on Overlap Sentences. As shown in table 3, our method significantly outperforms previous methods on the overlap sentences. The improvements may come from the property that our method avoids label conflicts compared to the sequence labeling methods, and builds more effective feature-level connections among subtasks compared to the pipeline methods.

Performance on Normal Sentences. As shown in table 4, our method still performs acceptable results on the normal sentences without overlapped event elements. The sequence labeling methods reveal similiar results on trigger extraction but relatively better results on argument extraction, where they avoid potential propagation errors of the cascade decoding. Besides, PLMEE performs similar results on trigger extraction but relatively better results on argument extraction, where the reason may be that it adopts elaborate re-weighting losses for different argument roles as in its original literature. In addition, MQAEE-2 predicts more accurate triggers since it jointly predicts triggers with types, but it unfortunately ignores feature-level connections among the subtasks, making the argument extraction results similar to CasEE. Even so, the vanilla CasEE still conducts acceptable performance on the normal sentences compared to the baselines. We would further tackle the potential propagation errors and improve the performance for the general event extraction in the future work.

Variants	P (%)	R (%)	F1 (%)
w/o self-attention	82.8	81.7	82.2
w/o indicator function	84.1	81.4	82.7
w/o position embedding	83.2	81.5	82.3
w/o condition	**84.7**	78.2	81.3
repl. concatenation	84.0	79.3	81.6
repl. addition	84.2	78.2	81.1
repl. gate mechanism	84.6	80.2	82.4
CasEE	84.1	**83.7**	**83.9**

Table 7: Results of argument extraction decoder variants. The evaluation metric is precision, recall and F1 score on AC metric with oracle results of type detection and trigger extraction.

4.6 Discussion for Model Variants

To investigate the effectiveness of each module, we conduct variant experiments for CasEE.

Detection Module Variants. Table 5 shows performance of type detection variants. Specifically, MaxP/MeanP aggregates textual representations by applying max/mean pooling over BERT hidden states; CLS utilizes the hidden state of the special token `<CLS>` as the sentence representation. The results show that our method outperforms all the above variants on F1 score, indicating that learning sentence representation adaptive to the event type produces better representation for type detection.

Extraction Module Variants. Table 6 and Table 7 show performance of decoder variants for trigger extraction and argument extraction, respectively. We remove the self-attention layer in the both extraction decoders, and remove the relative position embeddings and the indicator function in the argument extraction decoder. The results demonstrate the effectiveness of each module.

Furthermore, we conduct experiments to explore the impact of condition fusion function ϕ. The experiments include: 1) we simply remove condition integrate function; 2) we achieve ϕ by concatenating the condition and token representations; 3) we achieve ϕ by simply adding the condition embedding to token representations; 4) we achieve ϕ by the gate mechanism, which adds the condition embedding to token representations according to a learnable trade-off factor. The results show that the performance without condition fusion function decline significantly on the F1 score in the two decoders, since the model can not discern different targets to extract in the sentence. Besides, empirical results also show that CLN performs better performance than other fusion functions on F1 scores in the two decoders, indicating that CLN can generate better conditional token representations for downstream subtasks.

5 Conclusion

This paper proposes a joint learning framework with cascade decoding for overlapping event extraction, termed as CasEE. Previous studies usually assume that events appear in sentences without overlaps, which are not applicable to the complicated overlapping scenarios. CasEE sequentially performs type detection, trigger extraction and argument extraction, where the overlapped targets are separately extracted conditioned on former predictions. All subtasks are jointly learned to capture dependencies among subtasks. Experiments on the public dataset demonstrate that our model outperforms previous competitive methods on overlapping event extraction. Our future work may further tackle the potential error propagation problem in the cascade decoding paradigm, and improve the performance for the general event extraction.

A Hyper-parameter Settings

Our implementation is based on PyTorch[5]. We trained our models with a NVIDIA TESLA T4 GPU. For re-implementation, we report our hyper-parameter settings on the dataset in Table 8. Note that the hyper-parameter settings are tuned on the validation data by grid search with 3 trials.

Hyper-parameter	CasEE
type embedding dimension d	768
position embedding dimension d_p	64
dropout rate of decoders	0.3
batch size	8
training epoch	20
initial learning rate of BERT	$2e^{-5}$
learning rate of decoders	$1e^{-4}$
threshold ξ_1	0.5
threshold ξ_2	0.5
threshold ξ_3	0.5
threshold ξ_4	0.5
threshold ξ_5	0.5

Table 8: Hyper-parameter settings of CasEE.

B Details of MRC Based Baselines

Here we describe the details of the extended MRC baselines. Since the MRC paradigm could place condition information in the questions, we extend it to solve the overlapping event extraction.

MQAEE-1 contains two models: 1)A BERT classifier to detect event types; 2) A MRC BERT to extract triggers and arguments. The question template is like `<type>` to predict triggers with type `type`, and `<role>` to predict arguments with role `role`. Though this method neglects associations between the trigger and argument, it tackles overlapped trigger problem and overlapped argument problem since the overlapped targets are extracted separately according to different questions.

MQAEE-2 contains two models: 1) A MRC BERT to extract all triggers with types. The question template is a single word `trigger` to predict all typed triggers. 2) A MRC BERT to extract arguments in different roles. The question template is like `<type>and<trigger>` to predict all arguments associated with the type `type` and the trigger `trigger`. This method tackles overlapped trigger problem with multiple taggers, and tackles overlapped argument problem by extracting argument separately according to both the type and trigger.

MQAEE-3 contains three models: 1)A BERT classifier to detect event types; 2) A MRC BERT to extract triggers with different types. The question template is like `<type>` to predict triggers with type `type`. 3) A MRC BERT to extract arguments in different roles. The question template is like `<type>and<trigger>` to predict all arguments associated with the type `type` and the trigger `trigger`. This method tackles overlapped trigger problem by extracting triggers according to the type, and tackles overlapped argument problem according to both the type and trigger.

Abstract

Topic models are effective in capturing the latent semantics of large-scale textual data while existing methods are normally designed and evaluated on balanced corpora. However, it contradicts the fact that general corpora in our world are naturally long-tailed, and the long-tailed bias can highly impair the topic modeling performance. Therefore, in this paper, we propose a causal inference framework to explain and overcome the issues of topic modeling on long-tailed corpora. In a neat and elegant way, causal intervention is applied in training to take out the influence brought by the long-tailed bias. Extensive experiments on manually constructed and naturally collected datasets demonstrate that our model can mitigate the bias effect, greatly improve topic quality and better discover the hidden semantics on the tail.

1 Introduction

Topic models are proposed to discover the underlying topics and semantic structures from unlabelled text collections. Due to the effectiveness and interpretability, topic models have been applied in various downstream tasks like information retrieval (Wang et al., 2007), content summarization (Ma et al., 2012) and recommendation systems (McAuley and Leskovec, 2013). One of the most widely used topic models is Latent Dirichlet Allocation (LDA) (Blei et al., 2003), a probabilistic graphical model using the conjugate of Dirichlet and Multinomial distribution and inferring the parameters with approximation methods(Griffiths and Steyvers, 2004; Blei et al., 2017). Recently, some popular neural topic models based on Variational AutoEncoder (VAE) (Kingma and Welling, 2014; Rezende et al., 2014) have been introduced, such as Neural Variational Document Model (NVDM) (Miao et al., 2016) and Product of Experts LDA (ProdLDA) (Srivastava and Sutton, 2017). Compared to probabilistic ones, they can easily carry out the inference by gradient backpropagation.

However, these topic models are generally designed and evaluated on balanced corpora, such as the commonly used 20News (Lang, 1995) with evenly distributed labels through which we can infer that the latent topics are also evenly distributed. It hence conflicts with the fact that natural text collections are regularly long-tail distributed following Zipf's law (Reed, 2001), especially the textual data on social network platforms(Zhang and Luo, 2019). More precisely, Figure 1 illustrates that in a collected corpus, documents about some hot topics are numerous (*head topics*), while the documents about most topics are few (*tail topics*). Due to this bias, similar to long-tailed classification tasks where a classifier favors to predict an image as the head classes (Kang et al., 2020; Zhou et al., 2020), topic models on long-tailed corpora tend to reveal the semantics of documents about head topics and ignore the documents about tail topics to a great extent. Namely, the discovered topics are mostly about the latent head ones in the corpus. As a result, their diversities are much impaired and incomplete to represent the whole semantics of a corpus. Thus, it is crucial to explore effective ways for long-tailed topic modeling.

Different from other long-tailed tasks like image classification or relation extraction, the key challenge of this problem lies in that topic modeling is originally designed for unlabelled datasets, so we have no access to classification labels to infer the latent global topic distributions while designing solutions[1]. Owing to this factor, we intend not to introduce complicated modules conditioning

---

[1] Admittedly, there are supervised topic models (Mcauliffe and Blei, 2007; Card et al., 2018), but the necessity of labels will hugely narrow their application scopes. So, we concentrate on solving the issue without additional labels.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 175–185

on accessible labels, e.g., re-weighting (Mahajan et al., 2018) or re-sampling (Khan et al., 2017; Lin et al., 2017; Cui et al., 2019) approaches for other long-tail problems.

To overcome this challenge, in this paper, we present a Structural Causal Model (SCM) (Pearl et al., 2016; Pearl and Mackenzie, 2018) to precisely explain how the long-tailed bias undermines the topic modeling performance. Then, to remove the bias effect, we propose an approach via the causal intervention (Pearl et al., 2016) on topic distributions and adopt the backdoor adjustment (Pearl, 1995) to calculate the causality in the condition of no auxiliary information. Furthermore, we introduce a novel neural model named as **Deconfounded Topic Model (DecTM)** in the framework of VAE with deconfounded training through an approximation manner. Through comprehensive experiments, we manifest that our new model can mitigate the influence of the long-tailed bias and produce high-quality topics that are more diverse and better disclose the semantics of documents about tail topics. The main contributions of this paper can be concluded as follows:

1. We present a structural causal model to clarify how the problems of topic modeling are incurred by the long-tailed bias in detail;
2. We further propose a neat method to approximate the causal intervention for reducing bias influence, depending on which a novel neural topic is also introduced with deconfounded training;
3. We validate our model on both manually-constructed and extreme multi-label text classification datasets and demonstrate our model is effective to alleviate the impact of bias and greatly improve the topic quality compared to both probabilistic and neural baseline models.

2 Related Work

Topic Modeling Probabilistic topic models can date back to Probabilistic Latent Semantic Analysis (PLSA) (Hofmann, 1999) and LDA (Blei et al., 2003), derving numerous variants(Blei and Lafferty, 2006; Yan et al., 2013; Wu and Li, 2019). Previously, Wang et al. (2015) adapted LDA to discover long-tail semantics from large-scale corpora. Those models usually adopt Gibbs Sampling (Griffiths and Steyvers, 2004) or Variational Inference (Blei et al., 2017) for parameter estimations. Based on VAE (Kingma and Welling, 2014; Rezende et al., 2014), neural topic models (Miao et al., 2016; Srivastava and Sutton, 2017; Wu et al., 2020a) are introduced. They are derivation-free and can apply gradient backpropagation directly. Nevertheless, these former works including probabilistic and neural methods are normally evaluated on balanced datasets. Since long-tail distributed data are common in our natural world (Reed, 2001), this inspires us to find out how these topic models perform on long-tailed corpora and propose useful ways to alleviate the long-tailed bias impact.

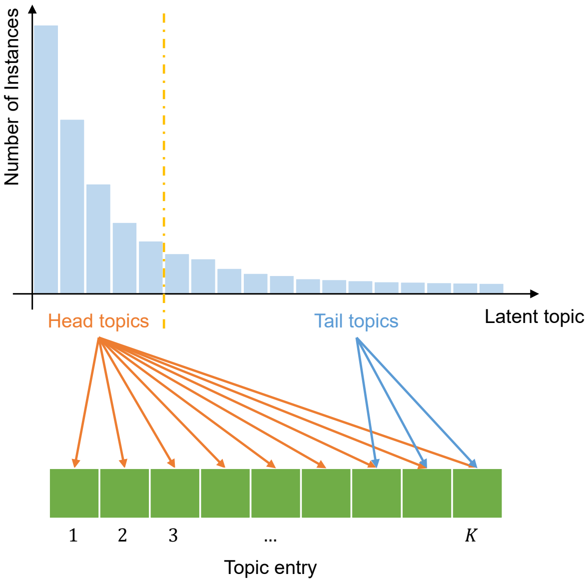

Figure 1: Illustration of topic entries assigned to documents in a long-tailed corpus.

Causal Inference Causal inference (Pearl et al., 2016) has been widely adopted in various fields for years, like psychology, epidemiology, and medicine (MacKinnon et al., 2007; Richiardi et al., 2013), providing solutions to investigate the causation between research objects. Recently, the causal inference has also increasingly attracted attention in computer vision and NLP society for removing the biases in datasets (Tang et al., 2020; Wu et al., 2020c) or providing counterfactual examples (Zeng et al., 2020) in domain-specific applications. In this paper, we propose to employ the causal inference mechanism to investigate wherefores for the issues of long-tailed topic modeling and propose a solution with deconfounded training via the intervention to alleviate the bias effect.

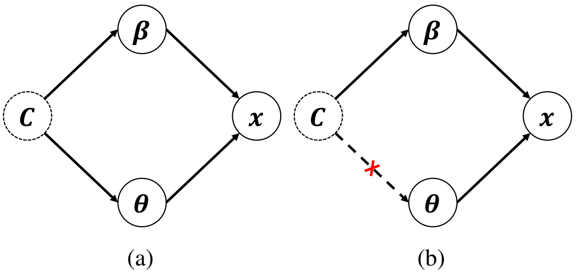
3 Method

In this section, we first explain how the long-tailed bias affects topic modeling from the perspective of causal inference, and then propose a novel model to overcome this issue with deconfounded training by the causal intervention.

3.1 SCM for Topic Modeling

First of all, we investigate the causal relationship between the latent variables in a topic model with a Structural Causal Model (SCM). SCMs are expressed visually by using directed acyclic graphs. In the graph, vertices are random variables, and directed edges represent direct causation from one variable to another (Pearl et al., 2016). There is a special vertex in the graph: *confounder*, a variable that influences both correlated and independent variables, creating a spurious statistical correlation. For example, considering an interesting study that chocolate consumption is statistically related to the number of Nobel prizes of a country (Dablander, 2020). Is it justified to argue that people can get Nobel prizes if they eat more chocolate? Common sense intuitively tells us this assertion is inaccurate. We can draw a causal graph to detail it: **chocolate consumption** ← **economy** → **number of Nobel prizes**, the chocolate consumption is usually higher in a developed country with good economy, and the number of Nobel prizes is also larger since the citizens' education level is higher in this country. Therefore, the economy acts as a confounder that creates a spurious correlation between chocolate consumption and the number of Nobel prizes.

Similar to the above example, we build a SCM shown in Figure 2a to describe how a biased corpus influences the text generation process of topic modeling. In the graph, $\boldsymbol{C}$ means the unobserved confounding bias in a long-tailed corpus. We note the vocabulary size is V and set K topic entries (the topic number is K) which means the model needs to discover K latent topics. In the setting of topic modeling, a topic entry k is interpreted as the related words and represented with a word distribution $\boldsymbol{\beta}_k \in \mathbb{R}^V$. Then, the word distributions of all topic entries (topic-word distribution matrix) is $\boldsymbol{\beta} = (\boldsymbol{\beta}_1, ..., \boldsymbol{\beta}_k, ..., \boldsymbol{\beta}_K) \in \mathbb{R}^{V \times K}$. A document $\boldsymbol{x}$ is assigned with various topic entries with each probability as θ_k, so the distribution over all topic entries (topic distribution of $\boldsymbol{x}$) is $\boldsymbol{\theta} = (\theta_1, ..., \theta_k, ..., \theta_K)^{\mathrm{T}} \in \mathbb{R}^K$. Then, $\boldsymbol{x}$ is generated with its topic distribution $\boldsymbol{\theta}$ and the topic-word distribution matrix $\boldsymbol{\beta}$ of the whole corpus. The paths in Figure 2a can be specifically interpreted as follows:



(a) (b)

Figure 2: The structural causal model of topic modeling. (a) Complete SCM without interventions. (b) Do intervention on the topic distribution $\boldsymbol{\theta}$.

- $\boldsymbol{C} \rightarrow \boldsymbol{\theta}$: This path says that the topic distributions are trained under bias. If there is no bias, different topic entries are ideally assigned to documents about various topics, and the inferred topic distributions of these documents are also different. However, in a long-tailed corpus with bias, the topic distributions of documents about different topics could be similar. As shown in Figure 1, since documents about the head topics are the absolute majority, most of the topic entries are assigned to them[2]. In this case, for a document about tail topics, its assigned topic entries probably are also assigned to the documents about head topics, as a result of which, its inferred topic distribution becomes similar to the topic distributions of some documents about head topics.

- $\boldsymbol{C} \rightarrow \boldsymbol{\beta} \rightarrow \boldsymbol{x}$: This link denotes the topic-word distribution matrix $\boldsymbol{\beta}$ is trained under the bias and is used to generate the document $\boldsymbol{x}$. Due to the long-tailed bias, the generated $\boldsymbol{x}$ tends to contain words in the documents about head topics.

- $\boldsymbol{\theta} \leftarrow \boldsymbol{C} \rightarrow \boldsymbol{\beta} \rightarrow \boldsymbol{x}$: Because of the confounder $\boldsymbol{C}$, the inferred topic distribution of a document about tail topics could be similar to the topic distributions of some documents about head topics, and the generated documents of these similar topic distributions tend to include words in the documents about head topics instead of tail topics. Therefore, this

---

[2] If the documents about tail topics are few enough to be ignorable, all the topic entries will be assigned to the documents about head topics.

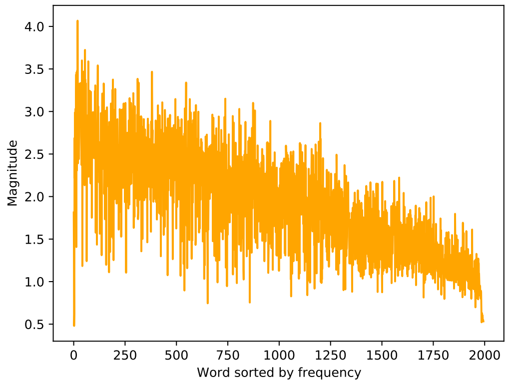


Figure 3: The magnitude of $\boldsymbol{\beta}_{i*}$ obtained from ProdLDA sorted by word frequency.

> backdoor path via $\boldsymbol{C}$ causes the spurious correlation between the topic distribution of a document about tail topics and the words in the documents about head topics.

In consequence, this spurious correlation through the confounder incurs that the discovered topics from documents about tail topics are mixed by the words of latent head topics. When the bias in the corpus gets severer, the discovered topics are even totally occupied by these words. Namely, topic models tend to ignore the semantics of the documents about tail topics and cannot discover the latent tail topics of a corpus.

In the above discussion, we clarify how the bias leads to the problems of long-tailed topic modeling with the presented SCM. In the next section, we propose a neat method to solve this issue without any auxiliary information.

3.2 Intervention on Topic Distribution

To remove the spurious correlation (deconfound), we propose to do causal intervention via *do*-operator (Pearl et al., 2016). Taking the chocolate and Nobel prizes for example again, intervening on the chocolate consumption means we fix its value through which we curtail the natural tendency of it to vary in response to the economy in nature. This amounts to remove the edges directed into the chocolate consumption. For example, if we were to close all chocolate factories, denoted as $do(\textbf{chocolate consumption} = 0)$, we will find the causality between the chocolate consumption and the number of Nobel prizes.

Similarly, we do intervention on the topic distribution $\boldsymbol{\theta}$ to compute the causality of $\boldsymbol{\theta}$ on $\boldsymbol{x}$, i.e., $p(\boldsymbol{x}|do(\boldsymbol{\theta}))$. As shown in Figure 2b, doing intervention on $\boldsymbol{\theta}$ means cutting off the edge $\boldsymbol{C} \rightarrow \boldsymbol{\theta}$ so that $\boldsymbol{C}$ cannot affect $\boldsymbol{\theta}$. But it is difficult to actually intervene variables (like closing all chocolate factories), so we utilize the backdoor adjustment (Pearl, 1995). The variable $\boldsymbol{\beta}$ meets the backdoor criterion and blocks the backdoor path $\boldsymbol{\theta} \leftarrow \boldsymbol{C} \rightarrow \boldsymbol{\beta} \rightarrow \boldsymbol{x}$. Following the backdoor adjustment, we use Inverse probability Weighting (Pearl et al., 2016) as

$$\begin{aligned} &p(\boldsymbol{x}|do(\boldsymbol{\theta})) \\ &\quad= \sum_{\boldsymbol{\beta}} p(\boldsymbol{x}|do(\boldsymbol{\theta}), \boldsymbol{\beta}) p(\boldsymbol{\beta}|do(\boldsymbol{\theta})) \quad (1) \\ &\quad= \sum_{\boldsymbol{\beta}} p(\boldsymbol{x}|\boldsymbol{\theta}, \boldsymbol{\beta}) p(\boldsymbol{\beta}) \quad (2) \\ &\quad= \sum_{\boldsymbol{\beta}} \frac{p(\boldsymbol{x}, \boldsymbol{\theta}, \boldsymbol{\beta})}{p(\boldsymbol{\theta}|\boldsymbol{\beta})} \quad (3) \end{aligned}$$

In Figure 2b, all of $\boldsymbol{\theta}$ and $\boldsymbol{x}$ association flows along the directed path from $\boldsymbol{\theta}$ to $\boldsymbol{x}$ since there cannot be any backdoor paths because $\boldsymbol{\theta}$ has no incoming edges, so $p(\boldsymbol{x}|do(\boldsymbol{\theta}), \boldsymbol{\beta}) = p(\boldsymbol{x}|\boldsymbol{\theta}, \boldsymbol{\beta})$. Also, $p(\boldsymbol{\beta}|do(\boldsymbol{\theta})) = p(\boldsymbol{\beta}|\boldsymbol{\theta})$ since there's no other edges from $\boldsymbol{\theta}$ to $\boldsymbol{\beta}$ except through the collider $\boldsymbol{x}$.

But this equation is intractable, we need to approximate it. To find a proper way, we bury in mind that topics are interpreted as word distributions, so long-tail distributed topics can also be seen as long-tail distributed words. If we treat these words as "labels", then the generative process of a document is roughly predicting the probability under each "label". This inspires us to discover the relation between long-tailed topics and long-tailed classification tasks (Kang et al., 2020; Tang et al., 2020). Similar to these tasks, as shown in Figure 3, we observe that the magnitudes of topic distributions of words, i.e., $\boldsymbol{\beta}_{i*}$ for word i, gradually decrease along with the word frequency. Intuitively, the magnitude of $\boldsymbol{\beta}_{i*}$ means the "correlation score" between word i and all topics; therefore, this phenomenon may be because most inferred topics tend to relate to the words in documents about the head topics as mentioned before. Due to this finding, we propose an approximation method following the propensity score modeling (Rosenbaum and Rubin, 1983; Austin, 2011):

$$p(\boldsymbol{x}|do(\boldsymbol{\theta})) \approx \prod_{i} \frac{\boldsymbol{\beta}_{i*}\boldsymbol{\theta}}{\|\boldsymbol{\beta}_{i*}\|_2 \|\boldsymbol{\theta}\|_2} \quad (4)$$

where i refers to a word in $\boldsymbol{x}$ and we also empirically add the magnitude of $\boldsymbol{\theta}$. Here, the denominator works as a normalizer that balances the magnitude of the variables: $\boldsymbol{\beta}_{i*}$ and $\boldsymbol{\theta}$ for approximating the intervention probability.

3.3 Proposed Model

In this section, we propose a neural topic model for long-tailed corpora with deconfounded training based on the aforementioned intervention method, named as **Deconfounded Topic Model** (**DecTM**). Our network architecture is under the basic framework of VAE (Kingma and Welling, 2014; Rezende et al., 2014) with an encoder and a deconfounded decoder.

3.3.1 Encoder

The encoder transforms a text $\boldsymbol{x}$ into its topic distribution $\boldsymbol{\theta}$. Following the setting of Miao et al. (2016), we take the bag-of-words (BoW) assumption that ignores the word orders since topic models normally leverage word co-occurrences for topic inference. Inputted the BoW representation of $\boldsymbol{x}$, we first obtain its intermediate representation $\boldsymbol{\pi}$ with a Multi-Layer Perceptron (MLP). Based on $\boldsymbol{\pi}$, we then compute $q(\boldsymbol{r}|\boldsymbol{x})$, the variational distribution of the latent representation $\boldsymbol{r}$. Since the prior distribution $p(\boldsymbol{r})$ is assumed to be a Logistic Normal distribution for approximating the Dirichlet distribution (Srivastava and Sutton, 2017), we model the $q(\boldsymbol{r}|\boldsymbol{x})$ as $\mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$. The mean $\boldsymbol{\mu}$ and variance $\boldsymbol{\Sigma}$ are calculated as

$$\boldsymbol{\mu} = \boldsymbol{W}_{\mu}\boldsymbol{\pi} + \boldsymbol{b}_{\mu} \tag{5}$$

$$\boldsymbol{\Sigma} = \mathrm{diag}(\boldsymbol{W}_{\Sigma}\boldsymbol{\pi} + \boldsymbol{b}_{\Sigma}) \tag{6}$$

where $\boldsymbol{W}_{\mu}$, $\boldsymbol{W}_{\Sigma}$, $\boldsymbol{b}_{\mu}$ and $\boldsymbol{b}_{\Sigma}$ are weight matrices and biases respectively , and $\mathrm{diag}(\cdot)$ means converting a vector to a diagonal matrix. Later, to reduce the gradient variance, we adopt the reparameterization trick (Kingma and Welling, 2014) to sample $\boldsymbol{r}$ as

$$\boldsymbol{r} = \boldsymbol{\mu} + \boldsymbol{\Sigma}^{1/2}\boldsymbol{\epsilon}, \quad \boldsymbol{\epsilon} \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I}). \tag{7}$$

Next, $\boldsymbol{r}$ is normalized with a softmax function to get the topic distribution $\boldsymbol{\theta}$ as

$$\boldsymbol{\theta} = \mathrm{softmax}(\boldsymbol{r}). \tag{8}$$

3.3.2 Deconfounded Decoder

After getting the topic distribution of the input text, we then feed it to the proposed deconfounded decoder for reconstruction. According to the method in Equation (4), the objective function of DecTM can be written as

$$\mathcal{L}(\boldsymbol{x}) = \mathrm{KL}\left(q(\boldsymbol{r}|\boldsymbol{x}) \| p(\boldsymbol{r})\right) - \mathbb{E}_{\epsilon \sim \mathcal{N}(\boldsymbol{0},\boldsymbol{I})}\left[\sum_{i=1}^{N} \log \frac{\boldsymbol{\beta}_{i*}\boldsymbol{\theta}}{\|\boldsymbol{\beta}_{i*}\|_2 \|\boldsymbol{\theta}\|_2}\right] \tag{9}$$

where the first term is the Kullback-Leibler (KL) divergence between the posterior and prior distribution. It can be computed with the analytical solution for two Normal distributions. The second term is the reconstruction error between the input and output text. Different from normal neural topic models (Miao et al., 2016; Srivastava and Sutton, 2017), the deconfounded decoder in our model employs the approximated probability for causal intervention on $\boldsymbol{\theta}$ to weaken the long-tailed bias. Note that our model can be directly applied to naturally collected corpora since no additional auxiliary information is necessary for our model.

4 Experiment Setup

4.1 Datasets

Unfortunately, common datasets for topic modeling are almost all balanced, so we manually construct the long-tailed variants of them by repeating and deleting documents according to the given labels, making them follow a long-tailed distribution. Through the distribution of labels, we can roughly assume the latent topics are long-tailed distributed. In this way, we form the long-tailed versions (-LT) of 20News (Lang, 1995)[3] and Yahoo Answer[4], called 20News-LT and Yahoo Answer-LT respectively. Moreover, to better evaluate the performance of long-tailed topic modeling, we adopt the datasets for eXtreme Multi-label Text Classification (XMTC) (You et al., 2019), a task to predict the most relevant multiple labels for texts from an extremely large-scale label set. The label set includes hundreds and thousands, even millions of labels, and most are tail labels with very few positive samples. These plentiful labels can be naturally interpreted as the latent topics of documents; thus, we can evaluate the proposed model on these long-tailed distributed datasets. We conducted experiments on the the subsets of standard benchmark XMTC datasets Amazon-670K, Wiki-500K, AmazonCat-13K and Amazon-3M (Bhatia

et al., 2016)[5].

For all datasets, we conduct the following steps for preprocessing: (1) tokenize texts and lowercase words; (2) remove stop words and illegal characters; (3) remove low-frequency words. The statistics of preprocessed datasets are reported in Table 1. It is worth noting that although labels are provided in these datasets, they are not used by our model.

4.2 Baseline Models

We take both probabilistic and neural topic models as baselines. For probabilistic models, we consider the widely used LDA (Blei et al., 2003) with python-lda[6] package for topic inference. For neural topic models, we use NVDM (Miao et al., 2016)[7], ProdLDA (Srivastava and Sutton, 2017)[8] and Scholar (Card et al., 2018)[9]. Scholar is an extension of ProdLDA via optionally incorporating metadata of documents like sentiments.

5 Experiment Results

5.1 Topic Quality Analysis

5.1.1 Evaluation Metrics

Following Nan et al. (2019) and Wu et al. (2020b), we evaluate the topic quality concerning two aspects, topic coherence and diversity. Topic coherence means that the words in the discovered topics are supposed to be as coherent as possible instead of irrelevant ones, and topic diversity means that topics should differ from each other instead of being similar ones.

Topic Coherence For topic coherence, we employ C_V (Röder et al., 2015), an improved variant of the Normalized Pointwise Mutual Information (NPMI) (Bouma, 2009; Chang et al., 2009; Newman et al., 2010). Its detailed calculation can be found in Wu et al. (2020b). We need to mention that given a topic z and its top T probable words $(x_1, x_2, ..., x_T)$, the NPMI of (x_i, x_j) used in the C_V computation is defined as

$$\text{NPMI}(x_i, x_j) = \frac{\log \frac{p(x_i,x_j)+\epsilon}{p(x_i)p(x_j)}}{-\log(p(x_i, x_j) + \epsilon)} \qquad (10)$$

where $p(x_i)$ is the occurrence probability of word x_i and $p(x_i, x_j)$ the co-occurrence probability of (x_i, x_j). These probabilities are estimated in a reference corpus. To exhaustively assess the topic coherence performance of long-tailed topic modeling, we use three kinds of C_V scores with the probabilities estimated in different reference corpora. First, we adopt the public tool[10] which uses Wikipedia documents as the external reference corpus (-E), so it is named as C_V-E. Then, we directly use the internal training documents (-I) as the reference corpus, named as C_V-I. However, since documents about head topics occupy the main portion of a long-tailed corpus, previous C_V-E and C_V-I probably are insufficient to appraise the performance on the documents about tail topics. To this end, we heuristically introduce C_V-T that employs the documents including the tail labels (-T) provided by the datasets instead of all the training documents as the reference corpus, so it can assess whether the discovered topics can reveal the hidden semantics of documents about tail topics, i.e., discover the tail topics.

Topic Diversity For topic diversity evaluation, we employ the Topic Unique (TU) (Nan et al.,

Table 2: Topic quality results concerning topic coherence and diversity. The best in each column is in bold.

2019) defined as

$$TU(z) = \frac{1}{T}\sum_{i=1}^{T}\frac{1}{\text{cnt}(x_i)} \tag{11}$$

where $\text{cnt}(x_i)$ is the total number of times that word x_i appears in the top T words of all topics. Accordingly, TU ranges from $1/K$ to 1, and a higher TU score means topics are more diverse since fewer words are repeated across all.

Comprehensive Evaluation It is necessary to mention that if the topic coherence performance of a model remains about the same and the diversity gets higher, it means the overall topic quality is also improved since it can unearth more various semantics of documents. To provide a forthright and comprehensive evaluation of both coherence and diversity performance, following Dieng et al. (2019), we propose Topic Quality (TQ) that combines C_V and TU as

$$TQ = TU \times \frac{1}{3}(C_V\text{-E} + C_V\text{-I} + C_V\text{-T}) \tag{12}$$

which is the product of TU and the average of three different C_V scores. Thus, TQ can provide a direct comparison of the overall topic quality performance.

Figure 4: TU and average C_V scores on Wiki-500K under different topic numbers.

5.1.2 Results Analysis

Table 2 reports the topic quality results concerning different metrics of the top 15 words with the topic number $K = 50$. At first, we notice that C_V-E scores of DecTM are the highest on 20News-LT and are very close to the best on Yahoo Answer-LT and Wiki-500K. Although C_V-E scores of some baseline models are higher on other datasets, DecTM stably outperforms them in terms of TU by a large margin, and the C_V-I scores of DecTM are also mostly better. This implies that baseline models are disposed to generate repetitive topics because of the bias of these long-tailed corpora, while the topics of our DecTM are more diverse. Therefore, despite that C_V-E of some baselines are higher, their lower diversity performance indicates that their yielded topics are redundant. More significantly, DecTM commonly surpasses baseline models in terms of C_V-T, which shows the

Figure 5: Topic quality performance (TQ) under different topic numbers.

discovered topics can preferably reflect the semantics of documents about tail topics; thus, the produced topics of DecTM are more complete. These arguments are further illustrated with topic examples in Section 5.3. At last, we find that DecTM achieves the highest TQ scores on all datasets, showing the overall performance of our model is fairly better.

From the above experimental results, we observe the problems of the long-tailed topic modeling formerly mentioned in Section 1 and Section 3.1, that the performance of existing topic models, especially topic diversity, is deteriorated on account of the bias. But with the help of the deconfounded decoder, our proposed method can alleviate the effect of the bias and hugely improve the topic diversity while remain good coherence performance with a better ability to expose the semantics of documents about tail topics.

5.2 Impact of Topic Number

To investigate how performance varies concerning the topic number, we report the TU and the average C_V (Avg C_V) scores defined in Equation (12) under topic number K ranging from 50 to 100 on Wiki-500K in Figure 4. We can see that the Avg C_V of DecTM is relatively better in Figure 4a. Besides, as shown in Figure 4b, TU scores of all models gradually decline when the topic number gets bigger, but the performance of DecTM is constantly higher and decreases slower. The reason is that those baseline models tend to focus on documents about head topics which are inadequate to support larger topic numbers, while DecTM can also discover semantics of documents about tail topics. Furthermore, Figure 5 presents the TQ with different topic numbers of all datasets. We can observe that whether on manually constructed or XMTC datasets, our model DecTM outperforms baseline models under different topic numbers. These experiments demonstrate that the performance of our model is relatively stable.

5.3 Discovered Topic Examples

To further illustrate the topic quality performance of different models, Table 3 reports some discovered topic examples. As shown by the comparison of topic diversity in Section 5.1.2, we can see baseline models produce some topics including repeated words. To be more specific, LDA generates topics with repetitive words like “subject”, “organization” from 20News-LT and “book”, “author” from Amazon-3M. Similar topics about “newcastle”, “orchestra” and “hockey” are yielded by NVDM, ProdLDA, and Scholar respectively. We also notice that NVDM, ProdLDA and Scholar all yield several same topics about “census” from Wiki-500K. These topics are coherent indeed, but they can trickily improve the C_V scores and are redundant in the downstream applications. On the contrary, we find only one coherent topic generated by DecTM corresponding to the aforementioned ones.

Table 3: Topic examples. Repeated words are underlined.

What is more, DecTM also discovers some latent topics like “printer”, “series” and “europe” while these cannot be found by baseline models, which could verify the superior C_V-T performance of our model. These topic examples qualitatively show the overall topic quality performance of DecTM is adequately preferable.

6 Conclusion

In this paper, for discovering the topics in long-tailed corpora, we present a causal inference model to describe how the bias influences topic modeling, and to reduce the impact of the bias, we then propose a causal intervention method for deconfounding, relying on which we introduce the Deconfounded Topic Model (DecTM) with a deconfounded decoder. Comprehensive experiments demonstrate that our model can produce topics with better quality and mitigate the effect of long-tailed bias.

More than just Frequency?
Demasking Unsupervised Hypernymy Prediction Methods

Thomas Bott, Dominik Schlechtweg and Sabine Schulte im Walde
Institute for Natural Language Processing, University of Stuttgart, Germany
`{bottts,schlecdk,schulte}@ims.uni-stuttgart.de`

Abstract

This paper presents a comparison of unsupervised methods of hypernymy prediction (i.e., to predict which word in a pair of words such as *fish–cod* is the hypernym and which the hyponym). Most importantly, we demonstrate across datasets for English and for German that the predictions of three methods (WeedsPrec, invCL, SLQS Row) strongly overlap and are highly correlated with frequency-based predictions. In contrast, the second-order method SLQS shows an overall lower accuracy but makes correct predictions where the others go wrong. Our study once more confirms the general need to check the frequency bias of a computational method in order to identify frequency-(un)related effects.

1 Introduction

Hypernymy represents a major paradigmatic semantic relation between two concepts, a hypernym (superordinate) and a hyponym (subordinate), as in *tree–oak* and *fish–cod*, where the hyponym implies the hypernym, but not vice versa. From a cognitive perspective hypernymy is central to the organisation of the mental lexicon (Deese, 1965; Miller and Fellbaum, 1991; Murphy, 2003), next to further semantic relations such as synonymy, antonymy, etc. From a computational perspective hypernymy is central to solving a number of Natural Language Processing (NLP) tasks such as taxonomy creation (Hearst, 1998; Cimiano et al., 2004; Snow et al., 2006; Navigli and Ponzetto, 2012), textual entailment (Dagan et al., 2006; Clark et al., 2007) and text generation (Biran and McKeown, 2013).

Accordingly, the field has witnessed active research on two subtasks involved in computational models of hypernymy (see Shwartz et al. (2017) for an extensive overview): *hypernymy detection* (i.e., distinguishing hypernymy from other semantic relations) and *hypernymy prediction* (i.e., determining which word in a pair of words is the hypernym and which is the hyponym). The target subtask of the current study is hypernymy prediction: we perform a comparative analysis of a class of approaches commonly refered to as *unsupervised hypernymy methods* (Weeds et al., 2004; Kotlerman et al., 2010; Clarke, 2012; Lenci and Benotto, 2012; Santus et al., 2014). These methods all rely on the distributional hypothesis (Harris, 1954; Firth, 1957) that words which are similar in meaning also occur in similar linguistic distributions. In this vein, they exploit asymmetries in distributional vector space representations, in order to contrast hypernym and hyponym vectors.

While these unsupervised hypernymy prediction methods have been explored and compared extensively on a number of benchmark datasets (Shwartz et al., 2017), this study takes a novel perspective and performs a detailed analysis of whether and where the methods make similar or different decisions. Our prediction experiments on simplex and complex nouns in English and German WordNets and evaluation benchmarks show that most of the methods we investigate overlap in their specific predictions to a surprisingly high degree, and that the predictions strongly correlate with those based on raw frequencies. Our study therefore emphasises the general need to check the frequency bias of a computational method and to distinguish between frequency-related and frequency-unrelated effects.

2 Data and Methods

In the following we describe our gold standard datasets (Section 2.1), our corpora and vector spaces (Section 2.2) and our hypernymy prediction methods (Section 2.3). The code and links to the gold standards are available from `https://github.com/Thommy96/hyp-freq-comp`.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 186–192
August 1–6, 2021.

2.1 Gold Standard Datasets

Our study focuses on hypernymy between nouns and uses two types of gold standard resources for hypernymy relations. On the one hand, we rely on WordNets as classical large-scale taxonomies where hypernymy represents one of the core semantic relations for organisation: the English *WordNet*[1] (Miller et al., 1990; Fellbaum, 1998), version 3, and the German *GermaNet*[2] (Hamp and Feldweg, 1997; Kunze and Wagner, 1999; Lemnitzer and Kunze, 2007), version 11. From both WordNets, we extracted all noun–noun pairs with a hypernymy relation and removed duplicates, autohyponyms and space-separated multiword expressions. We also distinguish between compounds (which frequently represent hyponyms of their constituent heads, as in *dog–lapdog*) and non-compounds by applying a simple heuristic, i.e., categorising all hypernym–hyponym pairs as compounds if one is a substring of the other. We expected this subset to exhibit idiosyncratic behaviour in our prediction experiments.

On the other hand, we rely on a number of benchmark datasets for hypernymy evaluation: *BLESS* (Baroni and Lenci, 2011) provides related concepts for 200 English concrete nouns connected through a semantic relation (hypernymy, co-hyponymy, meronymy, attribute, event) or a null-relation. The dataset by Lenci and Benotto (2012) contains a subset of BLESS relation pairs, as created for previous comparisons of hypernymy detection methods. A dataset similar to BLESS, *EVALution*, was induced from ConceptNet and WordNet (Santus et al., 2015). Its semantic relations include hypernymy, synonymy, antonymy and meronymy. For quality reasons, the pairs were filtered by automatic methods and crowd-sourcing to improve consistency and to determine prototypical pairs. Finally, we use the Weeds dataset (Weeds et al., 2004; Weeds and Weir, 2005) which contains word pairs related by hypernymy and co-hyponymy across word classes. From all four benchmark datasets we extracted all noun–noun pairs related by hypernymy.

The first row in Table 1 shows the numbers of hypernymy pairs in the WordNets and in the benchmark datasets.

2.2 Corpora and Vector Spaces

We created our distributional vector spaces based on the *WaCky*[3] corpora (Baroni et al., 2009) for English and for German. The English *PukWaC* corpus is the syntax-annotated version of *ukWaC* (Ferraresi et al., 2008) and contains ≈1.9 billion words; the German *SdeWaC* corpus (Faaß and Eckart, 2013) is a cleaned version of the *WaCky* corpus *deWaC* and contains ≈880 million words; both corpora are pos-tagged with the *TreeTagger* (Schmid, 1994).

For each corpus we created a traditional count vector space[4] based on a co-occurrence window of ± 10 words within sentences (because sentences in the SdeWaC are shuffled, so going beyond sentence border is meaningless). We used a bag-of-words approach only taking into account lemmatised nouns, verbs and adjectives.

2.3 Hypernymy Methods and Baselines

We selected four unsupervised hypernymy methods and defined two baselines. The methods were chosen from different families with regard to how they exploit the distributional hypothesis for hypernymy detection: *WeedsPrec* and *InvCL* rely on the *Distributional Inclusion Hypothesis*, according to which a significant number of distributional features of a word x is included in the distributional features of a word y, if x is semantically more specific than y. *SLQS Row* and *SLQS Sec*[5] rely on the *Distributional Informativeness Hypothesis* using first- and second-order variants of word entropy, respectively. The methods are defined as follows regarding the distributional features f in the two word vectors $\vec{x}$ and $\vec{y}$ for a word pair $\langle x, y \rangle$.

WeedsPrec: An asymmetric precision method suggested by Weeds et al. (2004) that quantifies the weighted inclusion of the features of word x in the features of word y. If $WeedsPrec(x, y) > WeedsPrec(y, x)$, then x is predicted as the hyponym and y as the hypernym, and vice versa.

$$WeedsPrec(x, y) = \frac{\sum_{f \in (\vec{x} \cap \vec{y})} x_f}{\sum_{f \in \vec{x}} x_f}$$

---

[1] https://wordnet.princeton.edu

[2] https://uni-tuebingen.de/en/142806

[3] http://wacky.sslmit.unibo.it/

[4] Note that not all of the selected methods are applicable to embeddings, and it also not our goal to identify the optimal vector spaces, rather than analysing their predictions; this is why our analyses rely on standard count dimensions.

[5] Originally, this method is called SLQS, but to distinguish it from SLQS Row we refer to it as SLQS Sec.

	WordNet		GermaNet		BLESS	EVALution	LB	Weeds

sizes:	106,397	3,366	102,714	35,963	1,337	606	1,747	1,117
Word Length	47.26	**94.65**	56.14	**99.41**	23.19	34.86	52.42	44.76
Word Frequency	**73.19**	92.81	73.66	98.78	62.30	**68.96**	76.48	**76.63**
WeedsPrec	72.22	92.93	74.01	98.87	57.52	64.22	**77.02**	74.22
InvCL	72.97	92.84	73.92	98.78	63.05	68.86	76.48	76.45
SLQS Row	71.82	93.02	**74.40**	98.79	58.56	55.91	71.27	72.43
SLQS Sec	65.05	74.66	70.38	90.15	**71.80**	59.63	62.66	65.71

Table 1: Sizes of datasets and overall prediction results across datasets.

InvCL: An asymmetric precision method suggested by Lenci and Benotto (2012) that takes both feature inclusion as well as feature non-inclusion (originally suggested as *ClarkDE (cde)* by Clarke (2012)) into account. If $invCL(x, y) > invCL(y, x)$, then x is predicted as the hyponym and y as the hypernym, and vice versa.

$$cde(x, y) = \frac{\sum_{f \in (\vec{x} \cap \vec{y})} min(x_f, y_f)}{\sum_{f \in \vec{x}} x_f}$$

$$invCL(x, y) = \sqrt{cde(x, y) \cdot (1 - cde(y, x))}$$

SLQS Row: An asymmetric method suggested by Shwartz et al. (2016) which relies on the word entropy $H(w)$ for a word w, taking all context words as features into account: w_f. If $SLQS_{Row}(x, y) > 0$, then x is predicted as the hyponym and y as the hypernym, and vice versa.

$$SLQS_{Row}(x, y) = 1 - \frac{H(x)}{H(y)}$$

$$H(w) = -\sum_{w_f} p(w_f|w) \cdot log_2(p(w_f|w))$$

SLQS Sec: An asymmetric method suggested by Santus et al. (2014) which relies on second-order word entropy $E(w)$ and is calculated as the median entropy Med of a word's most strongly associated context words w_f. We use the 50 strongest contexts in our vector spaces, as determined by weighted co-occurrence scores using *positive local mutual information* (Evert, 2005). If $SLQS_{Sec}(x, y) > 0$, then x is predicted as the hyponym and y as the hypernym, and vice versa.

$$SLQS_{Sec}(x, y) = 1 - \frac{E(x)}{E(y)}$$

$$E(w) = Med_{w_f}\ H(w_f)$$

Baselines: In comparison to the hypernymy methods we applied two baselines, cf. Zipf's principles of least effort (Zipf, 1949):

- ***Word Length***: Given that hyponyms refer to more specific concepts than their hypernyms, and assuming that more specific concepts tend to have a longer word length, this baseline predicts the longer word in a word pair (as measured by the number of characters) as the hyponym.
- ***Word Frequency***: Given that hyponyms refer to more specific concepts than their hypernyms and assuming that more specific concepts appear less often in a corpus, this baseline predicts the less frequent word in a word pair (as measured by corpus frequency) as the hyponym.

3 Prediction Results and Comparisons

3.1 Overall results

Table 1 shows the overall accuracy results of the predictions across methods and datasets (best results in bold fonts). Accuracy is defined by the proportion of correct predictions given that we know which word in a word pair is the hypernym and which is the hyponym.

For each WordNet we list two results, one for the non-compound pairs (in blue, as the benchmark results) and one for the compound pairs (in grey). For compound pairs word length is an almost perfect predictor,[6] as expected, and all unsupervised methods are also above 90%, with SLQS Sec as an exception. In all other columns we can see that word length is generally a poor baseline. Word frequency, however, is a very powerful baseline; across datasets it keeps up or even outperforms the respective best methods, which are SLQS Sec

---

[6] The prediction does not reach 100% because our heuristic included non-compound pairs, such as *selection–election*.

	Length	Freq	WeedsPrec	InvCL	SLQS Row
Freq	0.592				
WeedsPrec	0.604	0.947			
InvCL	0.592	0.992	0.951		
SLQS Row	0.599	0.914	0.938	0.912	
SLQS Sec	0.547	0.715	0.719	0.714	0.727

	Length	Freq	WeedsPrec	InvCL	SLQS Row
Freq	0.666				
WeedsPrec	0.669	0.959			
InvCL	0.664	0.990	0.961		
SLQS Row	0.662	0.937	0.957	0.939	
SLQS Sec	0.592	0.767	0.766	0.768	0.778

Figure 1: SMC correlations between methods for WordNet (above) and GermaNet (below) non-compound pairs.

on BLESS; InvCL on EVALution and Weeds; and WeedsPrec on LB. Across datasets, the best results vary between 68.96% and 77.02% for non-compounds; compounds obviously represent “easy” cases of hypernymy.

3.2 Correlations between predictions

To explore similarities in predictions across methods, we applied the *Simple Matching Coefficient (SMC)* (Sokal, 1958) to determine for each two methods to which degree their decisions overlap, by comparing the number of matching decisions (i.e., where both methods predicted the same noun in a noun pair as the hypernym) against the number of decisions (i.e., the total number of noun pairs). The heatmaps in Figure 1 show the results for the non-compounds in the English WordNet (left) and in GermaNet (right). They clearly demonstrate that word length makes very different decisions to word frequency and the unsupervised methods, and that word frequency and all unsupervised methods but SLQS Sec highly correlate in their predictions.

3.3 Role of frequency

We go one step further to explore the role of frequency. Figure 2 presents the prediction results on 10 equally-sized subsets of the non-compound pairs in the WordNets after the target pairs were sorted by decreasing difference in hypernym corpus frequency minus hyponym corpus frequency. I.e., in the left-most subset on the x-axis we see the results on the subset with largest differences in hypernym–hyponym frequencies.

We can clearly see that up to subset 7 (up to which the hyponym frequencies are all below the hypernym frequencies), decisions based on word frequency, WeedsPrec, invCL and SLQS Row predict the hypernym almost perfectly; for subset 8 (where the hyponym frequencies start to become larger than the hypernym frequencies) their predictions are becoming worse; and for subsets 9–10 the predictions are mostly wrong. Results by relying on word length and SLQS Sec are clearly worse for the first seven subsets but also better for the last two subsets, thus confirming that they make different predictions.

3.4 Correctness of predictions

While SMC in Section 3.2 informed us about overlap in decisions, it did not tell us whether one of the methods is qualitatively superior, so we analysed whether some methods are simply worse than others, according to their lower accuracy in prediction, or whether the methods all have their own strengths. We calculated for each pair of methods which proportion of wrongly predicted pairs of one method was predicted correctly by the other method. Figure 3 illustrates for the English WordNet how many pairs wrongly predicted by word frequency are predicted correctly by another method (see x-axis).

As we can see, while word length and SLQS Sec are often worse in performance than frequency, they still manage to make correct predictions when frequency fails, which is much less the case for the frequency-alike methods WeedsPrec, invCL and SLQS Row. In particular, invCL seems to make almost identical predictions as frequency, which was already indicated by their almost perfectly overlapping lines in Figure 2.

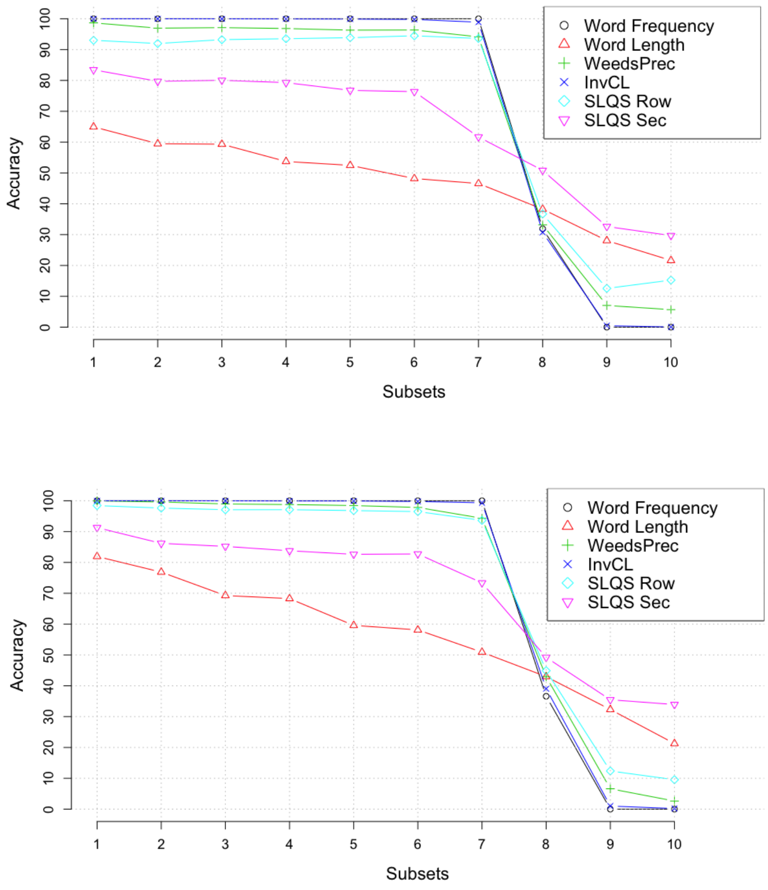

Figure 2: Prediction results for WordNet (above) and GermaNet (below) non-compound pairs across equally-sized subsets of target pairs sorted by difference in hypernym frequency and hyponym frequency.

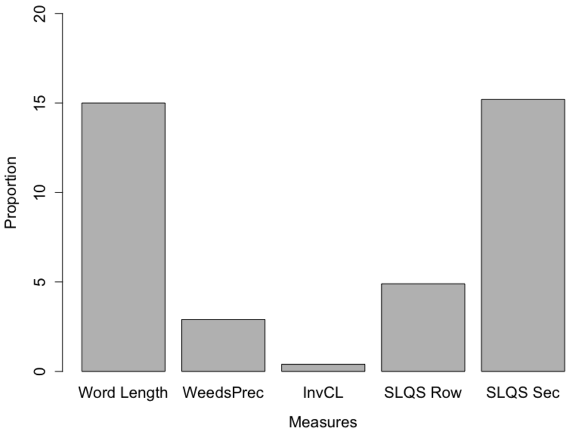

Figure 3: Proportions of pairs predicted wrongly by word frequency but correctly by the given method.

4 Conclusion

This study performed a series of hypernymy predictions by unsupervised methods. We demonstrated that across datasets for English and for German the predictions of three methods (WeedsPrec, invCL and SLQS Row) are highly correlated and also mostly identical with frequency-based predictions. In contrast, word length and SLQS Sec show an overall lower accuracy but at the same time make correct predictions where the others go wrong. Our study once more confirms the general need to check the frequency bias of a computational method in order to identify frequency-(un)related effects.

WIKITABLET: A Large-Scale Data-to-Text Dataset for Generating Wikipedia Article Sections

Mingda Chen **Sam Wiseman** **Kevin Gimpel**
Toyota Technological Institute at Chicago, Chicago, IL, 60637, USA
{mchen,swiseman,kgimpel}@ttic.edu

Abstract

Datasets for data-to-text generation typically focus either on multi-domain, single-sentence generation or on single-domain, long-form generation. In this work, we cast generating Wikipedia sections as a data-to-text generation task and create a large-scale dataset, WIKITABLET, that pairs Wikipedia sections with their corresponding tabular data and various metadata. WIKITABLET contains millions of instances, covering a broad range of topics, as well as a variety of flavors of generation tasks with different levels of flexibility. We benchmark several training and decoding strategies on WIKITABLET. Our qualitative analysis shows that the best approaches can generate fluent and high quality texts but they struggle with coherence and factuality, showing the potential for our dataset to inspire future work on long-form generation.[1]

1 Introduction

Data-to-text generation (Kukich, 1983; McKeown, 1992) is the task of generating text based on structured data. Most existing data-to-text datasets focus on single-sentence generation, such as WIKIBIO (Lebret et al., 2016), LogicNLG (Chen et al., 2020), and ToTTo (Parikh et al., 2020). Other datasets are relatively small-scale and focus on long-form text generation, such as ROTOWIRE (Wiseman et al., 2017) and MLB (Puduppully et al., 2019). In this work, we cast generating Wikipedia sections as a data-to-text generation task and build a large-scale dataset targeting multi-sentence data-to-text generation with a variety of domains and data sources.

To this end, we create a dataset that we call WIKITABLET ("Wikipedia Tables to Text") that pairs Wikipedia sections with their corresponding tabular data and various metadata. The data resources we consider are relevant either to entire Wikipedia articles, such as Wikipedia infoboxes and Wikidata tables, or to particular sections. Data from the latter category is built automatically from either naturally-occurring hyperlinks or from named entity recognizers. This data construction approach allows us to collect large quantities of instances while still ensuring the coverage of the information in the table. We also perform various types of filtering to ensure dataset quality.

WIKITABLET contains millions of instances covering a broad range of topics and a variety of flavors of generation with different levels of flexibility. Figure 1 shows two examples from WIKITABLET. The first instance has more flexibility as it involves generating a fictional character biography in a comic book, whereas the second is more similar to standard data-to-text generation tasks, where the input tables contain all of the necessary information for generating the text. While the open-ended instances in WIKITABLET are to some extent similar to story generation (Propp, 1968; McIntyre and Lapata, 2009; Fan et al., 2018), the fact that these instances are still constrained by the input tables enables different evaluation approaches and brings new challenges (i.e., being coherent and faithful to the input tables at the same time).

Because of the range of knowledge-backed generation instances in WIKITABLET, models trained on our dataset can be used in assistive writing technologies for a broad range of topics and types of knowledge. For example, technologies can aid students in essay writing by drawing from multiple kinds of factual sources. Moreover, WIKITABLET can be used as a pretraining dataset for other relatively small-scale data-to-text datasets (e.g., ROTOWIRE). A similar idea that uses data-to-text generation to create corpora for pretraining language models has shown promising results (Agarwal et al.,

2021).

In experiments, we train several baseline models on WIKITABLET and empirically compare training and decoding strategies. We find that the best training strategies still rely on enforcing hard constraints to avoid overly repetitive texts. Human evaluations reveal that (1) humans are unable to differentiate the human written texts from the generations from our neural models; (2) while the annotations show that grammatical errors in the reference texts and the generations may prevent humans from fully understanding the texts, the best decoding strategy (i.e., beam search with n-gram blocking (Paulus et al., 2018)) does not have such a problem and shows the best performance on several aspects; (3) the degree of topical similarity between the generations and the reference texts depends on the open-endedness of the instances.

Our analysis shows that the generations are fluent and generally have high quality, but the models sometimes struggle to generate coherent texts for all the involved entities, suggesting future research directions. For example, when the instance has a high degree of flexibility, we find the models making mistakes about what a particular entity type is capable of. We also find errors in terms of the factuality of the generated text, both in terms of contradictions relative to the tables and commonsense violations.

2 Related Work

There have been efforts in creating data-to-text datasets from various resources, including sports summaries (Wiseman et al., 2017; Puduppully et al., 2019), weather forecasts (Liang et al., 2009), and commentaries (Chen and Mooney, 2008). Most of the recent datasets focus on generating single sentences given tables, such as WIKIBIO, ToTTo, LogicNLG, and WikiTableText (Bao et al., 2018), or other types of data formats, such as data triples (Vougiouklis et al., 2017; Gardent et al., 2017; Nan et al., 2021), abstract meaning representations (Flanigan et al., 2016), minimal recursion semantics (Hajdik et al., 2019), or a set of concepts (Lin et al., 2020). Other than single sentences, there have been efforts in generating groups of sentences describing humans and animals (Wang et al., 2018), and generating a post-modifier phrase for a target sentence given a sentence context (Kang et al., 2019). In this work, our focus is long-form text generation and we are interested in automatically creating a large-scale dataset containing multiple types of data-to-text instances. As shown in Table 1, WIKITABLET differs from these datasets in that it is larger in scale and contains multi-sentence texts. More details are in the next section.

Wikipedia has also been used to construct datasets for other text generation tasks, such as generating Wikipedia movie plots (Orbach and Goldberg, 2020; Rashkin et al., 2020) and short Wikipedia event summaries (Gholipour Ghalandari et al., 2020), and summarizing Wikipedia documents (Zopf, 2018; Liu* et al., 2018) or summaries of aspects of interests (Hayashi et al., 2020) from relevant documents.

As part of this work involves finding aligned tables and text, it is related to prior work on aligning Wikipedia texts to knowledge bases (Elsahar et al., 2018; Logan et al., 2019).

3 The WIKITABLET Dataset

The WIKITABLET dataset pairs Wikipedia sections[2] with their corresponding tabular data and various metadata; some of this data is relevant to entire Wikipedia articles ("article data") or article structure ("title data"), while some is section-specific ("section data"). Each data table consists of a set of **records**, each of which is a tuple containing an **attribute** and a **value**.

The instances in WIKITABLET cover a range of flavors of language generation. Some have more flexibility, requiring models to generate coherent stories based on the entities and knowledge given in the tables. The first instance in Figure 1 is such an example. The text is from the Wikipedia article entitled "Wolfsbane (comics)" and resides within two nested sections: the higher-level section "Fictional character biography" and the lower-level section "Messiah Complex". The task is challenging as models need to generate a coherent passage that can connect all the entities in the section data, and the story also needs to fit the background knowledge provided in the article data.

Other instances are more similar to standard data-to-text generation tasks, where the input tables contain all the necessary information for generating

---

[2] We define a Wikipedia section to be all text starting after a (sub)section heading and proceeding until the next (sub)section heading. We include Wikipedia sections at various nesting levels. For example, a top level section may start with a few paragraphs describing general information followed by two subsections with more specific information, in which case the example will be converted into three instances in our dataset.

During the 2007–2008 "Messiah Complex" storyline, Rahne helps Rictor infiltrate the Purifiers; she fakes being shot by Rictor. She is also a member of the new X-Force. During a battle against Lady Deathstrike and the Reavers, Rahne learns that Father Craig was in league with the Purifiers, supposedly divulging enough information about her that the Purifiers can claim to "know her well." She travels with X-Force to her former home Muir Island, now the base of the Marauders. During the climactic battle, Rahne is injured by Riptide, but her wounds, according to Professor X, are superficial and she will recover.

Section Data

Attribute	Value

Journey to the Center of the Earth (also called Jules Verne's Journey to the Center of the Earth) is a 1959 American science fiction adventure film in color by De Luxe, distributed by 20th Century Fox. The film, produced by Charles Brackett and directed by Henry Levin, stars James Mason, Pat Boone, and Arlene Dahl. Bernard Herrmann wrote the film score, and the film's storyline was adapted by Charles Brackett from the 1864 novel of the same name by Jules Verne.

Figure 1: Two examples from WIKITABLET. Only parts of the tables are shown due to space constraints. Underlined texts are hyperlinks. Records with the attributes "DATE", "PER", "PERSON", or "GPE" are from NER. The subscripts for section titles indicate the ordering of nesting, where smaller numbers are for higher level sections.

the text. The second instance in Figure 1 is an example of this sort of task. However, these tasks are still challenging due to the wide variety of topics contained in WIKITABLET.

3.1 Dataset Construction

We begin by describing the steps we take to construct WIKITABLET. More details are in the supplementary material. In general, the steps can be split into two parts: collecting data tables and filtering out texts. When collecting data, we consider five resources: Wikidata tables, infoboxes in Wikipedia pages,[3] hyperlinks in the passage, named entities in the passage obtained from named entity recognition (NER), and Wikipedia article structure. For a given Wikipedia article, we use the same infobox and Wikidata table for all sections. These tables can serve as background knowledge for the article. For each section in the article, we create a second table corresponding to section-specific data, i.e., section data. The section data contains records constructed from hyperlinks and entities identified by a named entity recognizer.[4]

We form records for named entities by using the type of the entity as the attribute and the identified entity as the value. We form records for hyperlinks as follows. For the attribute, for a hyperlink with surface text t and hyperlinked article ℓ, we use the value of the "instance of" or "subclass of" tuple in the Wikidata table for ℓ. For example, the first instance in Figure 1 will be turned into a record with attribute "superhero" and value "Wolfsbane (comics)". If ℓ does not have a Wikidata table or no appropriate tuple, we consider the parent categories of ℓ. For the value of the tuple, we use the document title of ℓ rather than the actual surface text t to avoid giving away too much information in the reference text.

Complementary to the article data, we create a title table that provides information about the position in which the section is situated, which includes the article title and the section titles for the target section. As the initial sections in Wikipedia articles do not have section titles, we use the section title "Introduction" for these.

We also perform various filtering to ensure the quality of the data records, the coverage of the input data, and the length of the reference text. The final dataset contains approximately 1.5 million instances. We randomly sample 4533 instances as the development set and 4351 as the test set. We

---

[3] Wikidata is a consistently-structured knowledge base (e.g., has a fixed set of attributes), whereas infoboxes are not consistently-structured and this flexibility sometimes allows the infobox to contain extra information. Therefore, we consider using infoboxes as extra resources.

[4] We use the NER tagger from spaCy (Honnibal and Montani, 2017) and a BERT model (Devlin et al., 2019) finetuned on CoNLL03 data (Tjong Kim Sang and De Meulder, 2003).

also ensure that there are no overlapping Wikipedia articles among splits.

3.2 Dataset Characteristics

Table 1 shows statistics for WikiTableT and related datasets. While the average length of a WikiTableT instance is not longer than some of the existing datasets, WikiTableT offers more diverse topics than the sports-related datasets RotoWire and MLB, or the biography-related dataset WikiBio. Compared to the prior work that also uses Wikipedia for constructing datasets, WikiBio, LogicNLG, ToTTo, and DART (Nan et al., 2021) all focus on sentence generation, whereas WikiTableT requires generating Wikipedia article sections, which are typically multiple sentences and therefore more challenging. WikiTableT is also much larger than all existing datasets.

To demonstrate the diversity of topics covered in WikiTableT, we use either the "instance of" or "subclass of" relation from Wikidata as the category of the article.[5] We show the top 10 most frequent document categories in Table 2. Due to the criteria we use for filtering, only 1.05% of articles in WikiTableT do not have these relations or Wikidata entries, and we omit these articles in the table. As the table demonstrates, more than 50% of the articles in WikiTableT are not about people (i.e., the topic of WikiBio), within which the most frequent category covers only 4.61%.

3.3 Dataset Challenges

In this subsection, we highlight two challenges of WikiTableT.

1. In contrast to work on evaluating commonsense knowledge in generation where reference texts are single sentences describing everyday scenes (Lin et al., 2020), WikiTableT can serve as a testbed for evaluating models' abilities to use world knowledge for generating coherent long-form text.
2. Compared to other long-form data-to-text datasets such as RotoWire where the input tables are box scores, the input tables in WikiTableT are more diverse, including both numbers (e.g., economy and population data of an area throughout years), and short phrases. This makes WikiTableT more challenging and applicable to various scenarios.

4 Methods

In this section, we describe details of models that we will benchmark on WikiTableT.

Our base model is based on the transformer (Vaswani et al., 2017). To encode tables, we linearize the tables by using special tokens to separate cells and using feature embeddings to represent records in tables. For the title table in the first instance in Figure 1 the linearized table will be

$$\begin{aligned}&\langle\text{boc}\rangle_1\text{Doc.}_1\ \text{title}_1\langle\text{bov}\rangle_1\ \text{Wolfsbane}_1\ \text{(comics)}_1\\&\langle\text{boc}\rangle_2\text{Sec.}_2\ \text{title}_2\langle\text{bov}\rangle_2\ \text{Fictional}_2\ \text{character}_2\\&\text{biography}_2\langle\text{boc}\rangle_3\cdots\langle\text{eoc}\rangle\end{aligned} \tag{1}$$

As shown in Eq. 1, we employ several techniques when encoding tables: (1) we use special tokens $\langle\text{boc}\rangle$ and $\langle\text{bov}\rangle$ to separate attributes and values, and $\langle\text{eoc}\rangle$ to indicate the end of a sequence; (2) we use subscript indices to indicate unique ID embeddings that are added to the embeddings for each record, which helps models align attributes with values; and (3) we restart the positional embeddings at each $\langle\text{boc}\rangle$, such that models will not use the ordering of the input records. In addition, we add a special embedding to each record to indicate if it is from the section table or the article/title table. In Wikidata, there could be multiple qualifiers attached to a record, in which case we replicate the record for each qualifier separately.

Similar linearization approaches have been used in prior work (Dhingra et al., 2019; Hwang et al., 2019; Herzig et al., 2020; Yin et al., 2020). With linearized tables, training and inference become similar to other sequence-to-sequence settings. We train our models with teacher-forcing and standard cross entropy loss unless otherwise specified.

4.1 Training Strategies

We experiment with three types of modifications to standard sequence-to-sequence training:

α-entmax. α-entmax (Peters et al., 2019) is a mapping from scores to a distribution that permits varying the level of sparsity in the distribution. This mapping function has been used in machine translation (Peters et al., 2019) and text generation (Martins et al., 2020). When using α-entmax in the decoder, we also replace the cross entropy loss with the α-entmax loss (Peters et al., 2019). Both

---

[5] When there are multiple values in these two relations, we pick the one that has the smallest number of words, as it often is the most generic phrase, suitable for representing the topic.

	Vocab.	Tokens	Examples	Avg. Len.	Record Types	Avg. Records	Domain
WikiTableText	-	185.0k	13.3k	13.9	3.0k	4.1	Wikipedia
WIKIBIO	400.0k	19.0M	728.0k	26.1	1.7k	19.7	Biography
ROTOWIRE	11.3k	1.6M	4.9k	337.1	39.0	628.0	Sports
MLB	38.9k	14.3M	26.3k	542.1	53.0	565.0	Sports
LogicNLG	122.0k	52.7k	37.0k	14.2	11.7k	13.5	Wikipedia
ToTTo	136.0k	1.3M	136.0k	17.4	41.8k	32.7	Wikipedia
DART	33.2k	717.1k	82.2k	21.6	-	-	Wikipedia+Restaurant
WIKITABLET	1.9M	169.0M	1.5M*	115.9	147.4k†	51.9	Wikipedia

Table 1: Statistics for several data-to-text datasets. WIKITABLET combines a large number of examples, moderate generation length (typically more than one sentence), and a large variety of record types. We omit record types and avg. records for DART as its input units are triple sets instead of table records. *887.7k unique Wikipedia articles. †Number of record types for each resource: 31.8k (Infobox), 1.7k (Wikidata), 115.6k (Hyperlinks), 17 (NER).

Category	Fraction (%)
human	45.62
film	4.61
single (music)	1.74
human settlement	1.53
album	1.41
sports season	1.26
television series	1.17
village	1.12
taxon	0.89

Table 2: Top 10 most frequent article categories and their corresponding proportions in WIKITABLET.

α-entmax and the α-entmax loss have a hyperparameter α. We follow Martins et al. (2020) and use $\alpha = 1.2$ as they found it to be the best value for reducing repetition in generation.

Copy Mechanism. Similar to prior work on data-to-text generation (Wiseman et al., 2017; Puduppully et al., 2019), we use pointer-generator network style copy attention (See et al., 2017) in the decoder.

Cyclic Loss. Cyclic losses have been shown to be effective in textual style transfer (Shetty et al., 2018; Pang and Gimpel, 2019) and neural machine translation (Cheng et al., 2016; He et al., 2016; Tu et al., 2017). Wiseman et al. (2017) also used this for data-to-text and found it helpful for generating long sequences. In this work, we experiment with adding the cyclic loss to our transformer models, where the backward model can be seen as an information extraction system. We expect that adding the cyclic loss should enable a data-to-text model to generate sentences that are more faithful to the conditioned tables. The cyclic loss is used during training only and does not affect the models during inference. More details are in the appendix.

4.2 Decoding Strategies

Massarelli et al. (2020) showed that the choice of decoding strategy can affect the faithfulness or repetitiveness of text generated by language models. We are also interested in these effects in the context of data-to-text generation, and therefore benchmark several decoding strategies on WIKITABLET. Our models use byte-pair encoding (BPE; Sennrich et al., 2016) and for all of the following strategies, we always set the minimum number of decoding steps to 100 as it improves most of the evaluation metrics, and the maximum number of decoding steps to 300.

Specifically, we benchmark (1) greedy decoding; (2) nucleus sampling (Holtzman et al., 2020) with threshold 0.9 as suggested by Holtzman et al. (2020); (3) beam search; and (4) beam search with n-gram blocking (Paulus et al., 2018) where we set the probabilities of repeated trigrams to be 0 during beam search. We set the beam size to be 5 by default. The appendix has more details about the decoding strategies.

5 Experiments

5.1 Setup

We experiment with two sizes of transformer models. One is "Base", where we use a 1-layer encoder and a 6-layer decoder, each of which has 512 hidden size and 4 attention heads. The other one is "Large", where we use a 1-layer encoder and a 12-layer decoder, each of which has 1024 hidden size and 8 attention heads. Models similar to the base configuration have shown strong performance on ROTOWIRE (Gong et al., 2019).[6] Due to limited

---

[6] When training the base model with entmax on WIKIBIO, it achieves BLEU-4 45.75 and ROUGE-4 39.39 on the test set using greedy decoding, which are comparable to the current state-of-the-art results of Liu et al. (2018).

Table 3: Test set results for our models. When training the large models, we use the "copy + cyclic loss" setting as it gives the best performance for the base models for most of the metrics.

computational power, we parameterize our backward model as a transformer model with a 2-layer encoder and a 2-layer decoder.[7]

We use BPE with 30k merging operations. We randomly sample 500k instances from the training set and train base models on them when exploring different training strategies. We train a large model with the best setting (using the copy mechanism and cyclic loss) on the full training set. We train both models for 5 epochs. During training we perform early stopping on the development set using greedy decoding.

We report BLEU (Papineni et al., 2002), ROUGE-L (RL) (Lin, 2004), METEOR (MET) (Banerjee and Lavie, 2005), and PARENT (Dhingra et al., 2019), including precision (PAR-P), recall (PAR-R), and F1 (PAR-F1) scores. The first three metrics consider the similarities between generated texts and references, whereas PARENT also considers the similarity between the generation and the table. When using PARENT, we use all three tables, i.e., the section, article, and title tables.

As we are also interested in the repetitiveness of generated texts, we define a metric based on n-gram repetitions which we call "REP". REP computes the ratio of the number of repeated n-grams to the total number of n-grams within a text, so when REP has higher value, it indicates that the text has more repetitions. Here we consider n-grams that appear 3 or more times as repetitions and the n-grams we consider are from bigrams to 4-grams. When reporting REP scores for a dataset, we average the REP scores for each instance in the dataset. Similar metrics have been used in prior work (Holtzman et al., 2020; Welleck et al., 2020).

5.2 Results

In Table 3, we report the test results for both our base models and large models. We also report a set of baselines that are based on simply returning the linearized tables and their concatenations with the references. The linearized table baselines show how much information is already contained in the table, while the reference baselines show the upper bound performance for each metric.

In comparing training strategies, we find that using α-entmax improves REP significantly but not other metrics. Adding the cyclic loss or the copy mechanism helps improve performance for the PAR scores and REP, and combining both further improves these metrics.

When comparing decoding strategies, we find that both nucleus sampling and n-gram blocking are effective in reducing repetition. Nucleus sampling harms the PAR scores, especially PAR-P, but has less impact on the other metrics, indicating that it makes the model more likely to generate texts that are less relevant to the tables. Using beam search improves all metrics significantly when compared to greedy decoding, especially the PAR-P and REP scores. Adding n-gram blocking further reduces the REP score, pushing it to be even lower than that from nucleus sampling, but still retains the improvements in PAR scores from beam search. The best overall decoding strategy appears to be beam search with n-gram blocking.

---

[7] We did not experiment with pretrained models because they typically use the entirety of Wikipedia, which would presumably overlap with our test set.

	Grammar	Coherence	Faithfulness
Reference	4.0 (1.0)	4.1 (0.9)	3.8 (0.8)
Beam search	4.0 (1.0)	4.0 (1.0)	3.9 (1.0)
Nucleus sampling	4.0 (0.8)	4.1 (0.9)	3.9 (0.8)
n-gram blocking	4.2 (0.9)	4.2 (0.9)	3.9 (1.0)

Table 4: Average human ratings (standard deviations in parentheses) for grammaticality, coherence, and faithfulness to the input article table.

	Relevance	Support
Beam search	3.8 (1.1)	3.6 (1.2)
Nucleus sampling	3.7 (1.2)	3.8 (1.1)
n-gram blocking	3.9 (1.0)	3.8 (1.0)

Table 5: Average human ratings (standard deviations in parentheses) of relevance and support when comparing to the reference text.

6 Analysis

We now describe a manual evaluation and analyze some generated examples. All results in this section use the development set. We also conduct experiments on analyzing the effect of using the section data and the article data during training, finding that the benefits that they bring to the model performance are complementary. See the appendix for more details.

6.1 Human Evaluation

We conduct a human evaluation using generations from the large model on the development set. We choose texts shorter than 100 tokens and that cover particular topics as we found during pilot studies that annotators struggled with texts that were very long or about unfamiliar topics.[8]

We design two sets of questions. The first focuses on the text itself (i.e., grammaticality and coherence) and its faithfulness to the input article table. Since this set does not involve the reference, we can ask these questions about both generated texts and the reference texts themselves. The second set of questions evaluates the differences between the generations and the reference texts (i.e., relevance and support), allowing us to see if the generated text matches the human written section text. Specifically, relevance evaluates topical similarity between generations and references, and support evaluates whether the facts expressed in the generations are supported by or contradictory to those in the references. The full questions and numerical answer descriptions are in the appendix.

We report results in Tables 4 and 5. The scores are on a 1-5 scale with 5 being the best. For the first set, we collect 480 annotations from 38 annotators. For the second set, we collect 360 annotations from 28 annotators. We also ensure that each system has the same number of annotations.[9]

It is interesting to note from Table 4 that human annotators are unable to differentiate the human written texts from the generations from our neural models. Since the Wikipedia section texts are parts of Wikipedia articles, showing the section texts in isolation can make them difficult to understand, potentially resulting in noisy annotations. As shown by the first instance in Table 6, the text uses the pronoun “he” without clarifying what the pronoun refers to. The paragraph is rated 3 for coherence, presumably due to this ambiguity. Also, Wikipedia texts are sometimes grammatically complex and annotators can mistake them for being ungrammatical, e.g., the second instance in Table 6.

On the other hand, the coherence errors in the generated texts are not always easy to spot. See, for example, the last two instances in Table 6, where the incoherence lies in the facts that (1) it is impossible to marry a person before the person is born, and (2) senior year takes place after junior year. These details are embedded in long contexts, which may be overlooked by annotators and lead to results favorable to these neural models.

To study the relationship between coherence and grammaticality, we compute Spearman’s correlations between the human annotations for coherence and grammaticality after removing the ones with perfect scores for coherence. Table 7 shows the results. The correlations are much higher for references, beam search, and nucleus sampling than for n-gram blocking. This trend suggests that the imperfect coherence scores for the reference texts are likely because annotators find the texts to contain grammatical errors (or to possess grammatical complexity) which may prevent them from fully understanding the texts. However, n-gram blocking does not have this problem and thus achieves the best results for both coherence and grammaticality. We hypothesize that n-gram blocking is able to avoid the types of grammatical errors that

---

[8] We did not find the filtering to change the observed trends for the automatic metrics and provide the list of selected topics in the appendix.

[9] We used Amazon Mechanical Turk. To ensure annotation quality, we only recruited annotators with master qualification. We collected one annotation for each instance (so that we can cover more instances) and paid 30 cents per annotation. The amount of wage per annotation is decided by (1) the amount of time each annotator spent on the task during our pilot study and (2) a target hourly wage of approximately \$11.

Method	Text	G	C

Table 8: Averaged perplexities and the corresponding numbers of annotations for each option for the relevance and support questions (5 is the best option). We aggregate annotations for different decoding algorithms. We note that the perplexities are computed based on the reference texts using the large model.

prevent understanding because (1) unlike nucleus sampling, n-gram blocking does not rely on randomness to avoid repetition; (2) n-gram blocking does not suffer from repetitions like beam search.

We report results for the second set of questions in Table 5. The three evaluated systems show similar performance. To investigate the relationship between the degree of open-endedness of a WIKITABLET instance and its corresponding evaluation scores, we compute the averaged perplexities (based on our large models) for each option in Table 8. The most relevant generations are typically from more closed-ended or constrained instances.[10] Similarly for the support scores, more open-ended instances are distributed at score 3, which means that there is no fact supported by or contradictory to the shown tables. While the open-endedness of an instance usually depends on its topics (e.g., movie plots are open-ended), there are many cases where the models can benefit from better entity modeling, such as understanding what a particular entity type is capable of (e.g., see the last example in Sec. 6.3).

percentile	train perp.	dev perp.
10	2.3	2.5
20	3.1	3.6
30	4.0	4.7
40	4.9	6.1
50	6.1	7.6
60	7.6	9.8
70	9.8	12.9
80	13.3	18.2
90	20.6	29.3
100	278.8	129.4

Table 9: Percentiles of perplexities for training and development splits of our dataset. We use the large model.

Recent work has also found conducting human evaluation for long-form generation to be challenging, for example in the context of question answering (Krishna et al., 2021) and story generation (Akoury et al., 2020). Our observations for data-to-text generation complement theirs and we hope that our dataset can inspire future research on human evaluation for long-form text generation.

6.2 Distribution of Perplexity

To determine the fraction of WIKITABLET that can be seen as constrained, we report the percentiles of perplexities for training and development splits in Table 9. From Table 8, it can be observed that instances with perplexities around 9.0 generally lead to model generations that are closely relevant to the reference texts and mostly supported by the input tables, and therefore are likely to be the constrained instances. From Table 9, we see that at least half of our dataset has perplexities lower than 9.0, so we conjecture that half of our dataset consists of constrained instances.

6.3 Generation Examples

Table 10 shows generation examples for nucleus sampling and beam search with n-gram blocking.

---

[10] Li and Hovy (2015) use entropy as a proxy to quantify complexity of tasks. In this work, we use perplexity to measure how open-ended the instances are.

Method	Generated Text
Nucleus sampling (threshold 0.9)	In a two-issue mini-series titled ”Messiah Complex”, portrayed by Maisie Williams, Father Craig is ordered to rescue the world from Reavers and run out of the X-Force causing the X-Force to permanently withdraw. The original humans were replaced by slots and Muir Island being pulled away. They also possessed the entire X-Force after issue #9 in which the X-Force appeared. Claremont and Sinclair later reprised their parts in ”The Donderful World of Wolverine” with Wolfsbane as one of the new X-Men and her group taken back to their reservation for unknown reasons.
n-gram blocking	In the ”Messiah Complex” storyline, Wolfsbane is a member of the X-Men, a group of mutants recruited by Father Craig to fight the Reavers in Muir Island. Father Craig is killed in the battle with Reavers, but Father Craig manages to rescue the mutant from the Rain of Gesham and retrieve the mutant. She is later revealed to have been killed by Rain in a battle with Father Craig. In the aftermath, Father Craig tells Father Craig that she is the only mutant to be killed by a mutant.
Nucleus sampling (threshold 0.9)	In May 2013, McCoy allegedly assault a Spoiler business official. The incident motivated him to take a business trip to Harrisburg, Pennsylvania and sign a letter from the Buffalo Bills paying him over $50,000 as well as verbally prohibiting legal kickoff work. In September 2014, McCoy shared the issue with some former players of the first two film franchises. McCoy played a leading role in the 2012 Marvel Cinematic Universe film ”Erab of the Press”, and was named one of the film's biggest stars on Twitter. On September 9, 2014, McCoy filed a lawsuit against PYT to change its Twitter name to LeSean McCoy Productions.
n-gram blocking	On September 9, 2014, McCoy was arrested in Harrisburg, Pennsylvania on suspicion of assault. He was charged with assault and battery. In May 2013, he was fined over $50,000 by the Buffalo Bills. In September 2014, he was suspended for two games by the PYT for violating the Marvel Cinematic Universe. He was released by the Bills in October of the same year. He was cleared of all charges on Twitter, and was banned from playing in the 2014 Pro Bowl due to his Twitter account.

Table 10: Generation examples from the large model. The first example corresponds to the first instance in Figure 1. The complete set of generations is in the appendix.

We observe very different trends between the two instances in Figure 1. For the first instance about the X-Men, although both generations look fluent, their stories differ dramatically. The generated text for nucleus sampling describes a story that starts by saying Father Craig rescues the world from Reavers and ends with Wolfsbane joining as one of the new X-Men. On the other hand, n-gram blocking generates a story where Wolfsbane already is a member of X-Men, and the story says Father Craig fought and was killed by the Reavers, but manages to rescue the mutant. For the less open-ended instances (e.g., the second instance in Figure 1), different decoding strategies mostly generate similar details (see the appendix for generations).

Despite having different details, these generations appear to try to fit in as many entities from the tables as possible, in contrast to beam search (shown in the appendix) which mostly degenerates into repetition for more open-ended instances. This explains our previous observation that n-gram blocking helps with the PAR-R score.

Even though the generations are of good quality for most instances, their implausibility becomes more apparent when readers have enough background knowledge to understand the involved entities. For example, the second instance in Table 10 comes from the Wikipedia page “LeSean McCoy” (a football player) under the sections “Personal life” and “Controversies” (details in the appendix). The generation from nucleus sampling is implausible/nonsensical in some places (“assault a Spoiler business official”) and factually incorrect elsewhere (McCoy did not play a leading role in any film, and “Erab of the Press” is not an actual film). The fourth generation is implausible because a player is unlikely to be suspended for “violating the Marvel Cinematic Universe”, and it is unlikely for a person to be cleared of all charges on Twitter. Our models have limited access to knowledge about entities, e.g., the capabilities of a social media company like Twitter. Future research may incorporate extra resources, make use of pretrained models, or incorporate factuality modules to solve these problems.

7 Conclusion

We created WIKITABLET, a dataset that contains Wikipedia article sections and their corresponding tabular data and various metadata. WIKITABLET contains millions of instances covering a broad range of topics and kinds of generation tasks. Our manual evaluation showed that humans are unable to differentiate the references and model generations, and n-gram blocking performs the best on grammaticality and coherence. However, qualitative analysis showed that our models sometimes struggle with coherence and factuality, suggesting several directions for future work.

Acknowledgments

This work was supported in part by a Google Fellowship to M. Chen.

Impact Statement

We highlight a few limitations as follows: (1) Wikipedia texts are generally written in objective tones, but some of the texts may contain controversial content that even the community contributors do not agree upon; (2) models trained on our dataset may generate deceitful texts that are unfaithful to what actually happened to particular entities; (3) though the instances in WIKITABLET cover various topics, the writing style is almost always the same. Future work may explore more diverse writing styles.

A Dataset Construction

When collecting data, we consider five resources: Wikidata tables, infoboxes in Wikipedia pages, hyperlinks in the passage, named entities in the passage obtained from named entity recognition (NER), and Wikipedia article structure. For each article in Wikipedia, we use the same infobox and Wikidata table for all sections. These tables can serve as background knowledge for the article. For each section in the article, we create a second table corresponding to section-specific data, i.e., section data. The section data contains records constructed from hyperlinks and entities identified by a named entity recognizer. Section data contributes around 25% of the records in WIKITABLET.

We filter out several entity types related to numbers[11] as the specific meanings of these numbers in the section of interest are difficult to recover from the information in the tables. After filtering, we use the identified entities as the values and the entity types as the attributes. This contributes roughly 12% of the records in our final dataset.

We also create records from hyperlinks in the section of interest. We first expand the hyperlinks available for each section with hyperlinks available in the parent categories. We first group hyperlinks across all Wikipedia articles with those same categories, and then we perform string matching between these hyperlinks and the text in the section. If there are exact matches, we will include those hyperlinks as part of the hyperlinks in this section.

Details for constructing a record with attribute a and value v for a hyperlink with surface text t and hyperlinked article ℓ are as follows. To set a, we use the value of the "instance of" or "subclass of" tuple in the Wikidata table for ℓ. If ℓ does not have a Wikidata table or no appropriate tuple, we consider the parent categories of ℓ as candidates for a. If there are multiple candidates for a, we first embed these candidates and a using GloVe (Pennington et al., 2014) embeddings and then choose the one that maximizes cosine similarity between the document titles or section titles and the candidates for a. For the value v of the tuple, we use the document title of ℓ rather than the actual surface text t to avoid giving away too much information in the reference text. The records formed by hyperlinks contribute approximately 13% of the records in WIKITABLET.

We shuffle the ordering of the records from NER and the hyperlinks to prevent models from relying on the ordering of records in the reference text.

The records from the section data can be seen as section-specific information that can make the task more solvable. Complementary to the article data, we create a title table that provides information about the position in which the section is situated, which includes the article title and the section titles for the target section. As the initial sections in Wikipedia articles do not have section titles, we use the section title "Introduction" for these.[12]

As the records in our data tables come from different resources, we perform extra filtering to remove duplicates in the records. In particular, we give Wikidata the highest priority as it is a human-annotated well-structured data resource (infoboxes are human-annotated but not well-structured due to the way they are stored on Wikipedia) and the entities from NER the lowest priority as they are automatically constructed. That is, when we identify duplicates across different resources, we will keep the records from the higher priority resource and drop those from the lower one. More specifically, the duplicates between Wikidata records and infoboxes are determined by whether there are duplicate values or duplicate attributes: for hyperlinks and infoboxes or Wikidata, they are judged by duplicate values; for NER and hyperlinks, they are based on whether there is any token overlapping between values.

After table collection, we have the following criteria for filtering out the texts: (1) we limit the text length to be between 50 and 1000 word tokens; (2) to ensure that there is sufficient information in the table, we only keep data-text pairs that contain more than 2 records per sentence and more than 15 records per 100 tokens from Wikidata and infoboxes; (3) to avoid texts such as lists of hyperlinks, we filter out texts where more than 50% of their word tokens are from hyperlink texts.

B Human Evaluation

The selected topics for human evaluations are: human (excluding the introduction and biography section), film, single (song), song, album, television series. When evaluating grammaticality and coherence, only the generated text is shown to annotators.

---

[11] List of filtered entity types: PERCENT, TIME, QUANTITY, ORDINAL, CARDINAL.

[12] Among millions of section titles in Wikipedia, there are only 4672 sections, including nested sections, that are called "Introduction". Therefore, we believe this process will not introduce much noise into the dataset.

1 = it is completely ungrammatical, as it is impossible to understand the text.
2 = it has many grammatical errors, and these errors make the text very difficult to understand.
3 = it has grammatical errors, and some of them make part of the text difficult to understand.
4 = it has some grammatical errors, but they are minor errors that do not affect reading.
5 = it is completely grammatical, as it does not have any grammatical errors.

Table 11: Rating explanations for grammaticality.

1 = it is completely incoherent, as it is impossible to piece together information in the text.
2 = it is incoherent in most places. You can only understand part of the story.
3 = it is incoherent in many places, but if you spend time reading it, you still can understand the whole story.
4 = it is mostly coherent. Although the text is incoherent in some places, it does not affect reading.
5 = it is completely coherent.

Table 12: Rating explanations for coherence.

1 = it is completely contradictory to what is described in the table.
2 = it has some facts contradictory to what is described in the table.
3 = it is not supported by the table, and it does not contradict the table.
4 = some of the text is supported by the facts in the table, and the rest of it does not contradict the facts in the table.
5 = it is completely supported by the table.

Table 13: Rating explanations for faithfulness.

1 = the text is completely irrelevant to the reference.
2 = most of the text is irrelevant to the reference.
3 = some of the text is relevant to the reference.
4 = most of the text is relevant to the reference.
5 = the text is talking about the same thing as the reference.

Table 14: Rating explanations for relevance.

The question for grammaticality is "On a scale of 1-5, how much do you think the text is grammatical? (Note: repetitions are grammatical errors.)" (option explanations are shown in Table 11), and the question for coherence is "On a scale of 1-5, how much do you think the text is coherent? (Coherence: Does the text make sense internally, avoid self-contradiction, and use a logical ordering of information?)" (rating explanations are in Table 12).

When evaluating faithfulness, we show annotators the article data and the generation. The question is "On a scale of 1-5, how much do you think the text is supported by the facts in the following table?" (rating explanations are in Table 13).

When evaluating coherence and relevance, annotators were shown the reference text and the generation, as well as the Wikipedia article title and section titles for ease of understanding the texts. Annotators were asked two questions, with one being "On a scale of 1-5, how much do you think the text is relevant to the reference" (Table 14), and the other being "On a scale of 1-5, how much do you think the text is supported by the facts in the reference?" (Table 15).

C Effect of α-entmax

In this section, we disentangle the effect of α-entmax and that of α-entmax loss. We note that (1) when not using the α-entmax loss, we use standard cross entropy loss (e.g., in the case of "base+ent." we maximize the log probabilities generated by α-entmax); (2) when combining α-entmax and copy mechanism, we aggregate the probabilities generated by α-entmax and those from softmax. This is because we use the first attention head in the transformer decoder as the copy attention, following the implementation in OpenNMT (Klein et al., 2017). While it is feasible to combine the α-entmax and α-entmax loss with the copy mechanism if we use the sparse transformer (Correia et al., 2019), we leave this for future study. We report the results in Table 16. It is interesting to see that when using greedy decoding, "ent. + ent. loss" outperforms the baseline model by a significant margin on all the metrics, however the improvement disappears (except for repetition) after we switch to use beam search as the decoding strategy. This is likely because α-entmax promotes sparsity in the generated probabilities, making beam search decoding unnecessary. Removing the α-entmax loss hurts the performance, but its gains become larger in switching to beam search decoding. Adding copy mechanism improves the performance, leading to comparable performance to the baseline model. Although "base+ent.+copy" still underperforms "base+copy" when using beam search, we believe that combining α-entmax and α-entmax loss with the copy mechanism is promising as (1) α-entmax is not used in our large models and the initial results have shown that α-entmax and the copy mechanism are complementary, so it may further improve our current best performance; (2) α-entmax already shows the best performance when using greedy decoding, which has speed and optimization advantages compared to the beam search based decoding strategies especially considering the long-form characteristic

1 = it has quite a few facts contradictory to what is described in the reference.
2 = it has some facts contradictory to what is described in the reference.
3 = it is not supported by the reference, and it does not contradict the reference.
4 = some of the text is supported by the facts in the reference, and the rest of it does not contradict the reference.
5 = it is completely supported by the reference.

Table 15: Rating explanations for supportedness.

	REP	BLEU	PAR-P	PAR-R	PAR-F1
Greedy decoding					
base	38.1	14.7	61.6	27.7	35.8
+ ent. + ent. loss	36.0	16.2	62.2	28.9	37.0

+ ent. + copy	34.1	15.0	69.4	28.1	37.6
+ copy	30.1	15.9	67.1	29.4	38.5

Table 16: Effect of using α-entmax and α-entmax loss. When not using the α-entmax loss, we use standard cross entropy loss.

of WIKITABLET.

D Details of Cyclic Loss

In this section, we will denote the linearized table where the values are replaced with a special $\langle$mask$\rangle$ token by $u_1, \cdots, u_n$, and denote the reference text by $x_1, \cdots, x_m$. Formally, the training loss is

$$\sum_{w \in S} -\log p(w|u_1, \cdots, u_n, \boldsymbol{v}_1, \cdots, \boldsymbol{v}_m) \quad (2)$$

where S represents the set of masked tokens, and $\boldsymbol{v}_1, \cdots, \boldsymbol{v}_m$ is the sequence of token-level probabilities predicted by the forward model (in our experiments, these could either come from the softmax function, or the α-entmax function). Specifically, we multiply the backward transformer's input embedding matrix by the $\boldsymbol{v}$ probability vectors to obtain the input representations to the first encoder layer. We find that it is helpful to add a "reference loss" while training with the cyclic loss, defined as

$$\sum_{w \in S} -\log p(w|u_1, \cdots, u_n, x_1, \cdots, x_m) \quad (3)$$

This loss does not contain the generation model in it explicitly, but it does lead to an improved backward model by training it with clean inputs. Improving the backward model then increases the benefits of the cyclic loss.[13]

	REP	BLEU	PAR-P	PAR-R	PAR-F1
Both	38.1	14.7	61.6	27.7	35.8
Art. only	60.9	8.4	55.2	14.7	20.8
Sec. only	39.0	13.4	56.1	24.3	31.7

Table 17: Effect of dropping section or article data from the input (using the "base" setting).

	REP	BLEU	PAR-P	PAR-R	PAR-F1

Both	35.9	15.8	62.0	28.5	36.7
Art. only	37.2	15.8	61.7	28.1	36.2
Sec. only	34.8	15.9	61.9	28.2	36.2

Table 18: Effect of dropping section or article data when using cyclic training. The results are based on the "base + copy" and "base + copy + cyclic loss" settings.

E Effect of Article Data and Section Data

We report results in Table 17 for the models that are trained with partial data input, where art. only and sec. only indicate that we use only article data or section data, respectively. We always use title data. Section data contributes the most to the BLEU and PAR scores, but using section data and article data together is the best setting.

We also investigate the effect of partial data input for the cyclic loss in Table 18, where "None" is the model that is not trained with the cyclic loss. We note that in this setting, we still use both data resources as the input to the forward model, but vary the input data and the gold standard for the backward model. Although using only section data gives the best REP score and improves the PAR-P score, it does not help the model in other metrics. Combining the article data with the section data gives significant improvements to the PAR-F1 score compared to section data alone.

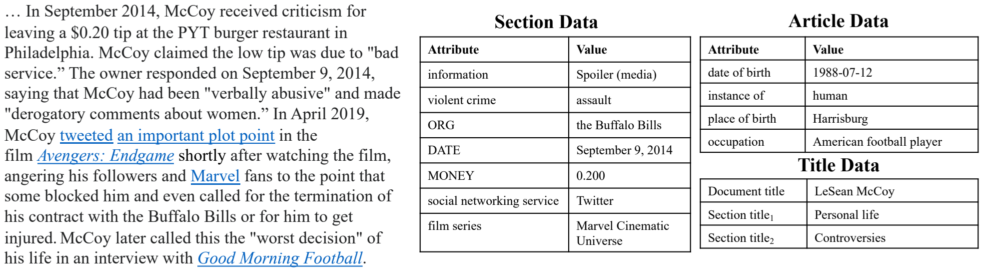
Both experiments show that there are interactions between these two data resources that can help models to learn better from both kinds.

F Generation Examples

We show the full set of generations in Table 19. The part of input data and reference text for Table 19 is shown in Figure 2.

---

[13] We experimented with initializing the backward model with pretrained checkpoints, but did not find it helpful.



… In September 2014, McCoy received criticism for leaving a $0.20 tip at the PYT burger restaurant in Philadelphia. McCoy claimed the low tip was due to "bad service." The owner responded on September 9, 2014, saying that McCoy had been "verbally abusive" and made "derogatory comments about women." In April 2019, McCoy tweeted an important plot point in the film *Avengers: Endgame* shortly after watching the film, angering his followers and Marvel fans to the point that some blocked him and even called for the termination of his contract with the Buffalo Bills or for him to get injured. McCoy later called this the "worst decision" of his life in an interview with *Good Morning Football*.

The film was produced by CinemaScope and 20th Century Fox and distributed by Twentieth Century-Fox Film Corporation and Joseph M. Schenck Enterprises, Inc. It was nominated for an Academy Award for Best Art Direction.
sampling 0.9	In May 2013, McCoy allegedly assault a Spoiler business official. The incident motivated him to take a business trip to Harrisburg, Pennsylvania and sign a letter from the Buffalo Bills paying him over $50,000 as well as verbally prohibiting legal kickoff work. In September 2014, McCoy shared the issue with some former players of the first two film franchises. McCoy played a leading role in the 2012 Marvel Cinematic Universe film "Erab of the Press", and was named one of the film's biggest stars on Twitter. On September 9, 2014, McCoy filed a lawsuit against PYT to change its Twitter name to LeSean McCoy Productions.
beam search (size=5)	On September 9, 2014, McCoy was arrested in Harrisburg, Pennsylvania on suspicion of assault. He was charged with assault and battery. In May 2013, McCoy was fined over $50,000 by the Buffalo Bills. In September 2014, McCoy was arrested in Harrisburg, Pennsylvania on suspicion of assaulting a woman who had been raped by McCoy. McCoy was charged with assault and possession of marijuana. McCoy was suspended from the PYT for the first two games of the Marvel Cinematic Universe.
blocking (size=5)	On September 9, 2014, McCoy was arrested in Harrisburg, Pennsylvania on suspicion of assault. He was charged with assault and battery. In May 2013, he was fined over $50,000 by the Buffalo Bills. In September 2014, he was suspended for two games by the PYT for violating the Marvel Cinematic Universe. He was released by the Bills in October of the same year. He was cleared of all charges on Twitter, and was banned from playing in the 2014 Pro Bowl due to his Twitter account.

Table 19: Top: generation examples for the first instance in Figure 1. Middle: generation examples for the second instance in Figure 1. Bottom: generation examples that correspond to the instance in Figure 2.

G Details of Decoding Strategies

Nucleus Sampling. Generating long sequences usually suffers from repetitions. Nucleus sampling (Holtzman et al., 2020) aims to reduce the repetitions in generations by sampling from truncated probability distributions. The truncation is based on whether the cumulative probability is above a threshold. We set the threshold to be 0.9 as suggested in Holtzman et al. (2020).

Beam Search with n-gram Blocking. Paulus et al. (2018) found it effective to reduce the repetitions during beam search by "blocking" n-grams that have been generated in previous decoding steps. We follow their approach by using trigram blocking and setting the probability of repeated trigrams to be 0 during beam search.

Abstract

Translation between natural language and source code can help software development by enabling developers to comprehend, ideate, search, and write computer programs in natural language. Despite growing interest from the industry and the research community, this task is often difficult due to the lack of large standard datasets suitable for training deep neural models, standard noise removal methods, and evaluation benchmarks. This leaves researchers to collect new small-scale datasets, resulting in inconsistencies across published works. In this study, we present CoDesc - a large parallel dataset composed of 4.2 million Java methods and natural language descriptions. With extensive analysis, we identify and remove prevailing noise patterns from the dataset. We demonstrate the proficiency of CoDesc in two complementary tasks for code–description pairs: code summarization and code search. We show that the dataset helps improve code search by up to 22% and achieves the new state-of-the-art in code summarization. Furthermore, we show CoDesc's effectiveness in pre-training–fine-tuning setup, opening possibilities in building pretrained language models for Java. To facilitate future research, we release the dataset, a data processing tool, and a benchmark at https://github.com/csebuetnlp/CoDesc.

1 Introduction

Neural models for natural language processing have benefited from large datasets and standard evaluation benchmarks (Wang et al., 2019b,a; Rajpurkar et al., 2016; Hermann et al., 2015; CommonCrawl). However, the programming language counterpart is lagging behind due to a lack in such large datasets and benchmarks. To put this into perspective, the original Transformer network (Vaswani et al., 2017) was trained on WMT'14 English–German and English–French datasets (Bojar et al., 2014) containing 4.5 million and 36 million parallel sentences, respectively, whereas a similar network that achieved state-of-the-art results in source code summarization has been trained on only 69 thousand code-description pairs (Ahmad et al., 2020). We argue that the existing models used for programming language tasks in the literature have a significant scope of improvement given a large, good-quality dataset, and such a dataset is the missing link for effectively applying deep learning methods on programming languages.

In this work, we collect and release a large (4.2 million) Java source code - natural language (NL) parallel dataset along with denoising methods and baseline results. We apply our dataset to established works in both training from scratch and pre-training–fine-tuning setting and we demonstrate a notable performance gain in both settings. We gain 10% to 22% improvement over baseline code search models using CoDesc, and attain performances comparable to models having 8× more parameters. We achieve a new state-of-the-art BLEU score of 45.89 in code summarization by pretraining a Transformer network with our dataset for two epochs. With extensive empirical analysis, we propose a set of noise removal techniques for the source code and the NL descriptions in our dataset.

Our work brings together several datasets and multiple tasks on the intersection of Natural Language Processing (NLP) and Software Engineering (SE), such as code summarization, code search and code synthesis, and allows researchers to compare their methods on the same benchmark. It also opens the door for building large pretrained models to jointly learn code and NL representations that can be leveraged in downstream tasks that do not have adequate data, such as, code refactoring, clone detection, etc. as done by Feng et al. (2020).

2 Related Works

Code-Description Parallel Datasets With the advent of data-driven code search and code summarization methods, several datasets are proposed to facilitate research in code-NL parallel tasks. Husain et al. (2019) introduced CodeSearchNet (CSN), a benchmark for code search techniques with 2.1 million code-NL parallel data in 6 programming languages, 6.4 million monolingual code data, a leader-board, and baseline results with 5 code search techniques. CONCODE (Iyer et al., 2018), DEEPCOM (Hu et al., 2018a), FunCom (LeClair and McMillan, 2019) are some notable dataset papers that released 2.18 million, 2.15 million, and 0.59 million parallel data respectively. Clement et al. (2020) released a parallel corpus of 26 million monolingual Python methods and 7.7 million method-docstring pairs. CoNaLa (Yin et al., 2018) is a Python line by line natural language description dataset containing nearly 3k parallel data.

Code Search and Summarization CODE-NN (Iyer et al., 2016) is a pioneering work in data-driven code summarization. The CodeSearchNet dataset paved the way for CodeBERT (Feng et al., 2020), a pretrained BERT (Devlin et al., 2019) model trained on CSN data with Masked Language Modeling (MLM) (Devlin et al., 2019) and Replaced Token Detection (RTD) (Clark et al., 2020) objective that achieved a high performance in the CSN benchmark. Wei et al. (2019) proposed a dual learning method that simultaneously trained code summarization and code generation and improved both of them using 60k parallel data. In the same dataset, Ahmad et al. (2020) achieved state-of-the-art results in source code summarization using a Transformer network (Vaswani et al., 2017). Along with the mentioned dataset, Clement et al. (2020) presented PyMT5, a text to text transformer that notably improved method generation and code summarization. Ahmad et al. (2021) collected more than 300 GB monolingual code and NL data, and trained PLBART, a pretrained seq2seq model for both program understanding and comprehension.

3 CoDesc Dataset

3.1 Data Sources

We collect our data from several sources and formulate rules for data cleaning. 5 of the authors spent 45-50 man-hours manually going over the dataset to identify patterns of noises in different data sources. Upon group discussion, common patterns were identified and a noise removal method was established. Details about these noise patterns are provided in Appendix A.

One of the datasets used in CoDesc is CodeSearchNet (CSN)[1] (Husain et al., 2019) - a parallel method-description dataset for code search. Furthermore, other datasets used are DeepCom[2] (Hu et al., 2018a), CONCODE[3] (Iyer et al., 2018), FunCom[4] (LeClair and McMillan, 2019) - datasets created for code summarization. The CodeSearchNet dataset originally contained 6 programming languages, from which the Java methods are directly used in CoDesc, however, the Python methods are used after being automatically translated to Java. We combine all aforementioned datasets to create CoDesc. Appendix B shows a

[4] http://leclair.tech/data/funcom/

sample code-description parallel data from each of these datasets. Table 1 describes our data sources and their characteristics in detail.

CSN Python to Java Translation To utilize maximum possible data from the CSN CORPUS, we translate the Python methods to Java using TransCoder (Lachaux et al., 2020), a state-of-the-art, neural source-to-source compiler. We modified and re-released the open-source implementation of TransCoder[5], enabling it to translate data in batches instead of one at a time, and resulting in a 16X faster translation. Upon empirical inspection, we found that the converted Java codes are human-readable and bear a strong resemblance to the original Python code intent. The converted codes seem correct to the human eye and their syntax matches with Java syntax. However, a few cases the transcompiler suffers are – converting to Java library methods, and converting from Python coding conventions that does not have a Java equivalent (e.g. use of SELF). These conversion errors, however, were not severe enough to affect our model to learn the NL-source code mapping.

3.2 Data Cleaning and Noise Removal

We created an easy-to-use, parameterized data processing tool for removing the different types of noise that we observed in our dataset. From the natural language descriptions, we remove symbols and characters that do not carry a meaning in a natural language description, such as, comment tags (e.g., `//, /*, */`), stray code characters (e.g., `@, #, {, }`, etc.), HTML and XML tags, non-ASCII and escape characters, and some patterns of autogenerated tags (e.g., `@param, @return, @throws`, etc.). From source code, we remove comments and the non-ASCII and escape characters. In previous studies, many meaningful data are discarded due to having some noisy patterns/symbols either in the code or description (Husain et al., 2019; Iyer et al., 2018; LeClair and McMillan, 2019). We identify and remove the noisy part of the data points without excluding them from the dataset to reduce data loss during preprocessing.

For both source code and NL description, we split CamelCase and snake_case code tokens into subtokens (e.g., Camel Case, snake case) and separate linked alphabets and numbers (e.g., var0 to var 0) (Ahmad et al., 2020; LeClair and McMillan, 2019). After the aforementioned processing, we remove the data points where the source code is less than 3 tokens, or the description contains less than 2 alphabets (Husain et al., 2019). We lowercase the natural language as the case is not necessary for describing codes. We release our data processing tool along with the CoDesc dataset for applying the dataset to diverse tasks.

3.3 Dataset Characteristics

After the previous steps, we are left with nearly 4.2 million Java method and description parallel data. Table 1 presents the statistics characteristics of our dataset. The combined CoDesc dataset consists of more than one million unique tokens, which is significantly larger than natural language vocabulary (Chen et al., 2019). This can be partially attributed to inseparable multi-words (e.g. 'updateproductvariationlocalizeddeltaprice') in our dataset. Hence, we perform BPE (Sennrich et al., 2016) tokenization in our preprocessing pipeline. We also see that although the average token length of Java source codes vary in the different dataset sources, the natural language descriptions have a relatively uniform length. We create a balanced, deduplicated, and representative *train–valid–test* dataset by splitting individual source-dataset in 8:1:1 ratio (Table 1).

4 Experiments

We evaluate our code-description corpus in two well-known complementary tasks: source code summarization and natural language code search. In this section, we demonstrate that models trained on CoDesc bring about a noticeable improvement over two established baselines in code search and code summarization. Each benchmarking follows a standard cleaning, preprocessing, and train-test de-duplication process.

4.1 Natural Language Code Search

We use the code search models used by Husain et al. (2019) that jointly trains a source code and an NL encoder networks to minimize their encoded vector distance (Figure. 1). We apply our dataset on the CODESEARCHNET (CSN) (Husain et al., 2019) – a well-studied benchmark in the semantic code search literature. We train 5 different encoder networks (Table. 2) with the CSN Java dataset, and CoDesc respectively. We compare our results with CodeBERT and RoBERTa (code) (Feng et al., 2020), two pretrained models achieving state-of-

the-art results in CSN Benchmark. They are trained with a Masked Language Modeling (MLM) (Devlin et al., 2019) objective on 2.1 million bimodal code-NL data, and 6.4 million unimodal data released with CODESEARCHNET.

Results We use Mean Reciprocal Rank (MRR) – the commonly used evaluation metric for code search (Husain et al., 2019; Sachdev et al., 2018; Cambronero et al., 2019) as the evaluation criteria for code search. Table 2 shows our results, along with state-of-the-art models (Liu et al., 2019; Feng et al., 2020) that have nearly 8-10 times more parameters than the baseline networks and a more complex training objective. We achieve remarkably close performance with the state-of-the-art models with much simpler and smaller networks.

4.2 Source Code Summarization

For this task, we follow the methodology proposed by Ahmad et al. (2020). They used a seq2seq Transformer (Vaswani et al., 2017) network with 77M parameters with relative positional encoding (Shaw et al., 2018) and copying mechanism (See et al., 2017) and achieved state-of-the-art results.

Methods	BLEU	METEOR	ROUGE-L
Transformer	44.58	26.43	54.76
CoDesc pretrained	**45.89**	**28.01**	**56.59**

Table 3: Code summarization with Ahmad et al. (2020) proposed Transformer network with and without pretraining with CoDesc.

Data preparation Ahmad et al. (2020) used a Java dataset released by Hu et al. (2018b) and preprocessed by Wei et al. (2019) consisting of *training*, *validation*, and *test* datasets of size 69,708, 8,714, and 8,714 respectively. We refer to this training data as *train-small*. We create a new dataset *CoDesc-train* by combining *train-small* with CoDesc. We replace all literals as Wei et al. (2019) and tokenize the dataset using Character BPE Tokenization (Sennrich et al., 2016) to create the same size vocabulary as the previous works.

Training We train a Transformer model proposed by Ahmad et al. (2020) with *CoDesc-train* dataset. We use Adam optimizer with an initial learning rate of 10^{-4}, mini-batch size of 32, and dropout rate 0.2, vocabulary size 50k for code and 30k for NL. However, we use maximum input length of 200 token instead of 150 based on our observation of CoDesc dataset from Table 1. Each epoch of the model took nearly 8 hours in an NVIDIA V100 16GB GPU. In comparison, the *train-small* dataset took 8.5 minutes only. For limitation of computational resource, we saved the network weights after training it with the large dataset for two epochs, and to be consistent with the original implementation, trained them further with the *train-small* dataset for a maximum of 198 more epochs. We perform an early stop if the validation performance does not improve for consecutive 20 epoch. The pretraining provides the network parameters a more favorable initialization than random, helping the network find better local minima.

Results Table 3 shows that our two epoch pretraining with CoDesc significantly improves the state-of-the-art code summarization methods in all three evaluation metrics – BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and ROUGE-L (Lin, 2004). We observe that the pretrained model often generates more descriptive summary even when it achieves lower BLEU score (Fig. 2). We believe the model has more room for

```
public void makeImmutable(){
   if(mutable){
      if(results ! = null){
         int length = results.size();
         for(int i = NUM; i < length; i + +){
            Result result = (Result)results.get(i); result.makeImmutable();
         } results = Collections.unmodifiableList(results);
      } mutable = BOOL; } }
```

Human written: makes the object immutable

Transformer prediction (BLEU: 1.0): makes the object immutable

CoDesc pretrained model prediction (BLEU: 0.12): if there are any object in the list then the object is not immutable

Figure 2: CoDesc pretrained model generates more descriptive summary, even in cases it achieves lower score.

Dataset	**Raw data**	**Clean data**	**Inc. (%)**
CSN (Java)	0.5870	0.6427	5.57
DeepCom	0.4677	0.6069	13.92
FunCom	0.5379	0.6366	9.87
CONCODE	0.5444	0.6234	7.90
CSN (Python2Java)	0.5081	0.5546	4.65
CoDesc (All)	0.5852	0.6826	9.74

Table 4: MRR of individual datasets (Section 3.1) before and after noise removal.

improvement with further pretraining and we wish to validate this in future work.

4.3 Ablation & Analysis

To quantify the effect of individual data sources and our noise removal methodology, we train each dataset before and after applying our data cleaning method using an NBOW model and test them in the CSN benchmark using their released test set.

Although our collected data was already cleaned by the respective authors, Table 4 shows that the performance of every dataset improves drastically after our noise removal. Interestingly, without our extra layer of data cleaning, CoDesc dataset performs worse than training with only CSN data although being significantly larger. This shows the importance of a standard cleaning and processing method. Moreover, CSN (Java) have the highest accuracy, which can be attributed to the fact that it came from the same distribution of data as the evaluation and test sets, and hence contains similar tokens and patterns (Husain et al., 2019). We can see from Table 4 that the model trained with CSN (Python2Java) achieves an MRR score of 0.5548. Although this score is lower than other datasets, it is still a good indication that the translated data is helping the model is to learn NL-code association.

New Benchmark Results in Code Search We provide a new set of benchmark results for CoDesc dataset in natural language code search. We train, validate, and test an NBOW, an RNN, and a Self-attn code search network with the balanced *train*, *validation*, and *test* data shown in Table 1. The three models achieve MRR score of **0.812**, **0.766**, and **0.839** respectively.

5 Discussion and Conclusion

In this work, we have accumulated CoDesc – a large code-description parallel dataset and established baseline results. CoDesc brings a noteworthy improvement in two tasks: code search and code summarization. We believe CoDesc will serve as a base for future studies on code-description joint tasks. We also show that automatically translated source code from a source-to-source compiler can be applied in a code-NL parallel task, suggesting that, translating our Java dataset to other programming languages can also be helpful.

The most striking finding of our study is that, by training with 2X larger parallel data, we achieve equivalent performance to models having 8X parameters (Feng et al., 2020) in code search. This raises an interesting question: are we fully utilizing the model capacities in code–description studies? From our pretraining results in code summarization, it can be reasonably assumed that pretraining with our large dataset the larger models will also improve further. In future works, we wish to apply new techniques for code search, code summarization, along with exploring our dataset for general-purpose code synthesis, where the best models are still struggling in accuracy (Wei et al., 2019; Yin and Neubig, 2017).

A Dataset Details

CodeSearchNet (CSN) Corpus is a code search dataset for 6 programming languages (Husain et al., 2019).[6] Despite the authors' effort for data cleaning, in our observation, CSN CORPUS is one of the noisiest. The dataset contains duplicate descriptions, inseparable multi-words (e.g., `updateproductvariationlocalizeddeltaprice`, `updatelocationinventory`), XML tags (e.g., `<tt>`, `<soup>`, `<sub>`), non-English documentation, non-ASCII and escape characters, unwanted symbols (e.g., `@`, `#`, `{`, `}`), deprecated methods and descriptions, comments inside code, annotations (e.g., `@link`, `@code`, `@inheritdoc`) in description, etc. Datapoints truncated by TransCoder during Python to Java translation (total 27,471) are marked with a special flag in our released corpus.

DeepCom Hu et al. (2018a) released a dataset of 588,108 Java method and documentation pairs collected from 9,714 GitHub projects for code summarization[7]. Similar to CODESEARCHNET (Husain et al., 2019), they considered the first sentence of a documentation as the summary of the method as it typically describes the functionalities of Java methods. They filter out empty and single world descriptions and the setter, getter, constructors, and test methods, since they are easy for a model to summarize. In our manual analysis, we found HTML tags (e.g. `<tt>`, `<p>`, `<p class = ...>` , `<li>`, `<ul>`), comment tags, annotations, escape characters inside descriptions, empty parentheses as descriptions, repetitive and non-meaningful descriptions, comments inside source code, etc. Despite the authors' claim, we found numerous test methods in the dataset, which were mostly meaningful data.

CONCODE Iyer et al. (2018) released a dataset named CONCODE, collected by mining nearly 33,00 GitHub repositories[8]. In their preprocessed dataset, they replaced the names of the identifier and method names with generic terms, (e.g., `arg0`, `loc0`, `function`, etc.) and replaced all string literals with constants. This created a discrepancy with the other datasets, hence, we opted for their unprocessed dataset rather than the processed version. The unprocessed dataset released with CONCODE contained approximately 2.1 million Java methods and lowercased Javadoc-style document pairs. Upon duplicate removal, we were left with 733,878 datapoints.

Although some noises were present in this dataset, we found this data to be least noisy in manual observation. We find that because of lower casing the documentations, some CamelCase tokens became inseparable. The dataset also contained non-English comments with English alphabets (mostly Italian). We found these documents hard to identify and remove.

FunCom LeClair and McMillan (2019) released a dataset of over 2.1 million pairs of Java methods and one-sentence method descriptions from over 28k Java projects[9]. They collected this dataset by filtering over 51 million Java methods from UCI Source Code datasets (Lopes et al., 2010). In their preprocessing step, LeClair and McMillan (2019) removed all datapoints where the method is more than 100 tokens long, or the method description is over 13 tokens or below 3 tokens.

In our observation of this dataset, we found method descriptions containing HTML tokens (e.g. `<tt>`, annotations (e.g., `@link`, `@param`), comment tokens, unwanted symbols, solely non-alphabetic characters, etc. It also contained comments inside methods, and a large portion of the data were `getter`, `setter`, `tester`, and `toString` methods.

B Sample Data

```
protected void hideTabs(){
  if (getPageCount() <= 1) {
    setPageText(0,"");
    if (getContainer() instanceof
        CTabFolder) {
      ((CTabFolder)getContainer())
      .setTabHeight(1);
      Point point =
          getContainer().getSize();
      getContainer().setSize(point.x,
        point.y + 6);
    }
  }
}

Abstract

Knowledge Graphs (KGs) provide human knowledge with nodes and edges being entities and relations among them, respectively. Multi-hop question answering over KGs—which aims to find answer entities of given questions through reasoning paths in KGs—has attracted great attention from both academia and industry recently. However, this task remains challenging, as it requires to accurately identify answers in a large candidate entity set, of which the size grows exponentially with the number of reasoning hops. To tackle this problem, we propose a novel **D**eep **C**ognitive **R**easoning **N**etwork (DCRN), which is inspired by the *dual process theory* in cognitive science. Specifically, DCRN consists of two phases—the *unconscious* phase and the *conscious* phase. The unconscious phase first retrieves informative evidence from candidate entities by leveraging their semantic information. Then, the conscious phase accurately identifies answers by performing sequential reasoning according to the graph structure on the retrieved evidence. Experiments demonstrate that DCRN significantly outperforms state-of-the-art methods on benchmark datasets.

1 Introduction

Knowledge Graphs (KGs) store structured human knowledge, in which nodes represent entities and edges represent relations between pairs of entities. Multi-hop Question Answering over KGs (KGQA) aims to find answer entities by reasoning over paths in KGs. We illustrate this task with an example in Figure 1. Recently, multi-hop question answering over KGs has attracted great attention from both academia and industry (Li et al., 2017; Fu et al., 2020; Saxena et al., 2020). However, this task remains challenging, because the number of candidate entities grows exponentially with the number of reasoning hops (Sun et al., 2018, 2019a), making it difficult to accurately identify answers.

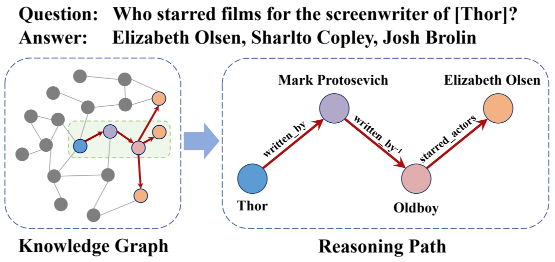

Figure 1: Illustration of multi-hop question answering over KGs. Given a natural language question, we start from the topic entity in it, and reason along paths in KGs to find answers.

Previous works mitigate this problem by reducing the size of the candidate entity sets, but they often sacrifice the recall of answers. These methods including GRAFT-Net (Sun et al., 2018) and PullNet (Sun et al., 2019a) first extract question-specific subgraphs, and then perform multi-hop reasoning on the extracted subgraph via Graph Neural Networks (GNNs) to find answers. However, these approaches often sacrifice the recall of answers in exchange for small candidate entity sets. That is, the extracted subgraph may contain no answer at all. This trade-off between the recall of answer entities and the size of candidate entity sets limits their practical usage. Therefore, it is still desirable to find an approach that is capable of accurately identifying answers without sacrificing their recalls.

To tackle this problem, we take inspiration from the *dual process theory* (Evans, 1984, 2003, 2008) in cognitive science and propose a novel **D**eep **C**ognitive **R**easoning **N**etwork (DCRN). In cognitive science, researchers found that humans can reason over a large-capacity memory to find answers (Wang et al., 2003). Specifically, the *dual*

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 219–229
August 1–6, 2021.

process theory (Evans, 1984, 2003, 2008) suggests that humans accomplish cognitive tasks by first exploiting *fast intuition* to retrieve task-relevant evidence via an *unconscious process*, and then performing *sequential reasoning* based on the aforementioned evidence to derive answers via a *conscious process*. Similarly, the proposed DCRN consists of two phases. The first one is the unconscious phase, which can retrieve informative evidence by *softly* selecting candidate entities that are most likely to be correct answers. The second one is the conscious phase, which can accurately identify answers by performing sequential reasoning with Bayesian networks based the retrieved evidence from the first phase. Experiments demonstrate that DCRN significantly outperforms state-of-the-art methods on benchmark datasets.

2 Preliminaries

In this section, we first review the background of this paper and then introduce the notations used throughout this paper.

2.1 Background

In this part, we review the background of knowledge graph and milti-hop KGQA.

Knowledge Graph Given a set of entities $\mathcal{E}$, a set of relations $\mathcal{R}$, and a set of triplets $\mathcal{T} = \{(e_i, r_j, e_k)\} \subset \mathcal{E} \times \mathcal{R} \times \mathcal{E}$, we define a knowledge graph $\mathcal{G}$ by $\mathcal{G} = \{\mathcal{E}, \mathcal{R}, \mathcal{T}\}$.

Multi-hop KGQA Given a knowledge graph $\mathcal{G} = \{\mathcal{E}, \mathcal{R}, \mathcal{T}\}$ and a natural language question q with its topic entity $e_{topic} \in \mathcal{E}$, the task of KGQA is to predict the answer e^* to question q by

$$e^* = \arg\max_{e_i \in \mathcal{E}} f(e_i),$$

where $f(e_i)$ is the score function that measures the plausibility of e_i being the correct answer. In multi-hop KGQA, the answers are not guaranteed to be direct neighbours of the topic entity in the given question. Therefore, it often requires multi-hop reasoning over KGs to find answers.

Bayesian Network A Bayesian network is a probabilistic graphical model that represents a set of variables and their conditional dependencies via a directed acyclic graph (DAG). In a Bayesian network, the nodes represents random variables and the directed edges represent the conditional dependencies between random variables.

2.2 Notations

In this paper, we use lower-case letters e and r to represent an entity and a relation, respectively. The corresponding boldface letters $\mathbf{e}$ and $\mathbf{r}$ denotes the embeddings of e and r, respectively.

3 Related Work

In this section, we review related work for multi-hop KGQA and knowledge graph embeddings.

3.1 Multi-hop KBQA

Recent work in multi-hop KBQA can be divided into two categories: semantic parsing methods and information retrieval methods. Semantic parsing methods first parse the given question into an executable query, and then execute the query to locate answers. Information retrieval methods embeds questions and the knowledge graph into low-dimensional spaces, and then find answers based on question-answer semantic similarity. Our proposed DCRN belongs to information retrieval methods.

Key-Value Memory Network (KV-Mem) KV-Mem (Miller et al., 2016) is a variant of Memory Network (Weston et al., 2015), which performs reasoning based on a memory component, i.e., an array storing triplets in KGs. KV-Mem iteratively reads from the memory to update the question embedding, which is used to match correct answers.

Variational Reasoning Network (VRN) VRN (Zhang et al., 2018) proposes a variational framework for multi-hop KGQA. To identify answers, it computes the compatibility scores between the question type and the reasoning graph of each candidate. However, its performance is limited on the question that requires long reasoning paths to answer, due to the exponentially grown candidates.

GRAFT-Net GRAFT-Net (Sun et al., 2018) first extracts question-specific subgraph based on Personalized Page Rank (PPR), and then encode the subgraph with Graph Neural Networks (GNN) to identify answers. However, as described in Sun et al. (2019a), the extracted subgraphs are often too large and have a low recall for answer entities.

PullNet PullNet (Sun et al., 2019a) mitigates the problem of GraftNet with a trainable subgraph expansion strategy. It constructs question-specific subgraph starting from the list of entities mentioned in the question, and then iteratively "pulls" the relevant entities to expand the subgraph. However, it inevitably sacrifices the recall of answer entities

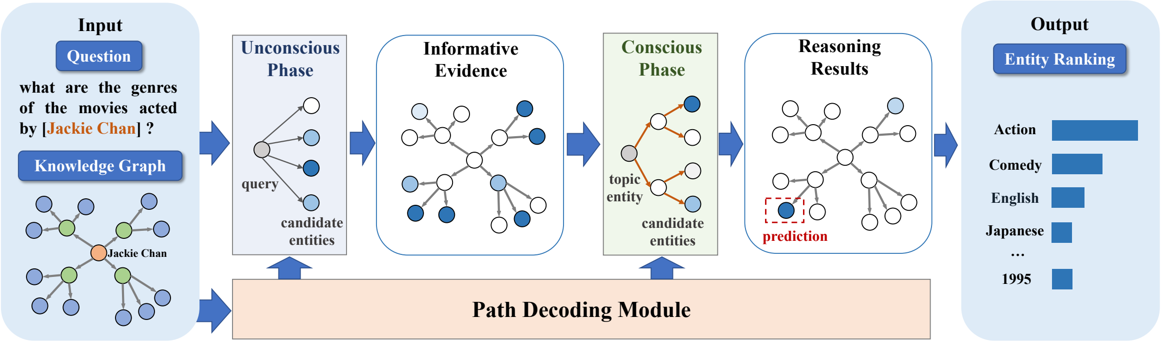

Figure 2: Overview of the proposed Deep Cognitive Reasoning Network (DCRN). DCRN consists of a Path Decoding Module and two phases—the unconscious phase and the conscious phase. Deeper color in coarse/fine-grained results denotes higher prediction score as the correct answer.

in exchange for small candidate entity sets, which limits its performance in practical usage.

EmbedKGQA EmbedKGQA (Saxena et al., 2020) models multi-hop KBQA as a link prediction task. It first embeds the given question into a latent relation embedding, and then exploits knowledge graph embedding techniques to identify answers.

3.2 Knowledge Graph Embedding in KGQA

Knowledge Graph Embedding (KGE) methods (Hitchcock, 1927; Trouillon et al., 2016; Sun et al., 2019b; Zhang et al., 2020a,b) aim to map entities and relations within KGs into distributed representations (vectors, matrices, etc.). These embeddings are often trained by the link prediction task, where the model is required to predict the missing head or tail entity of a triplet.

EmbedKGQA (Saxena et al., 2020) use ComplEx (Trouillon et al., 2016) to train knowledge graph embeddings, which represents entity and relation embeddings as vectors in complex spaces. For fair comparison with previous work including GRAFT-Net (Sun et al., 2018) and PullNet (Sun et al., 2019a), we use Canonical Polyadic (CP) decomposition (Hitchcock, 1927) to train knowledge graph embeddings in our proposed DCRN, which represents entity and relation embeddings as vectors in real spaces.

3.3 The Dual Process Theory

The *dual process theory* (Evans, 1984, 2003, 2008) is originally proposed in cognitive science. Inspired by this theory, researchers propose to mimic human cognition in various cognitive tasks. For example, Du et al. (2019) applies the theory to one-shot KG reasoning, and Ding et al. (2019) proposes a cognitive framework for multi-hop reasoning over documents. Different from these work, we focus on the task of multi-hop question answering over knowledge graphs.

4 Method

In this section, we introduce our proposed Deep Cognitive Reasoning Network (DCRN) for multi-hop KGQA. In section 4.1, we introduce the motivation and the overall architecture of DCRN. In Section 4.2, 4.3, and 4.4, we introduce the components of the proposed DCRN.

4.1 Motivation

For multi-hop questions, it is challenging to accurately identify answers from a large candidate set, of which the size grows exponentially with the number of reasoning steps. Existing approaches (Sun et al., 2018, 2019a) aim to reduce the size of candidate entity set by extracting question-specific subgraphs. However, these approaches often sacrifice the recall of answers in exchange for small candidate sets, which limits their performances in practical usage.

We take inspiration from the *dual process theory* (Evans, 1984, 2003, 2008) in cognitive science. Specifically, the theory suggests that humans accomplish cognitive tasks by first exploiting *fast intuition* to retrieve task-relevant evidence via an *unconscious process* (System 1), and then performing *sequential reasoning* based on the aforementioned evidence to derive answers via a *conscious process* (System 2).

Inspired by the *dual process theory* in cognitive science, we propose Deep Cognition Reasoning Network (DCRN) for multi-hop KGQA. The proposed DCRN consists of two phases. The first one is the *unconscious phase*, which can retrieve informative evidence from candidate entities by leveraging their semantic information. The second one is the *conscious phase*, which can accurately identify answers by performing sequential reasoning according to the graph structure on the retrieved evidence from the first phase.

The overall architecture of DCRN is shown in Figure 2. In DCRN, the basic module is the Path Decoding Module, based on which are the two phases—unconscious phase and conscious phase.

4.2 Path Decoding Module

, The Path Decoding Module is the basic component of DCRN. As multi-hop KGQA requires multi-hop reasoning to arrive at answer entities, we decode the reasoning path information from the question in this module.

Specifically, we adopt an RNN-based encoder-decoder structure, which first encodes the question into a hidden representation, and then decodes this representation to obtain the reasoning path information, i.e., the scores of each relation at each reasoning step. These scores will be used in the unconscious and conscious phase.

First, we encode the given question q with an RNN to obtain its latent representation $\mathbf{q} \in \mathbb{R}^d$.

$$\mathbf{q} = \text{RNN-Encoder}(q).$$

Then, we decode this representation $\mathbf{q}$ to obtain reasoning path information. We illustrate this process in Figure 3. At each step of decoding, the decoder predicts the scores of each relation. The predictions at step t is the input of the decoder at step $t + 1$.

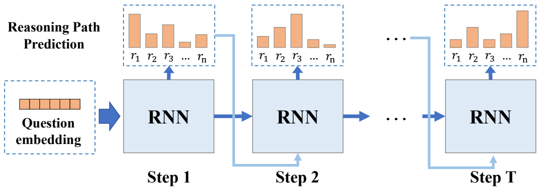

Figure 3: Illustration of the Path Decoding Module.

At step t, given the hidden state $\mathbf{h}^{(t-1)}$ of the previous iteration and the input $\mathbf{i}^{(t)}$, the RNN decoder outputs the updated hidden state $\mathbf{h}^{(t)}$ by

$$\mathbf{h}^{(t)} = \text{RNN-Decoder}(\mathbf{h}^{(t-1)}, \mathbf{i}^{(t)}),$$

where the initial hidden state $\mathbf{h}^{(0)}$ is initialized as the question embedding $\mathbf{q}$, and the initial input $i^{(0)}$ is a zero vector. Then, we compute the output of step t by

$$\mathbf{o}^{(t)} = \sum_i \alpha_i^{(t)} \mathbf{r}_i,$$

where the weights $\alpha_i^{(t)}$ is computed as

$$\alpha_i^{(t)} = \frac{\exp\left(f_{rel}^{(t)}(r_i)\right)}{\sum_j \exp\left(f_{rel}^{(t)}(r_j)\right)}.$$

Note that $f_{rel}^{(t)}(r_i)$ denotes the scores of each relation at step t, which is computed by

$$f_{rel}^{(t)}(r_i) = \mathbf{h}^{(t)} \mathbf{r}_i^\top.$$

Then, the output of step t will be the input of step $t + 1$. That is, $\mathbf{i}^{(t+1)} = \mathbf{o}^{(t)}$.

4.3 The Unconscious Phase

The unconscious phase corresponds to the *unconscious process* (System 1) in the *dual process theory* from cognitive science. In this phase, we retrieve informative evidence from candidate entities by leveraging their semantic information.

The *evidence* refers to sketched results that predicts which candidates are most likely to be correct answers. We expect the retrieved evidence to effectively filter out those candidate entities that are irrelevant to the given question.

To achieve this, we perform semantic matching between the given question and each candidate entity. The semantic matching scores $f_s(e)$ of candidate entity e is

$$f_s(e) = \overline{\mathbf{q}} \mathbf{e}^\top,$$

where $\overline{\mathbf{q}} \in \mathbb{R}^{1\times d}$ is the query embedding obtained based on the given question, and $\mathbf{e} \in \mathbb{R}^{1\times d}$ is the embedding of entity e.

In our model, the entity embedding $\mathbf{e} \in \mathbb{R}^d$ is pretrained by the CP (Hitchcock, 1927) model. Therefore, the key of the unconscious phase is to design informative query representation $\overline{\mathbf{q}} \in \mathbb{R}^d$.

To design informative query representations, we take inspiration from PTransE (Lin et al., 2015), which extends knowledge graph embedding to relation paths. In PTransE, if a relation path $e_1 \xrightarrow{r_1} e_2 \xrightarrow{r_2} \dots \xrightarrow{r_{n-1}} e_n$ holds, then PTransE optimize the following objective:

$$\mathbf{e}_1 \circ \mathbf{r}_1 \circ \dots \circ \mathbf{r}_{n-1} = \mathbf{e}_n,$$

where $\circ$ is an composition operation, and it can be addition, element-wise multiplication, RNN, etc. This objective can be considered as the semantic matching between the query $\mathbf{e}_1 \circ \mathbf{r}_1 \circ ... \circ \mathbf{r}_{n-1}$ and its target $\mathbf{e}_n$.

Similarly, we encode the query representation $\overline{\mathbf{q}}$ as follows. First, the start entity of the reasoning path is the topic e_{topic} in the given question. Second, recall that we decode reasoning path information in the Path Decoding Module, in which the output at step t (i.e., $\mathbf{o}^{(t)}$) represents the weighted sum of relation embeddings. Therefore, we represent the query embedding as

$$\overline{\mathbf{q}} = \mathbf{e}_{topic} \circ \mathbf{o}^{(1)} \circ ... \circ \mathbf{o}^{(T)},$$

where $\circ$ denotes element-wise multiplication in this formula, and T denotes the number of steps in the Path Decoding Module (i.e., the number of reasoning steps).

4.4 The Conscious Phase

The conscious phase corresponds to the *conscious process* (System 2) in the *dual process theory* from cognitive science. In this phase, we accurately identify answers by performing sequential reasoning according to the graph structure on the retrieved evidence from the unconscious phase.

To model the sequential reasoning, we take inspiration from the *consciousness prior* (Bengio, 2017). It suggests that the conscious process only refers to a few variables at a time, which can be modeled as *factor graphs*, a form of knowledge representation which is factored into pieces involving a few variables at a time.

In this work, we perform sequential reasoning based on Bayesian networks, which can be seen as a type of factor graphs. First, we build question-specific Bayesian networks from the given KG, in which we view the predictions of entities as random variables and relations as the relational dependencies between them. Second, we perform marginal inference on the Bayesian networks to predict the probability of each candidate entity as a correct answer.

4.4.1 Building Bayesian Networks

We build question-specific Bayesian networks from the given KG with the following two steps. First, we perform graph pruning on the KG to obtain a directed acyclic graph (DAG). Second, we transform the DAG into a Bayesian network.

Given a knowledge graph $\mathcal{G} = \{\mathcal{E}, \mathcal{R}, \mathcal{T}\}$ and a question q with a topic entity $e_{topic} \in \mathcal{E}$, we prune G to obtain a directed acyclic graph (DAG) by applying the breadth-first search (BFS) algorithm starting from e_{topic}. Specifically, we only keep the visited edges during searching, and remove the unvisited edges. We illustrate this process in Figure 4, in which we perform two-step BFS starting from the topic entity, and prunes the unvisited edges. Note that we add inverse relations r^{-1} for each relation r in KGs following previous work (Sun et al., 2018, 2019a). That is, if (e_i, r_j, e_k) is a valid triplet, then (e_k, r_j^{-1}, e_i) is also valid.

The reasons to perform the graph pruning is two-fold. First, the number of potential reasoning paths from e_{topic} to an arbitrary candidate entity e in the KG can be extremely large. Therefore, we apply graph pruning to reduce the search space, and only keep the shortest paths. Second, Bayesian Network is required to be a directed acyclic graph (DAG). Therefore, the graph pruning procedure only removes redundant edges, and the answer entities are guaranteed to be within the candidate set.

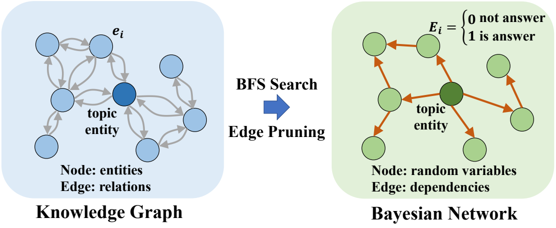

Figure 4: Illustration of question-specific Bayesian networks built from KGs. In KGs, we add an inverse relation r^{-1} for each relation r. That is, if a triplet (e_i, r, e_j) exists, then (e_j, r^{-1}, e_i) also exists.

We use $\hat{\mathcal{G}}(e_{topic})$ to denote the pruned graph given the topic entity e_{topic}. Then, we have the following proposition.

Proposition 1. *The pruned graph $\hat{\mathcal{G}}(e_{topic})$ is a directed acyclic graph (DAG).*

For detailed proof, please refer to the appendix. According to the properties of BFS, if $\mathcal{G}$ is connected, then there exists a path in the pruned graph $\hat{\mathcal{G}}(e_{topic})$ that starts from e_{topic} and ends with e. Furthermore, this path must be the shortest one among all paths in $\mathcal{G}$ that connects e_{topic} and e.

We then introduce how this DAG corresponds $\hat{\mathcal{G}}(e_{topic})$ to a Bayesian network. The transformed Bayesian Network $\mathcal{B}(_{topic})$ shares the same graph structure with $\hat{\mathcal{G}}(_{topic})$, but the definitions on nodes and edges are different. In Table 1, we illustrate the

Table 1: The relationship between the DAG and the corresponding Bayesian Network.

	DAG $\hat{\mathcal{G}}(e_{topic})$	**Bayesian Network** $\mathcal{B}(e_{topic})$
Nodes	entity e_i	random variable $X_{e_i} = \{0, 1\}$
Edges	relation r_j between e_i and e_k	conditional dependencies between X_{e_i} and X_{e_k}

relationship between the DAG and the corresponding Bayesian network.

Each entity e in $\hat{\mathcal{G}}(e_{topic})$ corresponds to a random variable $X_e = \{0, 1\}$ in $\mathcal{B}(e_{topic})$, where $X_e = \{0, 1\}$ represents the prediction of a candidate entity e. Given a question q, $X_e = 0$ denotes that e is an incorrect answer and $X_e = 1$ denotes that e is a correct answer. In $\hat{\mathcal{G}}(_{topic})$, each relation r connecting entity e_i and e_j corresponds to an directed edge connecting X_{e_i} and X_{e_j} in $\mathcal{B}(_{topic})$, which denotes the dependencies between them.

4.4.2 Bayesian Reasoning

Based on the Bayesian network $\mathcal{B}(_{topic})$, we can make marginal inferences to predict whether an entity e is a correct answer, which can be represented in a probabilistic way:

$$\mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic}),$$

where $\mathcal{G}$ is the KG, q is the given question, and e_{topic} is the topic entity. To calculate this marginal probability, we have the following proposition.

Proposition 2. *The marginal probability* $\mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic})$ *that predicts a candidate entity e can be calculated via variable elimination:*

$$\begin{aligned}&\mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic})\\&= \overline{\mathbb{P}}(X_e = 1) \prod_{e' \in pa(e)} \mathbb{P}(X_{e'} = 0|\mathcal{G}, q, e_{topic}),\end{aligned}$$

where $pa(e)$ *denotes the set of parent nodes of e, i.e., the nodes that have edges directing at e. The first component* $\overline{\mathbb{P}}(X_e = 1)$ *is the abbreviation of*

$$\mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic}, X_{pa(e)} = 0).$$

For detailed proofs, please refer to the appendix. The marginal probability $\mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic})$ is the product of two components. The first component denotes the probability that entity e is an answer given that all e's parent entities $\text{pa}(e)$ are incorrect. The second component $\prod_{e' \in \text{pa}(X_e)} \mathbb{P}(X_{e'} = 0|\mathcal{G}, q, e_{topic})$ denotes the product of the predictions of X_e's parent nodes. Note that we assume $\mathbb{P}(X_{e'} = 0|\mathcal{G}, q, e_{topic}) = 1$ when computing $\mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic}$ in our implementation for convenience of computation.

We model the first component as follows.

$$\begin{aligned}&\mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic}, X_{\text{pa}(e)} = 0)\\&= \text{sigmoid}(g(f_s(e), f_b(e))),\end{aligned}$$

where $f_s(e)$ is the evidence provided by the unconscious phase, $f_b(e)$ represents the score computed in the Bayesian network. $g(\cdot, \cdot)$ is a function for combining the two scores, and we choose $g(x, y) = x + y$ in this work. The score $f_b(e)$ is defined as follows:

$$f_b(e) = \sum_{\substack{e' \in \text{pa}(e),\\ (e', r, e) \in \mathcal{T}}} \alpha_r^{(t)} f_b(e') + f_{rel}^{(t)}(r),$$

where $f_{rel}^{(t)}(r)$ represents the prediction score of relation r at reasoning step t in the Path Decoding Module, $\alpha_r^{(t)}$ is defined in section **??**. Note that t also denotes the topological distance between e_{topic} and e, i.e., the required reasoning steps from e_{topic} to e. We initialize the score for the topic entity to zero. That is, $f_b(e_{topic}) = 0$.

The conscious phase is different from previous multi-hop reasoning approaches (Zhang et al., 2018; Sun et al., 2018, 2019a) in the following two aspects. First, we model the reasoning process in a probabilistic perspective with Bayesian networks, while previous works often apply GNN for reasoning. Second, the conscious phase propagates scalar scores along the paths for multi-hop reasoning, while previous works often propagates embeddings with GNNs.

4.5 Loss Function

We use the Binary Cross Entropy Loss for training. Specifically, given a question q, the loss $\mathcal{L}$ is computed as

$$\mathcal{L} = \frac{1}{|\mathcal{E}|}(\sum_{e \in \mathcal{A}} \log p(e) + \sum_{e' \in \mathcal{E}/\mathcal{A}} \log(1 - p(e'))),$$

where $\mathcal{E}$ is the set of entities, $\mathcal{A}$ is the set of correct answers, and $p(e) = \mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic})$.

5 Experiments

This section is organized as follows. In Section 5.1, we introduce experimental settings in detail. In Section 5.2, we show the effectiveness of our model on benchmark datasets. In Section 5.3, we conduct ablation studies and analysis.

5.1 Experimental Settings

In this part, we introduce the benchmark datasets and the protocols for training and evaluation.

5.1.1 Datasets

We conduct experiments on two public datasets—WebQuestionSP (Yih et al., 2015) and MetaQA (Zhang et al., 2018), which have been divided into training, validation, and testing set by previous works. The statistics are shown in Table 2.

Table 2: The statistics of benchmark datasets. The second to fourth columns show the number of entities, relations, and triplets, respectively. The fifth to seventh columns show the size of training, validation, and testing dataset, respectively.

Dataset	Entity	Relation	Triplet	Train	Valid	Test
WebQuestionSP	601,445	567	1,261,849	2,848	250	1,639
MetaQA 1-hop	43,233	9	134,741	96,106	9,992	9,947
MetaQA 2-hop	43,233	9	134,741	118,980	14,872	14,872
MetaQA 3-hop	43,233	9	134,741	114,196	14,274	14,274

WebQuestionSP WebQuestionSP is a small dataset containing 4,737 questions. Those questions are 1-hop or 2-hop questions that can be answered with the Freebase (Bollacker et al., 2008) knowledge graph. Note that WebQuestionSP mainly consists of 1-hop questions, and only 0.5% of the questions are 2-hop.

MetaQA MetaQA is a large dataset containing over 400k questions in the movie domain. It is split into 1-hop, 2-hop, and 3-hop questions. Following previous work (Sun et al., 2018, 2019a; Saxena et al., 2020), we use the “vanilla” version of the dataset. On MetaQA, we evaluate our model under two settings: “full” setting and “half” setting. In the “full” setting, we use the vanilla knowledge graph for training. In the “half” setting, we follow previous work (Saxena et al., 2020) to randomly drop 50% of triplets in the knowledge graph.

5.1.2 Evaluation Protocols

Following previous work (Sun et al., 2018, 2019a), we use Hits at N (H@N) to evaluate model performance. For each given question, we rank the candidates in descending order according to their scores, and compute the percentage of correct answers that ranks at top N.

5.1.3 Training Protocols

We choose Adam (Kingma and Ba, 2015) as the optimizer, and use grid search to find the best hyperparameters based on the model performance on the validation datasets. For the details of hyperparameter selection, please refer to the appendix.

Following previous work (Sun et al., 2018, 2019a), we use GloVe (Pennington et al., 2014) as word embeddings, and use bidirectional LSTM as the encoder. We also use CP (Hitchcock, 1927) to train entity and relation embeddings.

5.1.4 Candidate Set Generation Protocol

In the ”full” setting, the candidate set of a n-hop question q consists of all entities that are within the n-hop of the topic entity of q. In the ’half’ setting, the candidate set of any question consists of all entities in the KG. Therefore, the answers are guaranteed to be included in the candidate sets, and the recall of answers is 1.0.

5.1.5 Hyperparameters

We use grid search to find the best hyperparameters. Specifically, we search the learning rate in $\{0.1, 0.01, 0.001\}$, and dropout rate in $\{0.1, 0.2, 0.3\}$. The optimal configurations of DCRN is that learning rate $= 0.01$ and dropout rate $= 0.2$. For fair comparison with previous work (Sun et al., 2018, 2019a; Saxena et al., 2020), we set the embedding size to 300. When training the knowledge graph embeddings with CP (Hitchcock, 1927), we search the learning rate in $\{0.1, 0.01, 0.001\}$, and the optimal configuration is learning rate $= 0.1$. We choose the values hyperparameter T as follows. On WebQuestionSP, we set $T = 2$. On MetaQA with ”full” setting, we set $T = t$ for t-hop questions. On MetaQA with ”half” setting, we set $T = 4$.

5.2 Main Results

In Table 3, we show the results of our proposed DCRN on WebQuestionSP and MetaQA datasets. Overall, our model significantly outperforms state-of-the-art models on benchmark datasets.

WebQuestionSP is a small dataset but it uses a large-scale KG, which is a subset of Freebase. This dataset follows an inductive setting—some entities in the test set have not appeared in the training set. Experiments demonstrate that our DCRN achieves 67.8 on H@1, which outperforms GraftNet and KV-Mem, and performs comparatively against previous state-of-the-art PullNet.

MetaQA is a large dataset consisting of 1 to 3-hop questions. Overall, our DCRN achieves state-of-the-art on all the three subdatasets. On MetaQA 1-hop and 2-hop, although some previous methods exhibits satisfying performance, they fail to achieve

Table 3: Evaluation results (H@1) of the proposed DCRN and previous state-of-the art methods on WebQuestionSP and MetaQA datasets.

Methods	WebQSP	MetaQA 1-hop	MetaQA 2-hop	MetaQA 3-hop
KV-Mem (Miller et al., 2016)	46.7	96.2	82.7	48.9
VRN (Zhang et al., 2018)	-	**97.5**	89.9	62.5
GraftNet (Sun et al., 2018)	66.4	97.0	94.8	77.7
PullNet (Sun et al., 2019a)	**68.1**	97.0	**99.9**	91.4
EmbedKGQA (Saxena et al., 2020)	66.6	**97.5**	98.8	94.8
DCRN (Ours)	67.8	**97.5**	**99.9**	**99.3**

consistent performances on both datasets. For example, PullNet only achieves 97.0 on MetaQA 1-hop, and EmbedKGQA only achieves 98.8 on MetaQA 2-hop. Different from previous methods, our DCRN achieves state-of-the-art on both MetaQA 1-hop and 2-hop.

The questions in the MetaQA 3-hop dataset are more difficult to answer compared to those in MetaQA 1-hop and 2-hop, as they require longer reasoning paths to find answers. However, experiments demonstrate that our model achieves 99.3 on H@1, which significantly outperforms previous state-of-the-arts. Specifically, it gains 7.9 against PullNet and 4.5 against EmbedKGQA. The results on MetaQA 3-hop illustrates the effectiveness of our model on answering questions that require long reasoning paths.

We also conduct experiments in "half" setting. In this setting, 50% of triplets are dropped, making it more challenging to accurately identify answers. The results are shown in Table 4. Experiments demonstrate our model achieves state-of-the art on all subsets of MetaQA.

Table 4: The evaluation results (H@1) of DCRN and previsou state-of-the art methods on MetaQA datasets under the "**half**" setting. In this setting, 50% triplets are randomly dropped.

Methods	MetaQA 1-hop	MetaQA 2-hop	MetaQA 3-hop
KV-Mem	63.6	41.8	37.6
GraftNet	64.0	52.6	59.2
PullNet	65.1	52.1	59.7
EmbedKGQA	83.9	91.8	70.3
DCRN (Ours)	**88.5**	**91.9**	**72.5**

5.3 Analysis

In this part, we conduct analysis on our model. In Section 5.3.1, we conduct ablation studies on the two phases in DCRN. In Section 5.3.2, we conduct a case study to illustrate the two-phase strategy of the proposed DCRN.

5.3.1 Ablation Studies on the Two Phases

In Table 5, we conduct ablations studies to show the performances of the two phases in DCRN.

Table 5: Ablation results (H@1) of the two modules on WebQuestionSP and MetaQA datasets. "Unconscious" and "Conscious" denote the unconscious phase and the conscious phase, respectively.

Methods	WebQSP	MetaQA 1-hop	MetaQA 2-hop	MetaQA 3-hop
DCRN	**67.8**	**97.5**	**99.9**	**99.3**
Unconscious Phase	60.8	96.9	92.1	68.4
Conscious Phase	47.2	97.4	93.8	37.2

Overall, the experiments show that both two phases are indispensable in our model. The reason is that the unconscious and the conscious phase are designed to better exploit node-level and path-level features, respectively. Both levels of features are critical to the accurate answer identification. Therefore, the cooperation of the two phases brings significant improvements to the performance, as shown in Table 5. On MetaQA 1-hop and 2-hop, both two phases achieves satisfying performances, as the number of candidate entities is relatively small. Furthermore, the conscious phase outperforms the unconscious phase. This is because the unconscious phase exploits the coarse-grained semantic of entities, while the conscious phase considers the fine-grained relational dependencies between entities. Therefore, on small candidate entity sets, the conscious phase could make more accurate predictions.

On MetaQA 3-hop, the unconscious phase outperforms conscious phase. This is because 3-hop questions usually have large candidate entity set, and the errors can propagate along reasoning paths. Therefore, to make accurate predictions, DCRN requires the unconscious phase to softly filter out irrelevant candidates. Experiments demonstrate that, by considering both phases, DCRN achieves 99.3 on H@1.

We further compare between the unconscious phase of DCRN and EmbedKGQA (Saxena et al., 2020). EmbedKGQA consists of two parts—knowledge graph embedding and relation matching. The former part use the question representation as latent relation embedding. Different from EmbedKGQA, the unconscious phase in DCRN decode a question into relation paths. To illustrate the effectiveness of the unconscious phase, we compare it with EmbedKGQA (w/o relation matching), and the results are shown in Table 6.

Table 6: Comparisons between EmbedKGQA (w/o relation matching) and the unconscious phase in the proposed DCRN on the MetaQA datasets.

Methods	**MetaQA 1-hop**	**MetaQA 2-hop**	**MetaQA 3-hop**
EmbedKGQA (w/o relation matching)	94.7	86.5	67.2
Unconscious Phase	**96.9**	**92.1**	**68.4**

Note that EmbedKGQA (Saxena et al., 2020) use RoBERTa (Liu et al., 2019) for word embeddings and ComplEx (Trouillon et al., 2016) for entity embeddings. For fair comparison with previous work including GRAFT-Net (Sun et al., 2018) and PullNet (Sun et al., 2019a), we use GloVe (Pennington et al., 2014) for word embeddings and CP (Hitchcock, 1927) for entity embeddings, and we reimplement EmbedKGQA (w/o relation matching) under our settings.

Experiments demonstrate that the unconscious phase outperforms EmbedKGQA (w/o relation matching) on all the three datasets of MetaQA, illustrating the effectiveness of our design on the query representation in the unconscious phase.

5.3.2 Case Study

In this part, we conduct a case study to illustrate the effectiveness of the two-phase strategy in DCRN. In Figure 5, we show the predictions made by DCRN on a 2-hop question *who is listed as screenwriter of John Derek acted films?*. This question is taken from the test set of MetaQA 2-hop.

The figure on the left shows the predictions of the unconscious phase. It shows that the unconscious phase successfully filters out the candidates that are unlikely to be correct answers. The predictions made by the unconscious phase provide informative evidence for the subsequent conscious phase. The figure on the right shows the predictions of the conscious phase. Based on the retrieved evidence, the conscious phase successfully ranks the correct answers in the first place.

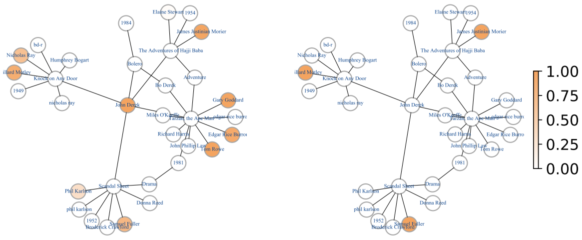

Figure 5: Illustration of the predictions made by the unconscious phase (**left**) and the conscious phase (**right**) to the question *who is listed as screenwriter of John Derek acted films?*. We exhibit the 2-hop subgraph of the topic entity *John Derek*. Deeper color for an entity indicates higher prediction score as a correct answer.

6 Conclusion

Multi-hop question answering over knowledge graphs aims to answer questions by multi-hop reasoning over knowledge graphs to find answers. In this work, we propose a novel Deep Cognitive Reasoning Network (DCRN), which is inspired by the dual process theory in cognitive science. DCRN can accurately identify answers with two phases—unconscious phase and conscious phase. Experiments demonstrate that our model outperforms state-of-the-art methods on benchmark datasets.

Appendix

A Proofs of the Propositions

Proposition 1. *The pruned graph $\hat{\mathcal{G}}(e_{topic})$ is a directed acyclic graph (DAG).*

Proof. *The pruned graph $\hat{\mathcal{G}}(e_{topic})$ is obtained by employing the Breadth-First Search (BFS) algorithm starting from e_{topic}. During the search process, we only keep the visited edges.*

First, it is clear that $\hat{\mathcal{G}}(e_{topic})$ is a directed graph. Second, we prove that $\hat{\mathcal{G}}(e_{topic})$ is acyclic. During the BFS search, the nodes are classified into several categories according to their topological distance to e_{topic}. After the pruning, each edge in $\hat{\mathcal{G}}(e_{topic})$ must connect a node with topological distance n to e_{topic} and a node with distance $(n+1)$ to e_{topic}. Therefore, there is no loop in $\hat{\mathcal{G}}(e_{topic})$.

Proposition 2. *The marginal probability $\mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic})$ that predicts a candidate entity e can be calculated via variable elimination:*

$$\mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic}) \\ = \overline{\mathbb{P}}(X_e = 1) \prod_{e' \in pa(e)} \mathbb{P}(X_{e'} = 0|\mathcal{G}, q, e_{topic}),$$

where $pa(e)$ denotes the set of parent nodes of e, i.e., the nodes that have edges directing at e. The first component $\overline{\mathbb{P}}(X_e = 1)$ is the abbreviation of

$$\mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic}, X_{pa(e)} = 0).$$

Proof. *First, the marginal probability is defined as*

$$\mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic}) = \\ \sum_{e_1, e_2, \ldots \in \mathcal{E}/e} \mathbb{P}(X_e = 1, X_{e_1}, X_{e_2}, \ldots|\mathcal{G}, q, e_{topic}),$$

where $\mathbb{P}(X_e = 1, X_{e_1}, X_{e_2}, \ldots|\mathcal{G}, q, e_{topic})$ is the joint probability of variables $X_{e_1}, \ldots X_{e_{|\mathcal{E}|}}$.

By the definition of Bayesian networks, the joint probability is factorized into several components:

$$\mathbb{P}(X_e = 1, X_{e_1}, X_{e_2}, \ldots|\mathcal{G}, q, e_{topic}) = \\ \prod_{v \in \mathcal{E}} \mathbb{P}(X_v|X_{pa(v)}, \mathcal{G}, q, e_{topic}),$$

Therefore, the marginal probability is represented as follows:

$$\mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic}) = \\ \sum_{v \in \mathcal{E}/e} \prod_{v \in \mathcal{E}} \mathbb{P}(X_v|X_{pa(v)}, \mathcal{G}, q, e_{topic}).$$

We then perform variable elimination, which eliminates the variables other than X_e and $X_{pa(e)}$. The results are as follows:

$$\mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic}) = \\ \sum_{e' \in pa(e)} \hat{\mathbb{P}}(X_e = 1)\mathbb{P}(X_{e'}|\mathcal{G}, q, e_{topic}),$$

where the notation $\hat{\mathbb{P}}(X_e = 1)$ denotes

$$\mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic}, X_{pa(e)}).$$

We then make the following assumption: if any parent of e is an answer, then e is not an answer. This assumption represents the fact that each question corresponds to a unique reasoning path.

Following this assumption, we have that

$$\mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic}, X_{pa(e)}) = 0,$$

if there exists $e' \in pa(e)$ such that $X_{e'} = 1$. Therefore, we have the following conclusion:

$$\mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic}) = \\ \overline{\mathbb{P}}(X_e = 1) \prod_{e' \in pa(e)} \mathbb{P}(X_{e'} = 0|\mathcal{G}, q, e_{topic}),$$

where $pa(e)$ denotes the set of parent nodes of e, i.e., the nodes that have edges directing at e. The first component $\overline{\mathbb{P}}(X_e = 1)$ is the abbreviation of

$$\mathbb{P}(X_e = 1|\mathcal{G}, q, e_{topic}, X_{pa(e)} = 0).$$

GoG: Relation-aware Graph-over-Graph Network for Visual Dialog

Feilong Chen, Xiuyi Chen, Fandong Meng, Peng Li, Jie Zhou
Pattern Recognition Center, WeChat AI, Tencent Inc, Beijing, China

{fandongmeng,patrickpli,withtomzhou}@tencent.com

Abstract

Visual dialog, which aims to hold a meaningful conversation with humans about a given image, is a challenging task that requires models to reason the complex dependencies among visual content, dialog history, and current questions. Graph neural networks are recently applied to model the implicit relations between objects in an image or dialog. However, they neglect the importance of 1) coreference relations among dialog history and dependency relations between words for the question representation; and 2) the representation of the image based on the fully represented question. Therefore, we propose a novel relation-aware graph-over-graph network (GoG) for visual dialog. Specifically, GoG consists of three sequential graphs: 1) H-Graph, which aims to capture coreference relations among dialog history; 2) History-aware Q-Graph, which aims to fully understand the question through capturing dependency relations between words based on coreference resolution on the dialog history; and 3) Question-aware I-Graph, which aims to capture the relations between objects in an image based on fully question representation. As an additional feature representation module, we add GoG to the existing visual dialogue model. Experimental results show that our model outperforms the strong baseline in both generative and discriminative settings by a significant margin.

1 Introduction

Vision-language tasks have drawn more attention with the development of multi-modal natural language processing (Baltrušaitis et al., 2018; Chen et al., 2020b, 2019), such as image captioning (Xu et al., 2015; Anderson et al., 2016, 2018; Cornia et al., 2020; Ghanimifard and Dobnik, 2019), visual question answering (Ren et al., 2015a; Gao et al., 2015; Lu et al., 2016; Anderson et al., 2018; Li et al., 2019; Huang et al., 2020) and visual dialog (Das et al., 2017; Kottur et al., 2018; Agarwal et al., 2020; Wang et al., 2020; Qi et al., 2020). Relations in these tasks are significant for reasoning and understanding the textual and visual information. Specifically, visual dialog, which aims to hold a meaningful conversation with a human about a given image, is a challenging task that requires models to reason complex relations among visual content, dialog history, and current questions.

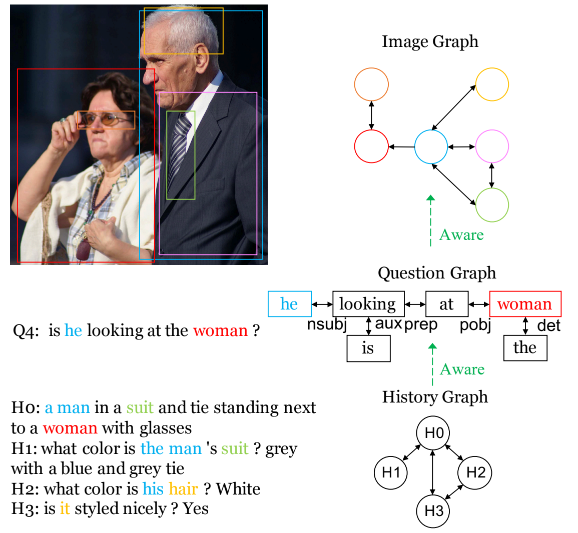

Figure 1: An example of complex relationships in visual dialog. The color in the text corresponds to the same color box in the image, which indicates the same entity. In visual dialog, we construct three graphs. History graph (H-Graph): arrows indicate the coreference relations between QA pairs in dialog history. Question graph (Q-Graph): arrows indicate dependency relations of the question. Image graph (I-Graph): arrows indicate spatial relations between objects in an image. The dark green dotted line indicates the bottom graph affects the upper graph.

Kinds of attention mechanisms are served as the backbone of previous mainstream approaches (Lu et al., 2017; Wu et al., 2018; Kottur et al., 2018;

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 230–243
August 1–6, 2021. ©2021 Association for Computational Linguistics

Gan et al., 2019; Guo et al., 2019b), following Das et al. 2017. HCAIE (Lu et al., 2017) provides a history-conditioned image attentive encoder to represent the question, the question-attended history, and the attended image. CoAtt (Wu et al., 2018) provides a sequential co-attention encoder to realize that each input feature is co-attended by the other two features in a sequential fashion. ReDAN (Gan et al., 2019) and DMAM (Chen et al., 2020a) use multi-step reasoning based on dual attention to answer a series of questions about an image. DAN (Guo et al., 2019b), MCAN (Agarwal et al., 2020) and LTMI (Nguyen et al., 2020) utilize multi-head attention mechanisms to manage multi-modal intersection. However, these approaches tend to catch only the most discriminative information, ignoring other rich complementary clues, such as relations between objects in an image.

Recent visual dialog studies (Zheng et al., 2019; Schwartz et al., 2019; Jiang et al., 2020b; Guo et al., 2020; Jiang et al., 2020a) explore the higher-level semantic representation of images or dialog history, notably with graph-based structures for modeling the image or dialog history. Although graph-based structures have been considered, these graph-based models lack explicitly capturing complex relations within visual content or textual contexts, and relations between them. As shown in Figure 1, there are complex relations such as coreference relations among dialog history, dependency relations between words in the question, spatial relations between objects in the image. For example, to answer the question Q4 *"is he looking at the woman ?"*, we firstly need to reason in dialog history to know who *"he"* is, then further understand the intention of the question with the understood of history and syntax of questions, and finally know clearly the spatial location and relation about *"the man"* and *"the woman"* in the image based on fully question understanding. How to 1) understand the coreference among history, 2) understand the intention of the question with its syntax and history, 3) understand the image with fully question understanding are worth exploring.

Therefore, in this paper, we propose a novel relation-aware graph-over-graph network (GoG) for visual dialog. Specifically, GoG consists of three sequential graphs: 1) H-Graph, which aims to capture coreference relations among dialog history; 2) History-aware Q-Graph, which aims to fully represent the question through capturing dependency relations between words based on coreference resolution on the dialog history; and 3) Question-aware I-Graph, which aims to capture the relations between objects in an image on the basis of fully question representation. As an additional feature representation module, we add GoG to the strong visual dialogue model LTMI (Nguyen et al., 2020). We test the effectiveness of our proposed model on two large-scale datasets: VisDial v0.9 and v1.0 (Das et al., 2017). Both automatic and manual evaluations show that our approach can be used to improve the prior strong models. The contributions of this work are summarized as follows:

- We explore how to construct complex explicit relations in visual dialog, i.e., coreference relations among dialog history, dependency relations between words in the question, spatial relations between objects in the image.
- We propose a novel relation-aware graph-over-graph network to reason relations within and among different graphs to obtain a high-level representation of multi-modal information and use it to generate a visually and contextually coherent response.
- We conduct extensive experiments and ablation studies on two large-scale datasets VisDial v0.9 and v1.0. Experimental results show that our GoG model can be used to improve the previous strong visual dialog model in both generative and discriminative settings.

2 Relation-aware Graph-over-Graph Network

2.1 Preliminary

Following Das et al. (Das et al., 2017), a visual dialog agent is given three inputs, i.e., an image I, dialog history (the caption and question-answer pairs) till round $t-1$: $H = (\underbrace{Cap}_{H_0}, \underbrace{(Q_1, A_1)}_{H_1}, \cdots, \underbrace{(Q_{t-1}, A_{t-1})}_{H_{t-1}})$ and the current question Q_t at round t, where Cap is the caption describing the image taken as H_0, and $H_1, \ldots, H_{t-1}$ are concatenations of question-answer pairs. The goal of the visual dialog agent is to generate a response A_t to the question Q_t.

As shown in Figure 2, our relation-aware graph-over-graph network (GoG) firstly takes the image, the dialog history, and the question as inputs and represent them using Faster RCNN (Ren et al.,

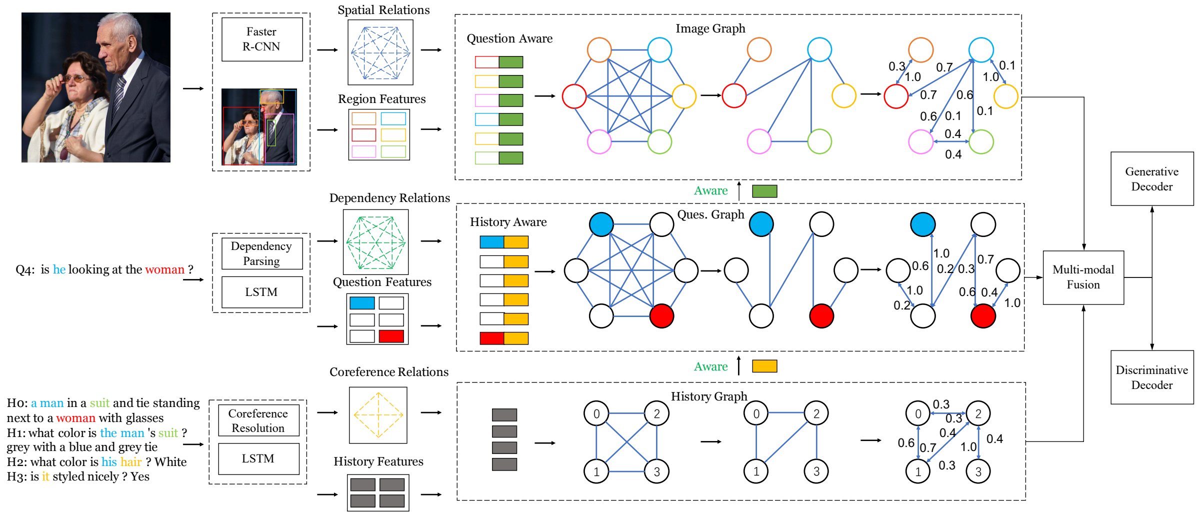

Figure 2: Framework of our Relation-aware Graph-over-Graph Network.

2015b) and LSTM (Hochreiter and Schmidhuber, 1997). Secondly, GoG constructs the history graph, the history-aware question graph, and the question-aware image graph. Thirdly, GoG utilizes the attention alignment module to fuse the three graphs. Finally, GoG uses the fused multi-modal information to give corresponding answers.

Firstly, we simply describe the feature representation of three inputs. Secondly, we introduce our graph attention. Then we describe how we apply our graph attention to the history graph, question graph and image graph to construct our graph-over-graph network. Finally, we describe how we apply our graph-over-graph network to the strong visual dialog models.

2.2 Feature Representation

Similar to (Anderson et al., 2018), we extract the image features by using a pretrained Faster RCNN (Ren et al., 2015b). We select μ object proposals for each image, where each object proposal is represented by a 2048-dimension feature vector. The obtained visual region features are denoted as $v = v_{i=0}^{\mu} \in R^{\mu \times d_v}$.

To extract the question features, each word is embedded into a 300-dimensional vector initialed with the Glove vector (Pennington et al., 2014). The word embeddings are taken as inputs by an LSTM encoder (Hochreiter and Schmidhuber, 1997), which produces the initial question representation $q \in R^{\lambda \times d_q}$. Each history sentence features are obtained as same as the question features. We concatenate the last state $h^{last} \in R^{d_h}$ of each turn history features to get the initial history representation $h = h_0^{t-1} = [h_0^{last}, \ldots, h_{t-1}^{last}] \in R^{t \times d_h}$. λ denotes the length of the question, t denotes the turn of dialog history, d_q denotes the dimension of each word in questions, d_h denotes the dimension of each word in history and $[\cdot, \cdot]$ denotes the concatenation operation.

2.3 Graph Attention

Given a target node i and a neighboring node $j \in \mathcal{N}(i)$ with a $k \times k$ adjacency matrix R, where $\mathcal{N}(i)$ is the set of k nodes neighboring with node i, and the representations of node i and node j are u_i and u_j, respectively. To obtain the correlation score s_{ij} between node i and j, self-attention (Vaswani et al., 2017) is then performed on the vertices, which generates a relation score s_{ij} between node features u_i and u_j:

$$s_{ij} = \frac{(U_i u_i)^T \cdot V_j u_j}{\sqrt{d_u}}, \tag{1}$$

where U_i and V_j are trainable parameters. We apply a softmax function over the correlation score s_{ij} to obtain weight α_{ij} :

$$\alpha_{ij} = \frac{\exp(s_{ij} + c_{u,lab(i,j)})}{\sum_{j \in \mathcal{N}(i)} \exp(s_{ij} + c_{u,lab(i,j)})}, \tag{2}$$

where $c_{\{\cdot\}} = W_{lab} A_{ij}$ is a bias term, $lab(i,j)$ represents the label of each edge, and W_{lab} is a learned parameter. The representations of neighboring nodes u_j are first transformed via a learned linear transformation with W_u. Those transformed representations are then gathered with weight α_{ij} , followed by a non-linear function σ. This propaga-

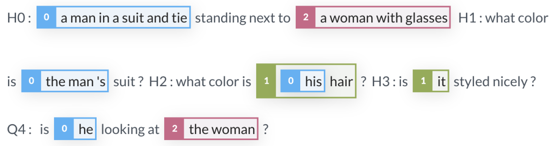

Figure 3: The history is performed by coreference resolution. The same color box and the same number indicate the coreference relation between different expressions of the same entity.

tion can be denoted as:

$$u_i^* = \sigma\Big(u_i + \sum_{j \in \mathcal{N}(i)} R_{ij}\alpha_{ij}W_u u_j\Big). \tag{3}$$

We utilize $\mathrm{GraphAtt}(\cdot)$ to denote equations from Eq. (1) to Eq. (3)

2.4 History Graph Construction

In practice, we observe that coreference relations exist in dialog history. To fully understand the coreference among dialog history, we utilize the coreference resolution tool (Lee et al., 2017) to identify coreference relations. We use the caption and questions to identify the relations instead of QA pairs because there is no ground truth answer in the test split. As shown in Figure 3, we provide a four-turn dialog to show coreference resolution. The same color boxes with the same numbers indicate the coreference relations. For example, the blue box with number 0 indicates they are related to the word “a man” with its attribute “in a suit and tie”.

Pruned History Graph with Coreference Relations. We treat each turn history as a node. By analyzing the coreference relations of the history, we obtain the relations between history as shown in Figure 3. According to coreference relations, we construct a sparse graph, as shown in the history graph of Figure 2.

History Graph Attention. Given a graph with t nodes, i.e. a t-turn dialog, each turn representation in history is a node. We represent the graph structure with a $t \times t$ adjacency matrix A, where $A_{ij} = 1$ if there is a coreference relation between node i and node j; else $A_{ij} = 0$.

The relation-aware graph based history representation h_i^* is as follows:

$$h_i^* = \mathrm{GraphAtt}(h_i, A) \tag{4}$$

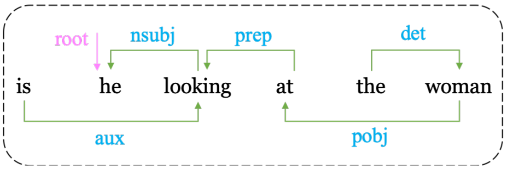

Figure 4: The question is performed by dependency parsing. The word in pink is the root node. The direction of green arrows indicates the dependency relation between two words, and the blue words (e.g., det, dobj) are relation types.

2.5 Question Graph Construction

In practice, we observe that two words in a sentence usually hold a certain relation. Such relations can be identified by the Neural Dependency Parsing (Dozat and Manning, 2017).

Pruned Question Graph with Dependency Relations. We treat each word in a question as a vertex. By parsing the dependency relations of a question, we obtain the relations between words as shown in Figure 4. According to dependency relations, we obtain our sparse question graph, as shown in the question graph of Figure 2.

History-aware Question Graph Attention. Given a graph with λ nodes, each word in a question is a node. We represent the graph structure with a $\lambda \times \lambda$ adjacency matrix B, where $B_{ij} = 1$ if there is a dependency relation between node i and node j; else $B_{ij} = 0$.

In order to utilize the history to help understand questions, we use a history-aware attention mechanism to inject semantic information from the history into the question graph. The aware history representation is calculated as follows:

$$\hat{h} = \mathrm{softmax}\big(W_{h_1}\sigma(W_{h_2}h^*)\big)h^*, \tag{5}$$

where $\hat{h} \in R^{d_h}$, h^* is the final representation of dialog history. W_{h_1} and W_{h_2} are learned parameters. The history-aware question features are achieved by concatenating the adaptive history representation $\hat{h}$ with each of question features q_i, denoted as:

$$q_i' = [q_i, \hat{h}], \quad \text{for} \quad i = 1, \dots, \lambda. \tag{6}$$

The history-aware and relation-aware graph based question representation q_i^* is as follows:

$$q_i^* = \mathrm{GraphAtt}(q_i', B) \tag{7}$$

2.6 Image Graph Construction

Pruned Image Graph with Spatial Relations. By treating each object region in an image as a vertex, we can construct a fully-connected undirected graph, as shown in the image graph of Figure 2. Each edge represents a relation between two object regions. Spatial relations represent an object position in an image, which correspond to a 4-dimension spatial coordinate $[x_1, y_1, x_2, y_2]$. Note that (x_1, y_1) is the coordinate of the top-left point of the bounding box and (x_2, y_2) is the coordinate of the bottom-right point of the bounding box. Following Yao et al. (Yao et al., 2018), we classify different spatial relations into 11 different categories, such as *inside*, *cover* and *overlap*. We utilize the overlapping region between two object regions to judge whether there is an edge between two regions. If two object regions have overlapping parts, it means that there is a strong correlation between these two objects. If two object regions are too far away from each other, it means that there is no relation between these two objects. According to the spatial relations, we prune some irrelevant relations between objects and obtain a sparse graph, as shown in the image graph of Figure 2.

Question-aware Image Graph Attention. Given a graph with μ nodes, each object in an image is a node. We represent the graph structure with a $\mu \times \mu$ adjacency matrix D, where $D_{ij} = 1$ if there is a spatial relation between node i and node j; else $D_{ij} = 0$.

Based on the fully question understanding, we use a question-aware attention mechanism to inject semantic information from the question into the image graph. The adaptive question representation is calculated as follows:

$$\hat{q} = \mathrm{softmax}\big(W_{q_1}\sigma(W_{q_2}q^*)\big)q^*, \qquad (8)$$

where W_{q_1} and W_{q_2} are learned parameters. The question-aware image features are achieved by concatenating the aware question representation $\hat{q}$ with each of the μ image features v_i, denoted as:

$$v_i' = [v_i, \hat{q}], \quad \text{for} \quad i = 1, \ldots, \mu. \qquad (9)$$

The question-aware and relation-aware graph based image representation v_i^* is as follows:

$$v_i^* = \mathrm{GraphAtt}(v_i', D) \qquad (10)$$

2.7 Multi-modal Fusion

After obtaining the relation-aware representation, we fuse the question representation q^*, history representation h^*, visual representation v^* through a multi-modal fusion strategy. We can use any existing visual dialog models to learn a joint representation $\mathcal{J}$:

$$\mathcal{J} = \mathcal{F}(q^*, h^*, v^*; \Theta), \qquad (11)$$

where $\mathcal{J}$ is a visual dialog model and Θ are trainable parameters of the fusion module. The design of generative and discriminative decoders (Das et al., 2017), and multi-task learning strategy (Nguyen et al., 2020) can be referred to Appendix A.

3 Experiments

3.1 Experiment Setup

Datasets and Implementation Details. We conduct experiments on the VisDial v0.9 and v1.0 datasets (Das et al., 2017) to verify our approach. VisDial v0.9 contains 83k dialogs on COCO-train (Lu et al., 2017) and 40k dialogs on COCO-val images as the test set, for a total of 1.23M dialog question-answer pairs. VisDial v1.0 dataset is an extension of VisDial v0.9 dataset with additional 10k COCO-like images. VisDial v1.0 dataset contains 123k, 2k, and 8k images as train, validation, and test splits, respectively.

To represent image regions, we use Faster R-CNN (Ren et al., 2015b) with ResNet-101 (He et al., 2016) finetuned on the Visual Genome dataset (Krishna et al., 2017), thus obtaining a 2048-dimension feature vector for each region. Following (Nguyen et al., 2020), we detect K = 100 objects from each image. For the question and history features, we first build the vocabulary composed of 11,322 words that appear at least five times in the training split. The captions, questions, and answers are truncated or padded to 40, 20, and 20 words, respectively. We employ multi-head attention with 4 heads for all three graph attention networks. The dimension of hidden features is set to 512.

Our model is implemented based on PyTorch (Paszke et al., 2017). In experiments, we use Adam (Kingma and Ba, 2014) optimizer for training, with the mini-batch size as 32. For the choice of the learning rate, we employ the warm-up strategy (Goyal et al., 2017). Specifically, we begin

Underline indicates the highest performance among previous approaches except pretraining-base models. (t-test, p-value<0.01)

with a learning rate of 0.0001, linearly increasing it at each epoch till it reaches 0.0002 at epoch 4. After 15 epochs, the learning rate is decreased by 1/4 for every 2 epochs up to 20 epochs. We use 4 Titan-XP GPU for training. We spend about 4 hour / 1 epoch for the discriminative setting and 1 hour / 1 epoch for the generative setting. The total parameter of our GoG model is 46.94M, while the total parameter of LTMI (Das et al., 2017) is 42.20M. GoG only has an increase of 4.74M than LTMI.

Automatic Evaluation. We use a retrieval setting to evaluate individual responses at each round of a dialog, following (Das et al., 2017). Specifically, at test time, a list of 100-candidate answers is also given. The model is evaluated on retrieval metrics: (1) Rank of human response, (2) existence of the human response in $top-k$ ranked responses, i.e., R@k (3) Mean reciprocal rank (MRR) of the human response and (4) Normalized discounted cumulative gain (NDCG) for VisDial v1.0.

Human Evaluation. We randomly extract 100 samples for human evaluation (Wu et al., 2018) and then ask 3 human subjects to guess whether the last response in the dialog is human-generated or machine-generated. If at least 2 of them agree it is generated by a human, we think it passes the Truing Test (M1). We record the percentage of responses that are evaluated better than or equal to human responses (M2), according to the human subjects' evaluation.

3.2 Main Results

Baseline methods. In our experiment, compared methods can be grouped into four types: (1) Fusion-based models. (2) Attention-based models: ReDAN, CorefNMN, RvA, DVAN, DMRM, DAM. (3) The pretraining model: VDBERT and VisualBERT. (4) Graph-based models: GNN-EM, DualVD, FGA, KBGN. Please refer to Appendix B for more compared methods.

GoG denotes our relation-aware graph-over-graph network. We use the strong model LTMI (Nguyen et al., 2020)[1] as our multi-modal fusion module. LTMI is a very strong model which achieves some the-state-of-the-art results. "Multi" indicates the model uses multi-task learning at training but utilizes the generative or discriminative decoder at inference, respectively. "Multi*" indicates the model uses multi-task learning and utilizes the discriminative decoder to improve the generative decoder. In general, our model outperforms the strong baseline by a significant margin. We use t-test to analyze our model and LTMI (Nguyen et al., 2020). The p-values is less than 0.01, indicating that the results are significantly different.

Generative Results As shown in the right half of Table 1, we compare generative performance on the val v1.0 split. Our method improves significantly (about 1% on all metrics) on the strong baseline LTMI (Nguyen et al., 2020) and outperforms all the compared methods on all metrics with large margins, which proves that GoG can

improve the performance of visual dialog models by introducing explicit relation reasoning. Compared with the graph-based model KBGN (Jiang et al., 2020a), our GoG-gen improves NDCG from 60.42 to 62.63 (+2.21%), MMR from 50.05 to 51.32 (+1.27%), which illustrates that our explicit relation reasoning is more effective because our approach reduce the noise of implicit relation modeling. LTMI-GoG-Multi and LTMI-GoG-Multi* obtain higher performance with large margins comparing with LTMI (Nguyen et al., 2020), which shows that our approach is effective on multi-task setting. As shown in the left half of Table 1, we come to a similar conclusion on the val v0.9 split. Our method improves a big margin (about 0.5% on all metrics) on LTMI (Nguyen et al., 2020) and outperforms all the none pre-trained methods on MRR, R@1, and R@5.

Discriminative Results As shown in the right half of Table 2, our method improves a lot (near 1.5% on all metrics except NDCG) based on LTMI (Nguyen et al., 2020) on the test-std v1.0 split. We also compare the performance on the val v1.0 split as shown in Table 3. As shown in the left half of Table 2, we compare discriminative performance on the val v0.9 split. Our method improves a lot based on the LTMI (Nguyen et al., 2020). As shown in Table 3, our approach outperforms VDBERT (Wang et al., 2020)‡ which trains from scratch without extra datasets. All the comparison show that our approach is valid due to explicit relation modeling.

3.3 Ablation Study

As shown in Table 4, we firstly remove the I-Graph, Q-Graph, H-Graph to validate the effect of each graph, respectively. Secondly, we validate the importance of concatenating operation. Finally, we use full connections to replace the relation in the graph to validate the importance of each relation. Firstly, the comparison between line 0 and line 1/2/3 shows all three graphs are crucial for visual dialog, leading to higher performance, and the I-Graph is most important. Secondly, the comparison between line 0 and line 4/5 shows that adding adaptive features gives a gain of approximately

	LTMI (Nguyen et al., 2020)	GoG
Method 1 (M1)	53	64
Method 2 (M2)	60	67

Table 5: Human evaluation on 100 sampled responses on VisDial val v1.0. M1: percentage of responses pass the Turing Test. M2: percentage of responses evaluated better than or equal to human responses.

about +0.2. Thirdly, the comparison between line 1 and line 6/7/8 shows that doing graphs with relations gives better gain than simple fully-connected graphs. Spatial relation is the pick of the bunch because the full connection of 100 objects in an image will bring lots of noise.

3.4 Human Study

As shown in Table 5, we conduct human study to further prove the effectiveness of our model. Our model achieves the highest scores both on the metric M1 and M2 compared with the previous model, LTMI (Nguyen et al., 2020). These results show that our model can generate a better contextually and visually coherent response.

3.5 Qualitative Results

As shown in Figure 5, we visualize the learned attention maps. For the image, the colorful region means higher attention weights. We draw the bounding boxes of the first three highest scores. For the question, the word which has the darker color has higher attention weights. For dialog history, the darker QA pairs have a higher coreference score with the question. Figure 6 provides some dialog examples, as a comparison of the results between GoG and the state-of-the-art LTMI model in the supplementary material. We have two observations by analyzing a set of randomly selected examples. Firstly, GoG generally provides more accurate answers. Secondly, GoG tends to provide longer and more natural human-like answers. More examples can be referred to Appendix B.

4 Related Work

4.1 Visual dialog

For the visual dialog task (Das et al., 2017), GNN-EM (Zheng et al., 2019) utilizes an EM-style GNN to conduct the textual coreference, which regards the caption and the previous question-answer (QA) pairs as observed nodes, and the current answer is deemed as an unobserved node inferred using EM algorithms (Moon, 1996) on the textual contexts. FGA (Schwartz et al., 2019) realizes a factor graph attention mechanism, which constructs the graph over all the multi-modal features and estimates their interactions. DualVD (Jiang et al., 2020b) constructs a scene graph to represent the image while embedding both relationships provided by (Zhang et al., 2019b) and original object detection features (Anderson et al., 2018). CAG (Guo et al., 2020) focuses on an iterative question-conditioned context-aware graph, including both fine-grained visual-objects and textual-history semantics. In this paper, we model explicit complex relations within and among visual content, dialog history and the current question and design a graph-over-graph structure which are different from graph-based models mentioned above.

4.2 Graph Neural Network

Graph neural networks (Kipf and Welling, 2016; Veličković et al., 2017; Xinyi and Chen, 2018; Zhang et al., 2019a) have attracted attention in various tasks (Wang et al., 2019; Liu et al., 2018; Gu et al., 2019). The core idea is to combine the graphical structural representation with neural networks, which is suitable for reasoning-style tasks. For visual question answering, Liu et al. (Teney et al., 2017) propose the first GNN-based approach, which builds a scene graph of the image and parses the sentence structure of the question, and calculates their similarity weights. Li et al. (Li et al., 2019) propose to encode each image into a graph and model multi-type inter-object relations via a graph attention mechanism, such as spatial relations and semantic, and implicit relations (Li et al., 2019). Huang et al. (Huang et al., 2020) propose a novel dual-channel graph convolutional network for better combining visual and textual advantages. These approaches are limited to built independent graphs. There is no exploration of the coreference among dialog history and relations between graphs in the approach mentioned above.

5 Conclusion

In this paper, we present a relation-aware graph-over-graph network (GoG), a novel framework for visual dialog, which models and reasons the explicit complex relations among visual content, dialog history, and the current question. GoG exploits the graph-over-graph structure to obtain three relation-aware multi-modal representation which

Our model provides answers that are more accurate than LTMI (green denotes correct answers, and red denotes wrong answers). Results from our model are also more natural and comprehensive (highlighted in blue).

can be added to prior visual dialog models. Experimental results on two large-scale datasets show that our approach improves the previous models by a significant margin.

A Relation-aware Graph-over-Graph Network

A.1 Question Graph Construction

In practice, we observe that two words in a sentence usually hold certain relations. Such relations can be identified by the Neural Dependency Parsing (Dozat and Manning, 2017). As shown in Table 6, we list a part of commonly-used dependency relations.

A.2 Attention Alignment Module

After obtaining relation-aware features, we fuse the question representation q^*, history representation h^*, visual representation v^* through a multi-modal fusion strategy. We can use any existing multi-modal fusion method to learn a joint representation $\mathcal{J}$:

$$\mathcal{J} = \mathcal{F}(q^*, h^*, v^*; \Theta), \tag{12}$$

where $\mathcal{J}$ is a multi-modal fusion method and Θ are trainable parameters of the fusion module. Here we utilize an efficient attention mechanism method (Nguyen et al., 2020) to fuse the multi-modal information, which is the state-of-the-art model in visual dialog.

Let $A_X(Y)$ denotes the efficient attention mechanism (Nguyen et al., 2020) from the information X to the information Y. For example, $A_{v^*}(v^*)$ denotes the efficient self-attention. The fused visual representation is obtained as follows:

$$\begin{aligned} v_{contact} &= [A_{v^*}(v^*), A_{q^*}(v^*), A_{h^*}(v^*)], && (13) \\ \overline{v}' &= \mathrm{LayerNorm}(\sigma(v_{concat} W_{v^*}) + v^*), && (14) \\ a_V &= \mathrm{softmax}(W_{V_1} \sigma(W_{V_2} \overline{v}')), && (15) \\ \overline{v} &= \sum_{i=1}^{\mu} a_{V,i} \overline{v}'_i, && (16) \end{aligned}$$

where W_{v^*}, W_{V_1}, W_{V_2} are learned parameters. $\overline{q}$ and $\overline{h}$ can be obtained similarly. Thus, the joint representation $\mathcal{J}$ is obtained:

$$\mathcal{J} = W_J[\overline{q}, \overline{h}, \overline{v}], \tag{17}$$

where W_J is a learned parameter.

Relations	Relation Description	Proportion
nsubj	nominal subject	16.1%

dobj	direct object	1.5%

Table 6: The main categories of relations classified by the dependency parsing tool (Dozat and Manning, 2017) in VisDial v1.0 training split (Das et al., 2017).

A.3 Generative and Discriminative Decoders

Following Das et al. (Das et al., 2017), we consider both generative and discriminative decoders to score the candidate answers using the likelihood scores and the log-likelihood scores, respectively.

Generative Decoder Following Das et al. (Das et al., 2017), we design the generative decoder to score the candidate answers using the log-likelihood scores. Specifically, the generative decoder utilizes a two-layer LSTM (Hochreiter and Schmidhuber, 1997) to generate an answer using the context vector $\mathcal{J}$ as the initial hidden state. In the training phase, the generative decoder generates the next token based on the current token from the ground truth answer. In detail, we first append the special token "SOS" at the beginning of the ground truth answer and "EOS" at the end. We use Glove (Pennington et al., 2014) to initialize the embedding and obtain the embedding vectors $a_{gt} = [w_0, w_1, \ldots, w_N]$ where w_0 is the embedding of "SOS" and w_N is the embedding of "EOS". The hidden state h_n at timestep n is computed as follows:

$$h_n = \mathrm{LSTM}(w_{n-1}, h_{n-1}), \tag{18}$$

where h_0 is intializaed by $\mathcal{J}$. Then we obtain the log-likelihood of n-th word as follows:

$$p = \mathrm{logsoftmax}(Wh + b), \tag{19}$$

where W and b are learned parameters. In the training phase, we minimize the summation of the

Table 7: Main comparisons on both VisDial v0.9 and v1.0 datasets using the generative decoder. † denotes that we re-implemented the model. Underline indicates the highest performance among previous approaches except pretraining-base models.

negative log-likelihood $\mathcal{L}_\mathcal{G}$ defined by:

$$\mathcal{L}_\mathcal{G} = -\sum_{n=1}^{N} p_n. \tag{20}$$

In the validation and test phase, we compute the summation s_i of the log-likelihood for each candidate answer $\hat{a}_i$:

$$s_i = \sum_{n=1}^{N} p_n^{\hat{a}_i}. \tag{21}$$

Then, the rankings of the candidate answers are derived as $\mathrm{softmax}(s_1, \ldots, s_{100})$.

Discriminative Decoder A discriminative decoder outputs the likelihood score for each of 100 candidate answers for the current question. Similar to the generative decoder, we use LSTM to obtain the hidden state h_n for b-th word but we do not use context vector J to initialize the h_0. The representation of each candidate answer is $a_i = h_N$. The score p_i for i-th candidate answer is computed by:

$$p = \mathrm{logsoftmax}(a_1^T \mathcal{J}, \ldots, a_{100}^T \mathcal{J}) \tag{22}$$

In the test phase, we sort the candidate answers using these scores. In the training phase, the cross-entropy loss $\mathcal{L}_\mathcal{D}$.

A.4 Multi-Task Learning

According to (Nguyen et al., 2020), we apply our GoG to the state-of-the-art model (Nguyen et al., 2020) in the multi-task learning setting that accuracy is improved by training the entire network using the two decoders simultaneously. This is simply done by minimizing the sum of the losses, $\mathcal{L}_\mathcal{D}$ for the discriminative one and $\mathcal{L}_\mathcal{G}$ for the generative one:

$$\mathcal{L} = \mathcal{L}_\mathcal{D} + \mathcal{L}_\mathcal{G} \tag{23}$$

The increase in performance may be attributable to the synergy of learning two tasks while sharing the same encoder.

B Experiments

B.1 Main Results

Comparison with previous approaches using generative decoders. As shown in Table 7, we provide the full comparison with all the previous generative approaches.

B.2 Qualitative Results

More examples generated and retrieved by our GoG are provided in Figure 7. Due to the limited number of pages, we only provide an additional example of Figure 7.

Abstract

Since traditional tokenizers are isolated from a downstream task and model, they cannot output an appropriate tokenization depending on the task and model, although recent studies imply that the appropriate tokenization improves the performance. In this paper, we propose a novel method to find an appropriate tokenization to a given downstream model by jointly optimizing a tokenizer and the model. The proposed method has no restriction except for using loss values computed by the downstream model to train the tokenizer, and thus, we can apply the proposed method to any NLP task. Moreover, the proposed method can be used to explore the appropriate tokenization for an already trained model as post-processing. Therefore, the proposed method is applicable to various situations. We evaluated whether our method contributes to improving performance on text classification in three languages and machine translation in eight language pairs. Experimental results show that our proposed method improves the performance by determining appropriate tokenizations.

1 Introduction

Tokenization, which converts a raw sentence into a sequence of tokens, is a crucial process that affects the performance of NLP tasks. Existing studies have proposed various tokenization methods including rule-based tokenization (Koehn et al., 2007), dictionary-based tokenization (Kudo, 2006; Morita et al., 2015; Tolmachev et al., 2018; Takaoka et al., 2018), supervised tokenization with neural networks (Yang et al., 2017; Cai et al., 2017; Yang et al., 2019), and unsupervised tokenization (Goldwater et al., 2006, 2009; Mochihashi et al., 2009; Sennrich et al., 2016; Kudo and Richardson, 2018). Much of prior research has reported that an appropriate tokenization depends on each downstream task (Xu et al., 2008; Chang et al., 2008; Nguyen et al., 2010; Domingo et al., 2018; Hiraoka et al., 2019; Gowda and May, 2020). Moreover, Hiraoka et al. (2020) implies that we have to consider a downstream model to determine an appropriate tokenization. In other words, we can improve the performance of a downstream model by determining an appropriate tokenization for the downstream model. However, since traditional tokenizers are isolated from a downstream model, we need to train a given downstream model with each possible tokenization and evaluate its performance to determine the appropriate tokenization. Performing such an exploration whenever we construct a new downstream model is impractical.

Several studies have addressed the optimization of a tokenizer based on a downstream task or/and model (He et al., 2020; Hiraoka et al., 2020), but existing methods are restricted to specific tasks. He et al. (2020) proposed DPE as a tokenization method for a sequence-to-sequence problem such as machine translation. Their method trains a tokenizer with a given training corpus, but it is isolated from a downstream model such as a neural encoder–decoder for machine translation. Hiraoka et al. (2020) proposed OpTok, which jointly trains a tokenizer and a downstream model. However, its architecture is specific to classification problems based on sentence representations, and thus, it cannot be applied for various tasks such as sequence-to-sequence problems. Therefore, there is no method to optimize a tokenizer depending on any downstream task and model.

In this paper, we propose a novel method to jointly optimize a tokenizer and downstream model without any restriction on a task[1]. The proposed method can determine an appropriate tokenization for a downstream model because it explores different tokenizations based on loss values of the down-

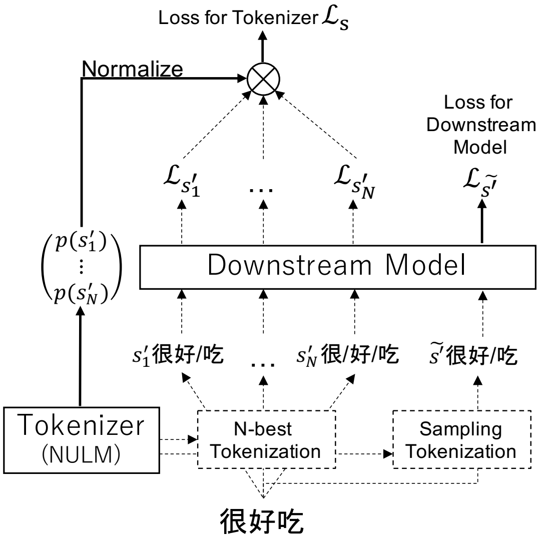

Figure 1: Overview of the proposed method calculating a loss for a tokenizer $\mathcal{L}_s$ and that for a downstream model $\mathcal{L}_{\tilde{s}'}$ using N-best tokenizations (Section 2.2) and a sampled tokenization (Section 2.3), respectively. The arrows with the continuous lines indicate the differentiable path for back-propagation.

stream model. Since the proposed method requires only loss values of the downstream model, we can apply it for any task and model. Moreover, even if a given downstream model is already trained, our proposed method can be applied to improve the performance by refining tokenization. We call this refinement of tokenization *post-processing*. Thus, we can easily use the proposed method in various situations including the case where we have a sufficiently trained downstream model.

We conducted experiments on text classification and machine translation tasks in various languages. Experimental results indicate that the proposed method outperformed existing tokenization methods in both the tasks. We also showed that our method can enhance the performance by refining tokenization as post-processing for downstream models trained with subword regularization (Kudo, 2018; Provilkov et al., 2020).

2 Proposed Method

The proposed method comprises a tokenizer and a downstream model. We optimize the two modules simultaneously. First, we present the training outline of the case where we use one sentence as an input in Section 2.1. Second, we introduce the training of the tokenizer (Section 2.2) and the downstream model (Section 2.3). Finally, we explain the training strategy for a task that requires multiple inputs such as machine translation (Section 2.4).

2.1 Optimizing Tokenization with Loss

The proposed method tokenizes a sentence s into a sequence of words w in vocabulary V, $s' = w_1, ..., w_I$, where I is the sequence length. In this tokenization process, our purpose is to minimize the following loss value:

$$\mathcal{L}_{s'} = q(f(s'), z), \tag{1}$$

where $f(s')$ is a downstream model that outputs a prediction of the downstream task from a tokenized sentence s', and $q(f(\cdot), z)$ is a task-specific loss function between a model prediction and supervisory signal z.

Figure 1 presents an outline of the proposed method. To determine the tokenization satisfying $\mathrm{argmin}_{s'}(q(f(s'), z))$, we update the tokenizer to assign a higher probability to a useful tokenization for the downstream model. Concretely, we construct N tokenizations $s'_1, ..., s'_n, ...s'_N$ for a training instance and then compute loss values for each tokenization. We weight each loss based on probability $p(s'_n)$ computed by the tokenizer and use the weighted sum to train the tokenizer, as follows:

$$a_n = \frac{p(s'_n)}{\sum_{m=1}^{N} p(s'_m)}, \tag{2}$$

$$\mathcal{L}_s = \sum_{n=1}^{N} a_n \mathcal{L}_{s'_n}. \tag{3}$$

In this study, we used N-best tokenizations. In these equations, we weight losses $\mathcal{L}_{s'_1}, ..., \mathcal{L}_{s'_N}$ corresponding to N-best tokenizations with their sentence probabilities normalized such that the sum is 1. By optimizing the tokenizer based on the weighted sum, $\mathcal{L}_s$, the tokenizer assigns high probability to the appropriate tokenization for the downstream model.

We can use any function for $f(\cdot)$ and $q(f(\cdot), \cdot)$ in Eq.(1). Therefore, the proposed method has no restrictions on the downstream task and model. For instance, in the case where text classification is the downstream task, $f(\cdot)$ is a neural network predicting a label of a given tokenized sentence, and $q(f(\cdot), \cdot)$ is the cross-entropy loss between the model prediction and the true label.

2.2 Tokenizer: NULM

We employ a neural unigram language model (NULM) as our tokenizer. It calculates the unigram probability of a word $p(w)$ with a word embedding

$\boldsymbol{v}_w$ as follows:

$$d_w = \mathrm{MLP}(\boldsymbol{v}_w), \tag{4}$$

$$p(w) = \frac{\exp(d_w)}{\sum_{\hat{w} \in V} \exp(d_{\hat{w}})}, \tag{5}$$

where $\mathrm{MLP}(\cdot)$ is a multilayer perceptron. We initialize vocabulary V with a reasonable size of words. For example, we can use a tokenization by SentencePiece (Kudo and Richardson, 2018) or BPE (Sennrich et al., 2016) for the initialization. We also calculate the probability of a tokenization $p(s')$ as follows:

$$p(s') = \prod_{w \in s'} p(w). \tag{6}$$

For the training with Eq.(3), we obtain N-best tokenizations by applying Forward-DP Backward-A* algorithm (Nagata, 1994) for possible tokens against sentence s. In the inference phase, we can also obtain the 1-best appropriate tokenization for the downstream task using Viterbi algorithm (Viterbi, 1967) for the trained NULM.

2.3 Downstream Model Training

We can train the downstream model with loss $\mathcal{L}_s$ in Eq.(3), but we use subword regularization (Kudo, 2018) to obtain a better model. Thus, we compute $\mathcal{L}_{\tilde{s}'} = q(f(\tilde{s}'), z)$ for a sampled tokenization $\tilde{s}'$ and use $\mathcal{L}_{\tilde{s}'}$ to train the downstream model.

We sample tokenization $\tilde{s}'$ from $p(\tilde{s}')^\alpha / \sum_{k=1}^{K} p(s'_k)^\alpha$ computed by the NULM in Eq.(5) (Kudo, 2018). Here, $\alpha \in \mathbb{R}^+$ is a hyperparameter that controls the diversity of the sampled tokenization. If we set α as a lower value, the distribution is similar to the uniform distribution; otherwise, the distribution strongly depends on each tokenization probability $p(\tilde{s}')$. K is also a hyperparameter denoting the number of candidates for sampling, and we use Forward Filtering Backward Sampling (Scott, 2002; Mochihashi et al., 2009) if $K = \infty$.

Subwod regularization not only sophisticates the downstream model but also provides various tokenizations to the downstream model during training. Therefore, subwod regularization helps in exploring the appropriate tokenization.

2.4 Training in Multiple Sentences as Inputs

Previous sections discussed the case where we use one sentence as an input, but we have to input multiple sentences to the downstream model in some tasks. This section describes our training strategy in such cases.

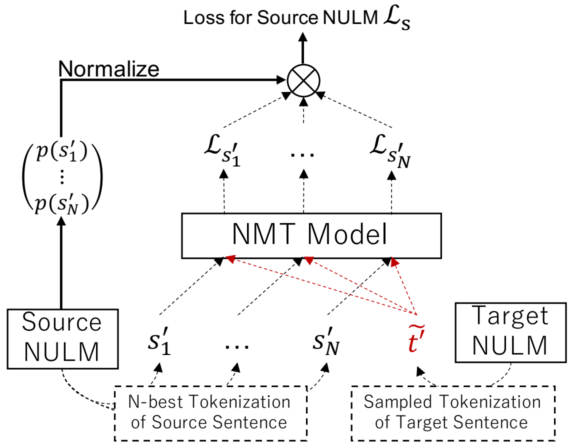

Figure 2: Overview of the calculation of a tokenization loss $\mathcal{L}_s$ for the source-side NULM in NMT requiring two inputs, source and target sentences s and t, respectively. The arrows with the continuous line indicate the differentiable path for back-propagation.

To compute the loss value for training the tokenizer, we consider multiple tokenizations for one sentence and use the sampled tokenization for the others. For example, in machine translation, we input the source and target sentences to train the downstream model. The source sentence is the input of the downstream model, and the target sentence is the supervisory signal. Let s and t be the source sentence and target sentences, respectively, and s' and t' be the corresponding tokenizations. We update the NULM of the source side using $\mathcal{L}_{s'_n} = q(f(s'_n), \tilde{t}')$, where $\tilde{t}'$ is a sampled tokenization for the target sentence. We also compute the loss for the NULM of the target side with $\mathcal{L}_{t'_n} = q(f(\tilde{s}'), t'_n)$, where $\tilde{s}'$ is a sampled tokenization. For training the downstream model, we use sampled tokenizations for all the input sentences. Thus, we compute $\mathcal{L}_{\tilde{s}', \tilde{t}'} = q(f(\tilde{s}'), \tilde{t}')$ for the downstream model. We outline this training process for the NULM of the source side in Figure 2, and the training for the target side is explained in the same manner.

3 Experiment

To validate the applicability of the proposed method to various downstream tasks, we conducted experiments on text classification and machine translation tasks from existing literature. To compare our method with the existing methods that determine the appropriate tokenization for a specific downstream task, we employ OpTok (Hiraoka

et al., 2020) for text classification and DPE (He et al., 2020) for machine translation.

3.1 Text Classification

Settings We utilized ten datasets of text classification tasks in three languages. Weibo(Zh)[2], Twitter(Ja)[3], and Twitter(En)[4] are sentiment analyses on SNS corpora in Chinese, Japanese, and English, respectively. Genre and Rating are genre prediction and rating predictions from reviews posted on E-commerce corpora, respectively, in Chinese (Zhang et al., 2015)[5], Japanese (Rakuten, Inc., 2014), and English (He and McAuley, 2016)[6]. In addition, we employed the SNLI corpus (Bowman et al., 2015) to evaluate our method on the setting requiring two sentences as the input.

We focus on SentencePiece (SP) (Kudo and Richardson, 2018) and OpTok (Hiraoka et al., 2020) as other tokenizers for comparison with the proposed method. OpTok is a method to optimize tokenization for text classification by weighting a sentence vector with N-best tokenization. In addition, we trained each model with subword regularization (SP+R) (Kudo, 2018) for fair comparisons. In subword regularization, we used a sampled tokenization for the training phase and a 1-best tokenization for the inference phase.

For the downstream model, we used a BiLSTM encoder since we followed the experimental configurations of OpTok[7]. We used SentencePiece to construct vocabulary V[8] and initialized unigram probabilities of our NULM. The initial vocabulary sizes are 16K for Twitter(Ja) and Twitter(En) and 32K for the others. The number of tokenizations is $N = 3$, and the hyperparameters for subword regularization are $\alpha = 0.2$ and $k = \infty$. For the SNLI corpus, the system shares the same NULM for the premise and hypothesis and optimizes the NULM in the manner explained in Section 2.4.

Results Table 1 presents the experimental results on text classification. This table indicates that our proposed method surpasses OpTok in eight datasets. For the other two datasets, the performance of our method is comparable to OpTok. These results indicate that the proposed method is a better alternative to the existing tokenizers for text classification tasks. We consider that the difference in the performance is caused by the difference in strategy between the training the downstream models. OpTok trains the downstream model with a weighted sum of sentence vectors corresponding to N-best tokenization with their tokenization probabilities, but it uses 1-best tokenization in the inference. This gap might harm the downstream model. In contrast, since our method trains the downstream model with only one sampled tokenization, the downstream model receives one tokenization in both training and inference consistently. We consider that this consistency improves the performance.

3.2 Machine Translation

Settings For experiments on the machine translation task, we employ IWSLT and WMT corpora on eight language pairs. We pre-tokenized all the datasets except for the Chinese corpus with Moses Tokenizer[9], and we used jieba[10] for the Chinese corpus. We evaluate the performance of each method with detokenized BLEU with SacreBLEU (Post, 2018) after detokenization.

As a recent tokenizer for machine translation, we compare the proposed method with DPE (He et al., 2020), which tokenizes a target sentence, considering the source tokenization, in addition to SentencePiece. We employed the official implementation of DPE[11] and train the DPE model using SentencePiece tokenization. In the same as text

classification, we used subword regularization as a strong baseline.

For the downstream model, we used Transformer (Vaswani et al., 2017) implemented in Fairseq (Ott et al., 2019). For the IWSLT dataset, we used the small Transformer, and we created the initial vocabulary using SentencePiece with a 16K size of the vocabulary for each language. For the WMT dataset, we employed Transformer (base), and the size of the vocabulary is 32K. Similar to the case of text classification tasks, we initialized our NULM with the result of SentencePiece. The hyperparameters for subword regularization are $\alpha = 0.2$ for IWSLT, $\alpha = 0.5$ for WMT, and $k = \infty$ for both datasets. The number of tokenizations for the training of the proposed method is $N = 8$ for ISWLT and $N = 3$ for WMT.

In the training of NMT with DPE, we applied subword regularization for the source side language, similar to He et al. (2020). For the proposed method, we prepared three configurations: used our method only for a source side language, only for a target side language, and for both side languages.

Results Table 2 details the performance of each configuration. This table indicates that the system employing our approach achieves the best performance in most datasets. The setting where the proposed method is used only for the decoder side succeeds on many datasets. In contrast, when we use our method for both sides, the performance degrades. These results imply that it is challenging to optimize the tokenization of source and target languages simultaneously, and it can degrade the performance. We discuss the simultaneous optimization of source and target languages on NMT in Section 5.1.

4 Tokenization as Post-processing

Settings As described in Section 1, our proposed method can be applied as post-processing to an already trained model. In this section, we evaluate the effectiveness of optimizing our tokenizer for the trained model. Concretely, we trained the NULM with $\mathcal{L}_s$ in Eq.(3) without updating the parameters of the downstream model.

We conducted experiments on text classification (Sentiment) and machine translation (IWSLT15) tasks. We trained the downstream models used in Section 3 with subword regularization (Kudo, 2018). We trained the models with 30 epochs for text classification and 100 epochs for machine translation. After the training, we trained only our tokenizer with five epochs using the loss values computed by the trained models. Moreover, for text classification, we trained OpTok in the same manner as our proposed method as a baseline.

Results Table 3 details the performance of each method. This table indicates that the proposed method also improves the performance from the base model trained with subword regularization. The proposed method outperforms OpTok on two datasets of text classification. Moreover, the proposed method increases the BLEU scores consistently in machine translation. These results show that the proposed method is useful to improve the performance of the downstream model even if we

use a sufficiently trained model as the downstream model. In other words, since we do not necessarily require training for the proposed method with the downstream model from scratch, our proposed method can be applied to various situations such as the combination with a pre-trained model.

5 Discussion

5.1 Learning Both Encoder and Decoder

The results of the machine translation task (Section 3.2) reveal that the performance decreases when we incorporate our method into both the encoder and the decoder sides. We consider that the cause of this decrease to be the gap in the tokenization strategy between the source and target languages. In this section, we attempt to make it stable to train our method on both the encoder and decoder sides simultaneously with three possible strategies.

Enc→Dec: We train only the encoder-side NULM in the first 50 epochs, with the decoder-side NULM being frozen; then, we train the decoder-side NULM in the last 50 epochs, with the encoder NULM being frozen.

Dec→Enc: We train our method with the reversed version of the strategy Enc→Dec strategy.

Random: We randomly update either of the NULM on the encoder or that on the decoder sides with at a 0.5 ratio in each mini-batch training.

Table 4 presents the results of the experiments. These results indicate that the Enc→Dec strategy contributes to improving the performance of the simultaneous learning of tokenization on both sides. In particular, the scores of Vi-En, En-Vi, and Zh-En surpass the best scores reported in Table 2, indicating that the Enc→Dec strategy is effective for the training of our method. In contrast, the Dec→Enc strategy decreases the performance in many language pairs. The performance obtained using the Random strategy is slightly lower than that obtained using the original method (Both). From these results, we can conclude that it is effective for the machine translation task to learn the tokenization of each side step-by-step, specifically, from the encoder-side to the decoder-side, instead of optimizing both sides simultaneously.

	Both	Enc→Dec	Dec→Enc	Random
Vi-En	29.44	**30.22**	29.47	29.37

Zh-En	21.89	**21.99**	21.82	21.66
En-Zh	15.31	**15.54**	14.88	15.14

Table 4: Performance of NMT on the IWSLT15 datasets with three strategies for the simultaneous training of our method. The scores of Both are taken from the Ours-Ours column in Table 2. The highest scores are highlighted in bold.

5.2 Analysis of Tokenization

Optimized Tokenization In this section, we analyze the tokenization obtained using the proposed method on a machine translation task. Table 5 presents the comparison of tokenization among SentencePiece, DPE, and our method. We utilized the IWSLT15 Zh-En corpus for this comparison and tokenized English side sentences using each method. For our method, we only optimized the English side tokenization.

Table 5a presents a comparison of the tokenization on the source side between SentencePiece and the proposed method. Our method splits words into smaller segments than SentencePiece, which is the initial tokenization of our method. For example, our method cuts off the suffix from a stem word, such as splitting "don" into "do-n," "have" into "hav-e," and "hours" into "hour-s."

Table 5b presentas a comparison of the tokenization on the target side between SentencePiece, DPE, and the proposed method. Compared to the tokenization on the source side, our method does not split words into tiny units on the target side. The proposed method exhibits the same tendency of tokenization as DPE, such as splitting the past-suffix "-ed." However, the DPE tokenization contains smaller units than our tokenization; an example of this is the difference in the tokenization for "away."

Tokenization Granularity To compare the granularities of each tokenizer, we confirm the number of tokens in the corpus tokenized by each method. Table 6 presents the ratio of the number of tokens in the training corpus between the initial tokenization (SentencePiece) and the optimized tokeniza-

SP	Gra vity **separate d away** from the other force s .
DPE	Gra vity **separat ed a way** from the other force s .
Ours	Gra vity **separat ed away** from the other force s .

(b) Tokenization difference for the target language (Zh-En)

Table 5: Comparison of English tokenization on Zh-En pairs using SentencePiece (SP), DPE, and our method. SRC and TGT indicate the tokenization of source and target side, respectively. The different tokenization is highlighted in bold.

tion (DPE and the proposed method). In the table, a value greater than 1 indicates an increase in the number of tokens compared to SentencePiece.

The results reveal that the number of tokens in the proposed method increases for the source side tokenization, which means that our method tokenizes a source corpus into small units by splitting morphemes, as shown in Table 5a.

For the tokenization of the target side, the ratio of the number of tokens for the proposed method is slightly smaller than the initial tokenization, other than for the En-Zh pair. We consider that our method seeks appropriate tokenization to aid in the decoding process while maintaining the granularity of the initial tokenization. With respect to the translation of the En-Zh pair, our method splits a Chinese sentence into smaller tokens. Chinese characters contain much more information than English characters, and the number of Chinese tokens in a sentence is smaller than that of English. We consider that this difference causes the increased tokens on the target side to use the same granularity as the source English corpus.

Compared with the tokenization by the proposed method, the number of tokens for the DPE varies for each language pair. DPE tokenization is more flexible than our method because DPE employs the Transformer and a special decoding algorithm for tokenization, whereas we simply use a unigaram language model and the Viterbi algorithm. In addition, DPE tokenizes the target sentence by directly considering the source tokenization by inputting a source sentence to the Transformer. In contrast, we use the target side NULM trained with the both side information to find the target side tokenization. Although our tokenization flexibility is limited, our method improves the performance on NMT tasks, as demonstrated in the experimental results.

5.3 Effect of Hyperparameter N

The proposed method updates the NULM using N-best tokenized candidates. In this section, we confirm the effect of the hyperparameter N on the performance for the downstream tasks.

We conducted experiments on text classification and machine translation with different N, as mentioned in Section 3. Figures 3 and 4 show the results respectively. In these figures, we illustrate the difference from the performance of the model with the settings used in Section 3, i.e., $N = 3$ for text classification and $N = 8$ for machine translation.

For the text classification task, we confirm the effect of N on the sentiment analysis datasets. In Figure 3, we can observe that the number of N does not have a strong effect on the performance of the proposed method. In addition, the larger N leads to slightly better performance for the Japanese and English datasets. In contrast, the performance for the Chinese dataset decreases with a large N. We consider that this occurs because a Chinese sentence has more tokenization candidates than the others, and the optimization of tokenization becomes unstable with larger N.

Compared to the existing OpTok method (Hiraoka et al., 2020) the proposed method is robust to large N. As described in Section 3, our method avoids the gap between training and inference in terms of the weighting strategy. Because the proposed method uses one sampled tokenization to train the downstream model, the number of N does not affect the text classification performance. The experiment with various N verifies that our method is superior to Hiraoka et al. (2020).

For the machine translation task, we conduct ex-

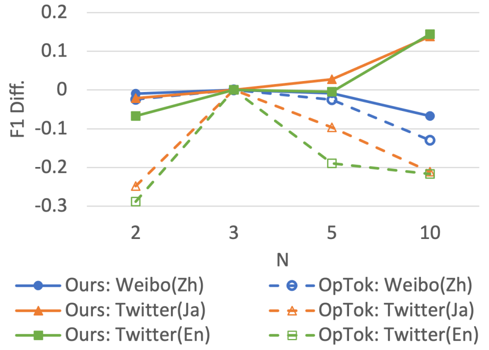

Figure 3: Difference in performance on text classification tasks against N.

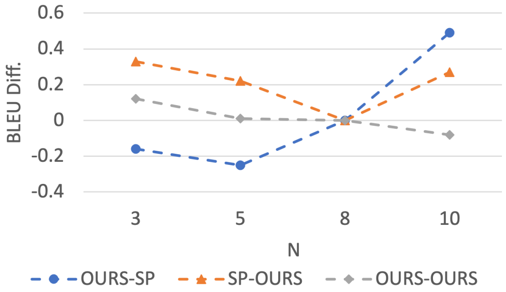

Figure 4: Difference in performance on machine translation tasks (Vi-En) against N.

periments on the Vi-En pair of IWSLT15. Figure 4 illustrates that the number of N does not have a strong effect on the performance when we use the proposed method solely for the target side (SP-OURS). When we incorporate our method to the source side (OURS-SP), the performance increases with a large N. We consider that the proposed method is able to seek appropriate tokenization from the large search space when we set a large number as N because the neural encoder of NMT allows various tokenizations for its input. When we use our method for both the encoder and the decoder (OURS-OURS), the performance decreases slightly with higher N. We consider that optimization of the tokenization of both sides with a large N becomes unstable because tokenization on the source side varies vastly during training.

6 Related Work

Many researchers have tackled the problem of optimizing tokenization, especially in the machine translation field. For statistical machine translation, Nießen and Ney (2004) and Goldwater and McClosky (2005) attempted to obtain good tokenization using hand-crafted linguistic information. Some studies explored appropriate tokenization using alignment information between the source and target languages (Xu et al., 2008; Chung and Gildea, 2009; Nguyen et al., 2010).

Recent studies have attempted to obtain appropriate tokenization for the downstream task using neural networks. Gowda and May (2020) analysed the optimal granularity of tokenization on NMT. Salesky et al. (2020) proposed Incremental-BPE, which automatically explores the appropriate granularity of BPE tokenization. They stopped the merge operation of the BPE depending on the loss on a validation split. He et al. (2020) proposesd DPE, which obtains the appropriate tokenization of a target language depending on the tokenization of the source side on the NMT. Our method is different from DPE in that our method can optimize tokenization considering the parameters of the downstream model. Moreover, our method can be applied to both the source and target languages of the machine translation task. Hiraoka et al. (2020) proposed OpTok, which optimizes the tokenizer and the downstream model on text classification simultaneously. We extend their idea to be applicable to any downstream task, including machine translation. Moreover, our method uses a different training strategy to that used in OpTok. We split the training loss for the downstream loss and tokenization loss, as mentioned in Section 2, and the experimental results demonstrate that our strategy is superior to OpTok.

We employ subword regularization to train the downstream model. Kudo (2018) proposed training a model by sampling tokenization with a unigram language model, and Provilkov et al. (2020) modified this idea to use the BPE (Sennrich et al., 2016) process to yield various tokenizations. Hiraoka et al. (2019) applied subword reguralization for text classification tasks.

7 Conclusion

We propose a novel method for optimizing tokenization by considering downstream tasks, such as a training corpus and a downstream model. Our method is the first approach to explore appropriate tokenization for any downstream task. Experimental results demonstrate that the proposed method achieves higher performance than existing systems with respect to text classification and machine translation tasks. Because the proposed method is applicable to any architecture using loss for its optimization, we expect our method to improve the performance for other NLP tasks.

A Detailed Experimental Settings

For all the experiments, we implement the proposed method using PyTorch, and we run all the experiments on NVIDIA Tesla V100 (16 GiB). For the initialization of the NULM, we terminate the pretraining when the loss is less than 1×10^{-7} or the training epoch achieves the maximum number (100,000).

A.1 Text Classification

In Section 3.1, we use two new datasets in addition to the datasets used in the existing research (Hiraoka et al., 2020). We prepare both datasets in the same manner as that used for Genre(En) and Rating(En).

For Genre(Zh) and Rating(Zh), we use 13 genres that contain a sufficient number of reviews and sample 30,000 reviews from each genre, balancing the number of ratings and limiting the number of characters in the review to 100. The dataset contains 390,000 reviews, and we split it at a ratio of 8:1:1 for training, validation, and testing. Each review has ratings from 1 to 5 attached by reviewers, and we use the sampled dataset for a rating prediction task and a genre prediction task.

For Genre(Ja) and Rating(Ja), we use 21 genres that contain a sufficient number of reviews and sample 5,000 reviews from each genre and rate, limiting the number of characters in the review to 100. The dataset contains 525,000 reviews, and we split it at a ratio of 8:1:1 for training, validation, and testing. Each review has ratings from 1 to 5 attached by reviewers, and we use them for rating and genre prediction tasks.

We conduct experiments on text classification tasks under the same settings as those used in the existing literature (Hiraoka et al., 2020). Thus, we conduct a text classification with BiLSTM encoders whose hidden size is 256. The size of the word embedding is 64, and we set the batch size to 256 and the maximum training epoch to 20. The pretrained word embeddings are frozen in the training of text classification, and both NULM and the downstream model share word embeddings.

A.2 Machine Translation

For experiments on machine translation, we do not freeze the word embeddings. We empirically find that the training becomes unstable when word embeddings are shared between NULM and the downstream model without freezing. Therefore, we prepare different word embeddings for NULM and the downstream model, called the Transformer. We set the word embedding size to 64 for the NULM. We make the mini-batch by specifying the number of maximum tokens, and we set it to 1,000. The maximum number of training epochs is 100 for all the experiments, and we average the parameters of the last 10 epochs for evaluation.

B Tokenization for Text Classification

We present examples for the tokenization on text classification tasks, Genre/Rating(En), in Table 7. As both Genre and Rating datasets are created from the same review corpus, we can confirm whether each method can tokenize a sentence depending on the task, which might be a genre prediction or a rating prediction. We compare the tokenization by SentencePiece, OpTok, and our method.

The tendency for tokenization by our method is similar to that by OpTok because our method is based on OpTok. In the example, both OpTok and our method split a suffix “s” from “episodes” only on the genre prediction task. This example implies that both methods yield tokenization that includes task-specific word such as “episode” for the “Movies_and_TV” genre. In addition, our method tokenizes “seasons” into “season-s,” which is also related to the movie genre.

With respect to the rating prediction, our method does not split “liked” into “like,” which might be helpful for predicting ratings, whereas OpTok does. We consider that our method uses the original word to distinguish the verb from the adjective/adverb “like.”

How does Attention Affect the Model?

Abstract

The attention layer has become a prevalent component in improving the effectiveness of neural network models for NLP tasks. Figuring out why attention is effective and its interpretability has attracted a widespread deliberation. Current studies mostly investigate the effect of attention mechanism based on the attention distribution it generates with one single neural network structure. However they do not consider the changes in semantic capability of different components in the model due to the attention mechanism, which can vary across different network structures. In this paper, we propose a comprehensive analytical framework that exploits a convex hull representation of sequence semantics in an n-dimensional Semantic Euclidean Space and defines a series of indicators to capture the impact of attention on sequence semantics. Through a series of experiments on various NLP tasks and three representative recurrent units, we analyze why and how attention benefits the semantic capacity of different types of recurrent neural networks based on the indicators defined in the proposed framework.

1 Introduction and Motivation

The first appearance of the attention mechanism in natural language processing (NLP) can be traced back to its successful application in Neural Machine Translation (NMT). Bahdanau et al. (2014a) proposed an attention mechanism in an Encoder-Decoder model, which achieved great success, and showed that attention weight produced in this mechanism improved the interpretability of the model by providing a way of aligning the source and target languages through a simple quantitative analysis. Subsequently, the assumption that attention could improve the interpretability and transparency of a model was acquiesced by many later works, such as AEN (Song et al., 2019) (applied to targeted sentiment classification), ATAE-LSTM (Wang et al., 2016) (applied to aspect-level sentiment classification), and CMLA (Wang et al., 2017) (applied to semantic sentiment analysis).

More recently, this hypothetical premise has aroused controversies. For example, Serrano and Smith (2019) and Jain and Wallace (2019) used an erasure-based approach and advocated the attention weight does not necessarily correspond to importance. Wiegreffe and Pinter (2019) and Vashishth et al. (2019) considered attention to be interpretable, using a more model-driven approach and manual verification. These investigations focus on whether the attention distribution is unique and the correlation between attention weight and model prediction results, based on a similar neural network setting that consists of an embedding layer, a specific Recurrent Neural Network (RNN) and an attention component. Complex components such as the encoder-decoder structure were removed from the network as they may bias the analysis on the effect of attention weights. However, these works fail to explain two critical issues as follows:

(1) Neglecting the changes in the rest of the model before and after introducing attention, especially the word embedding layer and the RNNs' hidden layer. Figure 1 shows the transition before and after the introduction of attention. When a model does not introduce attention, the model generates an embedding sequence $\mathcal{E} = \{e_1, e_2, ..., e_n\}$ from the original one-hot word representation. Subsequently, the sequence $\mathcal{E}$ is processed by a specific RNN and converted into a hidden layer sequence $\mathcal{H} = \{h_1, h_2, ..., h_n\}$, which is used to produce the output. The introduction of attention will cause the model to change the gradient during the back-propagation in the training phase, which will lead to the embedding and hidden sequences to move away from the pre-

---

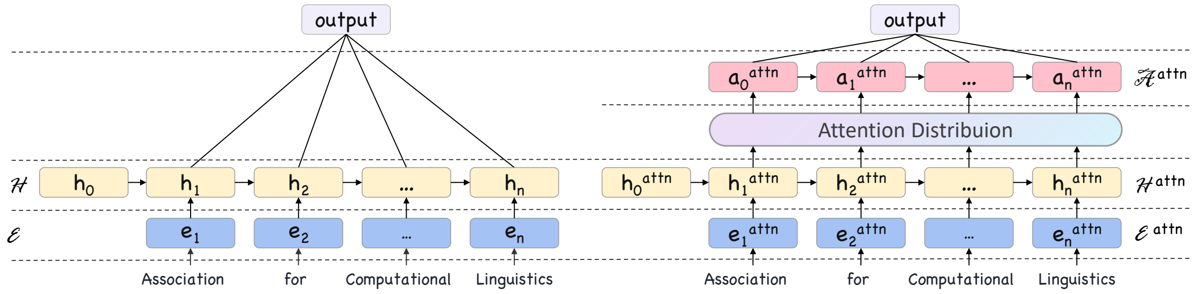

Figure 1: The transformation before and after the introduction of the attention in the RNNs.

vious values $\mathcal{E}$ and $\mathcal{H}$ when the model training step is done. The new embedding sequence is represented by $\mathcal{E}^{attn} = \{e_1^{attn}, e_2^{attn}, ..., e_n^{attn}\}$, and the hidden layer sequence is represented by $\mathcal{H}^{attn} = \{h_1^{attn}, h_2^{attn}, ..., h_n^{attn}\}$. After the attention layer, $\mathcal{H}^{attn}$ is adjusted by the attention distribution to produce a new sequence $\mathcal{A}^{attn} = \{a_1^{attn}, a_2^{attn}, ..., a_n^{attn}\}$. At this point, $\mathcal{A}^{attn}$ is used to generate the output of the model.

The existing works have focused on whether the attention distribution is unique or reasonable (if it is not unique). However, they ignore the extent of semantic changes in the sequences caused by the attention mechanism, including the changes in the embedding sequence ($\mathcal{E} \rightarrow \mathcal{E}^{attn}$), in the hidden layer sequence ($\mathcal{H} \rightarrow \mathcal{H}^{attn}$), and even in the emerging attention sequence ($\mathcal{A}^{attn}$). We posit that such ignorance would lead to an unfair and biased analysis of the attention.

(2) Lacking a systematic study of the attention effect on different types of RNNs. The attention layer is compatible with various types of RNNs, regardless of which recurrent unit out of Vanilla-RNN (Mikolov et al., 2010), LSTM (Hochreiter and Schmidhuber, 1997) or GRU (Cho et al., 2014), is used, or whether it has a uni-directional or bi-directional structure. Although the existing works have experimented on many datasets, they solely focus on a single type of RNN preceding the attention layer at a time. We argue that a comprehensive comparison of the changes before and after introducing attention to different types of RNNs mentioned above will better reveal the intrinsic interpretability of attention.

To address these two issues, we propose to explore the effect of attention from a new perspective by conducting a systematic investigation on the semantic changes across different sequences of a RNN model with or without attention, and comparing the differences in the changes across mainstream recurrent units. Based on the analysis results, we expect to better understand what happens before and after the introduction of attention into the model.

The proposed analysis requires a comprehensive framework with reasonable metrics to evaluate the quality of sequence semantics based on their vector representations. For this purpose, we adopt the concept of Convex Hull in n-dimensional Semantic Euclidean Space ($\mathbb{SR}^n$) (Zhang et al., 2020) to represent the semantics of a sequence. Since an attention mechanism always produces a point in the convex hull of its preceding hidden units, we can establish suitable metrics based on the convex hull formed by a sequence of vectors in $\mathbb{SR}^n$, to facilitate the analysis of attention effect. Section 2 will briefly introduce the Semantic Euclidean Space and the convex hull representation of the sequence semantics. In Section 3, we analyze the attention mechanism and establish the relationship between the attention weight and the sequence meaning (as convex hull in $\mathbb{SR}^n$). Section 4 formulates a set of indicators to analyze the semantic changes before and after attention. With the proposed framework, we conduct comparative experiments on various datasets concerning text classification and sentiment analysis tasks in Section 5. Based on the experimental results, we conduct in-depth analysis from the perspective of why and how the attention mechanism benefits the semantic capacity of different recurrent units of RNNs.

2 Background

Zhang et al. (2020) proposed an n-dimensional Semantic Euclidean Space ($\mathbb{SR}^n$), which defines the mapping relationship between points in an Euclidean Space ($\mathbb{R}^n$) and their semantics. As a semantic extension of $\mathbb{R}^n$, $\mathbb{SR}^n$ is defined as:

$$\mathbb{SR}^n = \{\forall x = (x_1, ..., x_n) \in \mathbb{R}^n | x \to \text{semantics}\} \tag{1}$$

In $\mathbb{SR}^n$, the points are divided into *specific semantic points* and *abstract semantic points*. A specific semantic point has a word corresponding to it, which can also be regarded as a word embedding. An abstract semantic point does not have a specific word corresponding to it, such as a point generated by the hidden layer of RNNs.

Zhang et al. (2020) then proposed to use the convex hull and centroid of points in $\mathbb{SR}^n$ to measure the **meaning** and **central idea** of a sequence of words. It provides a theoretical basis for exploring the semantic changes that occur before and after introducing attention into a model.

2.1 Meaning of a Sequence

Definition. *The meaning of a sequence composed of semantic points is represented by the convex hull composed of these points.*

Given a sequence $\mathcal{X}$ composed of semantic points, its meaning, denote as **ME**$(\mathcal{X})$, is formulated as:

$$\text{ME}(\mathcal{X}) = \text{Conv}(\mathcal{X}) \tag{2}$$

$\text{Conv}(\mathcal{X})$ denotes the convex hull of a finite point set $\mathcal{X}$, as the set of all convex combinations of the points (Faux and Pratt, 1979). In a convex combination, each point x_i in $\mathcal{X}$ is assigned with a weight or coefficient α_i in such a way that the coefficients are all non-negative and sum to one. These weights are used to produce a weighted average of points. It is formulated as:

$$\text{Conv}(\mathcal{X}) = \left\{ \sum_{i=1}^{|\mathcal{X}|} \alpha_i x_i \middle| \alpha_i \geq 0 \wedge \sum_{i=1}^{|\mathcal{X}|} \alpha_i = 1 \right\} \tag{3}$$

The mapping between the definition of the convex hull and the meaning of a sequence is intuitive. A sentence (sequence) consists of words (semantic points). In addition to the semantics expressed by the individual words, a sentence should also include the implicit semantics (abstract semantic points) produced by all possible combinations of words.

2.2 Central Idea of a Sequence

Definition. *The central idea of a sequence composed of semantic points is represented by the centroid of the sequence's meaning.*

The central idea of a sequence $\mathcal{X}$ of semantic points is denoted as $\text{Centroid}(\mathcal{X})$, formulated as:

$$\text{CI}(\mathcal{X}) = \text{Centroid}(\text{ME}(\mathcal{X})) \tag{4}$$

The centroid a subset $\mathcal{X}$ of $\mathbb{R}^n$ is the mean position of all the points in all coordinate directions. It is computed as:

$$\text{Centroid}(\mathcal{X}) = \frac{\int x g(x) dx}{\int g(x) dx} \tag{5}$$

where the integrals are taken over the whole space $\mathbb{R}^n$, and g is the characteristic function, which is 1 if a point is inside $\mathcal{X}$ and 0 otherwise (Protter and Morrey, 1977).

However, the central idea of a sequence needs to be calculated as $\text{Centroid}(\text{Conv}(\mathcal{X}))$, instead of $\text{Centroid}(\mathcal{X})$ directly, to guarantee that the central idea of the sequence lies within the convex hull (meaning) of the sequence. In contrast, even though the geometric centroid of a convex object always lies within the area representing its meaning, a non-convex object might also have a centroid that is outside the area, which is undesirable. As introduced above, ME scopes the meaning of a sequence as an area in $\mathbb{SR}^n$, while the central idea of the sequence should be at the centre of the ME area.

The central idea of a sequence can be considered as a "summary" of the sentence's meaning. Operationally, it is the centroid of the convex hull representation of the sentence meaning, within a $\mathbb{SR}^n$. Take the phrase "The Association for Computational Linguistics" as an example, the central idea of this phrase can be summarized as a semantic point, which corresponds to the abbreviation "ACL". Considering another phrase, "good enough but not excellent", the central idea of this phrase also can be summarized as a semantic point, but for the time being, there is no word that corresponds to this semantic point. Perhaps with the development of natural language, people will soon create a word to describe this semantic point. This is actually the specific semantic point and abstract semantic point defined in $\mathbb{SR}^n$. More explanations about $\mathbb{SR}^n$ can be found in Zhang et al..

3 Attention With Convex Hull

Motivated by the ability of $\mathbb{SR}^n$ to measure the meaning and central idea of sequences, we will theoretically analyze the role of attention from the perspective of semantic change.

Take the well-known Scaled Dot-Product attention (Vaswani et al., 2017) as an example (this will be abbreviated as **dot-attn** later). When a sequence $\mathcal{X} = \{x_1, x_2, ..., x_n\}$ passes through a dot-attn layer, the specific calculation process is shown as follows:

$$\alpha_i = softmax(\frac{x_i X}{\sqrt{m}}) \tag{6}$$

$$y_i = \alpha_i X \tag{7}$$

$X \in \mathbb{R}^{n \times m}$ denotes the matrix of word vectors corresponding to the input sequence $\mathcal{X}$, where m is the dimensionality of word vectors. Essentially this process can be described as the following two steps:

1. Construct an attention distribution $\alpha = (\alpha_1, \alpha_2, ..., \alpha_n)$ through the input sequence $\mathcal{X}$ and the softmax function,
2. Use the attention weight and $\mathcal{X}$ to generate a new sequence $\mathcal{Y} = \{y_1, y_2, ..., y_n\}$, which is called an attention sequence.

α_i is a probability distribution generated from the softmax function, which ensures that each component in it will be in the interval $(0, 1)$ and the components will add up to 1. Focusing on a specific vector y_i in $\mathcal{Y}$, it can be expressed as follows:

$$y_i = \sum_{j=1}^{n} \alpha_i^j x_j \left| \sum_{j=1}^{n} \alpha_i^j = 1, \alpha_i^j \geq 0 \right. \tag{8}$$

Comparing Formula 8 with Formula 3, we can find that under the action of dot-attn, the process of converting $\mathcal{X}$ to $\mathcal{Y}$ is indeed a process of continuously selecting new semantic points from the convex hull of $\mathcal{X}$ (i.e., the meaning of $\mathcal{X}$, ME($\mathcal{X}$)) to form a new semantic sequence $\mathcal{Y}$. Therefore, the new sequence $\mathcal{Y}$ is a semantic transformation of the original sequence $\mathcal{X}$ to some extent. An example of $\mathcal{X} \xrightarrow{\text{dot-attn}} \mathcal{Y}$ is shown in Figure 2.

Furthermore, although the convex hull of $\mathcal{X}$ can be used to express the meaning of a sentence, the model usually uses $\mathcal{X}$ to construct a vector $c = \frac{1}{n}\sum_{i=1}^{n} x_i$ as representation of a sentence, followed by a dense layer and activation function to generate prediction result. The form of sentence representation c is consistent with the definition of the central idea in $\mathbb{SR}^n$. Therefore, from the sentence representation's perspective, attention is to transform the central idea expressed by the original sequence (CI($\mathcal{X}$)) to a new semantic point CI($\mathcal{Y}$) (the central idea of $\mathcal{Y}$). The offset from the yellow diamond to the red triangle in Figure 2 represents the conversion from CI($\mathcal{X}$) to CI($\mathcal{Y}$).

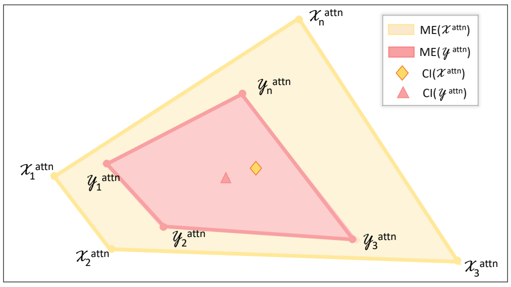

Figure 2: Use attention to convert sequence $\mathcal{X}$ to sequence $\mathcal{Y}$. The meaning of $\mathcal{X}$ is represented by the yellow shaded part, and the meaning of $\mathcal{Y}$ is represented by the red part.

In summary, the model has undergone the following changes after the introduction of attention:

1. Attention adjusts the meaning expressed by the original sequence by adjusting each semantic point in the sequence.
2. Attention changes the central idea (an instance representation) of the original sequence.

Through the above analysis, we have a deeper understanding of how attention transforms the original input from the perspective of the convex hull at the theoretical level. It is important to note that our proposed attention analysis framework above is applicable to other forms of attention, such as $\tanh$ attention (Zhou et al., 2016). No matter a popular dot-attn or a traditional $\tanh$ attention is used, they can be regarded as firstly adjusting the sequence $\mathcal{X}$ to sequence $\mathcal{Y}$, and then further averaging them to make predictions. The subtle difference between them lies in the dimensions of attention distributions. For an input sequence, the dot-attn generates a 2-dimensional distribution, while the $\tanh$ attention generates a 1-dimensional distribution.

However, only the above analysis framework is not enough. During the training process, due to the introduction of attention, the gradient change in the back-propagation process will cause the original sequence $\mathcal{X}$ to be converted into a new sequence $\mathcal{X}^{attn}$, and this has also been ignored in previous studies. To this end, we will first construct relevant evaluation indicators, and then give our complete analysis framework based on the theoretical analysis of attention in this section.

4 Assessing the Effect of Attention

Following the typical settings in this area, we use an RNN model as the basis to systematically analyze the changes between different sequences in the process of introducing attention to the model. We specify multiple indicators to measure these changes and accordingly present our analysis framework.

4.1 Various Sequences Before and After the Introduction of Attention

As shown in Figure 3, the model takes the one-hot representation of the word sequence as the initial input. When attention is not used by the model, the model contains an embedding sequence $\mathcal{E} = \{e_1, e_2, ..., e_n\}$ inferred from a dense layer and a hidden sequence $\mathcal{H} = \{h_1, h_2, ..., h_n\}$ produced by an RNN. When an attention mechanism is introduced, the model weight changes due to the gradient changes during the training process. Hence, $\mathcal{E}$ and $\mathcal{H}$ will be converted to new sequences $\mathcal{E}^{attn} = \{e_1^{attn}, e_2^{attn}, ..., e_n^{attn}\}$ and $\mathcal{H}^{attn} = \{h_1^{attn}, h_2^{attn}, ..., h_n^{attn}\}$. The introduction of attention will be further transformed $\mathcal{H}^{attn}$ into an attention sequence $\mathcal{A}^{attn} = \{a_1^{attn}, a_2^{attn}, ..., a_n^{attn}\}$. For the above five sequences, there is the following progressive relationship:

$$\mathcal{E} \rightarrow \mathcal{H} \tag{9}$$

$$\mathcal{E}^{attn} \rightarrow \mathcal{H}^{attn} \rightarrow \mathcal{A}^{attn} \tag{10}$$

The differences between the above two links of sequences should be carefully examined to explore the impact of attention on the model. In this work, we first define a series of indicators to measure the semantic expression ability of an independent sequence and the semantic relationship between two sequences that belong to the same link. A framework is proposed to systematically compare the differences between the two links to assess the effect of attention.

4.2 Degree of Semantic Unsaturation

In $\mathbb{SR}^n$, the meaning of a sequence $\mathcal{X}$ of length $|\mathcal{X}|$ is calculated by ME. We define the degree of semantic unsaturation of a sequence as follow:

$$\text{DSU}(\mathcal{X}) = \frac{\text{ME}(\mathcal{X})}{|\mathcal{X}|} \tag{11}$$

$\text{DSU}(\mathcal{X})$ reflects the degree of semantic unsaturation regarding $\mathcal{X}$. Normally, the smaller the semantic space contained in the meaning of a sequence, the more precise the semantics expressed. Specifically, for sequences $\mathcal{X}$ and $\mathcal{Y}$ have same sequence length, if the meaning expressed by $\mathcal{X}$ is more precise than the meaning expressed by $\mathcal{Y}$, i.e. $\text{ME}(\mathcal{X}) < \text{ME}(\mathcal{Y})$, then $\text{DSU}(\mathcal{X})$ is less than $\text{DSU}(\mathcal{Y})$, which means that the degree of unsaturation of $\mathcal{X}$ is lower than $\mathcal{Y}$. For this reason, the smaller $\text{DSU}(\mathcal{X})$, the better.

4.3 Semantic Coverage

For two sequences $\mathcal{X}, \mathcal{Y}$, the sequence $\mathcal{Y}$ is a semantic transformation of the previous sequence $\mathcal{X}$ (this transformation may be synonymous transformation or even semantic extraction), we use semantic coverage (SC) (Zhang et al., 2020) to indicate the overlap between two sequences:

$$\text{SC}(\mathcal{X}, \mathcal{Y}) = \text{ME}(\mathcal{X}) \cap \text{ME}(\mathcal{Y})$$

Since $\mathcal{X}$ is the original sequence and $\mathcal{Y}$ is the converted sequence, then three indicators Semantic Coverage Precision (SCP), Semantic Coverage Recall (SCR), and Semantic Coverage F-Measure (SCF) can be naturally defined to observe the changes between the two sequences:

$$\text{SCP}(\mathcal{X}, \mathcal{Y}) = \frac{\text{SC}(\mathcal{X}, \mathcal{Y})}{\text{ME}(\mathcal{Y})} \tag{12}$$

$$\text{SCR}(\mathcal{X}, \mathcal{Y}) = \frac{\text{SC}(\mathcal{X}, \mathcal{Y})}{\text{ME}(\mathcal{X})} \tag{13}$$

$$\text{SCF}(\mathcal{X}, \mathcal{Y}) = \frac{2 \times \text{SCP} \times \text{SCR}}{\text{SCP} + \text{SCR}} \tag{14}$$

4.4 Central Idea Offset

In addition to the difference in meaning between two sequences, it is crucial to check the deviation of the central idea between the two sequences $\mathcal{X}, \mathcal{Y}$. The offset distance between the central idea of $\mathcal{Y}$ and that of the original sequence $\mathcal{X}$ is called Central Idea Offset (CIO), formulated as follows:

$$\text{CIO}(\mathcal{X}, \mathcal{Y}) = \|\text{CI}(\mathcal{X}), \text{CI}(\mathcal{Y})\| \tag{15}$$

4.5 Analysis Framework

Base on the definition of the above five indicators, we propose a framework to analyze the impact of

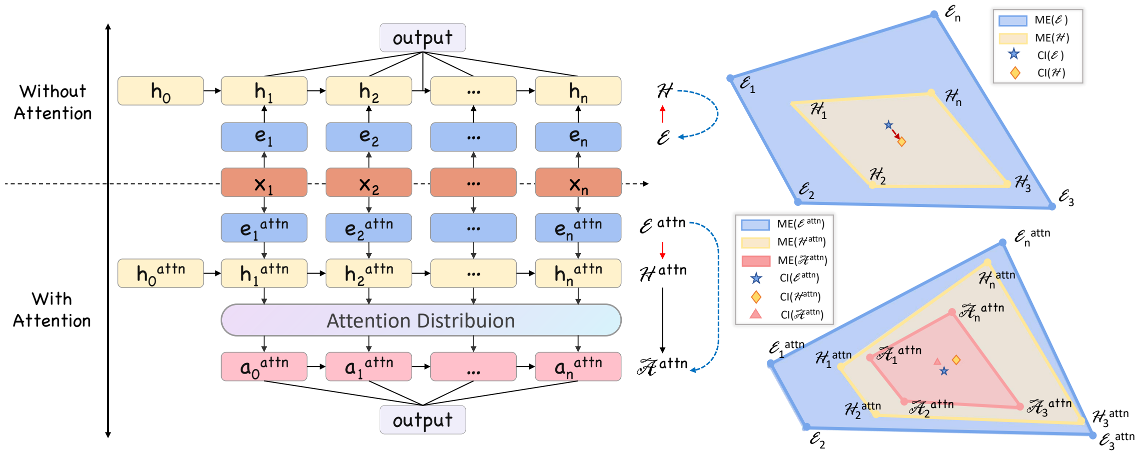

Figure 3: Splice the two models before and after the attention is introduced in a symmetrical manner. The word vector sequence and hidden layer sequence linked by the red arrow in the figure represent the observation from the corresponding perspective. The sequence linked at both ends of the blue dashed arrow represents observation from a shift perspective.

attention on a certain model. Recalling the two links in Eq. 9, since the number of sequences contained in each link is different, we propose two perspectives for comparison: the corresponding perspective and the shift perspective.

4.5.1 The Corresponding Perspective

The introduction of attention to a model has caused changes in its embedding sequence ($\mathcal{E} \rightarrow \mathcal{E}^{attn}$) and its hidden layer sequence ($\mathcal{H} \rightarrow \mathcal{H}^{attn}$). This observation on the changes in the corresponding layers of the model is called the corresponding perspective. Using Δ to represent the difference, $\Delta(\rho(\mathcal{E}), \rho(\mathcal{E}^{attn}))$ reflects the influence of the introduction of attention on the embedding layer from the corresponding perspective, and similarly for $\mathcal{H}$ and $\mathcal{H}^{attn}$.

In addition to the changes on a single sequence, the difference between the links between adjacent sequences ($\mathcal{E} \rightarrow \mathcal{H}$, $\mathcal{E}^{attn} \rightarrow \mathcal{H}^{attn}$) can also be used to observe the impact of attention. For example, $\Delta(\text{SCP}(\mathcal{E}, \mathcal{H}), \text{SCP}(\mathcal{E}^{attn}, \mathcal{H}^{attn}))$ is employed to compare the changes of semantic coverage precision between embedding layer and hidden layer before and after introduction of attention. This difference can also be computed for SCP, SCF and CIO.

4.5.2 The Shift Perspective

According to the analysis in Section 3, before attention is added, the generated attention sequence $\mathcal{H}$ is actually a conversion of the embedding layer. In the presence of attention, the embedding sequence $\mathcal{E}^{attn}$ is converted to the sequence $\mathcal{H}^{attn}$, which is further transformed to $\mathcal{A}^{attn}$ by the attention mechanism. Therefore, the difference between $\text{CIO}(\mathcal{E}, \mathcal{H})$ and $\text{CIO}(\mathcal{E}^{attn}, \mathcal{A}^{attn})$ can be used to reflect the influence of attention on the overall semantic shift along the link.

Dataset	Train/Valid/Test Size	Vocab Size	Label Size
AG_News	96000/24000/7600	95812	4
SST	8544/1101/2210	16583	4

Table 1: Dataset statistics.

In the mean time, an input sentence is finally converted into $\mathcal{H}$ or $\mathcal{A}^{attn}$ to express the meaning of the sentence, so we can alternatively express this change by $\Delta(\text{DSU}(\mathcal{H}), \text{DSU}(\mathcal{A}^{attn}))$.

5 Exploring the Attention

We first introduce the dataset and models used in the experiments and then explore the impact of attention using the analysis framework above.

5.1 Experimental Setup

In order to make our analysis concise, our experiments focused on both text classification task (Stanford Sentiment Treebank (SST) (Socher et al., 2013)) and sentiment analysis task (AGNews [1]). In the future, we will extend our work to more data

---

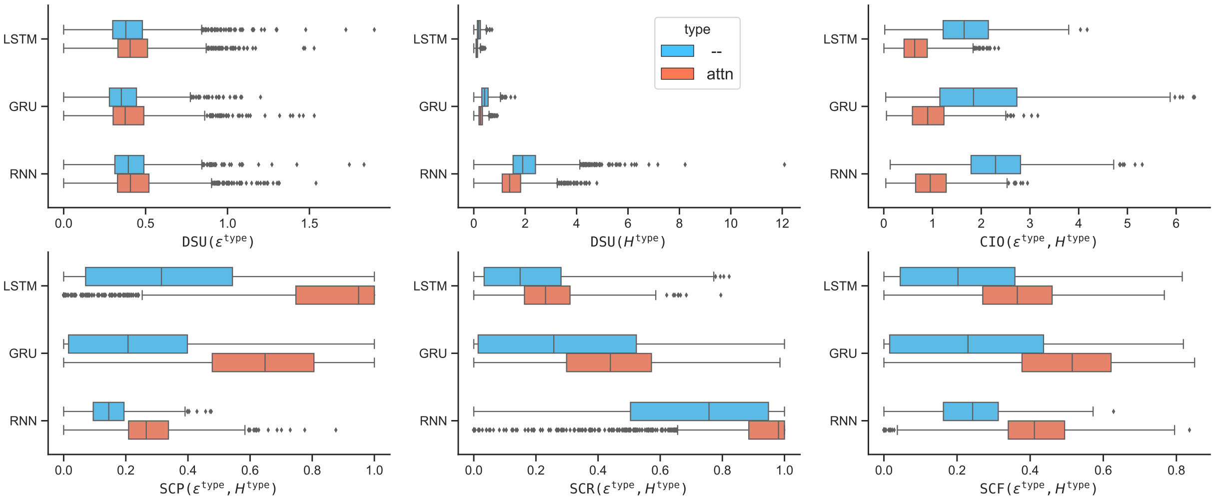

Figure 4: From the corresponding perspective observe the impact of the introduction of attention on the model. In each bin, top (blue) is the model without attention, bottom (red) is the model with attention.

	AG_News		SST	
	-	dot	-	dot
LSTM	0.969	0.976	0.918	0.946
Bi-LSTM	0.974	0.977	0.941	0.951
GRU	0.966	0.973	0.938	0.946
Bi-GRU	0.968	0.970	0.945	0.947
RNN	0.953	0.967	0.848	0.948
Bi-RNN	0.971	0.972	0.892	0.948

Table 2: The accuracy of different types of recurrent units before and after the introduction of attention.

sets, especially the machine translation dataset in the encoder-decoder model.

Since the AGNews dataset does not have a predefined validation set, the training set is split into a training set and validation set at a ratio of 8:2. The statistics of datasets are shown in Table 1. For each dataset, the base model we used for training is shown in Figure 1. It has an embedding layer for convert one-hot representation to distribution representation, a specific RNN-layer (recurrent units can be Vanilla-RNN, LSTM or GRU. The overall structure can be uni-directional or bi-directional, resulting in 6 different combinations.), without or with a dot-attn layer, followed by an additive layer and softmax prediction. The accuracy results of these models on the validation set are shown in Table 2, we calculate and analyze our indicators on the test set (The distribution of sentence length in the test set is shown in Appendix A). It should be pointed out that for the problem that the convex hull of high-dimensional vectors cannot be calculated temporarily, we use t-SNE to reduce the collected vectors to 2-dimensional at first (like the work of Zhang et al.), and further continue calculate the convex hull of the sequence, and use the area to represent the semantic size covered by the convex hull (The reproducibility is shown in Appendix B).

Both in the datasets, regardless of the uni-directional or bi-directional RNNs structure is used, the experimental results' trends are similar. Therefore, we only show the results generate by the use of bi-directional RNNs to compare different recurrent units before and after the introduction of attention on the dataset SST. The more experimental results can found in Appendix C, such as uni-directional RNNs in SST dataset, uni/bi-directional RNNs on AGNews.

5.2 Analysis from the Corresponding Perspective

As shown in Figure 4, by observing the difference in semantic density from the corresponding perspective. We can find that the embedding sequences ($\mathcal{E}, \mathcal{E}^{\text{attn}}$) learned by the model is basically the same for different recurrent types with or without attention. However, from the hidden layer sequence, $\mathcal{H}, \mathcal{H}^{attn}$, we can observe the change of this difference, no matter what type of recurrent unit, $\mathcal{H}^{\text{attn}}$ are less than $\mathcal{H}$, this shows that the hidden layer sequence of RNNs using the attention escapes or abstracts the original text with a smaller semantic range, and the semantics expressed are more accurate. After using the attention, the hidden layer sequence improves the accuracy of semantic expression (decrease the degree of semantic unsaturation) also brings about the improvement of the model effect, as shown in Table 2. The attention mechanism's introduction also led to the shortening of the central idea offset between embedding sequences and hidden sequences.

From the semantic coverage perspective, the introduction of attention makes the semantic conversion between the embedding layer and the hidden layer generally improve in all of the three indicators, semantic coverage recall, semantic coverage accuracy, and semantic coverage F-Measure. This improvement shows that the semantic closeness between embedding and hidden layer and the degree of unsaturation of the hidden layer greatly influence the model results. The introduction of attention improve the accuracy of hidden layer sequence expression semantics and makes the semantic conversion between the embedding sequence and the hidden layer sequence more natural. If we compare different types of recurrent units, it is not difficult to find that RNNs is significantly worse than LSTM and GRU on most indicators, which shows that the prediction accuracy of RNNs is lower than LSTM and GRU is truthfully reflected in our indicators.

5.3 Analysis from the Shift Perspective

The result of the shift perspective is shown in Figure 5, the picture on the top reflects $\Delta(\mathrm{CIO}(\mathcal{E}, \mathcal{H}), \mathrm{CIO}(\mathcal{E}^{attn}, \mathcal{A}^{attn}))$, the bottom picture reflects $\Delta(\mathrm{DSU}(\mathcal{H}), \mathrm{DSU}(\mathcal{A}^{attn}))$. After the introduction of attention, the sequence $\mathcal{A}^{attn}$ used for original semantic expression has a smaller degree of semantic unsaturation than $\mathcal{H}$ used for original semantic expression before the introduction of attention. At the same time, the distance between the central idea of the embedding sequence ($\mathrm{CI}(\mathcal{E})$, $\mathrm{CI}(\mathcal{E}^{attn})$) and the final vector used as an instance representation of the embedding sequence ($\mathrm{CI}(\mathcal{H}), \mathrm{CI}(\mathcal{A}^{attn})$) is also shortened. The improvement of these indicators is also reflected in the accuracy of the model.

It is worth mentioning that if we observe the changes from the perspective of different recurrent types, it is not difficult to find that the number of gate structures in the recurrent type is positively correlated with the degree of semantic unsaturation of embedding sequences and attention sequences. (There are three gate structures in LSTM, 2 in GRU and 0 in Vanilla-RNN.)

5.4 Analysis from the Holistic Perspective

Table 1 and Figure A in Appendix show that in terms of dataset size, vocabulary size and sentence length, the AGNews dataset is larger than SST. By observing the experimental results, it can be found that the changes in the many indicators of RNNs after adding attention on SST are the most obvious. On the other hand, the experimental results for LSTM and GRU without using attention are significantly better than RNN in term of semantic expression ability. However, this superiority is largely compromised by the introduction of attention, which can well recognize the central idea and effectively condense the semantics of a sequence. Therefore, for LSTM and GRU, the changes in performance caused by adding attention are relatively less than that for RNN. This also explains why the accuracy of any RNN variant can be greatly improved after the introduction of attention.

Through Figure 4 and Figure 7 in Appendix, we can see that the introduction of attention on the SST dataset has led to substantial improvements for all indicators, and the improvements on the AGNews dataset are significantly lower. Furthermore, for CIO indicators, RNN results are similar to LSTM and GRU after the introduction of attention. The CIO indicator measures the offset between central ideas and is directly related to the vector that the model finally uses to make predictions (see Formula 8 and Formula 15). Therefore, the high performance of RNN with dot-attn on SST validation set is explainable, especially a single-directional RNN model with dot-attn on the SST validation set reached 0.948.

All of these results verify that the analysis framework in our paper can objectively reflect the attention mechanism's effectiveness on the semantic expression ability.

6 Related Work

Guidotti et al. (2018) divided the problem of blackbox models in detail, and the interpretability problem of attention discussed in this paper belongs to the model explanation problem.

RNNs can be said to be the basic ancestor model that introduced the attention mechanism in NLP tasks. Karpathy et al. (2015) established a mapping between the neurons of hidden layers and the content represented to explore the RNNs, Du et al. (2019) proposed a quantitative analysis framework to pave the way for effective quality analysis of

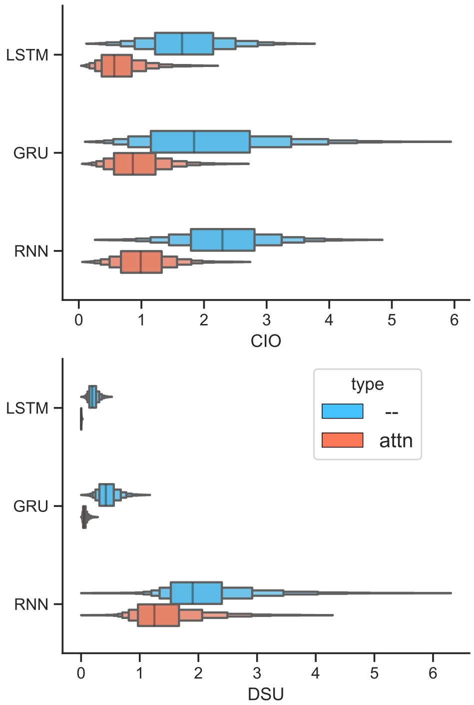

Figure 5: From the shift perspective observe the impact of the introduction of attention on the model. In each bin, top (blue) is the model without attention, bottom (red) is the model with attention.

RNNs, Zhang et al. (2020) assessing the memory ability of RNNs.

Bahdanau et al. (2014b) explained the attention from the perspective of translation alignment, Lee et al. (2017) presented an interactive interface for visualizing and intervening behavior of attention. Recently, a large amount of quantitative analysis work on the interpretability of attention has emerged, such as Vashishth et al. (2019); Jain and Wallace (2019); Serrano and Smith (2019); Wiegreffe and Pinter (2019); Jain et al. (2019), which explained the attention only focused on the attention distribution itself, and used an *erase* method.

7 Conclusions

In this paper, we have proposed a novel framework, based on a convex hull representation of sequence semantics over a Semantic Euclidean Space, to analyze the effect of attention on the semantic capacity of a RNN model and how the effect differs on different network structures. Extensive experiments on two NLP tasks provide in-depth insights on how and why attention impacts the model. From the corresponding perspective, the introduction of attention directly leads to (1) a reduction of semantic unsaturation in the hidden layer of RNNs, that is, an increase in accuracy of the original semantic expression, (2) narrowing the central idea distance between the hidden layer sequence and the embedding layer sequence, (3) an improved performance of semantic coverage between embedding layer sequence and hidden layer sequence. These are critical impacts of attention on the model and improve the capabilities of different types of RNNs. From the shift perspective, the attention layer sequence further reduces the degree of semantic unsaturation, and gets a closer proximity to the embedding layer sequence in the central idea. This is a critical factor in improving the model's accuracy. Our method illustrates how attention affects the model from the perspective of semantic transformation and makes up the limitations of the previous studies in which they only uses a single model to analyze attention.

We believe that the method proposed in this paper will help carry out more in-depth analysis of the role of attention and provide a brand-new perspective for semantic visualization in NLP tasks.

A Datasets Detail

The statistics of sentence length in the test dataset of SST and AGNews are shown in Figure 6. The distribution of sentence length in the figure shown the sentence length in the AGNews' test set is mainly concentrated in (0, 80), in the SST's test dataset is mainly concentrated in (0, 40).

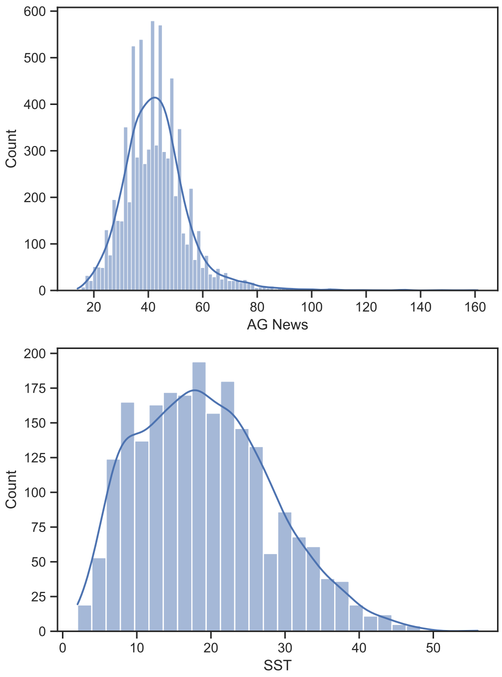

Figure 6: Sentence length statistics. The abscissa indicates the length of the sentence, and the ordinate indicates the count number.

B Reproducibility

Our experiment uses public dataset SST and AGNews. At the same time, in order to reproduce the experimental results more conveniently, we store the scores of each set of sequences in the dataset on defined indicators in a pickle binary file [2], which is convenient for you load it in and use Pandas [3] to view it. We uploaded all the pickle files saved under different models and different datasets to the code part and provided our drawing part of the code to view the experimental results disclosed in our paper, and the model code and training code will be released after some sorting.

C Experiment

Abstract

Recently, chest X-ray report generation, which aims to automatically generate descriptions of given chest X-ray images, has received growing research interests. The key challenge of chest X-ray report generation is to accurately capture and describe the abnormal regions. In most cases, the normal regions dominate the entire chest X-ray image, and the corresponding descriptions of these normal regions dominate the final report. Due to such data bias, learning-based models may fail to attend to abnormal regions. In this work, to effectively capture and describe abnormal regions, we propose the Contrastive Attention (CA) model. Instead of solely focusing on the current input image, the CA model compares the current input image with normal images to distill the contrastive information. The acquired contrastive information can better represent the visual features of abnormal regions. According to the experiments on the public IU-X-ray and MIMIC-CXR datasets, incorporating our CA into several existing models can boost their performance across most metrics. In addition, according to the analysis, the CA model can help existing models better attend to the abnormal regions and provide more accurate descriptions which are crucial for an interpretable diagnosis. Specifically, we achieve the state-of-the-art results on the two public datasets.

1 Introduction

A medical report is a paragraph containing multiple sentences that describe both the normal and abnormal regions in the chest X-ray image. Chest X-ray images and their corresponding reports are widely used in clinical diagnosis (Delrue et al., 2011). However, writing medical reports requires particular domain knowledge (Goergen et al., 2013), and only experienced radiologists can accurately interpret chest X-ray images and note down corresponding findings in a coherent manner. An automatic chest X-ray report generation system (Jing et al., 2018, 2019; Liu et al., 2021b,a, 2019c) can reduce the workload of radiologists and are in urgent need (Brady et al., 2012; Delrue et al., 2011).

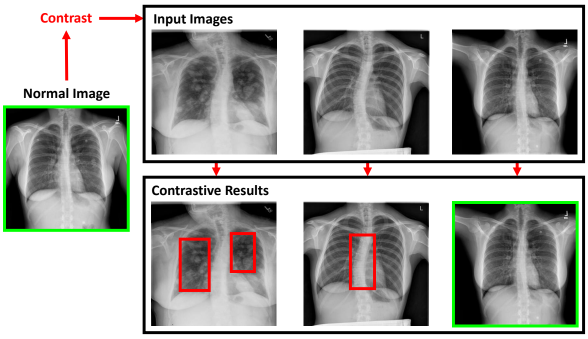

Figure 1: By contrasting current input images and known normal images, it could be easier to capture the suspicious abnormal regions (Red bounding boxes). The images with Green boxes are normal.

In recent years, several deep learning-based methods have been proposed (Jing et al., 2018, 2019; Li et al., 2018, 2019; Chen et al., 2020c; Liu et al., 2021b,a) for automatic chest X-ray report generation; however, there are serious data deviation problems in the medical report corpus. For example, 1) the normal images dominate the dataset over the abnormal ones (Shin et al., 2016); 2) given an input image, the normal regions usually dominate the image and their descriptions dominate the medical report (Jing et al., 2019; Liu et al., 2021b,a). Such data deviation may prevent learning-based methods from capturing the rare but important abnormal regions (e.g., lesion regions). As a result, the learning-based model tends to generate plausible general reports with no prominent abnormal narratives (Jing et al., 2019; Li et al., 2018; Yuan et al., 2019). In clinical practice, accurate detection and depiction of abnormalities are more helpful in disease diagnosing and treat-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 269–280

ment planning. Therefore, existing learning-based methods may fail to assist radiologists in clinical decision-making (Goergen et al., 2013).

To capture the abnormal regions from a chest X-ray image, a natural intuition is to compare it with normal images and identify the differences. As Figure 1 shows, given known normal images, it cloud be easier for models to learn and identify the suspicious abnormal regions (Red bounding boxes). Therefore, we propose the Contrastive Attention (CA) model (see Figure 2), which is based on the attention mechanism (Bahdanau et al., 2015a; Vaswani et al., 2017). The CA model can be easily integrated into existing learning-based methods and enable them to better capture and describe the abnormalities. We build the CA model in the following three steps: 1) we first build a set of normal images which are all extracted from the training dataset; 2) we introduce the Aggregate Attention to prioritize normal images that are closer to the current input image, and filter out normal images that appear differently; 3) and we further introduce the Differentiate Attention to distill the common features between the input image and the refined normal images. Then, the acquired common features are subtracted from the visual features of the input image. In this manner, the residual visual features of the input image are treated as the contrastive information that captures the differentiating properties between input image and normal images.

We evaluate our approach on two datasets, including a widely-used benchmark IU-X-ray dataset (Demner-Fushman et al., 2016) and a recently released large-scale MIMIC-CXR dataset (Johnson et al., 2019). On both automatic metrics and human evaluations, existing methods equipped with the proposed Contrastive Attention model outperform baselines, which proves our argument and demonstrates the effectiveness of our approach.

Overall, the main contributions of our work are:

- We propose the Contrastive Attention model to capture and depict the abnormalities by comparing the input image with known normal images. The proposed approach can be easily incorporated into existing models to improve their performance.

- We evaluate our approach on two public datasets. After equipping our Contrastive Attention model, the baselines achieve up to 14% gain and 17% gain in BLEU-4 on the MIMIC-CXR and IU-X-ray datasets, respectively.

- More encouragingly, we achieve the state-of-the-art performance on the two public datasets, i.e., IU-X-ray and MIMIC-CXR. Moreover, we invite professional clinicians to conduct human evaluation to measure the effectiveness in terms of its usefulness for clinical practice.

2 Related Works

In this section, we will describe the related works in three categories: 1) Image Captioning; 2) Chest X-ray Report Generation and 3) Contrastive Learning.

Image Captioning Image captioning aims to understand the given images and generate corresponding descriptive sentences (Chen et al., 2015). The task combines image understanding and language generation. In recent years, a large number of encoder-decoder based neural systems have been proposed for image captioning (Cornia et al., 2020; Pan et al., 2020; Pei et al., 2019; Venugopalan et al., 2015; Vinyals et al., 2015; Xu et al., 2015; Rennie et al., 2017; Lu et al., 2017; Anderson et al., 2018; Liu et al., 2018, 2019b, 2020, 2019a). However, the sentence generated by image captioning is usually short and describes the most prominent visual contents, which cannot fully represent the rich feature information of the image. Recently, visual paragraph generation (Krause et al., 2017), which aims to generate long and coherent reports or stories to describe visual contents, has recently attracted increasing research interests. However, due to the data bias in the medical domain, the widely-used hierarchical LSTM in the visual paragraph generation does not perform very well in automatic chest X-ray report generation and is tend to produce normal reports (Xue et al., 2018; Li et al., 2018; Jing et al., 2019; Yin et al., 2019).

Chest X-ray Report Generation Inspired by the success of deep learning models on image captioning, a lot of encoder-decoder based frameworks have been proposed (Jing et al., 2018, 2019; Liu et al., 2021b,a, 2019c; Yuan et al., 2019; Xue et al., 2018; Li et al., 2018, 2019, 2020; Zhang et al., 2020a; Kurisinkel et al., 2021; Ni et al., 2020; Nishino et al., 2020; Chen et al., 2020c; Wang et al., 2021; Boag et al., 2019; Syeda-Mahmood et al., 2020; Yang et al., 2020; Lovelace and Mortazavi, 2020; Zhang et al., 2020b; Miura et al., 2021). Specifically, Jing et al. (2018) proposed a hierarchical LSTM with the attention mechanism (Bahdanau et al., 2015b; Xu et al., 2015; You et al., 2016). Yuan et al. (2019) further incorporated the medical concept to enrich the decoder with descriptive semantics. Xue et al. (2018) proposed a multimodal recurrent model containing an iterative decoder with visual attention to improve the coherence between sentences. Miura et al. (2021) proposed an Exact Entity Match Reward and an Entailing Entity Match Reward to improve the factual completeness and consistency of the generated reports, resulting in significant improvements on clinical accuracy. Jing et al. (2019); Li et al. (2018); Liu et al. (2019c) and Zhang et al. (2020a); Li et al. (2019); Liu et al. (2021b) introduced the reinforcement learning and medical knowledge graph for chest X-ray report generation, respectively. However, some errors occur in the generated reports of the existing methods, like duplicate reports, inexact descriptions, etc (Xue et al., 2018; Yuan et al., 2019; Yin et al., 2019).

Contrastive Learning The most related work to our contrastive attention mechanism is in the field of contrastive learning (Chen et al., 2020a; He et al., 2020; Hénaff et al., 2020; Grill et al., 2020; Chen et al., 2020b; Radford et al., 2021; Jia et al., 2021), which learns similar/dissimilar image representations from data that are organized into similar/dissimilar image pairs. In image captioning, Dai and Lin (2017) introduced the contrastive learning to extract the contrastive information from additional images into the captioning models to improve the distinctiveness of the generated captions. Moreover, Song et al. (2018) and Duan et al. (2019) proposed the contrastive attention mechanism for person re-identification and summarization, respectively. Song et al. (2018) utilized a pre-provided person and background segmentation to learn features contrastively from the body and background regions, resulting they can be easily discriminated. Duan et al. (2019) contrastively attended to relevant parts and irrelevant parts of source sentence for abstractive sentence summarization. In this work, we leverage the contrastive information between the input image and the normal images to help models efficiently capture and describe the abnormalities for automatic chest X-ray report generation.

3 Approach

In Section 3.1, we formulate the automatic chest X-ray report generation problems; In Section 3.2, we introduce the Contrastive Attention in detail.

3.1 Problem Formulation

Given a chest X-ray image I, the goal of automatic chest X-ray report generation is to generate a coherent report R that addresses findings of I. Most existing methods (Jing et al., 2018) adopt the encoder-decoder frameworks, which normally include an image encoder (He et al., 2016) and a report decoder (Krause et al., 2017). The encoder-decoder framework can be formulated as:

$$\text{Image Encoder}: I \rightarrow V; \quad \text{Report Decoder}: V \rightarrow R. \quad (1)$$

The image encoder, e.g., ResNet (He et al., 2016), aims to generate the visual features $V \in \mathbb{R}^{N_\mathrm{I} \times d}$. The report decoder, e.g., Hierarchical LSTM (Krause et al., 2017), is used to generate the report R from V. Specifically, in the Hierarchical LSTM, a paragraph-level LSTM first generates topic vectors to represent the sentences, then a sentence-level LSTM takes each topic vector as input to generate the corresponding sentence. As a result, the Hierarchical LSTM can better model a paragraph of multiple sentences (report) than a single LSTM (Jing et al., 2018; Krause et al., 2017). Given the ground truth medical report provided by the radiologists for the input chest X-ray image, existing methods train the encoder-decoder frameworks by minimizing training loss, e.g., cross-entropy loss. Due to limited space, please refer to Huang et al. (2019); Jing et al. (2018) for detailed introduction.

In this paper, we adopt the ResNet-50 (He et al., 2016) to extract the visual features, i.e., the output of the last convolutional layer is used as the visual information:

$$V = \text{ResNet}(I)\mathrm{W}^I, \quad (2)$$

where I denotes the input image, $\text{ResNet}(I) \in \mathbb{R}^{49 \times 2048}$ and $\mathrm{W}^I \in \mathbb{R}^{2048 \times d}$ which reduces the dimension from 2,048 to d[1]. Specifically, the d is set to 512, resulting $V = \{v_1, v_2, \ldots, v_{N_\mathrm{I}}\} \in \mathbb{R}^{N_\mathrm{I} \times d}$, where $N_\mathrm{I} = 49$ and $d = 512$. Moreover, we apply the average pooling to obtain the global visual feature:

$$\hat{v} = \text{AveragePooling}(V) = \frac{1}{N_\mathrm{I}} \sum_{i=1}^{N_\mathrm{I}} v_i. \quad (3)$$

After the above calculations, we obtain the visual feature vectors $V = \{v_1, v_2, \ldots, v_{N_\mathrm{I}}\} \in \mathbb{R}^{N_\mathrm{I} \times d}$ and the global visual feature vector $\hat{v} \in \mathbb{R}^{1 \times d}$.

---

[1] For conciseness, all the bias terms of linear transformations in this paper are omitted.

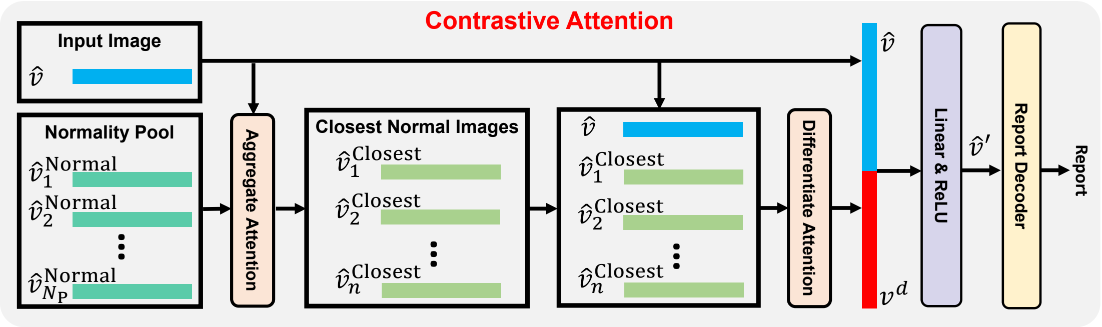

Figure 2: Illustration of our proposed Contrastive Attention, which consists of the Aggregate Attention and Differentiate Attention. In particular, the Aggregate Attention devotes to finding the normal images that are closest to the current input image in the normality pool. The Differentiate Attention devotes to summarizing the common information between the input image and the closest normal images and subtract it from the input image to capture the differentiating properties between the input image and the normal images.

3.2 Contrastive Attention

In this paper, we propose the Contrastive Attention to enable the models to capture the differentiating properties between the input image and normal images. To this end, we first collect a normality pool $P = \{\hat{v}_1^{\text{Normal}}, \hat{v}_2^{\text{Normal}}, \dots, \hat{v}_{N_\text{P}}^{\text{Normal}}\} \in \mathbb{R}^{N_\text{P} \times d}$ which consists of $N_\text{P} = 1,000$ normal images randomly extracted from the training dataset, where $\hat{v}_i^{\text{Normal}} \in \mathbb{R}^{1\times d}$ denotes the global visual feature of i^{th} extracted normal image. Then, as shown in Figure 2, the proposed Contrastive Attention introduces the Aggregate Attention and Differentiate Attention which aims to obtain the contrastive information between the input image $\hat{v}$ and the normality pool P.

Aggregate Attention Since the images in the normality pool P are all normal, there is no ranking order among these images. Therefore it's natural to treat all normal images equally in capturing the contrastive information. However, as shown in Figure 3, we note that there are many noisy images in the normality pool (see the Purple boxes in Figure 3). For example, some normal images have different orientation information or rotation angles from the input image, we cannot direct compare these images with the input image. Therefore, these noisy images will bring noise information, preventing the Contrastive Attention from capturing accurate abnormal regions efficiently. Motivated by the above observations, we introduce Aggregate Attention to increase the weights of normal images that are close to the current input image and lower the weights of images that are not close to the current input image. As a result, the contrasting process could be improved. To implement the Aggregate Attention, we utilize the dot-product attention[2] (Vaswani et al., 2017), which is defined as:

$$\begin{aligned} \text{Att}(x, y) &= \text{softmax}(M)y \\ \text{where } M &= \frac{x\text{W}^x(y\text{W}^y)^T}{\sqrt{d}}, \end{aligned} \tag{4}$$

where $\text{W}^x, \text{W}^y \in \mathbb{R}^{d\times d}$ are learnable parameters. Given $x \in \mathbb{R}^{N_x \times d}$ and $y \in \mathbb{R}^{N_y \times d}$, the acquired M is then of the shape of $N_x \times N_y$, the function $softmax$ is conducted on each row of M, resulting in $\text{Att}(x, y) \in \mathbb{R}^{N_x \times d}$. Then we apply Eq. (4) to $\hat{v} \in \mathbb{R}^{1\times d}$ and $P \in \mathbb{R}^{N_\text{P}\times d}$:

$$\hat{v}^{\text{Closest}} = \text{Att}(\hat{v}, P). \tag{5}$$

Since the attention mechanism is a function that computes the similarity of $\hat{v}$ and each $\hat{v}_i^{\text{Normal}}$ in P, and $\text{Att}(\hat{v}, P) \in \mathbb{R}^{1\times d}$ is the attended vector for the $\hat{v}$. In this way, we can increase the weights of normal images that are similar to current image and lower the weights of the ones that are dissimilar.

Moreover, following Lin et al. (2017), we repeat the Aggregate Attention n times with different learnable attention weights to further promote the performance of our approach, defined as follows:

$$\begin{aligned} P' &= \text{Aggregate-Attention}(\hat{v}, P) \\ &= [\text{Att}_1(\hat{v}, P); \text{Att}_2(\hat{v}, P); \dots; \text{Att}_n(\hat{v}, P)] \\ &= \{\hat{v}_1^{\text{Closest}}, \hat{v}_2^{\text{Closest}}, \dots, \hat{v}_n^{\text{Closest}}\} \in \mathbb{R}^{n\times d}, \end{aligned} \tag{6}$$

where $[\cdot;\cdot]$ stands for concatenation operation. In particular, for chest X-ray images, the result $\text{Att}(\hat{v}, P)$ in Eq. (5) turns out to be the found normal images that are closest to the current entire

---

[2] Our preliminary experiments show that using the dot-product attention (Vaswani et al., 2017) could achieve better performance than the additive attention (Bahdanau et al., 2015a; Xu et al., 2015; Lu et al., 2017) and bilinear attention (Kim et al., 2018; You et al., 2016).

input image. However, $\text{Att}(\hat{v}, P)$ cannot capture those normal images that are closest to the input image only in a specific part rather than the entire image. Fortunately, through repeating the function $\text{Att}(\hat{v}, P)$ in Eq. (5) n times, our Aggregate Attention can efficiently find the closest normal images $P' = \{\hat{v}_1^{\text{Closest}}, \hat{v}_2^{\text{Closest}}, \ldots, \hat{v}_n^{\text{Closest}}\}$ from n parts.

Differentiate Attention To learn the contrastive information between the input image and the closest normal images, we first attempt to capture their similarity, i.e., the common information, then we remove this similarity portion from the input image to obtain the contrastive information. To this end, we introduce the Differentiate Attention.

The first step is learning to summarize the common information $v^c \in \mathbb{R}^{1\times d}$ between the information of current input image $\hat{v} \in \mathbb{R}^{1\times d}$ and the information of closest normal images $P' \in \mathbb{R}^{n\times d}$. In implementation, we employ the same dot-product self-attention mechanism in Eq. (5) and average pooling operation to obtain the $v^c \in \mathbb{R}^{1\times d}$:

$$v^c = \text{AveragePooling}\left(\text{Att}\left([\hat{v}; P'], [\hat{v}; P']\right)\right), \quad (7)$$

where $[\cdot; \cdot]$ denotes row-wise concatenation operation, then the $[\hat{v}; P']$ is in the shape of $(n+1) \times d$ and the $\text{Att}\left([\hat{v}; P'], [\hat{v}; P']\right)$ function outputs a matrix in the shape of $(n+1) \times d$.

In this way, via such self-attention mechanism, we exploit the similarity between P' and $\hat{v}$ to capture the significant common information. Next, to obtain the contrastive information $v^d \in \mathbb{R}^{1\times d}$, we remove (i.e., subtract) the common information $v^c \in \mathbb{R}^{1\times d}$ from the input image $\hat{v} \in \mathbb{R}^{1\times d}$:

$$v^d = \hat{v} - v^c. \quad (8)$$

At last, we update the original image features, i.e., $\hat{v} \in \mathbb{R}^{1\times d}$ and $V = \{v_1, v_2, \ldots, v_{N_\text{I}}\} \in \mathbb{R}^{N_\text{I}\times d}$, with the contrastive information $v^d \in \mathbb{R}^{1\times d}$:

$$\hat{v}' = \text{ReLU}([\hat{v}; v^d]\text{W}') \quad (9)$$

$$v_i' = \text{ReLU}([v_i; v^d]\text{W}'), \quad (10)$$

where $\text{ReLU}(\cdot)$ represents the ReLU activation function and $\text{W}' \in \mathbb{R}^{2d\times d}$ is the matrix for linear transformation. The resulting $\hat{v}'$ and $V' = \{v_1', v_2', \ldots, v_{N_\text{I}}'\}$ are used to replace the original image features V in Eq. (1) and are then fed into existing models to generate coherent reports.

In our subsequent analysis, we show that the contrastive features indeed focus on the abnormal regions and provide a better starting point for downstream models.

4 Experiments

4.1 Datasets, Baselines and Settings

Datasets We use the widely-used benchmark IU-X-ray (Demner-Fushman et al., 2016) dataset and the recently released large-scale MIMIC-CXR (Johnson et al., 2019) datasets for evaluation.

- **IU-X-ray**[3] contains 3,955 radiology reports and 7,470 X-rays images. We use the widely-used splits in Chen et al. (2020c); Jing et al. (2019); Li et al. (2019, 2018); Liu et al. (2021b,a) for evaluation. There are 70%, 10% and 20% instances in training set, validation set and test set, respectively.
- **MIMIC-CXR**[4] is the recently released largest dataset to date and consists of 377,110 chest X-ray images and 227,835 reports from 64,588 patients. Following Chen et al. (2020c); Liu et al. (2021b,a), we use the official splits to report our results. Thus, there are 368,960 in the training set, 2,991 in the validation set and 5,159 in the test set. We convert all tokens of reports to lower-cases and remove the tokens whose frequency of occurrence in the training set is less than 10, resulting in 4k words.

Baselines We experiment with two lines of baselines that are originally designed for image captioning and chest X-ray report generation.

- **Image Captioning Baselines** We experiment on six representative models: NIC (Vinyals et al., 2015), Visual-Attention (Xu et al., 2015), Spatial-Attention (Lu et al., 2017), Att2in (Rennie et al., 2017), Adaptive-Attention (Lu et al., 2017) and Up-Down (Anderson et al., 2018).
- **Chest X-ray Report Generation Baselines** We conduct the experiment on four baselines consisting of HLSTM (Krause et al., 2017; Jing et al., 2018), HLSTM+att+Dual (Harzig et al., 2019), Co-Attention (Jing et al., 2018) and Multi-Attention (Huang et al., 2019).

Settings For our Contrastive Attention model, the model size d is set to 512. Based on the average performance on the validation set, the n in the Aggregate Attention is set to 6. For the normality pool, we randomly extract 1,000 normal images, i.e., $N_\text{P} = 1,000$, for both two datasets from their training set. To re-implement the baselines, following Jing et al. (2019); Li et al. (2019, 2018); Liu et al. (2021b,a), we adopt the ResNet-50 (He et al., 2016) pre-trained on ImageNet (Deng et al.,

Table 2: Comparison with existing state-of-the-art methods on the test set of the MIMIC-CXR dataset and the IU-X-ray dataset. As we can see, we achieve the state-of-the-art performance on major metrics on the two datasets.

2009) and fine-tuned on CheXpert dataset (Irvin et al., 2019) to extract the patch visual features with the dimension of each feature is 2,048, which will be projected to 512. Besides, we utilize paired images of a patient as the input for IU-X-ray and utilize single image as the input for MIMIC-CXR to ensure consistency with the experiment settings of previous works (Chen et al., 2020c). For all baselines, since our focus is to provide explicit abnormal region features, which tends to improve existing baselines, we keep the inner structure of the baselines untouched and preserve the original parameter setting and training strategy.

4.2 Main Evaluation

Metrics We first perform the automatic evaluation to conduct a fair comparison. To measure performance, we adopt the widely-used evaluation toolkit (Chen et al., 2015) to calculate the standard metrics: BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005) and ROUGE-L (Lin, 2004). Specifically, BLEU and METEOR are originally designed for machine translation evaluation, while ROUGE is originally proposed for automatic evaluation of the extracted text summarization.

Results The results on the test set of MIMIC-CXR and IU-X-ray datasets are reported in Table 1. As we can see, our Contrastive Attention can successfully boost baselines with improvement up to 14% and 17% for MIMIC-CXR and IU-X-ray in terms of BLEU-4 score, respectively, where the Setting (g) achieves the greatest improvements. The results prove the effectiveness and generalization capabilities of our approach to a wide range of models.

Moreover, in Table 2, we choose five competitive models including the current state-of-the-art models, i.e., SentSAT + KG (Zhang et al., 2020a) and R2Gen (Chen et al., 2020c), for comparison. For these competitive models, we directly report the results from the original paper. Table 2 shows that when our approach is applied to the Multi-Attention, we outperform these existing state-of-

Metrics	vs. Models	Dataset: MIMIC-CXR (Johnson et al., 2019)			Dataset: IU-X-ray (Demner-Fushman et al., 2016)		
		Baseline wins	Tie	'w/ CA' wins	Baseline wins	Tie	'w/ CA' wins

Table 3: Results of human evaluation on MIMIC-CXR and IU-X-ray datasets for comparing our method with baselines in terms of the **fluency** of generated reports, the **comprehensiveness** of the generated true abnormalities and the **faithfulness** to the ground truth reports. All values are reported in percentage (%).

the-art models on major metrics on the IU-X-ray and MIMIC-CXR datasets, which further proves the effectiveness of our Contrastive Attention.

4.3 Clinical Efficacy

Metrics The metrics used in the Table 1 measure the match between the generated reports and ground truth reports, but are not specialized for the abnormalities in the reports. Therefore, to measure the accuracy of descriptions for clinical abnormalities, we follow Chen et al. (2020c) to adopt the CheXpert labeler (Irvin et al., 2019), which will label the given reports in 14 different categories related to thoracic diseases and support devices, to further report the clinical efficacy metrics. As a result, we can calculate the clinical efficacy scores by comparing the generated reports with ground truth reports in 14 different categories, producing the Precision, Recall and F1 scores.

Results The results are shown in Table 4. As we can see, our approach can boost the performance of baselines under all clinical efficacy metrics. The results prove our arguments and the effectiveness of our approach in boosting the baselines to correctly capture and depict the abnormalities. Specifically, our Multi-Attention w/ CA outperforms the R2Gen (Chen et al., 2020c) with relatively 6%, 9% and 10% margins in terms of Precision, Recall and F1 scores, respectively The superior clinical efficacy scores, which measure the accuracy of descriptions for clinical abnormalities, demonstrate that our approach can help existing models produce higher quality descriptions for clinical abnormalities.

Methods	Clinical Efficacy Metrics

Table 4: Performance of automatic evaluations in terms of clinical efficacy metrics, which measure the accuracy of descriptions for clinical abnormalities, on the MIMIC-CXR dataset. Higher is better in all columns.

4.4 Human Evaluation

Metrics For medical-related task, it is important to know (1) on what fraction of images with abnormalities did the system not mention the abnormality and (2) on what fraction of images the system described abnormality that does not exist according to doctors. To this end, we randomly select 200 samples from the IU-X-ray and MIMIC-CXR test sets, which are 100 samples from each dataset. Specifically, it is important to generate accurate reports (*faithfulness*) with comprehensive true abnormalities (*comprehensiveness*) and it is unacceptable to generate repeated sentences (*fluency*). Therefore, we invite several professional clinicians to compare our approach and baselines independently and evaluate the perceptual quality, including the *fluency* of generated reports, the *comprehensiveness* of generated true abnormalities and the *faithfulness* to the ground truth reports. The clinicians are unaware of which model generates these reports.

Results To conduct the human evaluation, we select a representative chest X-ray report generation baseline: HLSTM (Krause et al., 2017) and a competitive chest X-ray report generation baseline: Multi-Attention (Huang et al., 2019). The results in Table 3 show that our approach enjoys the obvious advantage in terms of the three aspects, i.e., *fluency*, *comprehensiveness* and *faithfulness*, meaning that the reports generated by the "Baseline w/ Contrastive Attention" are of higher clinical quality, which also proves the advantage of our approach in

Settings	Methods	Attention Function	n	Dataset: IU-X-ray (Demner-Fushman et al., 2016)

(g)	w/ DA + AA		4	0.453	0.287	0.202	0.149	0.177	0.361	0.493	0.314	0.220	0.165	0.191	0.378
(h)	w/ DA + AA		6	0.453	0.290	0.203	0.153	0.178	0.361	0.492	0.314	0.222	0.169	0.193	0.381
(i)	w/ DA + AA		8	0.451	0.288	0.200	0.150	0.180	0.362	0.488	0.311	0.221	0.164	0.194	0.379
(j)	w/ DA + AA		10	0.448	0.284	0.197	0.142	0.175	0.355	0.490	0.310	0.219	0.162	0.188	0.375

Table 5: Quantitative analysis of our Contrastive Attention, which includes the Differentiate Attention (DA) and Aggregate Attention (AA). We conduct the analysis on a widely-used baseline model HLSTM (Krause et al., 2017) and a competitive baseline model Multi-Attention (Huang et al., 2019).

clinical practice. Especially, by using our proposed Contrastive Attention, the winning chances of models increased by maximum of $54 - 13 = 41$ points and $71 - 10 = 61$ points in terms of the *comprehensiveness* metric on the MIMIC-CXR and IU-X-ray datasets, respectively. It demonstrates the effectiveness of our approach in helping existing baselines generate more accurate abnormality descriptions, and thus improve the usefulness of models in better assisting radiologists in clinical decision-makings and reducing their workload.

Overall From the results of automatic and human evaluations, we can see that our proposed Contrastive Attention can provide a solid basis for describing chest X-ray images, especially for the abnormalities. As a result, our approach can successfully boost baselines and achieves new state-of-the-art results on the MIMIC-CXR and IU-X-ray datasets, which verifies the effectiveness of the proposed approach and indicates that our approach is less prone to the variations of model structures, hyper-parameters (e.g., learning rate and batch size), and learning paradigms.

5 Analysis

We conduct analysis on the benchmark IU-X-ray dataset to better understand our proposed approach.

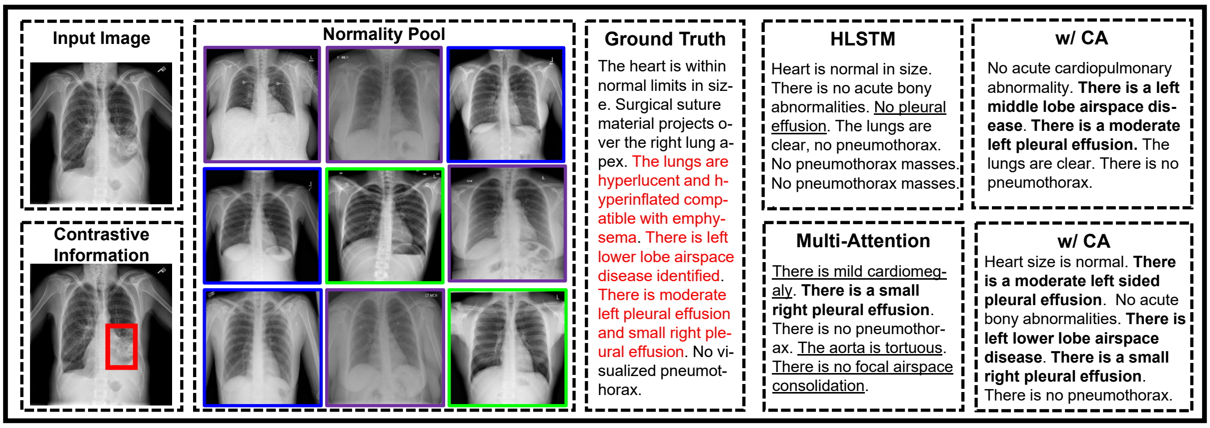
5.1 Quantitative Analysis

We conduct the quantitative analysis on two representative models, i.e., HLSTM and Multi-Attention, to evaluate the contribution of each component.

Effect of Contrastive Attention Our Contrastive Attention consists of the Differentiate Attention (DA) and Aggregate Attention (AA). As shown in Table 5(b), the DA can promote the performance over all metrics. Especially for the HLSTM (Krause et al., 2017), which does not incorporate the attention mechanism to allow more efficient use of the image features. We can see that an up to 5% gain in BLEU-4 score makes the "HLSTM w/ DA" an equally competitive model as the "HLSTM+att+Dual" model in Table 1(h). This indicates that the contrastive information extracted by the DA contains sufficient accurate abnormal information, which is vital in improving the performance of chest X-ray report generation. In other words, our approach can ease the design of the neural models for the task.

For the AA, it devotes to identifying the closest normal images and filtering out the noisy images, which can improve the contrasting process in the DA. As expected, Table 5(c) shows that the AA can consistently boost the performance of baselines under all metrics, which further demonstrates the effectiveness of our approach.

Effect of n In this section, we analyze the effect of n in our Aggregate Attention (see Eq. (6)). Table 5(f-j) shows that when n is smaller than 6, the performance will increase with as n increases. The reason may be that repeating the Aggregate Attention n times with different learnable attention weights can encourage the model to identify the closest normal images from n aspects, e.g., organs or tissues, i.e., if an aspect of the normal image is similar to the input image, it will be identified as the closest normal image. In this way, the Aggregate Attention can capture accurate and robust closest normal images from n aspects. To verify this, we randomly visualize two attention weights of Aggregate Attention in Figure 3. As we can see, the Aggregate Attention can indeed identify the closest normal images from multiple aspects, e.g., 'Bone/Clavicle' (Blue boxes) and 'Right Lung' (Green boxes), which proves our arguments. Moreover, larger n will bring noise, i.e., normal images that are not similar to the current input image, to the model and thus impair the performance.



Ground Truth

The heart is within normal limits in size. Surgical suture material projects over the right lung apex. The lungs are hyperlucent and hyperinflated compatible with emphysema. There is left lower lobe airspace disease identified. There is moderate left pleural effusion and small right pleural effusion. No visualized pneumothorax.

HLSTM

Heart is normal in size. There is no acute bony abnormalities. No pleural effusion. The lungs are clear, no pneumothorax. No pneumothorax masses. No pneumothorax masses.

Multi-Attention

There is mild cardiomegaly. **There is a small right pleural effusion**. There is no pneumothorax. The aorta is tortuous. There is no focal airspace consolidation.

w/ CA

No acute cardiopulmonary abnormality. **There is a left middle lobe airspace disease**. **There is a moderate left pleural effusion.** The lungs are clear. There is no pneumothorax.

w/ CA

Heart size is normal. **There is a moderate left sided pleural effusion**. No acute bony abnormalities. **There is left lower lobe airspace disease**. **There is a small right pleural effusion**. There is no pneumothorax.

Figure 3: Examples of the generated reports and the visualization of the Contrastive Attention (CA). Please view in color. CA model can capture the abnormal region (Red bounding box) by contrasting the input image with normal images. Besides, our Aggregate Attention in the CA model can find the closest normal images (Blue and Green boxes visualized from two different attention weights (see Eq. (6))) and filter out the noisy images (Purple boxes). The Red colored text denotes the abnormal descriptions in the ground truth report. Underlined text denotes the generated wrong sentences. **Bold** text denotes the generated true abnormalities. As we can see, the abnormal region and the abnormal descriptions generated by our method show significant alignment with ground truth reports.

5.2 Qualitative Analysis

In this section, we show the reports generated by the Baseline models, i.e., HLSTM and Multi-Attention, and the "Baseline w/ CA" models, and the visualization in Figure 3 to analyze the strength of our Contrastive Attention model intuitively. As we can see, for the HLSTM, it tends to produce repeated findings and normal findings, which results from the overwhelming normal findings in the dataset, i.e., data deviation (Shin et al., 2016). For the Multi-Attention, with the help of attention mechanism, it can describe abnormalities, but some abnormalities are incorrect (Underlined text). The reason is that it is difficult for the Multi-Attention model to efficiently learn the medical expertise from the dataset with data deviation to correctly detect the abnormal regions. Since our Contrastive Attention model can efficiently capture the suspicious abnormal regions by contrasting the input images and normal images and transfer such power to the downstream models and datasets, we can thus help multiple baseline models to detect and describe comprehensive and accurate abnormalities. As a result, the "Baseline w/ CA" models can generate fluent and accurate reports supported with accurate abnormal descriptions, showing significant alignment with ground truth reports.

6 Conclusion

In this paper, we propose the Contrastive Attention model to capture abnormal regions by contrasting the input image and normal images for chest X-ray report generation. The experiments on two public datasets demonstrate the effectiveness of our approach, which can be easily incorporated into existing models to boost their performance under most metrics. The clinical efficacy scores and human evaluation further prove our arguments and the effectiveness of our approach in helping existing models capture and depict the abnormalities. Specifically, we achieve the state-of-the-art results on the two datasets with the best human preference, which could better assist radiologists in clinical decision-making and reduce their workload.

In the future, there are two potential ways to improve the contrastive attention. First, it may be better to perform the contrastive attention in path feature rather than global feature. Second, it may be better to utilize multiple feature maps from different convolutional layers rather than just the feature maps of last convolutional layer.

Acknowledgments

This work is partly supported by Beijing Academy of Artificial Intelligence (BAAI). We would like to sincerely thank the clinicians (Xiaoxia Xie, Jing Zhang, Minghui Shao, etc.) of the Harbin Chest Hospital in China for providing the human evaluation. We also sincerely thank all the anonymous reviewers and chairs for their constructive comments and suggestions. Xu Sun and Ping Zhang are the corresponding authors of this paper.

Ethical Considerations

In this work, we focus on helping several existing chest X-ray report generation systems better capture and describe the abnormalities. To this end, we provide a detailed human evaluation in Table 3 (Section 4.4) and an automatic evaluation in terms of clinical efficacy metrics in Table 4 (Section 4.3) to know (1) on what fraction of images with abnormalities did the system not mention the abnormality and (2) on what fraction of images the system described abnormality that does not exist according to doctors. The results show that our work can help existing systems generate more accurate descriptions for clinical abnormalities, improving the usefulness of existing systems in better **assisting** radiologists in clinical decision-makings and reducing their workload. In particular, for radiologists, given a large amount of medical images, the systems can automatically generate medical reports, the radiologists only need to make revisions rather than write a new report from scratch. This study uses the public MIMIC-CXR and IU-X-ray datasets. All protected health information was de-identified. De-identification was performed in compliance with Health Insurance Portability and Accountability Act (HIPAA) standards in order to facilitate public access to the datasets. Deletion of protected health information (PHI) from structured data sources (e.g., database fields that provide patient name or date of birth) was straightforward. All necessary patient/participant consent has been obtained and the appropriate institutional forms have been archived.

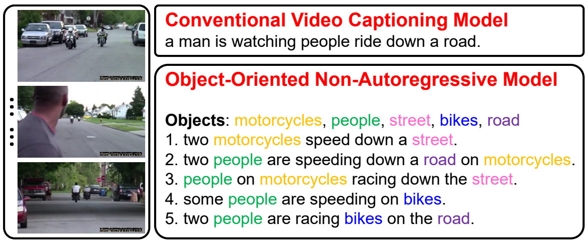
Abstract

Video captioning combines video understanding and language generation. Different from image captioning that describes a static image with details of almost *every* object, video captioning usually considers a sequence of frames and biases towards *focused* objects, e.g., the objects that stay in focus regardless of the changing background. Therefore, detecting and properly accommodating focused objects is critical in video captioning. To enforce the description of focused objects and achieve controllable video captioning, we propose an Object-Oriented Non-Autoregressive approach (O2NA), which performs caption generation in three steps: 1) identify the focused objects and predict their locations in the target caption; 2) generate the related attribute words and relation words of these focused objects to form a draft caption; and 3) combine video information to refine the draft caption to a fluent final caption. Since the focused objects are generated and located ahead of other words, it is difficult to apply the word-by-word autoregressive generation process; instead, we adopt a non-autoregressive approach. The experiments on two benchmark datasets, i.e., MSR-VTT and MSVD, demonstrate the effectiveness of O2NA, which achieves results competitive with the state-of-the-arts but with both higher diversity and higher inference speed.

1 Introduction

The task of video captioning, which aims to generate a descriptive sentence based on the input video, has a wide range of applications. In recent years, deep neural models, particularly the models based on the encoder-decoder framework (Venugopalan et al., 2015; Pan et al., 2016b; Xu et al., 2017; Aafaq et al., 2019), have achieved great success in advancing the state-of-the-art (Pan et al., 2020; Zheng et al., 2020; Perez-Martin et al., 2021; Yang et al., 2021). These models usually entail the autoregressive property, i.e., conditioning each word on the previously generated words.



Conventional Video Captioning Model
a man is watching people ride down a road.

Object-Oriented Non-Autoregressive Model

Objects: motorcycles, people, street, bikes, road
1. two motorcycles speed down a street.
2. two people are speeding down a road on motorcycles.
3. people on motorcycles racing down the street.
4. some people are speeding on bikes.
5. two people are racing bikes on the road.

Figure 1: Examples of the captions generated by a state-of-the-art conventional video captioning model (Zheng et al., 2020) and our model. Compared to the conventional model, whose generation process is hardly controllable, our model can be guided to mention the desired objects (i.e., the colored objects) and generate diverse, object-oriented captions for a video.

In video captioning, one critical step is to detect and include focused objects. As exemplified in Figure 1, when a dangerous situation occurs, a captioning-based blind-aid system should focus on the dangerous objects on the road to alert the visually-impaired people, rather than over-describe the presence of pedestrians or shops nearby. It means that in the above example, *speeding vehicles* should be considered as focused objects and should be mentioned in the generated caption. While people could identify focused objects in video easily (Shinn-Cunningham, 2008; Corbetta and Shulman, 2002; Posner and Petersen, 1990), existing captioning systems can hardly be controlled to generate focused objects because of their word-to-word generation practice. Motivated by those observations, we introduce the problem of controllable video captioning in the sense of controlling contents.

As shown in Figure 2, to solve the controllable video captioning problem, we propose the Object-

Oriented Non-Autoregressive approach (O2NA). Different from conventional models that adopt a left-to-right or word-by-word decoding process, O2NA applies a non-autoregressive manner to control the caption generation. O2NA first detects all objects that appear in the video and then selects the focused objects for the final caption. For example, in the aforementioned blind-aid system, the system would select the dangerous objects *speeding vehicles* in case of an emergency. Next, the caption generation process consists of three main steps: 1) locate all focused objects in the proper locations of the target caption; 2) generate the related attribute words and relation words to form a draft caption; and 3) adopt the iterative refinement approach (Ghazvininejad et al., 2019; Lee et al., 2018) to proofread and improve the draft caption.

For each step, as there is no dependency among generated words, the words can be generated in parallel, indicating a fixed computing time regardless of caption length, while computing time of the conventional autoregressive approach is linear with the caption length. For long captions, conventional methods embody high inference latency, which limits their adoption in real-time applications, e.g., blind-aid system (Voykinska et al., 2016) and human-robot interaction (Das et al., 2017). According to our experiments and analyses on two benchmark datasets, i.e., MSR-VTT (Xu et al., 2016) and MSVD (a.k.a. Youtube2Text) (Guadarrama et al., 2013), our O2NA is able to produce a descriptive and fluent caption which outperforms several existing methods in terms of both accuracy and efficiency.

Overall, the main contributions of this paper are:

- We introduce the problem of controllable video captioning in the sense of controlled contents, which has more practical values than the existing studies on syntactic variations.
- Specifically, we propose the Object-Oriented Non-Autoregressive approach (O2NA) to tackle the controllable video captioning problem by injecting strong control signals conditioned on selected objects, with the benefits of fast and fixed inference time, which are critical for real-time applications.
- We evaluate our approach on two datasets. In particular, our O2NA achieves competitive results with the state-of-the-art methods with higher diversity and higher inference speed.

The rest of this paper is organized as follows: Section 2 reviews the related work; Section 3 introduces the proposed Object-Oriented Non-Autoregressive approach (O2NA) in detail; Section 4 and Section 5 present the experimental results and analyses, respectively; and finally, Section 6 concludes the paper.

2 Related Work

In this section, we describe the related work from 1) Video Captioning, 2) Controllable Image Captioning and 3) Non-Autoregressive Decoding.

2.1 Video Captioning

Recently, a large number of encoder-decoder based neural models have been proposed for video captioning (Venugopalan et al., 2015; Yao et al., 2015; Pan et al., 2016b,a; Xu et al., 2017; Aafaq et al., 2019; Yang et al., 2019; Aafaq et al., 2020; Zheng et al., 2020; Yang et al., 2021; Perez-Martin et al., 2021). These methods mainly introduce a convolutional neural network (CNN) (Krizhevsky et al., 2012) to encode the video and employ a LSTM (Hochreiter and Schmidhuber, 1997) or a Transformer (Zhou et al., 2018) to generate the coherent captions with the attention mechanism (Bahdanau et al., 2015; Pan et al., 2016b). However, these methods lack controllability, i.e., their behaviors can hardly be influenced. Our model allows an easy way to control the contents of video captions rather than merely syntactic variations in existing studies.

2.2 Controllable Image Captioning

Different from image captioning (Xu et al., 2015; Vinyals et al., 2015; Lu et al., 2017; Anderson et al., 2018; Liu et al., 2018, 2019a,b, 2020) that processes a static image with details of almost every appeared object, video captioning considers a sequence of frames which biases towards focused objects. It is still worth noting that the controllable image captioning has been explored most recently (Cornia et al., 2019; Chen et al., 2020; Zheng et al., 2019). However, all of them are based on autoregressive decoding, i.e., conditioning each word on the previously generated outputs. Therefore, to control the generation of image captions, a major challenge is to decide the timing to attend to the region-of-interest (i.e., the object we care about). Zheng et al. (2019) first fixes the cared object and generates the rest captions to its left and right which can only apply to the case with a single cared object. To scale to multiple cared objects, Cornia et al. (2019) implements a region pointer mechanism to predict, at each timestep, whether this pointer should be incremented or not; Chen et al. (2020) introduces the abstract scene graph, to control the generation of captions, they proposed graph-based attention and graph updating mechanisms to adaptively select relevant nodes, which contain the concerned objects to generate next word.

In this work, we focus on controllable video captioning, which is a more challenging problem than controllable image captioning. It is hard for controllable video captioning to construct the same region-of-interests (RoIs) as in Cornia et al. (2019) and scene graphs as in Chen et al. (2020). To this end, based on the non-autoregressive decoding methods in neural machine translation (Gu et al., 2018; Lee et al., 2018; Ghazvininejad et al., 2019; Wang et al., 2019b; Shao et al., 2019), we propose Object-Oriented Non-Autoregressive model, which does not need the RoIs in Cornia et al. (2019) or scene graphs in Chen et al. (2020) to generate controllable video captions. Moreover, our approach can generate all the objects we care about in parallel, leading to fast generation speed.

It is worth noting that Wang et al. (2019a); Yuan et al. (2020) also introduced the controllable video captioning. However, they devoted to employing Part-of-Speech (POS) information to guide caption generation, which mainly focuses on improving diversity and adjusting the syntactic structure of the captions, instead of constraining the model to generate captions containing the focused objects.

2.3 Non-Autoregressive Decoding

Most recently, non-autoregressive decoding has received growing attention in the community of neural machine translation (NMT) (Gu et al., 2018; Ghazvininejad et al., 2019; Lee et al., 2018; Guo et al., 2019; Shao et al., 2019; Ghazvininejad et al., 2020; Kasai et al., 2020; Ren et al., 2020; Haviv et al., 2021; Hao et al., 2021). Such models remove the sequential dependency and can generate all words of a sequence in one step, resulting in high inference efficiency. Inspired by the success of non-autoregressive decoding, we propose the Object-Oriented Non-Autoregressive model. As for the network structure, these current non-autoregressive models usually employ a completely empty sequence as the input of decoder to generate the whole sentence in the early stages, which gives a high risk of producing translation errors. Different from these works, we consider exploiting the objects in the video and propose to first generate an object-oriented coarse-grained caption, and then refine each object word with rich contextual information to generate the whole caption to alleviate the description ambiguity problem.

3 Approach

We first briefly introduce the backgrounds of our approach and then describe the approach in detail.

3.1 Backgrounds

The backgrounds are introduced from the used Video Representations and Basic Module.

Video Representations For video captioning, image and motion features have been widely used. Image features are good at illustrating the shapes, the colors and the relationships of the items in the image; Motion features are important for capturing the actions and temporal interactions. Following Pei et al. (2019), given a video, $N = 8$ key frames are uniformly sampled to extract image features I. Considering both the past and the future contexts, we take each key frame as the center to generate corresponding motion features M. Specifically, for the image features, we adopt the ResNet-101 (He et al., 2016) pre-trained on ImageNet (Deng et al., 2009) to extract the 2048-D image features $I \in \mathbb{R}^{N \times d_i}$ ($d_i = 2048$), which are the output of the last convolutional layer. The motion features are usually given by the 3D CNN (Tran et al., 2015), we adopt the ResNeXt-101 (Hara et al., 2018) pre-trained on the Kinetics dataset (Kay et al., 2017) to extract the 2048-D motion features $M \in \mathbb{R}^{N \times d_m}$ ($d_m = 2048$). In this paper, both features are projected to $d_h = 512$. Then, we use the concatenation of the two projected features as the video representations $V \in \mathbb{R}^{2N \times d_h}$ to our model.

Basic Module Our approach is adapted from the non-autoregressive decoding models (Lee et al., 2018; Ghazvininejad et al., 2019), which is based on the Transformer decoder (TFM) (Vaswani et al., 2017). Specifically, the TFM consists of a self-attention, a source-attention and a feed-forward network (FF). The multi-head attention (MHA) is the basic of self-attention and source-attention. Overall, the TFM is defined as follows:

$$\text{TFM}(Q, K, V) = \text{FF}(\text{MHA}(\text{MHA}(Q, Q, Q), K, V)). \quad (1)$$

Please refer to Vaswani et al. (2017) for the detailed introduction of the Transformer decoder (TFM).

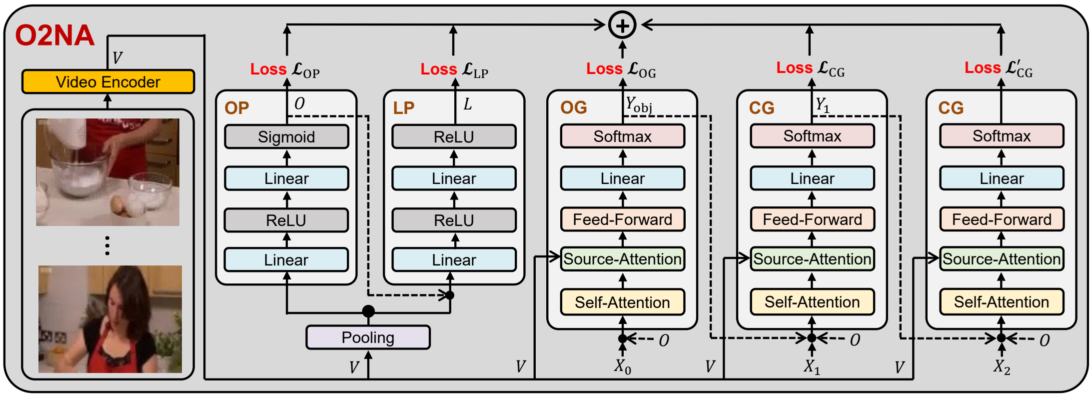

Figure 2: Illustration of our proposed O2NA, which consists of an object predictor (OP), a length predictor (LP), an object generator (OG) and a caption generator (CG). The object predictor and length predictor extract the objects appearing to the input video and estimate the length of target caption, respectively; The object generator locates all the focused objects we care about in the target caption; The caption generator generates the rest words to link focused objects to form a fluent caption. It is worth noting that the focused objects could be the objects predicted by the object predictor, the preferred objects given by the user or the pre-defined concerned objects, e.g., the dangerous objects in the captioning-based blind-aid system.

3.2 Object-Oriented Non-Autoregressive Approach (O2NA)

As stated above, we adopt the Transformer decoder (Vaswani et al., 2017) to implement our Object-Oriented Non-Autoregressive approach (O2NA). Specifically, as shown in Figure 2, O2NA consists of an object predictor, a length predictor and two Transformer decoders, where the first decoder focuses on generating all the objects we care about in parallel (i.e., object generator), and the second decoder pays attention to linking these objects to form a fluent caption (i.e., caption generator).

Object Predictor (OP) The OP is expected to predict the objects that appear in the given video. We first build an object vocabulary based on the training captions. Given this object vocabulary, we can associate each video with a set of objects according to its human-annotated captions. Specifically, we denote the ground truth objects as $O^* = \{o_1^*, o_2^*, \dots, o_M^*\}$, where M represents the size of object vocabulary; $o_i^* = 1$ if the video is annotated with object i, and $o_i^* = 0$ otherwise. During the training phase, we directly use the ground truth objects O^*. At the inference stage, we adopt a two-layer non-linear layer to predict the objects $O \in \mathbb{R}^M$, defined as:

$$\begin{aligned} O &= \text{Object-Predictor}(V) \\ &= \sigma\left(\text{ReLU}\left(\text{MP}\left(V\right) W_{\text{O}_1}\right) W_{\text{O}_2}\right) \\ \text{where } \ \text{MP}\left(V\right) &= \frac{1}{2N}\sum_{i=1}^{2N} v_i, \end{aligned} \tag{2}$$

where MP denotes the Mean Pooling, σ is the sigmoid function; $W_{\text{O}_1} \in \mathbb{R}^{d_h \times d_h}$ and $W_{\text{O}_2} \in \mathbb{R}^{d_h \times M}$ are the parameters to be learned. Next, following Wu et al. (2016), we minimize the element-wise logistic loss function $\mathcal{L}_{\text{OP}}$ to train our OP:

$$\mathcal{L}_{\text{OP}} = \sum_{i=1}^{M} \log\left(1 + \exp\left(-o_i^* o_i\right)\right). \tag{3}$$

During the inference procedure, to select the final predicted objects, we set a threshold γ, which means that if the $o_i > \gamma$, we reset $o_i = 1$, and reset $o_i = 0$ otherwise. In particular, if we care about some specific objects, for example, the user preferred objects or the pre-defined dangerous objects in the captioning-based blind-aid system, we could just set the value of these concerned objects equal to 1, and set the value of other objects equal to 0.

Length Predictor (LP) In the generation process, the non-autoregressive decoding model needs to know the length of target captions (Ghazvininejad et al., 2019). To this end, at training time, we use the sequence length l^* of ground truth caption. At inference stage, given the video information $V \in \mathbb{R}^{2N \times d_h}$ and the focused objects $O \in \mathbb{R}^M$, we adopt a LP to predict the length l. In detail, we apply a two-layer network to achieve the effect:

$$\begin{aligned} l \sim p_l &= \text{Length-Predictor}(V, O) \\ &= \text{softmax}\left(\text{ReLU}\left([\text{MP}(V) W_{\text{L}_V}; O W_{\text{L}_O}]\right) W_{\text{L}}\right), \end{aligned} \tag{4}$$

where $[\cdot;\cdot]$ represents the concatenation operation; $W_{\text{L}_V} \in \mathbb{R}^{d_h \times d_h}$, $W_{\text{L}_O} \in \mathbb{R}^{M \times d_h}$ and $W_{\text{L}} \in \mathbb{R}^{2d_h \times l_{max}}$ are learnable parameters; $l_{max} = 30$ denotes the pre-defined maximum sequence length. Thus, $p_l \in \mathbb{R}^{l_{max}}$ is a probability. We adopt the cross entropy loss $\mathcal{L}_{\text{LP}}$ to train the LP, which can be defined as follows:

$$\mathcal{L}_{\text{LP}} = -\log(p_l(l^*|V, O^*)). \tag{5}$$

Object Generator (OG) The object generator is based on the non-autoregressive decoder and is dedicated to generating all the objects we care about at once. To achieve such effect, we adopt a single-layer Transformer decoder[1], followed by a linear layer and a softmax function. In implementation, the object generator takes the fully masked sequence $X_0 = (x_{\text{m}_1}, x_{\text{m}_2}, \dots, x_{\text{m}_L})\,, x_{\text{m}_i} \in \mathbb{R}^{d_h}$ with predicted length l by length predictor as input. The $x_{\text{m}_i} = w_{\text{[MASK]}} + e_i$, where $w_{\text{[MASK]}}$ and e_i denotes the word embedding of [MASK] token and position embedding, respectively. Then the object information O is added to X_0, i.e., $x'_{\text{m}_i} = x_{\text{m}_i} + OW_O$, where $W_O \in \mathbb{R}^{M \times d_h}$. At last, the transformer decoder in the object generator takes the $X_0 \oplus OW_O$ as input ($\oplus$ denotes the matrix-vector addition), and generates all objects at the position in the final caption, i.e., an object-oriented coarse-grained caption, which can be defined as follows:

$$\begin{aligned} Y_{\text{obj}} \sim p_0 &= \text{Object-Generator}(X_0, V, O) \\ &= \text{softmax}(\text{TFM}(X_0 \oplus OW_O, V, V)W_{\text{OG}}), \end{aligned} \tag{6}$$

where $X_0 \in \mathbb{R}^{l \times d_h}$, $V \in \mathbb{R}^{2N \times d_h}$, $O \in \mathbb{R}^{M}$ represent the input sequence, the video representations and the predicted objects, respectively; $W_O \in \mathbb{R}^{M \times d_h}$ and $W_{\text{OG}} \in \mathbb{R}^{d_h \times |D|}$ are the matrices for linear transformation; $|D|$ is the size of vocabulary D. Each value of $p_0 \in \mathbb{R}^{l \times |D|}$ is a probability indicating how likely each word in D should be the current output word.

At training time, for each human-annotated caption, we mask all the non-object words based on the object vocabulary to acquire the ground truth object sequence $Y^*_{\text{obj}} = (\dots, \text{[MASK]}, \dots, \text{object}_i, \dots)$. Our goal is to minimize the following standard cross entropy loss:

$$\mathcal{L}_{\text{OG}} = -\sum\nolimits_{i=1}^{l^*} \log(p_0(y^*_{\text{obj}_i}|X_0, V, O^*)). \tag{7}$$

Caption Generator (CG) In implementation, the caption generator shares the same structure with object generator. The main differences between the two generators are the different generating objective and the input sequence. Specifically, the caption generator takes the object sequence X_1 as input, where X_1 equals to Y^*_{obj} and Y_{obj} at the training stage and inference stage, respectively, and generates the related attribute words and relation words to form a draft caption, which is defined as:

$$\begin{aligned} Y_1 \sim p_1 &= \text{Caption-Generator}(X_1, V, O) \\ &= \text{softmax}(\text{TFM}(X_1 \oplus OW'_O, V, V)W_{\text{CG}}), \end{aligned} \tag{8}$$

where $p_1 \in \mathbb{R}^{l \times |D|}$. Given the ground truth caption $Y^*_{\text{cap}} = (y^*_{\text{cap}_1}, y^*_{\text{cap}_2}, \dots, y^*_{\text{cap}_l})$, we adopt standard cross entropy loss as the loss function to train the CG, which can be defined as follows:

$$\mathcal{L}_{\text{CG}} = -\sum\nolimits_{i=1}^{l^*} \log(p_1(y^*_{\text{cap}_i}|X_1, V, O^*)). \tag{9}$$

Since the non-autoregressive approach removes the sequential dependency, we may have introduced the "multi-modality problem" (Gu et al., 2018) (i.e., a word could appear in multiple position to form different captions). So we further adopt the iterative refinement approach (Lee et al., 2018) to proofread Y_1. In implementation, to acquire the input sequence X_2, we randomly mask $n = \lfloor l * r \rfloor$ words in Y^*_{cap} and mask out top n words with the lowest confidence in Y_1 at the training time and inference time, respectively, where l and r represent the caption length and masking ratio, respectively, and the confidence is taken to be the output probability. To obtain the final caption, we employ the following equation, which is defined as:

$$Y_2 \sim p_2 = \text{Caption-Generator}(X_2, V, O). \tag{10}$$

Finally, the cross entropy loss is defined similar as Eq. (9):

$$\mathcal{L}'_{\text{CG}} = -\sum\nolimits_{i=1}^{l^*} \log(p_2(y^*_{\text{cap}_i}|X_2, V, O^*)). \tag{11}$$

Overall, by combining the $\mathcal{L}_{\text{OP}}$ in Eq. (3), $\mathcal{L}_{\text{LP}}$ in Eq. (5), $\mathcal{L}_{\text{OG}}$ in Eq. (7), $\mathcal{L}_{\text{CG}}$ in Eq. (9) and $\mathcal{L}'_{\text{CG}}$ in Eq. (11), the full training objective is:

$$\mathcal{L}_{\text{full}} = \lambda_1\mathcal{L}_{\text{LP}} + \lambda_2\mathcal{L}_{\text{OP}} + \lambda_3\mathcal{L}_{\text{OG}} + \lambda_4\mathcal{L}_{\text{CG}} + \lambda_5\mathcal{L}'_{\text{CG}}, \tag{12}$$

where $\lambda_1, \lambda_2, \lambda_3, \lambda_4$ and λ_5 are the hyperparameters that control the regularization. For simplicity, we set $\lambda_1 = \lambda_2 = \lambda_3 = \lambda_4 = \lambda_5 = 1$, since we find that our approach can achieve competitive results with the state-of-the-art models in major metrics under this setting (see Section 4.2), thus we do not attempt to explore other settings.

Overall, through Eq. (12), we are able to realize our Object-Oriented Non-Autoregressive approach (O2NA). The trained model is encouraged to describe the focused objects that a user cares about.

---

[1] Our experiments showed that using a single-layer Transformer decoder can achieve the best performance in major metrics with fastest inference speed (Please refer to Section 5.1.3).

4 Experiments

In this section, we first describe the datasets, metrics and settings used for evaluation, then followed by the experimental results of our approach.

4.1 Datasets, Metrics and Settings

4.1.1 Datasets

Our results are evaluated on the benchmark Microsoft Video Description (MSR-VTT) (Xu et al., 2016) and Microsoft Video Description (MSVD) (Guadarrama et al., 2013) datasets. For MSR-VTT, the dataset contains 10,000 video clips, and each video is paired with 20 annotated sentences. Following common practice (Pei et al., 2019; Yang et al., 2021; Pan et al., 2020), we use the official splits to report our results. Thus, there are 6513, 497 and 2990 video clips in the training set, validation set and test set, respectively. For MSVD, it contains 1,970 video clips and roughly 80,000 English sentences. We follow the split settings in Pei et al. (2019), resulting in 1,200, 100 and 670 videos for the training set, validation set and test set, respectively. Following previous works, we replace caption words that occur less than 3 times in the training set with the [UNK] token, plus with a [MASK] token, resulting in a vocabulary of 10,546 words for MSR-VTT and 9,467 words for MSVD.

Metrics We test the model performance with a standard captioning evaluation toolkit (Chen et al., 2015). It reports the widely-used automatic evaluation metrics CIDEr (Vedantam et al., 2015), ROUGE-L (Lin, 2004), METEOR (Lin and Hovy, 2003; Banerjee and Lavie, 2005) and BLEU (Papineni et al., 2002). Among them, CIDEr, which incorporates the consensus of a reference set for an example, is based on n-gram matching, is specifically designed for evaluating captioning systems. BLEU and METEOR are originally designed for machine translation evaluation, while ROUGE-L is proposed for automatic evaluation of the extracted text summarization. Besides, we further adopt the evaluation metrics Novel, Unique and Vocab Usage, provided by Dai et al. (2018), to evaluate the diversity of the generated captions. Novel is calculated by the percentage of generated captions that have not been seen in the training data; Unique is calculated by the percentage of generated unique words among the other all generated captions; Vocab Usage denotes the percentage of words that are used to generate captions in the vocabulary.

4.1.2 Settings

As stated in Section 3.1, we set $N = 8$, $d_i = d_m = 2048$ and $d_h = 512$ for the video representations. All category tags (Xu et al., 2016) included in MSR-VTT. For the object predictor, to compare with existing methods, we set the threshold $\gamma = 0.8$ and directly select all the predicted objects to generate captions. For the length predictor, the maximum sequence length l_{max} is set to 30. For the object generator and caption generator, following the original setting as in Transformer (Vaswani et al., 2017), the model size $d_h = 512$. The number of heads in multi-head attention is set to 8 and the feed-forward network dimension is set to 2048. The masking ratio $r = 0.5$. To build the object vocabulary, we use the spaCy library[2] for noun tagging from the training dataset, resulting in 5,647 and 4,681 noun words for MSR-VTT and MSVD, respectively. The tagged noun words are taken as the object words, building up the object vocabulary with sizes of 5,647 and 4,681 for MSR-VTT and MSVD, respectively. Therefore, we do not use external data to build the object vocabulary. Specifically, the object predictor labels will match the words used to name objects in the captions. We use Adam optimizer (Kingma and Ba, 2014) with a batch size of 64 and a learning rate of 5e-4 within maximum 50 epochs for parameter optimization.

As each video is annotated with multiple sentences, i.e., Video – $\{\text{Caption}_i\}$, where each sentence Caption_i includes a set of objects $\{\text{Object}_i\}$, we use all objects appearing in these sentences as the ground truth objects for each video to train the object predictor. However, we treat the different sentences as independent training samples, i.e., Video – Caption_i – $\{\text{Object}_i\}$, to train length predictor, object generator and caption generator. In this manner, we can ensure that the focused objects $\{\text{Object}_i\}$ appears in the target sentence Caption_i during training and inference, which allows an easy way to control the contents of video captions.

Following the non-autoregressive decoding models of neural machine translation, we incorporate the knowledge distillation (Kim and Rush, 2016; Gu et al., 2018) and de-duplication (Wang et al., 2019b) techniques to improve the performance of our non-autoregressive model on MSR-VTT. Furthermore, following Gu et al. (2018); Wang et al. (2019b); Yang et al. (2021), to generate the captions, we also adopt the teacher re-scoring tech-

Table 1: Performance of automatic evaluation on the test sets of MSVD and MSR-VTT. Higher is better in all columns. † denotes our own implementation. VPS stands for videos per second at the inference stage, which is measured on a single NVIDIA GeForce GTX 1080 Ti. In this paper, the Red- and the Blue- colored numbers denote the best and the second best results across all approaches, respectively. All existing video captioning systems follow the autoregressive approach to generate the captions and cannot control the video captioning process to ensure the inclusion of the focused objects. In comparison, O2NA can not only describe the focused objects, but also achieve competitive performances with the state-of-the-arts in major metrics with both higher diversity and faster inference.

nique and noisy parallel decoding (Gu et al., 2018; Yang et al., 2021) techniques, which could generate a set of candidate sentences in parallel, then, we select the candidate sentence with the highest output probability as the final generated caption. For the detailed introduction of these techniques, please refer to original papers (Kim and Rush, 2016; Gu et al., 2018; Wang et al., 2019b; Yang et al., 2021).

4.2 Evaluation Results

In comparable settings, twelve representative methods, including five most recently published state-of-the-art approaches, namely STAT (Yan et al., 2020), STGN-OAKD (Pan et al., 2020), ORG-TRL (Zhang et al., 2020), SAAT (Zheng et al., 2020), SGN (Ryu et al., 2021) and SemSynAN (Perez-Martin et al., 2021), are selected for comparison. Unless specifically stated, we directly report the results from the original papers. The results on the test of MSVD and MSR-VTT datasets are shown in Table 1. As we can see, our O2NA achieves the results competitive with the state-of-the-art models on the two datasets in major metrics. The competitive performances verify the validity of our O2NA for standard video captioning. More encouragingly, in terms of the metrics that evaluate the diversity of the generated captions, O2NA surpasses the previous state-of-the-art models with relatively 39%, 31% and 18% margins in terms of Novel, Unique and Vocab scores, which proves our arguments and corroborates the effectiveness of our approach. Moreover, since our O2NA generate the entire captions in three steps with a fixed generation time, we achieve the fastest inference speed (highest VPS in Table 1) among existing methods.

Overall, our O2NA achieves performances competitive with state-of-the-arts in major metrics but with higher diversity scores and faster inference speed. The experimental results show that our approach is able to generate fluent and diverse video captions with fast inference speed. More importantly, our O2NA allows an easy way to control the contents of video captions rather than merely syntactic variations in existing studies. These advantages of our approach could have the potential to promote the application of video captioning for real-time industrial applications, e.g., helping visually impaired people see (Voykinska et al., 2016) and human-robot interaction (Das et al., 2017).

5 Analysis

In this section, we conduct analysis on the benchmark MSR-VTT dataset from different perspectives to better understand our approach.

5.1 Quantitative Analysis

We first conduct the quantitative analysis to investigate the contribution of each component in our proposed O2NA.

5.1.1 Ablation Study

Compared to conventional non-autoregressive decoding models (Baseline) from neural machine translation (Lee et al., 2018; Gu et al., 2018; Ghazvininejad et al., 2019), our O2NA further introduces the *object predictor* and *object generator*

Sections	Settings	Methods	Iteration Times	Number of Layers	Dataset: MSR-VTT							
					BLEU-4	METEOR	ROUGE-L	CIDEr	Novel	Unique	Vocab	VPS
5.1.1	(a)	Baseline	1	1	40.0	26.9	60.2	44.6	6.6	27.1	2.6	113.7
	(b)	w/ OP	1	1	40.7	27.4	60.6	47.9	18.0	26.9	3.1	99.5
	O2NA	w/ OP + OG	1	1	41.6	28.5	62.4	51.1	37.2	46.7	4.6	70.8
5.1.2	(c)	w/ OP + OG	2	1	42.1	28.7	62.5	51.6	31.9	42.3	4.0	61.0
	(d)	w/ OP + OG	3	1	42.4	28.8	62.5	51.8	25.1	33.0	3.5	54.9
	(e)	w/ OP + OG	4	1	42.5	28.8	62.6	51.9	21.1	29.3	3.0	49.3
5.1.3	(f)	w/ OP + OG	1	2	41.8	28.5	62.1	50.8	36.0	43.7	4.5	48.5
	(g)	w/ OP + OG	1	3	41.1	28.4	61.5	50.3	30.4	38.6	3.9	36.9
	(h)	w/ OP + OG	1	4	40.5	27.6	61.0	48.7	22.3	30.6	3.4	30.2

Table 2: Quantitative analysis of O2NA. Baseline denotes the conventional non-autoregressive decoding model in neural machine translation (Lee et al., 2018; Gu et al., 2018; Ghazvininejad et al., 2019). OP and OG denote the object predictor and object generator, respectively.

for controllable video captioning. Therefore, we investigate the contribution of the two components and the results are shown in Table 2.

Effect of the Object Predictor (OP) As expected, since the OP can provide explicit visual clues (i.e., objects) of the input video, the model achieves improved results (c.f. Table 2(b)), especially in Novel and Unique scores, indicating that the OP helps to generate diverse captions. The improved results prove the effectiveness of our OP.

Effect of the Object Generator (OG) As shown in Table 2(O2NA), when further equipping with the OG, the model significantly outperforms the Baseline, which employs a completely empty sequence as the input to generate the whole sentence. Intuitively, such practice in Baseline may give high risk of producing errors. Fortunately, the object-oriented coarse-grained captions generated by our OG could provide rich contextual information for the following non-autoregressive decoding model to generated accurate revised captions. It proves our arguments and verifies the effectiveness of generating captions in a coarse-grained to fine-grained manner.

Overall, the proposed OP and OG can boost the performance from different perspectives, making our O2NA generate diverse and accurate captions.

5.1.2 Effect of the Iteration Times

In O2NA, we adopt the iterative refinement technique (Lee et al., 2018) to proofread and improve the generated captions (see Eq. (10)). However, in conventional non-autoregressive decoding methods for neural machine translation (Gu et al., 2018; Lee et al., 2018; Ghazvininejad et al., 2019; Guo et al., 2019; Shao et al., 2019), they usually adopt more iterations to obtain better results. As to O2NA, Table 2(c-e) shows that performances stabilize with the increasing number of iterations but do not show a significant increase as in Lee et al. (2018); Ghazvininejad et al. (2019). The reason is that our generated object-oriented coarse-grained captions have provided a solid guidance (i.e., rich contextual information) for non-autoregressive video captioning model, which further proves the effectiveness of our approach. The decreased performance of diversity may be due to the over-fitting problem brought by more iterations, making the model prone to generating frequent captions in the training data. Thus, considering the trade-off between "the performance of caption generation" and "the performance of diversity and inference speed", we only proofread the generated captions once.

5.1.3 Effect of the Number of Layers

When increasing the number of layers to 2 (c.f. Table 2(f)), the model can only achieve a slightly improved result on BLEU-4 (i.e., 41.6 → 41.8), but loses 31.5% inference speed. At the same time, if the number of layers is further increased, the performance decreases. We hypothesize that when training on video captioning datasets that are relatively small compared to those for neural machine translation, larger depths add to the difficulty of training, which is the same case with deep RNNs. In brief, considering the trade-off between the performance and inference speed, we adopt a single-layer Transformer decoder.

5.2 Case Study and Error Analysis

In this section, we list some correct and incorrect examples to show the controllability of our proposed O2NA intuitively. In the analysis, we manually select the predicted objects to encourage the model to generate a set of diverse captions. Fig-

(person, electronics) a person is showing a electronics.
(hand, electronics) a hand pointing to a electronics.
(electronics, device) an electronics device is shown.

(person, suitcase) a person is describing a suitcase.
(device, suitcase) a device sitting on a suitcase.
(suitcase) a suitcase is opening.

(woman, kitchen) a woman is in a kitchen .
(woman, food, pan) a woman is cooking some food with a pan.

(woman, shirt) a woman wearing a black shirt.
(woman, food, shirt) a woman with a black shirt is preparing food.

Figure 3: Examples of captions generated by our proposed O2NA. For each example, the left plot shows the input video. The upper, middle and lower parts in the right plot show the predicted objects, correct examples and error cases, respectively. The designated objects are listed in brackets. The color Red denotes unfavorable objects.

ure 3 shows that our approach is controllable and explainable. Specifically, it can generate multiple diverse captions for the same video, and can accurately follow the selected objects we care about. Besides, we find that the error mainly takes place when there are incorrectly predicted objects, e.g., “*suitcase*” and “*shirt*”. O2NA mistakes the incorrect object for an appropriate one during its object sequence generation. A more powerful object predictor may be helpful in solving these problems, but it is unlikely to be completely avoided.

6 Conclusions

In this work, we introduce the problem of controllable video captioning in the sense of controlled contents. In contrast to the existing studies considering syntactic variations, controlling contents is of more practical value. To tackle the problem, we propose the Object-Oriented Non-Autoregressive approach (O2NA), which encourages the model to describe the focused objects that a user cares about by generating captions conditioned on the focused objects non-autoregressively. The experiments and analyses verify the flexibility and demonstrate the effectiveness of O2NA, which achieves competitive results with existing state-of-the-art models on two benchmark datasets in major metrics with higher diversity and faster inference. These advantages could promote the application of video captioning adapting to real-world scenarios.

In the future, it may be interesting to implement a more fine-grained control of the objects, e.g., the order of the objects in the caption according to their priority in utterance.

Acknowledgments

This work is supported in part by Beijing Academy of Artificial Intelligence (BAAI). We sincerely thank all the anonymous reviewers and chairs for their constructive comments and suggestions that substantially improved this paper. We also sincerely thank Bang Yang for providing the implementation code of non-autoregressive framework for video captioning.[3] Xu Sun is the corresponding author of this paper.

Impact Statement

This paper introduces the problem of controllable video captioning in the sense of controlled contents to efficiently understand the visual content of a given video and generate corresponding descriptive sentences. As a result, our work can control the video captioning process and include focused objects, i.e., the video captions generated by our model are more likely to contain preferred objects given by a user or pre-defined objects that should be prioritized in generation. It improves the practicality of video captioning in real-world applications, such as visual retrieval, human-robot interaction and aiding visually-impaired people. However, the training of our proposed model relies on a large volume of video-caption pairs, which may not be easily obtained in the real world but could be alleviated using techniques such as distillation from publicly-available pre-trained models. Hence, it requires specific and appropriate treatment by experienced practitioners.

Better Chinese Sentence Segmentation with Reinforcement Learning

Abstract

A long-standing challenge in Chinese–English machine translation is that sentence boundaries are ambiguous in Chinese orthography, but inferring good splits is necessary for obtaining high quality translations. To solve this, we use reinforcement learning to train a segmentation policy that splits Chinese texts into segments that can be independently translated so as to maximise the overall translation quality. We compare to a variety of segmentation strategies and find that our approach improves the baseline BLEU score on the WMT2020 Chinese–English news translation task by +0.3 BLEU overall and improves the score on input segments that contain more than 60 words by +3 BLEU.

1 Introduction

Machine translation systems typically operate on sentence-like units, where sentences are translated independently of each other (Vaswani et al., 2017; Bahdanau et al., 2015; Koehn et al., 2003; Brown et al., 1993), in some cases with additional conditioning on a representation of adjacent sentences to improve coherence (Miculicich et al., 2018; Zhang et al., 2018). While many pairs of languages use similar orthographic conventions to designate sentence boundaries, English and Chinese diverge considerably: complete sentences in Chinese may be terminated either unambiguously with a full stop (。) or ambiguously with a comma. See Figure 1 for an example.

This divergence poses a challenge for Chinese–English translation systems since they must either be able to cope with potentially long, multi-sentence inputs (i.e., translating any text that falls between unambiguous sentence-ending punctuation) or, alternatively, they must be able to determine which comma occurrences terminate complete sentences that can be translated independently and which do not.

习近平主席2015年9月宣布成立的“中国-联合国和平与发展基金”，将支持非洲维和、反恐、实现可持续发展作为重点，迄今已开展34个涉非项目，成为中国、非洲、联合国三方合作的新平台。

The “China-United Nations Peace and Development Fund” announced by President Xi Jinping in September 2015，focuses on supporting African peacekeeping, counter-terrorism, and achieving sustainable development， So far, 34 projects involving Africa have been carried out， becoming a tripartite cooperation between China, Africa and the United Nations.

Figure 1: An example taken from the WMT2020 test set that shows a single source Chinese segment is translated into two separate English sentences. The highlighted comma separates the two corresponding complete sentences in the Chinese text, whereas the other two commas are sentence-internal boundaries.

Being able to directly accommodate long, multi-sentence inputs has clear appeal. However, in practice, the training data available for translation models is dominated by the relatively short (sub)sentence pairs that are preferentially recovered by standard approaches to sentence alignment (Tiedemann, 2011; Gale and Church, 1993), and as a result of the natural distribution of sentence lengths. Unfortunately, generalisation from training on short sequences to testing on long sequences continues to be an unsolved problem even in otherwise well-performing translation models (Lake and Baroni, 2018; Koehn and Knowles, 2017). Rather than addressing the length generalisation problem directly, in this paper we side-step it by learning to make decisions about segmentation so as to maximise the performance of an unreliable machine translation system that operates optimally only on shorter segments of input Chinese text.

While numerous text segmentation techniques designed to improve machine translation have been proposed over the years (§5), these have typically

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 293–302
August 1–6, 2021.

been based on heuristics that capture linguistic or statistical notions about what "minimal translatable units" consist of. In Chinese, robustly identifying such units is particularly challenging, on account of the lack of overt tense and frequent argument dropping which deprive an annotator of important clues (Huang, 1984). In contrast, we formalise the segmentation problem as a series of classification decisions about whether or not to split at candidate segmentation boundaries and use reinforcement learning to train the segmentation policy to optimise the aggregate BLEU score that results from translating the resulting segments with a *particular* translation system. Our approach is therefore robust to the idiosyncrasies of the underlying translation system, it is capable of discovering a policy that deviates from perhaps unreliable intuitions about minimal translatable units, and it can easily be retrained as the translation system improves.

Experiments indicate that the proposed approach outperforms a baseline that carries out no sentence splitting other than at unambiguous points, a classification approach based on linguistic criteria, and a heuristic system used in prior work. Overall, we improve the BLEU score on the WMT2020 Chinese–English news translation task by 0.3 BLEU, but for segments consisting of more than 60 words, the BLEU score increases by 3 BLEU.

2 Problem setup

We setup segmentation problem as a Markov decision problem (MDP) whose state, actions and rewards are characterized as follows. Every example in the training dataset is treated as a new episode and the objective is to maximise the sentence level BLEU score of the translation.

- The action set $\mathcal{A} = \{\textsc{split}, \textsc{continue}\}$.
- The state representation at time t, $\mathbf{s}_t = [\boldsymbol{\phi}(x)_{1,\dots,n}]; [\mathbf{p}^{(t)}_{1,\dots,n}]$ where n is the length of the input sequence $\boldsymbol{x}$ in words, $\boldsymbol{\phi}(x_i)$ is a vector encoding of ith token in context, and $\mathbf{p}^{(t)}_i$ is a record of previous decisions taken by the classifier about split decisions. The decision state for each token at timestep t can take on 4 possible discrete values: **no punctuation** (no actions are taken on these), **undecided punctuation** (punctuation on which an action still needs to be taken), **un-split** punctuation and **split** punctuation. At each timestep t, an action is taken at the next immediate undecided punctuation from the left and the state update involves appropriately updating the punctuation marker (to unsplit or split) corresponding to that position. The episode is considered terminal when there are no unattended punctuation markers in the sentence.
- For our reward, we use $r_t = \text{BLEU}(\tau(\mathbf{s}_{t+1}), \boldsymbol{y}^*) - \text{BLEU}(\tau(\mathbf{s}_t), \boldsymbol{y}^*)$, the marginal difference added to BLEU score based on the current action decision similar to Wu et al. (2018). τ represents the translation of the source inputs constructed from the state definition, where we split the sentence according to the punctuation markers in $\mathbf{s}_t$, translate each segment independently and recombine the best translation of each segment. An action of no split yields 0 rewards as segments remain identical and splitting would produce positive or negative rewards depending on the improvement/degradation to the quality of the overall sentence translation. Marginal BLEU sums to the sentence level BLEU obtained on the full sequence of translations, but provides a denser reward signal which makes policy learning more efficient.

Network and Learning Algorithm. We learn optimal segmentation policies using a distributed deep RL algorithm, IMPALA (Espeholt et al., 2018) which provides data-efficient stable learning at high throughput by combining decoupled acting and learning. At each time-step, our policy receives a state $\mathbf{s}_t$ and defines a distribution over the discrete action set $\mathcal{A}$ – i.e. $\pi(s_t) : \mathbb{R}^n \rightarrow \mathcal{A}\{\textsc{split}, \textsc{continue}\}$. Our algorithm also employs a value network that learns the value of a state $V(s_t) : \mathbb{R}^n \rightarrow \mathbb{R}$, which is used to regularize the policy network. In this work, we use a transformer encoder with self-attention layers as an observation encoder and then apply a feed-forward classifier on this encoded observation to learn the policy's action distribution. More details on the network architecture can be found in Appendix A.

3 Experiments

Our experiments are carried out on the WMT2020 Chinese–English news translation task, which is subjected to the same pre-processing steps as described in (Yu et al., 2020). Figure 2 shows the distribution of the maximum number of possible segments that we could split for each given example in our test dataset if a model were to split on every available punctuation (comma and full-stop

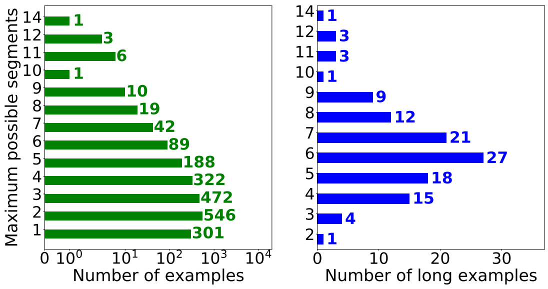

Figure 2: Distribution of maximum possible number of segments (if a model were to split on every available punctuation) for all the examples in the entire WMT Chinese–English test dataset and on long examples (source length ≥60 words) only. Note that the test dataset contains 2000 examples in total and 115 long examples.

in our case). We report case-sensitive BLEU, as computed with `sacrebleu` (Post, 2018). All the model/training details such as datasets, model architectures and hyperparameters pertaining to the baseline models are listed in Appendix B. We compare RLSEGMENT, our proposed solution's performance to six other baselines which help highlight different trade-offs involved in segmentation decisions for machine translation.

- NOSPLIT – Our key baseline that we wish to improve – a strategy of not doing any splits on the source inputs beyond unambiguous full stops.
- ALLSPLIT – An aggressive segmentation policy where we segment the source on every possible comma and full-stop.
- ORACLE – To compute the oracle score, we translate possible splits of a given source sentence and select the one that maximizes the example-level BLEU score. This benchmark is the upper limit of any segmentation policy, given a translation model. It is quite expensive to compute since it requires decoding all possible segmentations of every sequence.
- ORACLESUP – Oracle segmentation decisions from the training corpus are used to setup a supervised binary classification task with an architecture similar to RLSEGMENT's policy network.
- COMMACLASS – Using the syntactic patterns from the Penn Chinese Treebank 6.0, this system builds a comma classifier to disambiguate terminal and non-terminal commas similar to (Xue and Yang, 2011). This uses a transformer encoder followed by a positional feed-forward network to classify every comma.

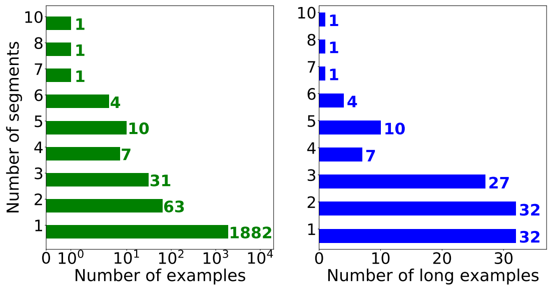

Figure 3: Distribution of number of segments split by our model RLSEGMENT on the entire WMT20 Chinese–English test dataset and on long examples (source length ≥60 words) only. Out of the 115 long examples, the model leaves 32 (28%) of them unsegmented and segments the rest into two or more segments.

Model	full BLEU	full BP	≥ 60 BLEU	≥ 60 BP
NOSPLIT (Baseline) [2000]	31.89	89.42	25.73	78.17
ALLSPLIT [6233]	29.45	93.18	27.88	94.43
ORACLESUP [3107]	31.57	90.89	27.66	88.02
COMMACLASS [2569]	31.82	89.98	26.93	81.16
HEURISTIC [2071]	32.02	89.59	27.05	80.80
RLSEGMENT (Ours) [2228]	**32.21**	**91.34**	**29.03**	**88.09**
ORACLE [3513]	*36.36*	*96.19*	*34.71*	*93.45*

Table 1: BLEU and brevity penalty scores, both on the corpus and long sentences only (source length ≥ 60 words) on the test dataset of WMT20 Chinese–English. Reported in square brackets are the number of segments independently translated under each policy.

- HEURISTIC – The uses a combination of predictions from COMMACLASS together with heuristic length constraints that only split long inputs (> 60 words) on terminal commas suggested by the model and terminal punctuations, and only if the resulting segments are not too short (> 10 words).

As discussed above, there is no standard segmentation of Chinese texts into sentences, and therefore all the "supervised" approaches—including our baselines ORACLESUP and HEURISTIC, construct their own training data to train a classifier. RLSEGMENT on the other hand, requires only a translation system and a corpus of standard parallel data for training and learns without any hand-engineered constraints on the model itself, thus presenting a generic solution that can scale across languages and system variants.

Figure 4: A example translation where segmentation with RLSEGMENT mitigates premature truncation in our system; material dropped by the baseline system is highlighted in grey.

4 Results

Figure 3 shows the distribution of segments proposed by our model RLSEGMENT. We see that a lot of the long sentences (source length ≥ 60 words) are split into two or more independent segments to mitigate premature truncation seen in transformer models with these long sentences. Table 1 compares different segmentation policies when translating the WMT20 Chinese–English news test dataset. While the BLEU scores indicate the quality of translations on the entire corpus, we also report BLEU scores on sources longer than 60 words as a metric to show the performance of these models on longer sentences where standard transformers tend to produce translations that are too short. In both the cases, we also report the brevity penalty (BP), a component of BLEU to show the impact on the overall length of the translation.

We see that our proposed segmentation policy, RLSEGMENT improves both the BLEU scores and brevity penalties as compared to the baseline translation case NOSPLIT. Specifically, the RL model improves BLEU scores on long sentences by 3+ BLEU points and BP on those sentences by about 9+ points. This shows that our model, via smart segmentation, suffers less because of premature truncation of long translations as compared to the baseline—a common problem (Meister et al., 2020; Koehn and Knowles, 2017). While segmentation of long sentences at appropriate punctuations helps performance, segmentation at all punctuations is expected to hurt performance as it is highly likely to produce extremely small segments which lose a lot of necessary source context when individually translated. This is demonstrated by poorer BLEU score of the ALLSPLIT baseline, even though it achieves good BP scores both on the corpus and long translations. Compared to supervised baselines trained on syntactic data such as COMMACLASS and HEURISTIC, our model performs competitively on both BLEU and BP without any supervised data for segmentation or hand-engineered length constraints. In Figure 4, we see an example where RLSEGMENT mitigates premature truncation of the resultant translation. In this example, although input (and resulting English translation) consists of three sentences separated by commas, the segmentation policy has only chosen to split at only *one* position, having learned that the underlying translation system is capable of translating some two-sentence inputs. This example thus illustrates the practicality of learning a segmentation policy based on the abilities of the underlying translation system, not just on the basis of normative notions of translatable units. (More examples can be found in Appendix C.1, C.2)

While our model does better than the baselines, there is a sufficient performance gap to the oracle BLEU scores (because of the different data/length characteristics between training and test time) that could be achieved via “perfect” segmentation, demonstrating the value for further research into better segmentation strategies. However, we also note that the RLSEGMENT outperforms ORACLESUP—especially on long sentences. We suspect this has to do with the relative scarcity of such examples in the training data—while a supervised learner can happily ignore those rare cases at little cost in terms of cross-entropy, they have an out-sized impact on BLEU, and therefore the RL learner is sensitive to them.

Finally, it is important to note that while RLSEG-

MENT improves BLEU at a corpus level, there exist cases where individual translation examples (Appendix C.3) are worse because of inappropriate segmentation.

5 Related Work

The segmentation of long texts and sentences into segments suitable for translation has been a recurring topic in machine translation research (Tien and Minh, 2019; Pouget-Abadie et al., 2014; Goh and Sumita, 2011; Doi and Sumita, 2003); however, we are the first to apply reinforcement learning to solve the problem. A related problem to the segmentation problem occurs in automated simultaneous interpretation, where the system must produce translations as quickly as possible, but it is necessary to wait until sufficient context has been received before an accurate translation can be produced. Grissom II et al. (2014) used an RL approach, targeting a reward that balances translation quality with translation latency.

Chinese comma disambiguation has likewise been studied. However, without exception these have sought to predict normative notions of what constitutes a complete clause or elementary discourse unit (Xu and Li, 2013; Xue and Yang, 2011; Jin et al., 2004), on the basis of syntactic annotations in the Chinese Treebank (Xue et al., 2005). In contrast, our solution is directly targeted at developing a segmentation strategy that results in a good downstream translation, rather than conforming to any single normative notion of what constitutes a complete sentence.

6 Conclusion

In this work, we have addressed a key challenge in Chinese-English machine translation : the ambiguity of English-like sentence boundaries in Chinese, resulting in long Chinese sentence data for machine translation tasks. Our solution casts the Chinese sentence segmentation problem into a sequential decision making problem and then uses Reinforcement Learning to learn an optimal segmentation policy to maximize the BLEU scores of the eventual translation from the independent segment translations. Our solution does not require any paired training data for segmentation and is able to learn an optimal strategy purely from paired machine translation data. Our model is able to outperform a baseline translation strategy that segments on only unambiguous full-stops by 0.3 BLEU at a corpus level and by 3 BLEU on a sub-corpus comprising only source sentences longer than 60 words.

A Data and Model details for RLSEGMENT

A.1 Dataset

We use the training, validation and test datasets from the WMT2020 Chinese-English constrained data provided to shared task participants. All the examples are aligned paired translations with sentence-like units provided as part of the dataset. Pre-processing of text is done in exactly the same methodology as described in Section 3 of (Yu et al., 2020). We also use the same `sentencepiece` tokenizer described in Section 3 of that work to convert the text into integer tokens. In total, we operate on a dataset with 18 million training examples, 1619 validation examples and 2000 test examples.

A.2 Translation Model

For all experiments and baselines, we use the same transformer model to translate any source input (Vaswani et al., 2017). The model used has 6 encoder layers and 2 decoder layers with 8 encoder and decoder attention heads each. The model uses a feed-forward layer of size 2048 and employs Multi-Query Attention layers (Shazeer, 2019) for faster inference. It uses different dropout values for different components: 0.1 for the attention, 0.05 in the feed-forward network, and finally 0.3 after the sub-layer. The other hyperparameters and learning rate schedules of the model are similar to those described in Section 4.1 of (Yu et al., 2020).

A.3 RL Models

The policy and value networks share common encoding layers, with different feed-forward networks on top of the shared encoder layer. The shared encoder consists of 2 stacked self-attention layers with 8 attention heads each and feed-forwards of size 512, with 0.1 as the rate for all attention, feed-forward and sub-layer dropouts. Sequence lengths for training were restricted to 280 tokens (maximum sentence length in the validation set is 277). The policy network applies a feed-forward network of sizes 256-2 on the outputs of the shared encoder and value network applies a feed-forward network of sizes 256-1. Adam optimizer with learning rate=0.0002, b1=0.0 and b2=0.99 was used for training. For the IMPALA style loss function (Espeholt et al., 2018), the weights of policy, baseline and entropy loss are set as 1.0, 0.5 and 0.0005 respectively. Key hyperparameters such as the weights of losses, learning rates and model sizes were tuned (a single trial for each hyperparameter configuration) using BLEU scores on the WMT20 Chinese–English validation dataset.

Bounds for hyperparameters - Number of attention layers [2,8], Number of attention heads [2,8], Size of feed-forward network [128, 2048], Learning rates [0.01, 0.00001], Weights of losses [0.0001, 1].

Compute and other details - For both inference and learning, we use 2x2 slices (4 TPUs) of Google TPU v2 with 2 cores per device (8 cores were split into 2 cores used for inference and 6 for learning). 512 actors on CPU were run in parallel to generate transition data for the distributed learner to learn from. Learning was done on 70 million episodes with a batch size of 256 per core and the entire experiment had an average run-time of approximately 6 hours.

B Data and Model details for BASELINES

All baseline models use the same inference model as described in Appendix A.2. All baselines are evaluated on the WMT20 Chinese–English test data as described in Appendix A.1. The baselines NOSPLIT, ALLSPLIT and ORACLE do not require any training data and are directly employed during test time.

B.1 COMMACLASS and HEURISTIC

Dataset - The comma classifier used in these baselines is trained on Chinese Treebank data prepared in the same format as described in (Xue and Yang, 2011).

Model - Both these baselines rely on a comma classifier model. In our experiments, this model uses a standard Transformer style encoder with a feed-forward classifier for Chinese comma disambiguation. It uses the encoder layers from a pre-trained transformer (which was trained on WMT20 Chinese–English translation task) since the Chinese Treebank dataset alone is small for training large models. The encoder of this model has 16 heads, 9 layers and a feed-forward size of 4096. On top of this encoder, a feed-forward classifier of size 512-128-2 is used for classification. The pre-trained encoders are further fine-tuned during classification. We use Adam Optimizer with a custom learning rate schedule similar to (Vaswani et al., 2017).

Bounds for hyperparameters - Number of attention layers [2,16], Number of attention heads [2,16], Size of feed-forward network [128, 4096], Learning rates [0.01, 0.00001].

B.2 ORACLESUP

Dataset - The ORACLESUP baseline uses WMT2020 Chinese-English data described in Appendix A.1. From this dataset, supervised labels were generated by splitting an example into its all possible splits on punctuations and then choosing the split set which optimized the BLEU score at an individual example level.

Model - This model uses the same network as the policy network described in Appendix A.3, but with 6 attention layers and 8 attention heads each. The model uses a learning rate schedule and Adam optimizer, similar to (Vaswani et al., 2017). The classes (No split:split - 1:2.2) were assigned different weights in the loss function to account for class imbalance in the data.

Bounds for hyperparameters - Number of attention layers [2,8], Number of attention heads [2,8], Size of feed-forward network [128, 2048], Learning rates [0.01, 0.00001], Weight for the split class [1,5].

Abstract

Transfer learning has become the dominant paradigm for many natural language processing tasks. In addition to models being pretrained on large datasets, they can be further trained on intermediate (supervised) tasks that are similar to the target task. For small Natural Language Inference (NLI) datasets, language modelling is typically followed by pretraining on a large (labelled) NLI dataset before fine-tuning with each NLI subtask. In this work, we explore Gradient Boosted Decision Trees (GBDTs) as an alternative to the commonly used Multi-Layer Perceptron (MLP) classification head. GBDTs have desirable properties such as good performance on dense, numerical features and are effective where the ratio of the number of samples w.r.t the number of features is low. We then introduce FreeGBDT, a method of fitting a GBDT head on the features computed during fine-tuning to increase performance without additional computation by the neural network. We demonstrate the effectiveness of our method on several NLI datasets using a strong baseline model (RoBERTa-large with MNLI pretraining). The FreeGBDT shows a consistent improvement over the MLP classification head.

1 Introduction

Recent breakthroughs in transfer learning ranging from semi-supervised sequence learning (Dai and Le, 2015) to ULMFiT (Howard and Ruder, 2018), ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019) have brought significant improvements to many natural language processing (NLP) tasks. Transfer learning involves pretraining neural networks, often based on the Transformer (Vaswani et al., 2017), on large amounts of text in a self-supervised manner in order to learn transferable language features useful for many NLP tasks. Pretraining is followed by fine-tuning the model on the target task. Pretrained models can also be further trained on intermediate labelled datasets which are similar to the target task before the final fine-tuning stage (Pruksachatkun et al., 2020). We refer to this as *intermediate supervised pretraining*. In this manner, the network learns more meaningful internal representations of the input text that are better aligned with the target task. In order to fine-tune the pretrained network, some latent representation of the text (e.g. the hidden state corresponding to the `[CLS]` token of BERT-like models) is used as the input to a *classification head*, usually a randomly initialised Multi-Layer Perceptron (MLP) (Wolf et al., 2019). The output of the classification head can then be interpreted as probability distribution over classes. The input to the classification head is referred to as *features* throughout the paper. It is a high-dimensional vector that serves as a rich, distributed representation of the input text.

We investigate whether replacing the commonly used MLP classification head with a GBDT (Friedman, 2001) can provide a consistent improvement, using NLI tasks as our use case. GBDTs are known for strong performance on dense, numerical features (Ke et al., 2019), which includes the hidden states in a neural network. The number of input features p, i.e. the dimension of the hidden state corresponding to the `[CLS]` token is not necessarily much larger than the number of samples n (it may even be smaller). GBDTs have proven effective for tasks where $n < p$ (Kong and Yu, 2018) and can be more effective compared to logistic regression if $n \ngtr p$ (Couronné et al., 2018). Therefore, for a language model that was trained on an intermediate supervised task before fine-tuning, we hypothesise that a GBDT may be able to outperform an MLP

classification head as the hidden states already encode information relevant to the target task at the start of fine-tuning. The head must learn to exploit this information exclusively during the fine-tuning stage in which the training data may consist of only a few samples. Our contributions are as follows:

- We integrate the GBDT into a near state-of-the-art (SOTA) language model as an alternative to an MLP classification head and train on the features extracted from the model *after* fine-tuning. We refer to it as standard GBDT.
- We introduce a method to train a GBDT on the features computed *during* fine-tuning, at no extra computational cost by the neural network, showing a consistent improvement over the baseline. We refer to it as **FreeGBDT**.

In the following, we recap different approaches to integrating tree-based methods with neural networks (Section 2). We introduce our FreeGBDT method in Section 3. We present our experimental setup in Section 4 and results on standard NLI benchmarks in Section 5. To conclude, we discuss improvements and limitations of our method in Section 6.

We release our code[1], implemented with LightGBM (Ke et al., 2017) and Huggingface's Transformers (Wolf et al., 2019), to the NLP community.

2 Related Work

Recent work on transfer learning in NLP has often been based on pretrained transformers, e.g. BERT (Devlin et al., 2019), XLNet (Yang et al., 2019), T5 (Raffel et al., 2020) and RoBERTa (Liu et al., 2019). These models are pretrained on large datasets using self-supervised learning, typically a variation of language modelling such as Masked Language Modelling (MLM). MLM consists of masking some tokens as in the Cloze task (Taylor, 1953). The objective of the model is to predict the masked tokens. Recently, approaches using alternatives to MLM such as Electra (Clark et al., 2020) and Marge (Lewis et al., 2020) have also been proposed. Pretraining transformers on large datasets aims to acquire the semantic and syntactic properties of language, which can then be used in downstream tasks. The models can additionally be trained in a supervised manner on larger datasets before being fine-tuned on the target task.

Natural Language Inference is one of the most canonical tasks in Natural Language Understanding (NLU) (Nie et al., 2020; Bowman et al., 2015). NLI focuses on measuring *commonsense reasoning* ability (Davis and Marcus, 2015) and can be seen as a proxy task that estimates the amount of transferred knowledge from the self-supervised phase of training. The task involves providing a *premise* (also called *context*) and a *hypothesis* that a model has to classify as:

- *Entailment*. Given the context, the hypothesis is correct.
- *Contradiction*. Given the context, the hypothesis is incorrect.
- *Neutral*. The context neither confirms nor disconfirms the hypothesis.

The task can also be formulated as binary classification between *entailment* and *not_entailment* (*contradiction* or *neutral*). We focus on NLI as a challenging and broadly applicable NLP task, with multiple smaller evaluation datasets being available as well as the large Multi-Genre Natural Language Inference corpus (Williams et al., 2018, MNLI), which is often used for effective intermediate pretraining (Liu et al., 2019). As such, it provides a testing ground for the GBDT classification head with intermediate supervised pretraining.

Tree-based methods Models based on decision trees have a long history of applications to various machine learning problems (Breiman et al., 1984). Ensembling multiple decision trees via bagging (Breiman, 1996) or boosting (Freund et al., 1999) further improves their effectiveness and remains a popular method for modelling dense numerical data (Feng et al., 2018). Ensemble methods such as Random Forests (Breiman, 2001) and GBDTs combine predictions from many weak learners, which can result in a more expressive model compared to an MLP. There have been several approaches to combining neural networks with tree-based models, approximately divided into two groups.

1. **Heterogeneous ensembling**: The tree-based model and the neural network are trained independently, then combined via ensembling techniques. *Ensembling* refers to any method to combine the predictions of multiple models such as *stacking* (Wolpert, 1992) or an arithmetic mean of the base models' predictions.

---

[1] Code will be available at `https://github.com/huawei-noah/free-gbdt`.

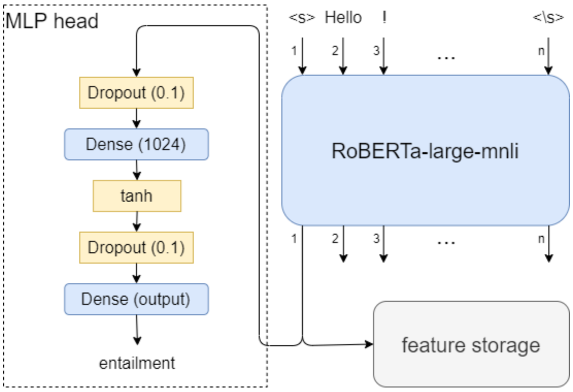

Figure 1: The baseline model architecture. Feature storage is populated *during* fine-tuning for the FreeGBDT but *after* fine-tuning for the standard GBDT method.

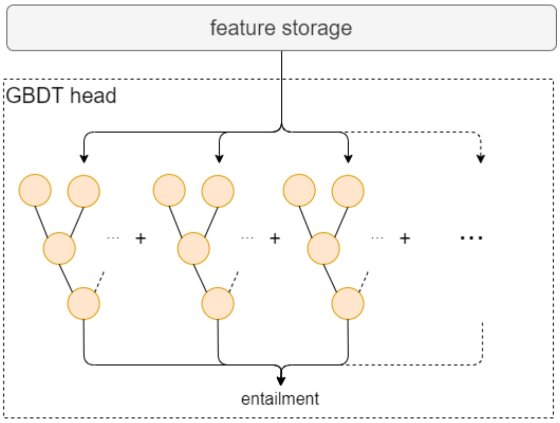

Figure 2: The GBDT classification head.

2. **Direct integration**: The tree-based model is jointly optimised with the neural network.

Heterogeneous ensembling (Li et al., 2019) has proven effective for many applications such as Online Prediction (Ke et al., 2019), Learning-to-Rank for Personal Search (Lazri and Ameur, 2018) and Credit Scoring (Xia et al., 2018). It is also suitable for multimodal inputs, e.g. text, images and/or sparse categorical features as some input types are better exploited by a neural network while others are amenable to tree-based models (Ke et al., 2019).

Direct integration makes the tree-based model compatible with back-propagation thus trainable with the neural network in an end-to-end manner. Examples include the Tree Ensemble Layer (Hazimeh et al., 2020), Deep Neural Decision Forests (Kontschieder et al., 2015) and Deep Neural Decision Trees (Yang et al., 2018). Deep Forests (Zhou and Feng, 2017) are also related although they aim to create deep non-differentiable models instead. Other examples include driving neural network fine-tuning through input perturbation (Bruch et al., 2020), which focuses specifically on using a tree ensemble to fine-tune the neural network representations.

As pretrained transformer-based models have recently achieved strong performance on various NLP tasks (Devlin et al., 2019), we see an opportunity to take advantage of their distributed representations by the means of using a tree-based model as the classification head. Our methods differ from direct integration in that they are not end-to-end differentiable. The training procedure is a sequence, i.e. the transformer-based model is fine-tuned first, then a GBDT is trained with features extracted from the model. We do not interfere with the model updates during training. Finally, the GDBT replaces the MLP classification head. Our approach is invariant to the method with which the neural network is fine-tuned as long as there exists a forward pass in which the features are computed. Recent methods for neural network fine-tuning include FreeLB (Zhu et al., 2020) and SMART (Jiang et al., 2020). FreeLB is an adversarial method, which perturbs the input during training via gradient ascent steps to improve robustness. SMART constrains the model updates during fine-tuning with smoothness-inducing regularisation in order to reduce overfitting. These approaches could theoretically be combined with both the standard GBDT and the FreeGBDT.

3 Methodology

We introduce the standard GBDT (Algorithm 1) and the FreeGBDT (Algorithm 2), our new method of using features generated during fine-tuning. *Features* refers to the hidden state corresponding to the `[CLS]` token of BERT-like pretrained models. We use these features as training data for the GBDT and FreeGBDT.

3.1 The standard GBDT classification head

In order to train the standard GBDT, we apply the feature extraction procedure shown in Algorithm 1. Using the fine-tuned neural network, we perform one additional forward pass over each sample in the training data. We store the features as training data for the GBDT, denoted 'feature storage' in Figures 1 and 2. The GBDT can be then used as a substitute for the MLP classification head.

Algorithm 1 Standard GBDT training procedure. Features are extracted after fine-tuning.

```
Require: training data $X$, pretrained network $f_p$ parametrised by $\theta_p$, classification head $f_h$ parametrised by $\theta_h$.
  for $epoch = 1..N_{epochs}$ do
    for minibatch $(X_b, y_b) \subset X$ do
      $cls \leftarrow f_p(X_b, \theta_p)$
      $y_{pred} \leftarrow f_h(cls, \theta_h)$
      $loss \leftarrow LossFn(y_{pred}, y_b)$
      update $\theta_h$ and $\theta_p$ via backpropagation of $loss$
    end for
  end for

  $features \leftarrow$ empty list
  $labels \leftarrow$ empty list

  for minibatch $(X_b, y_b) \subset X$ do
    $cls \leftarrow f_p(X_b, \theta_p)$
    extend $features$ with $cls$
    extend $labels$ with $y_b$
  end for

  $gbdt \leftarrow train_{gbdt}(features, labels)$
```

3.2 The FreeGBDT classification head

Instead of extracting features once after fine-tuning, the training data for the proposed FreeGBDT is obtained *during* fine-tuning. The features computed in every forward pass of the neural network are stored as training data, shown in Algorithm 2. As no additional computation by the neural network is required, this new classification head is called *FreeGBDT*. Accumulating features in this manner allows the FreeGBDT to be trained on $N \times E$ samples while the standard GBDT is trained on N samples where N is the size of the dataset and E is the number of fine-tuning epochs.

Corpus	Train	Dev	Test	Classes

Table 1: NLI evaluation datasets. The tasks with 3 classes contain labels: *entailment*, *neutral* and *contradiction*, tasks with 2: *entailment* and *not_entailment*.

Algorithm 2 FreeGBDT training procedure. Features are accumulated throughout fine-tuning.

```
Require: training data $X$, pretrained network $f_p$ parametrised by $\theta_p$, classification head $f_h$ parametrised by $\theta_h$.
  $features \leftarrow$ empty list
  $labels \leftarrow$ empty list

  for $epoch = 1..N_{epochs}$ do
    for minibatch $(X_b, y_b) \subset X$ do
      $cls \leftarrow f_p(X_b, \theta_p)$
      extend $features$ with $cls$
      extend $labels$ with $y_b$
      $y_{pred} \leftarrow f_h(cls, \theta_h)$
      $loss \leftarrow LossFn(y_{pred}, y_b)$
      update $\theta_h$ and $\theta_p$ via backpropagation of $loss$
    end for
  end for

  $gbdt \leftarrow train_{gbdt}(features, labels)$
```

4 Experimental Setup

We now describe the featured models, details of training procedures and evaluation datasets.

4.1 Datasets

We evaluate our methods on the following NLI datasets, summarised in Table 1.

- Adversarial NLI (ANLI) (Nie et al., 2020). This corpus consists of three rounds of data collection. In each round, annotators try to break a model trained on data from previous rounds. We use the concatenation of R1, R2 and R3.
- Counterfactual NLI (CNLI) (Kaushik et al., 2020). The CNLI corpus consists of counterfactually-revised samples of SNLI (Bowman et al., 2015). We use the full dataset i.e. samples with the revised premise and with the revised hypothesis.
- Recognising Textual Entailment (RTE) (Wang et al., 2019b). We use the data and format as used in the GLUE benchmark: a concatenation of RTE1 (Dagan et al., 2006), RTE2 (Bar Haim et al., 2006), RTE3 (Giampiccolo et al., 2007) and RTE5 (Bentivogli et al., 2009), recast as a binary classification task between *entailment* and *not_entailment*.

Method	CB	RTE	CNLI	ANLI	QNLI
MLP head	93.57 (2.2)	89.51 (0.8)	82.49 (0.8)	57.56 (0.5)	**94.32 (0.1)**
standard GBDT	94.11 (1.7)	89.33 (0.8)	80.84 (0.9)	57.22 (0.5)	94.29 (0.1)
FreeGBDT	**94.20 (1.7)**	**89.69 (0.8)**	**82.53 (0.7)**	**57.63 (0.5)**	94.30 (0.1)

Table 2: Mean Accuracy (Standard Deviation) on the development sets from 20 runs with different random seeds. A Wilcoxon signed-rank test conducted across all five datasets confirms significance with $p \approx 0.01$ c.f. Section 5.

- CommitmentBank (CB) (de Marneffe et al., 2019). We use the subset of the data as used in SuperGLUE (Wang et al., 2019a).
- Question-answering NLI (QNLI) (Demszky et al., 2018). This is a converted version of the Stanford Q&A Dataset (Rajpurkar et al., 2016), aiming to determine whether a given context contains the answer to a question.

4.2 Model and Training

We start all experiments from the RoBERTa-large model (Liu et al., 2019) with intermediate pretraining on the Multi-Genre Natural Language Inference (MNLI) corpus (Williams et al., 2018). The MNLI checkpoint is provided by the fairseq[2] library (Ott et al., 2019). Note that no task-specific tuning of hyperparameters was performed. Instead, we use one learning rate cycle (Smith, 2017) with a maximum learning rate of 1×10^{-5} for each task to fine-tune RoBERTa for 10 epochs with a batch size of 32. We use the Adam optimiser (Kingma and Ba, 2015) to optimise the network. In order to compare the FreeGBDTs with standard GBDTs, we apply Algorithm 1 and Algorithm 2 during the same fine-tuning session to eliminate randomness from different model initialisations.

We use LightGBM[3] to train the GBDT. We do not manually shuffle the data before training. The individual trees of a GBDT are learned in a sequence where each tree is fit on the residuals of the previous trees. One important parameter of the GBDT is thus the number of trees to fit. This is commonly referred to as *boosting rounds*.

We observe that the optimal number of boosting rounds varies significantly across tasks, with a tendency towards more boosting rounds for larger datasets. Thus, we select the number of boosting rounds from the set $\{1, 10, 20, 30, 40\}$ for each task. This is the only task-specific hyperparameter in our experiments. The hyperparameters are identical for the standard GBDT and the FreeGBDT, shown in Table 3, the model shown in Figure 2. The time it takes to train the standard GBDT and the FreeGBDT is negligible compared to the time it takes to fine-tune the RoBERTa model.

Parameter	CB	RTE	CNLI	ANLI	QNLI
learning rate	0.1	0.1	0.1	0.1	0.1
max. leaves	256	256	256	256	256
boosting rounds	10	10	10	40	30

Table 3: Hyperparameters of the standard GBDT and the FreeGBDT. All other hyperparameters are set to the default value as per LightGBM version 2.3.1.

4.3 Evaluation

Development set We evaluate our methods using accuracy. Each experiment is repeated 20 times with different random seeds. We report the mean and standard deviation.

Test set For each task, we train the GBDT with the following boosting rounds: $\{1, 10, 20, 30, 40\}$. We select the GBDT with the best score on the development set. Test scores are obtained with a submission to the SuperGLUE benchmark[4] for CB and the GLUE benchmark[5] for RTE and QNLI. We calculate the test scores on ANLI and CNLI ourselves as the test labels are publicly available. We report accuracy on the test set for each task except for CB, where we report the mean of F1 Score and Accuracy, same as the SuperGLUE leaderboard.

5 Results and Analysis

We summarise the results on the development sets in Table 2. The FreeGBDT is compared with a standard GBDT and the MLP classification head. The standard GBDT achieves a higher score than the MLP head on 1 out of 5 tasks. The FreeGBDT outperforms the standard GBDT on 5 out of 5 tasks and the MLP head on 4 out of 5

[5] `https://gluebenchmark.com/`

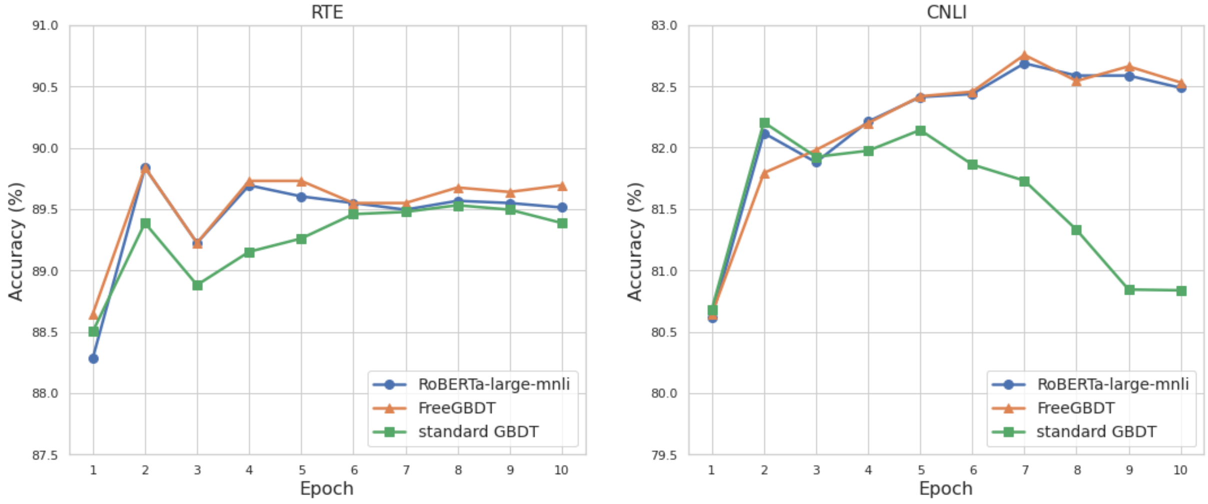

Figure 3: Accuracy on RTE and CNLI development sets. Training is paused after each epoch to compare the GBDT, FreeGBDT and MLP heads. We plot the mean from 20 runs (same hyperparameters but different seeds).

tasks. As recommended for statistical comparison of classifiers across multiple datasets (Demšar, 2006) we conduct a Wilcoxon signed-rank test (Wilcoxon, 1992) with the accuracy differences between the FreeGBDT and the MLP across the 20 seeds and 5 datasets. The test confirms that the improvement from our FreeGBDT method is significant with $p \approx 0.01$.

Method	**CB**	**RTE**	**CNLI**	**ANLI**	**QNLI**
MLP head	92.9	87.5	83.6	57.4	**94.3**
GBDT	91.3	87.5	82.1	57.2	**94.3**
FreeGBDT	**93.3**	**87.8**	**83.7**	**57.6**	**94.3**

Table 4: Results on the test sets.

Results on the test sets are shown in Table 4. The FreeGBDT achieves a small but consistent improvement over the MLP head on each task except QNLI. This task is not a conventional NLI task but a question-answering task converted to an NLI format (Demszky et al., 2018). It has been shown that QNLI does not benefit from MNLI pretraining (Liu et al., 2019) hence this result is not unexpected. Out of the four datasets which do benefit from MNLI pretraining, the FreeGBDT improves over the MLP head on each one with an average score difference of +0.23%. As our experiments start from a competitive baseline, RoBERTa-large with MNLI pretraining, we consider the results important because (a) to the best of our knowledge, this is the first tree-based method that achieves near state-of-the-art performance on benchmark NLI tasks and (b) our method is 'free' as it requires no additional computations by the model. We were able to demonstrate that a FreeGBDT head can be successfully integrated with modern transformers and is a good alternative to the commonly used MLP classification head.

For the Adversarial NLI (ANLI) dataset, we report results which are competitive with the state-of-the-art shown in Table 5, surpassing both SMART (Jiang et al., 2020) and ALUM (Liu et al., 2020). The RoBERTa-large model pretrained with SNLI, MNLI, FEVER (Thorne et al., 2018) and ANLI reported 53.7% accuracy on the ANLI test set (Nie et al., 2020). The state-of-the-art result of 58.3% accuracy on the ANLI dataset was achieved by InfoBERT (Wang et al., 2021). The FreeGBDT achieves a new state-of-the-art on the A2 subset of ANLI with 52.7%. Interestingly, it does not yield an improvement on the easier A1 subset but compares favourably to other recent approaches on the more difficult A2 and A3 subsets of ANLI.

To better understand how performance of the GBDTs evolves during fine-tuning, we carry out an additional experiment. We pause training after each epoch to extract features and train a standard GBDT. We compare it with the MLP classification head and a FreeGBDT trained on the features accumulated up to the current epoch. The result on the RTE and CNLI datasets is shown in Figure 3. Notably, the FreeGBDT does not improve on the standard GBDT after the first epoch where the number of instances the GBDT is trained on is

Method	**A1**	**A2**	**A3**	**All**
RoBERTa-large-mnli *(ours)*	72.0	52.5	49.4	57.4
RoBERTa-large-mnli + GBDT *(ours)*	72.1	52.2	49.0	57.2
SMART (Jiang et al., 2020)	72.4	49.8	**50.3**	57.1
ALUM (Liu et al., 2020)	72.3	52.1	48.4	57.0
InfoBERT (Wang et al., 2021)	**75.0**	50.5	49.8	**58.3**
RoBERTa-large-mnli + FreeGBDT *(ours)*	71.9	**52.7**	49.7	57.6

Table 5: Accuracy across different rounds of the ANLI test set. *All* denotes a sample-weighted average. Our FreeGBDT achieves SOTA on the A2 subset. InfoBERT (Wang et al., 2021) is the SOTA on the full test set.

equal to the size of the training dataset for both. As the FreeGBDT starts accumulating more training data, however, it consistently outperforms the standard GBDT and eventually, the MLP head.

The state-of-the-art in NLI provides some context for our method of combining tree-based models with modern neural networks. RoBERTa (large with MNLI pretraining) reports 89.5% accuracy on the development set of RTE (Liu et al., 2019) and 94.7% accuracy on the development set of QNLI. The same model obtains an F1 Score / Accuracy of $90.5/95.2$ on the CB test set and an accuracy of 88.2% on the RTE test set. Note that ensembles of 5 to 7 models (Liu et al., 2019) were used while our test figures achieve similar scores of $91.3/95.2$ for CB and 87.8% for RTE with a *single* model. These are not direct comparisons, however, the figures demonstrate that FreeGBDT can operate at SOTA levels while matching and exceeding the 'default' MLP head classifier accuracy. Across all datasets, the FreeGBDT improves by an average of 0.2% and 0.5% over the MLP head and the standard GBDT head, respectively.

6 Discussion

The FreeGBDT improves over the MLP head on each task where intermediate supervised pretraining on MNLI is effective. The improvement is significant but not large. This is expected since the input features of the classification head are already a highly abstract representation of the input. Thus, there is limited potential for improvement. However, our results show that a tree-based method is a viable alternative to the commonly used MLP head and can improve over a baseline chosen to be as competitive as possible. Notably, the FreeGBDT improves the MLP baseline on the CB dataset by $> 0.6\%$ solely by switching to our tree-based classification head.

Furthermore, the FreeGBDT outperforms a standard GBDT by a large margin in some cases. For instance, we observe a +1.5% improvement on the CNLI dataset. Figure 3 shows the gap forming towards the end of training. We think this may be due to overfitting to the training data. Recall that the standard GBDT is trained only on features extracted *after* fine-tuning. At this point, the features may exhibit a higher degree of memorisation of the training data. The FreeGBDT is able to mitigate this problem as it was trained with features collected throughout training. Let $f(x, \theta_t)$ denote a mapping from the input text x to the output space parameterised by θ_t where $t \in \{0..T\}$ and T is the total amount of steps the model is fine-tuned for. Then, the standard GBDT is trained on features from $f(x, \theta_T)$, while the FreeGBDT is trained on features from every t in $\{0..T\}$. As such, it may help to think of the FreeGBDT as a type of regularisation through data augmentation (from the FreeGBDT's point of view), having trained on several perturbed views of each training instance.

Figure 4 helps illustrate the regularisation effect by showing the differences between the FreeGBDT and standard GBDT training data beyond just size. The figure shows the temporal changes in a typical feature collected during fine-tuning and the same feature extracted after fine-tuning. We can see that the distribution gradually changes from earlier epochs but remains similar to the distribution of the feature at the end of fine-tuning. FreeGBDT is able to exploit the information at the start of fine-tuning as the features at $t = 0$ already encode information highly relevant to the target task hence all training data is useful. The FreeGBDT head compares favourably to an MLP head, which is randomly initialized at the start of the fine-tuning

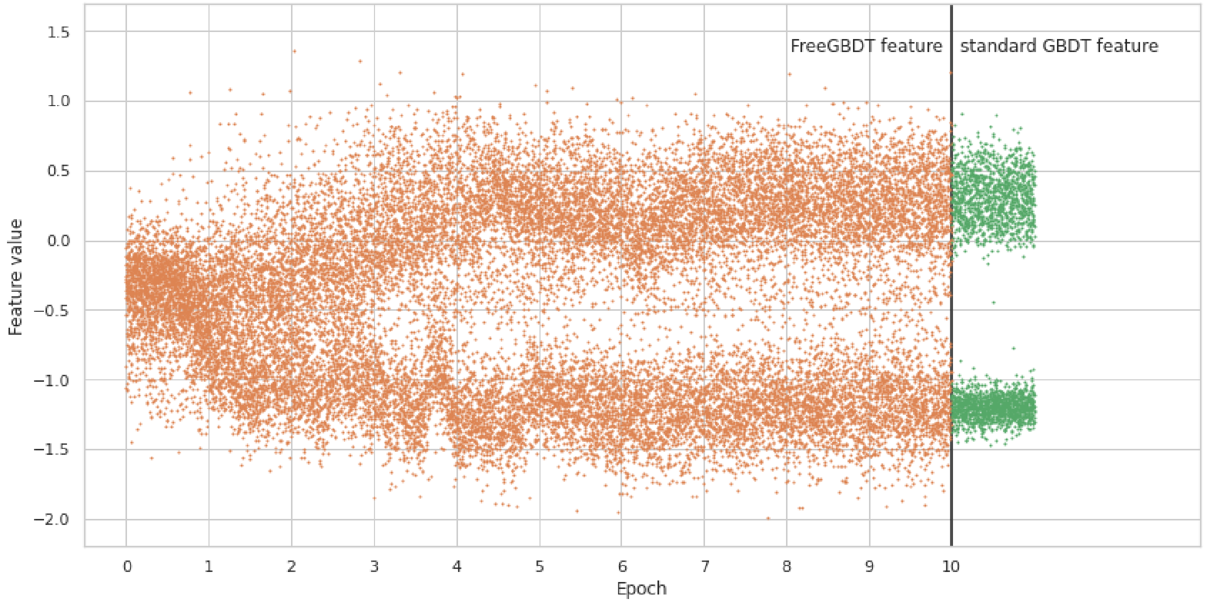

Figure 4: Values of a typical dimension from the 1,024 dimensional vector stored *during* fine-tuning to train a FreeGBDT (left). The same dimension extracted *after* fine-tuning to train a standard GBDT (right).

stage and must thus learn to exploit the latent information from a potentially small amount of training examples. Therefore, we believe intermediate supervised pretraining is essential for the effectiveness of the FreeGBDT, supported by the results from preliminary experiments on the BoolQ dataset (Clark et al., 2019) and QNLI, which does not benefit from pretraining on MNLI (Liu et al., 2019) where FreeGBDT matches the accuracy of the MLP head but does not exceed it. Our experiments also suggest that the potential for improvement from FreeGBDT depends on the size of the training dataset. The gap between FreeGBDT and the MLP head in Table 4 is larger for the smaller datasets CB and RTE and smaller for the larger datasets (ANLI, CNLI, QNLI). This is consistent with prior work showing that GBDTs are especially effective compared to other methods if $n \ggg p$ (Couronné et al., 2018) and hints that the FreeGBDT method might be especially useful for smaller datasets.

7 Future Work

One possible avenue for future work is exploring different features to train the GBDT, e.g. the hidden states from different layers of the pretrained model. This includes new combinations of top layer representations of the Transformer to generate richer input features for the classification head. This could lead to potential improvement by leveraging a less abstract representation of the input. Given that our method operates on distributed representations from a pretrained encoder, applications in other domains such as Computer Vision may be possible, e.g. using features extracted from a ResNet (He et al., 2016) encoder. Furthermore, a GBDT might not be the best choice for each task hence the use of Random Forests (Breiman, 2001) or Support Vector Machines (Cortes and Vapnik, 1995) may also be evaluated to investigate the effectiveness of combining Transformer neural networks with traditional supervised learning methods.

8 Conclusion

State-of-the-art transfer learning methods in NLP are typically based on pretrained transformers and commonly use an MLP classification head to fine-tune the model on the target task. We have explored GBDTs as an alternative classification head due to their strong performance on dense, numerical data and their effectiveness when the ratio of the number of samples w.r.t the number of features is low. We have shown that tree-based models can be successfully integrated with transformer-based neural networks and that the free training data generated during fine-tuning can be leveraged to improve model performance with our proposed FreeGBDT classification head. Obtaining consistent improvements over the MLP head on several NLI tasks confirms that tree-based learners are relevant to state-of-the-art NLP.

Empirical Error Modeling Improves Robustness of Noisy Neural Sequence Labeling

Marcin Namysl[1,2], **Sven Behnke**[1,2], and **Joachim Köhler**[1]

Abstract

Despite recent advances, standard sequence labeling systems often fail when processing noisy user-generated text or consuming the output of an Optical Character Recognition (OCR) process. In this paper, we improve the noise-aware training method by proposing an empirical error generation approach that employs a sequence-to-sequence model trained to perform translation from error-free to erroneous text. Using an OCR engine, we generated a large parallel text corpus for training and produced several real-world noisy sequence labeling benchmarks for evaluation. Moreover, to overcome the data sparsity problem that exacerbates in the case of imperfect textual input, we learned noisy language model-based embeddings. Our approach outperformed the baseline noise generation and error correction techniques on the erroneous sequence labeling data sets. To facilitate future research on robustness, we make our code, embeddings, and data conversion scripts publicly available.

1 Introduction

Deep learning models have already surpassed human-level performance in many Natural Language Processing (NLP) tasks[1]. Sequence labeling systems have also reached extremely high accuracy (Akbik et al., 2019; Heinzerling and Strube, 2019). Still, NLP models often fail in scenarios, where non-standard text is given as input (Heigold et al., 2018; Belinkov and Bisk, 2018).

NLP algorithms are predominantly trained on error-free textual data but are also employed to process user-generated text (Baldwin et al., 2013; Derczynski et al., 2013) or consume the output of prior Optical Character Recognition (OCR) or Automatic Speech Recognition (ASR) processes (Miller et al., 2000). Errors that occur in any upstream component of an NLP system deteriorate the accuracy of the target downstream task (Alex and Burns, 2014).

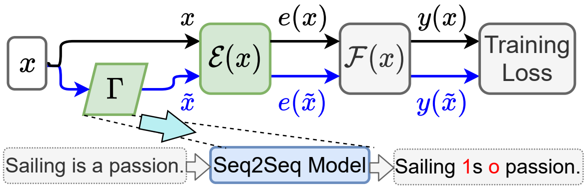

Figure 1: Our modification of the NAT approach (green boxes). We propose a learnable seq2seq-based error generator and re-train FLAIR embeddings using noisy text to improve the accuracy of noisy neural sequence labeling. Γ is a process that induces noise to the input x producing erroneous $\tilde{x}$. $\mathcal{E}(x)$ is an embedding matrix. $\mathcal{F}(x)$ is a sequence labeling model. $e(x)$ and $e(\tilde{x})$ are the embeddings of x and $\tilde{x}$, respectively. $y(x)$ and $y(\tilde{x})$ are the outputs of the model for x and $\tilde{x}$, respectively.

In this paper, we focus on the problem of performing sequence labeling on the text produced by an OCR engine. Moreover, we study the transferability of the methods learned to model OCR noise to the distribution of the human-generated errors. Both misrecognized and mistyped text pose a challenge for the standard models trained using error-free data (Namysl et al., 2020).

We make the following contributions (Figure 1):

- We propose a noise generation method for OCR that employs a sequence-to-sequence (seq2seq) model trained to translate from error-free to erroneous text (§4.1). Our approach improves the accuracy of noisy neural sequence labeling compared to prior work (§6.1).

- We present an unsupervised parallel training data generation method that utilizes an OCR engine (§4.2). Similarly, realistic noisy versions of popular sequence labeling data sets can be synthesized for evaluation (§5.5).

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 314–329
August 1–6, 2021. ©2021 Association for Computational Linguistics

- We exploit erroneous text to perform Noisy Language Modeling (NLM; §4.5). Our NLM embeddings further improve the accuracy of noisy neural sequence labeling (§6.3), also in the case of the human-generated errors (§6.4).
- To facilitate future research on robustness, we integrate our methods into the Noise-Aware Training (NAT) framework (Namysl et al., 2020) and make our code, embeddings, and data conversion scripts publicly available.[2]

2 Related Work

Errors of OCR, ASR, and other text generators always pose a challenge to the downstream NLP systems (Lopresti, 2009; Packer et al., 2010; Ruiz et al., 2017). Hence, methods for improving robustness are becoming increasingly popular.

Data Augmentation A widely adopted method of providing robustness to non-standard input is to augment the training data with examples perturbed using a model that mimics the error distribution to be encountered at test time (Cubuk et al., 2019).

Apparently, the exact modeling of noise might be impractical or even impossible—thus, methods that employ randomized error patterns for training recently gained increasing popularity (Heigold et al., 2018; Lakshmi Narayan et al., 2019). Although trained using synthetic errors, these methods are often able to achieve moderate improvements on data from natural sources of noise (Belinkov and Bisk, 2018; Karpukhin et al., 2019).

Spelling- and OCR Post-correction The most widely used method of handling noisy text is to apply error correction on the input produced by human writers (*spelling correction*) or the output of an upstream OCR component (*OCR post-correction*).

A popular approach applies *monotone seq2seq* modeling for the correction task (Schnober et al., 2016). For instance, Hämäläinen and Hengchen (2019) proposed *Natas*—an OCR post-correction method that uses character-level Neural Machine Translation (NMT). They extracted parallel training data using embeddings learned from the erroneous text and used it as input to their translation model.

Grammatical Error Correction Grammatical Error Correction (GEC; Ng et al., 2013, 2014; Bryant et al., 2019) aims to automatically correct ungrammatical text. GEC can be approached as a translation from an ungrammatical to a grammatical language, which enabled NMT seq2seq models to be applied to this task (Yuan and Briscoe, 2016). Due to the limited size of human-annotated GEC corpora, NMT models could not be trained effectively (Lichtarge et al., 2019), though.

Several studies investigated generating realistic erroneous sentences from grammatically correct text to boost training data (Kasewa et al., 2018; Grundkiewicz et al., 2019; Choe et al., 2019; Qiu and Park, 2019). Inspired by *back-translation* (Sennrich et al., 2016; Edunov et al., 2018), Artificial Error Generation (AEG) approaches (Rei et al., 2017; Xie et al., 2018) train an intermediate model in reverse order—to translate correct sentences to erroneous ones. Following AEG, we generate a large corpus of clean and noisy sentences and train a seq2seq model to produce rich and diverse errors resembling the natural noise distribution (§3.3, 4.2).

Noise-Invariant Latent Representations Robustness can also be improved by encouraging the models to learn a similar latent representation for both the error-free and the erroneous input.

Zheng et al. (2016) introduced *stability training*—a general method used to stabilize predictions against small input perturbations. Piktus et al. (2019) proposed *Misspelling Oblivious Embeddings* that embed the misspelled words close to their error-free counterparts. Jones et al. (2020) developed *robust encodings* that balance stability (consistent predictions across various perturbations) and fidelity (accuracy on unperturbed input) by mapping sentences to a smaller discrete space of encodings. Although their model improved robustness against small perturbations, it decreased accuracy on the error-free input.

Recently, Namysl et al. (2020) proposed the Noise-Aware Training method that employs stability training and data augmentation objectives. They exploited both the error-free and the noisy samples for training and used a *confusion matrix-based* error model to imitate the errors. In contrast to their approach, we employ a more realistic empirical error distribution during training (§3.3) and observe improved accuracy at test time (§6.1).

3 Problem Definition

3.1 Noisy Neural Sequence Labeling

Namysl et al. (2020) pointed out that the standard NLP systems are generally trained using error-free

---

[2] `https://github.com/mnamysl/nat-acl2021`

textual input, which causes a discrepancy between the training and the test conditions. These systems are thus more susceptible to non-standard, corrupted, or adversarial input.

To model this phenomenon, they formulated the *noisy neural sequence labeling* problem, assuming that every input sentence might be subjected to some unknown token-level noising process $\Gamma = P(\tilde{x}_i|x_i)$, where x_i is the original i-th token, and $\tilde{x}_i$ is its distorted equivalent. As a solution, they proposed the NAT framework, which trains the sequence labeling model using auxiliary objectives that exploit both the original sentences and their copies corrupted using a noising process that imitates the naturally occurring errors (Figure 1).

3.2 Confusion Matrix-Based Error Model

Namysl et al. (2020) used a confusion matrix-based method to model insertions, deletions, and substitutions of characters. Given a corpus of paired noisy and manually corrected sentences $\mathcal{P}$, they estimated the natural error distribution by calculating the alignments between the pairs $(\tilde{x}, x) \in \mathcal{P}$ of noisy and clean sentences using the *Levenshtein distance* metric (Levenshtein, 1966).

Moreover, as $\mathcal{P}$ is usually laborious to obtain, they proposed a *vanilla error model*, which assumes that all types of edit operations are equally likely:

$$\sum_{\tilde{c}\in\Sigma\setminus\{\varepsilon\}} P_{ins}(\tilde{c}|\varepsilon) = P_{del}(\varepsilon|c) = \sum_{\tilde{c}\in\Sigma\setminus\{c,\varepsilon\}} P_{subst}(\tilde{c}|c),$$

where c and $\tilde{c}$ are the original and the perturbed characters, respectively, Σ is an alphabet, and ε is a symbol introduced to model insertion and deletions.

3.3 Realistic Empirical Error Modeling

Namysl et al. (2020) compared the NAT models that used the vanilla- and the empirically-estimated confusion matrix-based error model and observed no advantages of exploiting the test-time error distribution during training. *Would we make the same observation given a more realistic error model?*

Even though the methods that used randomized error patterns were often successful, we argue that leveraging the empirical noise distribution for training would be beneficial, providing additional accuracy improvements. The data produced by the naïve noise generation methods may not resemble naturally occurring errors, which could lead the downstream models to learn misleading patterns.

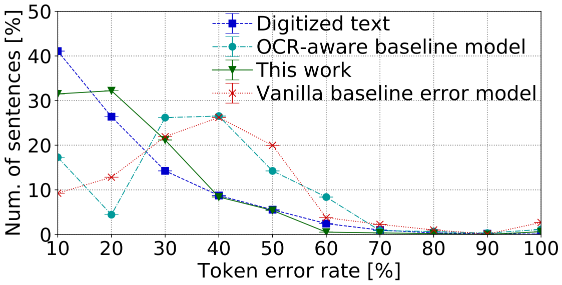

Figure 2: Distributions of the token error rates of sentences produced by the proposed and the baseline error models. For comparison, we plot the distribution of error rates in the text that contains naturally occurring errors. Each value n is the percentage of sentences with a token error rate in $[n-10, n)$.

In Figure 2, we compare the distributions of error rates of sentences produced by the proposed and the prior noise models with the distribution of errors in the digitized text. We can observe that the distribution of naturally occurring errors follows Zipf's law, while the baseline noise models produce Bell-shaped curves. Interestingly, both the vanilla and the empirical models exhibit similar characteristics, which could explain the observations from the prior work. In practice, the error rate is not uniform throughout the text. Some passages are recognized perfectly, while others can barely be deciphered. Our objective is thus to develop a noise model that produces a smoother distribution, imitating the errors encountered at test time more precisely (cf. *This work* in Figure 2).

Moreover, although the exact noise distribution in the test data cannot always be known beforehand, the noising process, e.g., an OCR engine, used to provide the input, can often be identified. We would thus take advantage of such prior knowledge to improve the efficiency of the downstream task.

3.4 Data Sparsity of Natural Language

Embeddings pre-trained on a large corpus of monolingual text are ubiquitous in NLP (Mikolov et al., 2013; Peters et al., 2018; Devlin et al., 2019). They capture syntactic and semantic textual features that can be exploited to solve higher-level NLP tasks.

Embeddings are generally trained using corpora that contain error-free text. Due to the data sparsity problem that arises from the large vocabulary sizes and the exponential number of feasible contexts, the majority of possible word sequences do not appear in the input data. Even though increasing the size of the training corpora was shown to improve the performance of language processing tasks (Brown et al., 2020), most of the misrecognized or mistyped tokens would still be unobserved and therefore poorly modeled when using the error-free text only. *Would it be beneficial to pre-train the embeddings on data that includes realistic erroneous sentences?*

3.5 The Flaws of Error Correction

Furthermore, we believe that the correction methods, although widely adopted, can only reliably manage moderately perturbed text (Flor et al., 2019). OCR post-correction has been reported to be challenging in the case of historical books that exhibit high OCR error rates (Rigaud et al., 2019).

We note that correction methods have no information about the downstream task to be performed. Moreover, in the automatic correction setting, they only provide the best guess for each token. Comparing their performance with the NAT approach in the context of sequence labeling would be informative.

4 Empirical Error Modeling

Figure 1 presents our modifications of the NAT framework. Firstly, we propose to replace the confusion matrix-based noising process (§3.2) with a noise induction method that generates a more realistic error distribution (§4.1-4.4). Secondly, to overcome the data sparsity problem (§3.4), we train language model-based embeddings using digitized text and use them as a substitution of the pre-trained model used in prior work (§4.5).

4.1 Sequence-to-Sequence Error Generator

Motivated by the AEG approaches (Rei et al., 2017; Xie et al., 2018), we propose a learnable error generation method that employs a character-level seq2seq model to perform monotone string translation (Schnober et al., 2016). It directly models the conditional probability $p(\tilde{x}|x)$ of mapping error-free text x into erroneous text $\tilde{x}$ using an attention-based encoder-decoder framework (Bahdanau et al., 2015). The encoder computes the representation $h=\{h_1, \ldots, h_n\}$ of x, where n is the length of x. The decoder generates $\tilde{x}$ one token at a time:

$$p(\tilde{x}|x) = \prod_{i=1}^{n} p(\tilde{x}_i|\tilde{x}_{<i}, x, c),$$

where $c=f_{attn}(\{h_1, \ldots, h_n\})$ is a vector generated from h, and f_{attn} is an attention function.

Our models are trained to maximize the likelihood of the training data. At inference time, we randomly sample the subsequent tokens from the learned conditional language model.

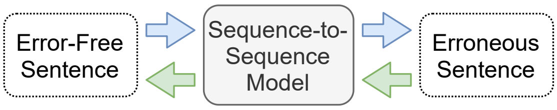

Figure 3: Schematic visualization of the error generation (blue arrows) and the error correction (green arrows) methods. The parallel data can be utilized to train seq2seq models for both tasks.

Note that our approach reverses the standard seq2seq error correction pipeline, which uses the erroneous text as input and trains the model to produce the corresponding error-free string (Figure 3). By interchanging the input and the output data, we can also readily train sentence correction models. One difference is that at inference time we would prefer to perform beam search and select the best decoding result rather than sampling subsequent characters from the learned distribution.

4.2 Unsupervised Parallel Data Generation

To train our error generation model (§4.1), we need a large parallel corpus $\mathcal{P}$ of error-free and erroneous sentences. AEG approaches use seed GEC corpora to learn the inverse models directly. Unfortunately, we are not aware of any comparably large resources for digitized text that could be used for this task.

To address this issue, we propose an unsupervised sentence-level parallel data generation approach for OCR (Figure 4). First, we collect a large seed corpus $\mathcal{T}$ that contains the error-free text. We then render each sentence and subsequently run text recognition on the rendered images using an OCR engine. Moreover, to increase the variation in training data, we sample different fonts for rendering. Furthermore, to simulate the distortions and degradation of the printed material, we induce pixel-level noise to the images before recognition.

Note that our approach is universal and could be used to generate parallel data sets for other tasks, e.g., an ASR system could be trained on samples from a Text-to-Speech engine (Wang et al., 2018b).

4.3 Sentence- and Word-Level Modeling

We note that the sequence labeling problem is formulated at the word-level, i.e., each word has a class label assigned to it. To employ our method in

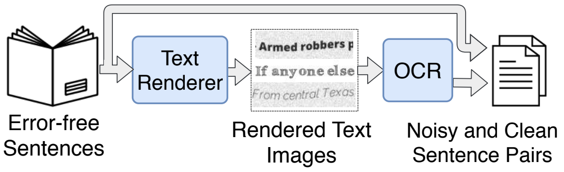

Figure 4: Our parallel data generation method for OCR. We render sentences extracted from a text corpus. Subsequently, an OCR engine recognizes the text depicted in the rendered images. Finally, the pairs of original and recognized sentences are gathered together to form a parallel corpus used to train translation models.

this scenario, we develop (i) a *sentence-level* and (ii) a *token-level* variant of our error generator.

Our sentence-level error generator uses a seq2seq model trained to translate from error-free to erroneous sentences. It can potentially utilize contextual information from surrounding words, which may improve the quality of the results. During the training of a NAT model, a learned seq2seq model translates the original input x to generate $\tilde{x}$. Subsequently, we use an alignment algorithm (§4.4) to transfer the word-level annotations from x to $\tilde{x}$.

Our token-level error generator uses a seq2seq model trained to translate from error-free to erroneous words. It relies exclusively on the input and the output words. We use the alignment algorithm to build a training set for this task, i.e., extract word-level parallel data from the corpus of parallel sentences (§4.2). During the training of a NAT model, a learned generator translates each word x_i from x to produce the erroneous sentence $\tilde{x}$.

4.4 Word-Level Sentence Alignment

Figure 5 illustrates the alignment procedure, which we developed to extract word-level parallel training data for our token-level generator and to transfer the labels to the erroneous sentences for the sentence-level generator in the sequence labeling scenario.

To this end, we align each pair of error-free and noisy sentences at the word-level using the Levenshtein Distance algorithm. Our alignment procedure produces pairs of aligned words. The annotations for words are transferred accordingly.

4.5 Noisy Language Modeling

Recently, Xie et al. (2017) drew a connection between input noising in neural network language models and smoothing in n-gram models. We believe that data noising could be an effective technique for regularizing neural language models that could help to overcome the data sparsity problem of imperfect natural language text and enable learning meaningful representation of erroneous tokens.

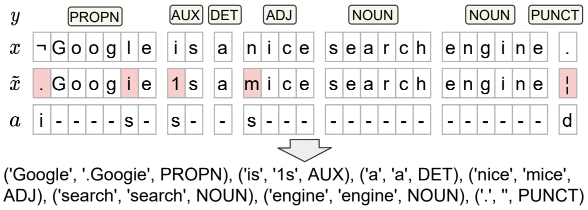

Figure 5: Our sentence alignment procedure. We align the original and the recognized sentences (x and $\tilde{x}$, respectively) using the sequence of edit operations a, which include insertions ”i”, deletions ”d”, and substitutions ”s” of characters. We use ”¬” and ”¦” as placeholders for the insertion and the deletion operation, respectively. Matched characters are marked with ”-”. The alignment procedure produces a list of paired error-free and possibly erroneous words with class labels (optional).

To this end, we propose to include the data from noisy sources in the corpora used to train LM-based embeddings. Specifically, in this work, we learn a noisy language model using the output of an OCR engine (§4.2) that captures the characteristics of OCR errors. Any other noisy source could be readily used to model related domains, e.g., ASR-transcripts or ungrammatical text.

5 Experimental Setup

5.1 Sequence-to-Sequence Error Generator

To learn our error generators (§4.1), we utilize the OpenNMT[3] toolkit (Klein et al., 2017).[4] We encode the input sentence at the character-level before feeding it to the seq2seq model. Subsequently, the output produced by the seq2seq model is decoded back to the original form (Figure 6).

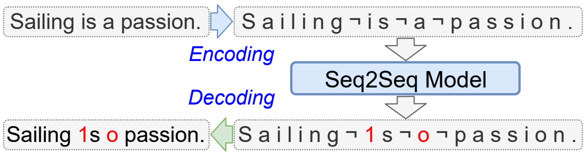

Figure 6: Sentence encoding-decoding schema. The whitespace characters are first replaced with a placeholder symbol ”¬”. The sentences are tokenized at the character-level by adding whitespace between every pair of characters. Decoding reverses this process.

---

[3] `https://github.com/OpenNMT/OpenNMT-py`

[4] We list all non-default hyper-parameters in Table 8.

5.2 Unsupervised Parallel Data Generation

Following the approach from §4.2, we generated a large parallel corpus $\mathcal{P}$ to train our error generation and correction models. We sampled 10 million sentences[5] from the English part of the *1 Billion Word Language Model Benchmark*[6] and used them as the source of error-free text, i.e., the seed corpus $\mathcal{T}$. We rendered each sentence as an image using the *Text Recognition Data Generator* package[7]. We used 90 different fonts for rendering and applied random distortions to the rendered images. Subsequently, we performed OCR on each image of text using a Python wrapper[8] for Tesseract-OCR[9] (Smith, 2007). We present the distribution of error rates in our noisy corpus in Figure 2 (cf. the *digitized text* plot).

5.3 Sequence Labeling

Training Setup We employed the NAT framework[10] (Figure 1) to study the robustness of sequence labeling systems. Following Akbik et al. (2018), we used a combination of *FLAIR* and *GloVe* embeddings in all experiments.[11] We employed the data augmentation ($\mathcal{L}_{\text{AUGM}}$) and the stability training ($\mathcal{L}_{\text{STAB}}$) objectives with default weights ($\alpha = 1.0$), as proposed by Namysl et al. (2020). Consistent with prior work, erroneous sentences $\tilde{x}$ were generated dynamically in every epoch.

Tasks We experimented with the Named Entity Recognition (NER) and Part-of-Speech Tagging (POST) tasks. NER aims to locate all named entity mentions in text and classify them into predefined classes, e.g., person names, locations, and organizations. POST is the process of tagging each word in the text with the corresponding part of speech.

Evaluation Setup The evaluation pipeline is shown in Figure 7. Following Akbik et al. (2018), we report the entity-level micro-average F1 score for NER and the accuracy for POST.

5.4 Baselines

Error Generation We compared our error generator with the OCR-aware noise model from Namysl et al. (2020). We used the noisy part of the parallel corpus $\mathcal{P}$ to estimate the confusion matrix employed by this baseline. Moreover, in the NLM experiment (§6.3), we also evaluated the vanilla error model proposed by Namysl et al. (2020).

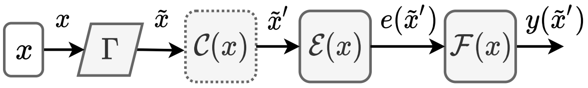

Figure 7: Evaluation pipeline. Γ is a noising process that transforms x into $\tilde{x}$. $\mathcal{C}(x)$ is an optional text correction module that returns $\tilde{x}'$ ($\tilde{x}'=\tilde{x}$, if $\mathcal{C}(x)$ is absent). $\mathcal{E}(x)$ is an embedding matrix. $\mathcal{F}(x)$ is a sequence labeling model. $e(\tilde{x}')$ and $y(\tilde{x}')$ are the embeddings and the output of the model for $\tilde{x}'$, respectively.

Error Correction To evaluate error correction, we trained the sequence labeling models using the standard objective ($\mathcal{L}_0$) and employed the text correction method on the erroneous input before feeding it to the network (Figure 7).

We examined *Natas*[12], the seq2seq OCR post-correction method proposed by Hämäläinen and Hengchen (2019). We trained context-free error correction models compatible with Natas using our parallel corpus (§5.2). Moreover, we also employed the widely adopted spell checker *Hunspell*[13].

5.5 Data Sets

Original Benchmarks For NER, we employed the CoNLL 2003 data set (Tjong Kim Sang and De Meulder, 2003). To evaluate POST, we utilized the Universal Dependency Treebank (UD English EWT; Silveira et al., 2014). We present the detailed statistics of both data sets in Table 5.

Data Set	Geom. Distort.	Pixel-level Noise	CoNLL 2003	UD English EWT
Tesseract 3♣	✗	✗	22.72%	23.31%
Tesseract 4◇	✓	✓	16.35%	22.12%
Tesseract 4♡	✓	✗	14.89%	20.38%
Tesseract 4♠	✗	✓	3.53%	5.83%
Typos	n/a	n/a	15.53%	15.22%

Table 1: The noisy sequence labeling data sets that we generated either by applying OCR on rendered sentences from an original benchmark (first four rows) or by inducing misspellings (last row). We generated multiple variants of the former data sets by combining geometrical distortions and pixel-level noise induction. The last two columns present the token error rates (the column headers indicate the names of the original benchmarks).

(b) UD English EWT

Table 2: Comparison of error generation (§6.1) and error correction (§6.2) approaches on the original and noisy English CoNLL 2003 and the UD English EWT test sets (§5.5). We report mean and standard deviation F1 scores (CoNLL 2003) and accuracies (UD English EWT) over five runs with different random initialization. $\mathcal{L}_0$, $\mathcal{L}_{\text{AUGM}}$, $\mathcal{L}_{\text{STAB}}$ is the standard, the data augmentation, and the stability objective, respectively (Namysl et al., 2020). **Bold** values indicate top results (within the models trained using the same objective) that are statistically inseparable (Welch's t-test; $p < 0.05$).

Noisy Benchmarks Unfortunately, we did not find any publicly available noisy sequence labeling data set that could be used to benchmark different methods for improving robustness. To this end, we generated several noisy versions of the original sequence labeling data sets (Table 1). We extracted the sentences from each original benchmark and applied the procedure described in §4.2.[14] We transferred the word-level annotations as described in §4.4. Finally, we produced the data in the CoNLL format (Table 7).

Moreover, to evaluate the transferability of error generators, we followed Namysl et al. (2020) and synthetically induced misspellings to the error-free data sets. To this end, we used the lookup tables of possible lexical replacements released by Belinkov and Bisk (2018) and Piktus et al. (2019).[15]

6 Experimental Results

6.1 Empirical Noise Generation Approaches

In this experiment, we compared the NAT models that employed either our seq2seq noise generators or the baseline error models (Table 2). In this evaluation scenario, we do not employ $\mathcal{C}(x)$ (Figure 7).

Our error generators outperformed the OCR-aware confusion matrix-based model on the noisy benchmarks generated using the Tesseract 4 engine. The advantage of our method was less emphasized in the case of the *Tesseract 3*$^{\clubsuit}$ data sets. The token-level translation method performed better than the sentence-level variant, while the latter was more efficient when the error rate of the input was lower (cf. the *original data* and the *Tesseract 4*$^{\spadesuit}$ columns), although it often struggled with translating long sentences. Moreover, data augmentation generally outperformed stability training, which is consistent with the observation from Namysl et al. (2020).

Furthermore, we observe a slight decrease in accuracy on the original UD English EWT with both auxiliary objectives. We believe that this was caused by the different proportions of the tokens that were perturbed during training by our seq2seq error generators (e.g., 18% and 19.5% in the case of our token-level model for CoNLL2003 and UD English EWT, respectively). The trade-off between accuracy for clean and noisy data has thus been shifted towards the latter. We also notice a greater advantage of the seq2seq method over the baseline

---

[14] We directly applied both Tesseract v3.04 and v4.0. We used different sets of distortions and image backgrounds than those employed to generate parallel training data.

[15] We merged both sets of misspellings for evaluation.

on the noisy UD English EWT data sets.

Additionally, in §A, we analyze the relationship between the size of the parallel corpus used for training and the F1 score of the NER task.

6.2 Error Generation vs. Error Correction

We compared the NAT approach with the baseline correction methods (§5.4). Preliminary experiments revealed that these baselines underperformed due to the *overcorrection* problem. To make them more competitive, we extended their default dictionaries by adding all tokens from the corresponding test sets for evaluation. Although the vocabulary of a test set could rarely be entirely determined, this setting would simulate a scenario where accurate in-domain vocabularies could be exploited.

Table 2 includes the results of this experiment. As expected, although more general, error correction techniques were outperformed by the NAT approach regardless of the noising method used. Surprisingly, Hunspell performed better than Natas on CoNLL 2003. We carried out a thorough inspection of the results of both methods and found out that Natas, although generally more accurate, had problems with recognizing tokens that were a part of entities. This behavior could be a flaw of data-driven error correction methods, as the entities are relatively rare in written text and are often out-of-vocabulary tokens (Alex and Burns, 2014).

6.3 Noisy Language Modeling

FLAIR (Akbik et al., 2018) learns a bidirectional LM to represent sequences of characters. We used the target side of our parallel data corpus (§5.2) to re-train FLAIR embeddings on the noisy digitized text.[16] Subsequently, we compared the accuracy of the vanilla NAT models (§3.2) that employed either the pre-trained or our NLM embeddings. Moreover, we do not use $\mathcal{C}(x)$ in this scenario (Figure 7).

Note that the noise model and the embeddings are two distinct components of the NAT architecture (Γ and $\mathcal{E}(x)$ in Figure 1, respectively) and therefore they could be easily combined. However, in this work, we do not mix our NLM with empirically estimated error models to avoid the twofold empirical error modeling effect. We leave the evaluation of this combination to future work.

Table 3 summarizes the results of this experiment. Our method significantly improved the accuracy across all training objectives, even when we employed exclusively the standard training objective for the sequence labeling task ($\mathcal{L}_0$). Surprisingly, we also achieved evident improvements for the noisy data set generated using the Tesseract 3 engine, which confirms that NLM embeddings can model the features of erroneous tokens even in the out-of-domain scenarios. On the other hand, the NLM slightly decreased the accuracy on the original data for the standard training objective. We plan to investigate this effect in future work by eliminating possible differences in the pre-training procedure and comparing our NLM against a model trained on the original error-free text corpus instead of using the embeddings from Akbik et al. (2018).

6.4 Human-Generated Errors

In this experiment, we evaluated the utility of our seq2seq error generators learned to model OCR noise (§6.1) and our NLM embeddings (§6.3) in a scenario where the input contains human-generated

(b) Empirical Error Generation Methods

Table 4: Transferability of the methods learned to model OCR noise to the distribution of the human-generated errors (§6.4): **(a)** Comparison of the NAT approach with and without our NLM embeddings on the English CoNLL 2003 test set with human-generated errors. **(b)** Comparison of empirical error generation approaches on the English CoNLL 2003 and the UD English EWT test sets with human-generated errors. We report mean and standard deviation F1 scores (CoNLL 2003) and accuracies (UD English EWT) over five runs with different random initialization. $\mathcal{L}_0$, $\mathcal{L}_{\text{AUGM}}$, $\mathcal{L}_{\text{STAB}}$ is the standard, the data augmentation, and the stability objective, respectively (Namysl et al., 2020). The *NLM* column indicates whether the model employed our NLM embeddings. **Bold** values indicate top results (within the models trained using the same objective) that are statistically inseparable (Welch's t-test; $p < 0.05$).

errors. For evaluation, we used the noisy data sets with synthetically induced misspellings (§5.5). We do not employ $\mathcal{C}(x)$ in this scenario (Figure 7).

Table 4 summarizes the results of this experiment. The models with our NLM embeddings outperformed the baselines for all training objectives (Table 4a). The seq2seq error generation approach performed on par with the confusion matrix-based models on the CoNLL 2003 data set, while the latter achieved better accuracy on the UD English EWT data set (Table 4b).

We believe that this difference was caused by the discrepancy between the data distributions. Note that although the data used in this experiment reflects the patterns of human-generated errors, the distribution of these errors does not necessarily follow the natural distribution of human-generated errors, as it was synthetically generated using a fixed replacement probability that was uniform across all candidates.[17] Nevertheless, our methods proved to be beneficial in this scenario, which would suggest that the errors made by human writers and by the text recognition engines have common characteristics that were exploited by our method.

7 Conclusions

In this work, we studied the task of performing sequence labeling on noisy digitized and human-generated text. We extended the NAT approach and proposed the empirical error generator that performs the translation from error-free to erroneous text (§4.1). To train our generator, we developed an unsupervised parallel data synthesis method (§4.2). Analogously, we produced several realistic noisy evaluation benchmarks (§5.5). Moreover, we introduced the NLM embeddings (§4.5) that overcome the data sparsity problem of natural language.

Our approach outperformed the baseline noise induction and error correction methods, improving the accuracy of the noisy neural sequence labeling task (§6.1-6.3). Furthermore, we demonstrated that our methods are transferable to the out-of-domain scenarios - human-generated errors (§6.4) and the noise induced by a different OCR engine (§6.1, 6.3). We incorporated our approach into the NAT framework and make the code, embeddings, and scripts from our experiments publicly available.

Grundkiewicz and Junczys-Dowmunt (2019) showed that that unsupervised systems benefit from domain adaptation on authentic labeled data. For future work, we plan to fine-tune NAT models pretrained on synthetic samples using the labeled data generated directly by the noising process.

A Relationship with the Corpus Size

Empirical error generators are especially beneficial when we can approximate the noise distribution to be encountered at test time. In this experiment, we aimed to answer the question, how much parallel training data is required to train a solid seq2seq error generation model.

Figure 8 shows that the NAT models that used our seq2seq error generator performed better than those employing the baseline vanilla error model proposed by Namysl et al. (2020) for all noisy benchmarks that were generated using the *Tesseract 4* OCR engine. The improvements were observed even when we used as few as 1000 parallel training sentences. Our method also outperformed the baseline on the original CoNLL 2003 benchmark. On the contrary, the accuracy of models trained using our generator fell slightly behind the baseline on the *Tesseract 3*♣ and *Typos* data sets.

B Sequence Labeling Data Sets

Original Benchmarks Table 5 presents the detailed statistics of the original sequence labeling benchmarks used in our experiments. For NER, we employed CoNLL 2003[18] (Tjong Kim Sang and De Meulder, 2003). To evaluate POST, we utilized Universal Dependency Treebank (UD English EWT[19]; Silveira et al., 2014).

Noisy Benchmarks Table 6 presents the error rates and the correction accuracies of the Natas and Hunspell methods calculated on the test sets of the noisy sequence labeling benchmarks. Moreover, Table 7 shows an excerpt from a noisy sequence labeling data set generated for evaluation.

Furthermore, Figure 9 presents the distribution of token error rates in relation to the percentage number of sentences in our noisy data sets. For comparison, we also included the distributions obtained by applying different noise generation methods - the vanilla- and the OCR-aware confusion matrix-based models by Namysl et al. (2020), and our token-level seq2seq error generator.

We note that the error distribution of our noisy data sets is closer to the Zipf distribution in contrast to the results of prior methods that exhibit a Bell-Curve pattern. Note that the *Typos* data set was generated by randomly sampling possible lexical replacement candidates from the lookup tables, hence its distribution exhibits slightly different characteristics than the noisy data sets generated by directly applying the OCR engine to the rendered text images. Based on the above results,

Figure 8: F1 score in relation to the number of parallel sentences. The experiments were conducted on the original English CoNLL 2003 benchmark and its noisy variants: Tesseract $3^{\clubsuit}$, Tesseract $4^{\diamondsuit}$, Tesseract $4^{\heartsuit}$, Tesseract $4^{\spadesuit}$, and Typos. We compare the accuracy of our token-level seq2seq approach with the vanilla error model (Namysl et al., 2020), and the standard objective ($\mathcal{L}_0$). We present the results for both auxiliary objectives: the data augmentation ($\mathcal{L}^{\text{ours}}_{\text{AUGM}}$, $\mathcal{L}^{\text{base}}_{\text{AUGM}}$) and the stability training ($\mathcal{L}^{\text{ours}}_{\text{STAB}}$, $\mathcal{L}^{\text{base}}_{\text{STAB}}$).

we believe that our noisy data sets are better suited for the evaluation of the robustness of sequence labeling models than the data generated by the prior approaches.

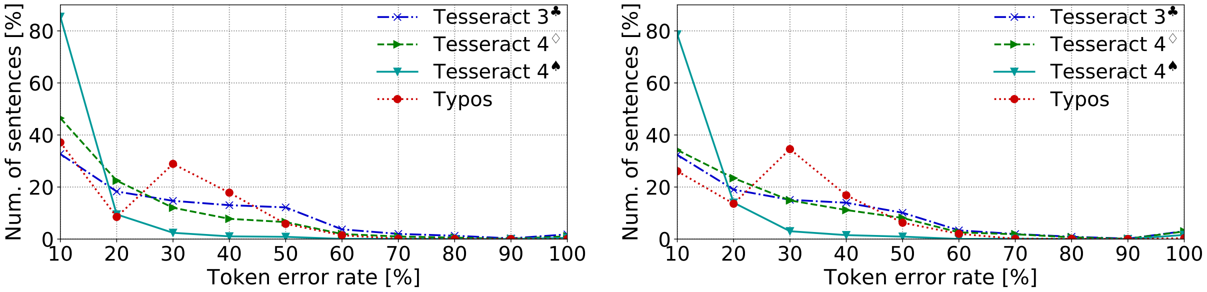
Data Conversion Scripts Because of licensing and copyright reasons, we did not submit the noisy data sets directly. Our code includes the scripts for the conversion of the original benchmarks into their noisy variants. For reference, we added excerpts of the noisy UD English EWT data set in the supplementary materials.

C Reproducibility

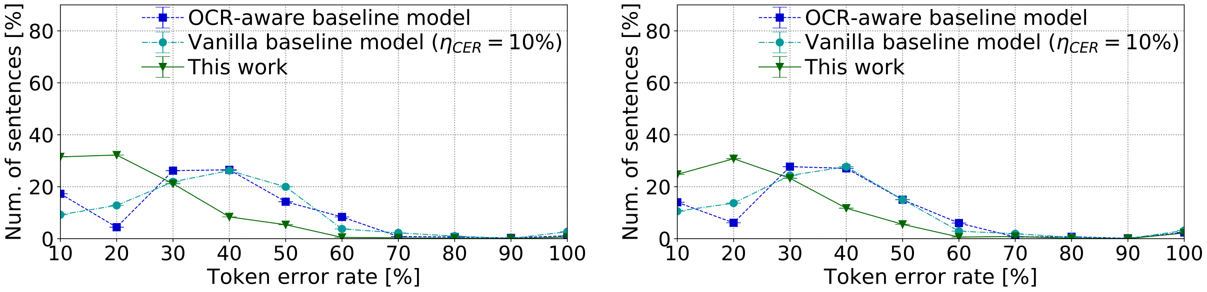
In this section, we present additional information that could facilitate reproducibility.

Hyper-parameters To train our seq2seq translation models, we generally used the default hyper-parameters of the OpenNMT toolkit. We list all non-default values in Table 8. Moreover, we decayed the learning rate eight times during the training for all models. Furthermore, we utilized *copy attention* (See et al., 2017) for our error generation models and *global attention* (Luong et al., 2015) for the error correction model.

Validation Accuracy Table 9 summarizes the validation accuracy of our seq2seq models for error generation. We trained the sentence-level models for 1.6×10^4 and the token-level models for 4×10^5 iterations or at least one epoch of training. Moreover, the token-level error correction model employed by Natas was trained for one epoch (about 4×10^5 iterations) on one million parallel sentences



(a) Noisy sentence labeling data sets (English CoNLL 2003). (b) Noisy sentence labeling data sets (UD English EWT).



(c) Noise induction methods (English CoNLL 2003). (d) Noise induction methods (UD English EWT).

Figure 9: Distributions of the token error rates of sentences in our noisy sequence labeling data sets (Tesseract 3$^{\clubsuit}$, Tesseract 4$^{\diamondsuit}$, Tesseract 4$^{\spadesuit}$, and Typos). For comparison, we include error distributions obtained by applying our seq2seq token-level error generator and the baseline confusion matrix-based error models (Namysl et al., 2020) to the sentences extracted from the original benchmark. η_{CER} is the character-level noising factor used by the vanilla error model. Each point is the percentage of sentences with a token error rate that falls into a specific token error range, i.e., the value of 50 corresponds to the sentences with a token error rate greater than 40 and lower than or equal to 50.

and achieved 96.9% accuracy on the validation set of 5000 sentences.

Learnable Parameters The number of parameters in our sequence labeling models was constant among different models, as we used the same architecture in all experiments. The number of all model parameters was 60.3 million (including embeddings that were fixed during the training), and the number of all trainable parameters was 25.5 million. Moreover, all our seq2seq error generation and correction models had about 7.7 million parameters.

Parameter	Description	Value
`-share_vocab`	Share source and target vocabulary	True
`-share_embeddings`	Share the embeddings between encoder and decoder	True
`-word_vec_size`	Word embedding size	25
`-src_seq_length`	Max. source sequence length	1000
`-tgt_seq_length`	Max. target sequence length	1000
`-encoder_type`	Type of encoder layer	brnn
`-learning_rate`	Starting learning rate	1.0

Table 8: The hyper-parameters of the OpenNMT toolkit used to train our seq2seq error generation models.

Training set size	Validation set size	Validation accuracy	
		token-level	sentence-level
10^7	5000	98.3%	95.7%
10^6	5000	95.4%	94.9%
10^5	5000	95.1%	95.3%
10^4	1000	94.6%	90.1%
10^3	100	93.3%	91.6%

Table 9: Validation accuracy of the seq2seq models for error generation. We trained both the token-level and the sentence-level variants. The first and the second column show the number of parallel sentences used for training and validation, respectively.

Average Runtime The evaluation of the complete test set took 7 and 10 seconds on average in the case of UD English EWT and English CoNLL 2003, respectively. The runtime did not depend on the training method that was used. Nevertheless, when we employed the correction method, the runtime was significantly lengthened, e.g., it took almost 3 minutes to evaluate a model that employed the Natas correction method on English CoNLL 2003.

Computing Architecture The evaluation was performed on a workstation equipped with an Intel Xeon CPU with 10 cores and an Nvidia Quadro RTX 6000 graphics card with 24GB of memory.

Spatial Dependency Parsing for Semi-Structured Document Information Extraction

Abstract

Information Extraction (IE) for semi-structured document images is often approached as a sequence tagging problem by classifying each recognized input token into one of the IOB (Inside, Outside, and Beginning) categories. However, such problem setup has two inherent limitations that (1) it cannot easily handle complex spatial relationships and (2) it is not suitable for highly structured information, which are nevertheless frequently observed in real-world document images. To tackle these issues, we first formulate the IE task as *spatial dependency parsing* problem that focuses on the relationship among text tokens in the documents. Under this setup, we then propose SPADE♤ (SPAtial DEpendency parser) that models highly complex spatial relationships and an arbitrary number of information layers in the documents in an end-to-end manner. We evaluate it on various kinds of documents such as receipts, name cards, forms, and invoices, and show that it achieves a similar or better performance compared to strong baselines including BERT-based IOB taggger.

1 Introduction

Document information extraction (IE) is the task of mapping each document to a structured form that is consistent with the target ontology (e.g., database schema), which has become an increasingly important task in both research community and industry. In this paper, we are particularly interested in information extraction from real-world, semi-structured document images, such as invoices, receipts, and name cards, where we assume Optical Character Recognition (OCR, i.e. detecting the locations of the text tokens if the input is an image) has been already applied. Previous approaches for semi-structured document IE often assume as if the input is a one-dimensional sequence and formulate the task as an IOB (Inside Outside Beginning) tagging problem. In this setup, the tokens in the document (either obtained through an OCR engine or trivially parsed from a web page or pdf) are first serialized, and then an independent tagging model classifies each of the flattened lists into one of the pre-defined IOB categories (Ramshaw and Marcus, 1995; Palm et al., 2017). While effective for relatively simple documents, their broader application in the real world is still challenging because (1) semi-structured documents often exhibit a complex layout where the serialization algorithm is non-trivial, and (2) sequence tagging is inherently not effective for encoding multi-layer hierarchical information such as the menu tree in receipts (Fig. 1c).

To overcome these limitations, we propose SPADE♤ (SPAtial DEpendency parser), an end-to-end, serializer-free model that is capable of extracting hierarchical information from complex documents. Rather than explicitly dividing the original problem into two independent subtasks of serialization and tagging, our model tackles the problem in an end-to-end manner by creating a directed relation graph of the tokens in the document (Fig. 1). In contrast to traditional dependency parsing, which parses the dependency structure in purely (one-dimensional) linguistic space, our approach leverages both linguistic and (two-dimensional) *spatial* information to parse the dependency.

We evaluate SPADE♤ on eight document IE datasets created from real-world document images, including invoices, name cards, forms, and receipts, with the varying complexity of information structure. In all of the datasets, our model shows a similar or better accuracy than strong baselines including BERT-based IOB taggers, and particularly outstands in documents with complex layouts (Table 3). These results demonstrate the effectiveness

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 330–343
August 1–6, 2021.

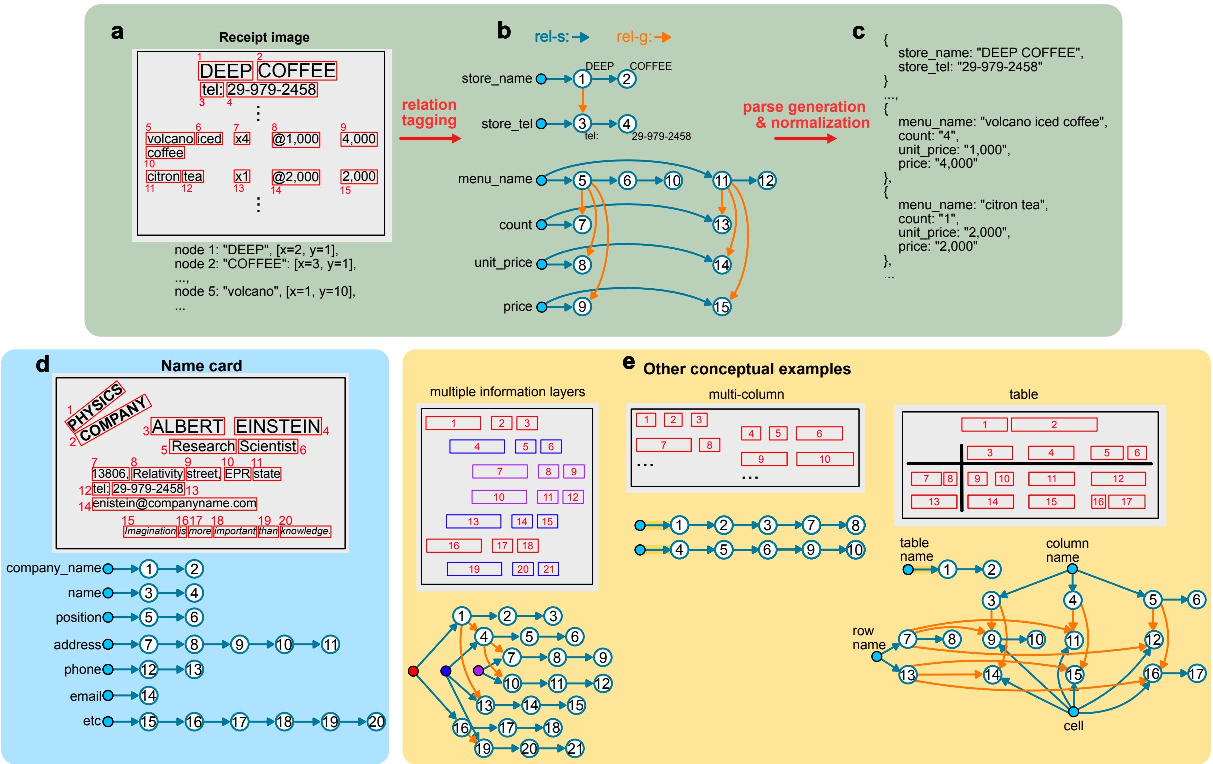

Figure 1: The illustration of spatial dependency parsing problem. Receipt parsing is explained in detail with three subfigures: (a) first, text tokens and their coordinates are extracted from OCR; (b) next, the relations between tokens are classified into two types: `rel-s` for serialization and information type (field) classification, and `rel-g` for inter-grouping between fields (the numbers inside of circles in (b) indicates the box numbers in (a)); (c) the final parse is generated by decoding the graph. (d) A sample name card and its spatial dependency parse. (e) Other conceptual examples showing the versatility of the spatial dependency parsing approach for document IE.

of our end-to-end, graph-based paradigm over the existing sequential tagging approaches.

In short, our contributions are threefold. (1) We present a novel view that information extraction for semi-structured documents can be formulated as a dependency parsing problem in two-dimensional space. (2) We propose SPADE♤ for spatial dependency parsing, which is capable of efficiently constructing a directed semantic graph of text tokens in semi-structured documents.[1] (3) SPADE♤ achieves a similar or better accuracy than the previous state of the art or strong BERT-based baselines in eight document IE datasets.

2 Related Work

The recent surge of interest in automatic information extraction from semi-structued documents are well reflected in their increased number of publication record from both research community and industry (Katti et al., 2018; Qian et al., 2019; Liu et al., 2019; Zhao et al., 2019; Denk and Reisswig, 2019; Hwang et al., 2019; Park et al., 2019; Xu et al., 2019; Jaume et al., 2019; Zhong et al., 2019; Rausch et al., 2019; Yu et al., 2020; Wei et al., 2020; Majumder et al., 2020; Lockard et al., 2020; Garncarek et al., 2020; Lin et al., 2020; Xu et al., 2020; Powalski et al., 2021; Wang et al., 2021; Hong et al., 2021; Hwang et al., 2021). Below, we summarize some of closely related works published before the major development of SPADE♤.

Serialized IE Previous semi-structured document information extraction (IE) methods often require the input text boxes (obtained from OCR) to be serialized into a single flat sequence. Hwang et al. (2019) and Denk and Reisswig (2019) combine a manually engineered text serializer that turn the OCR text boxes into a sequence and a Transformer-based encoder, BERT (Devlin et al., 2018), that performs IOB tagging on the sequence or semantic segmentation from images. In contrast to SPADE♤, these models rely on the serialization of the tokens and thus it is difficult to flexibly apply them to documents with complex layouts such as multi-column or distorted documents. Xu et al. (2019) propose LayoutLM that jointly embeds the

---

[1] `https://github.com/clovaai/spade`

image segments, text tokens, and positions of the tokens in an image to make a pretrained model for document understanding. However, LayoutLM still requires a careful serialization of the tokens as it relies on the position embeddings of BERT. Also, it is only evaluated on classification for the downstream task.

Serializer-free IE Existing serializer-free methods mostly extract flat key-value pairs, as they still formulate the task as tagging the text tokens. They fundamentally differ from SPADE♤ which generates a structured output that captures full information hierarchy represented in the document. Chargrid (Katti et al., 2018) performs semantic segmentation on invoice images to extract target key-value pairs. Although Chargrid uses additional "bounding boxes" for inter-grouping of certain fields, the application to the documents that have more than two information hierarchy levels is non-trivial. Also, when fields that belong to the same group are remotely located, the bounding boxes may need to be modified to have a more complex geometrical shape to avoid overlap between the boxes.

Graph-based IE Liu et al. (2019); Qian et al. (2019); Wei et al. (2020); Yu et al. (2020) utilize a graph convolution network to contextualize the tokens in a document and a bidirectional LSTM with CRF to predict the IOB tags. However, the range of possible parse generations is limited as IOB tagging can be performed only within each OCR bounding box, ignoring inter-box relationship. On the contrary, SPADE♤ predicts both the intra-box relationship and the inter-box relationship by constructing a dependency graph among the tokens.

Lockard et al. (2019, 2020) also utilize a graph to extract semantic relation from semi-structrued web-page. The graph is constructed based on rules from "structured html DOM" and mainly used for information encoding. On the other hand SPADE♤ accepts "unstructured text distributed in 2D" and generates graphs as the result of decoding (in a data-driven way).

Dependency parsing Dependency parsing is the task of obtaining the syntactic or semantic structure of a sentence by defining the relationships between the words in the sentence (Zettlemoyer and Collins, 2012; Peng et al., 2017; Dozat and Manning, 2018). The relations are often expressed as directed, labeled arcs. In our work, we view the problem of information extraction for semi-structured documents as a *spatial* dependency parsing task such that two-dimensional spatial information is mainly considered. This setup enables SPADE♤ to flexibly handle documents with complicated layouts while representing the full information hierarchy.

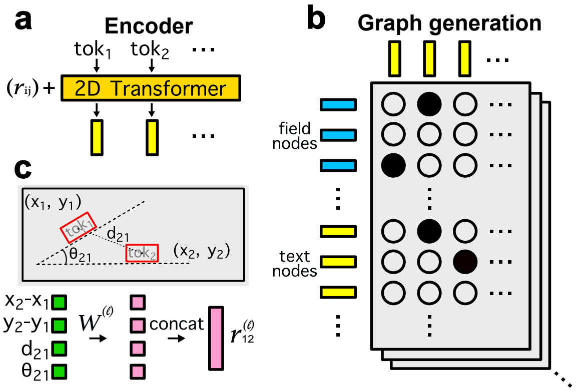

Figure 2: The illustration of SPADE♤. (a) Spatial text encoder contextualizes tokens using their relative spatial vectors $\{r_{ij}\}$ (Eq. 1). (b) The dependency graph is inferred by mapping the vector representations of each pair of tokens into a scalar value. The field embeddings are blue-colored. (c) At each encoder layer ℓ, r_{ij}^{ℓ} is prepared by concatenating four embedding vectors: relative coordinates, distance, and angles embeddings. W^{ℓ} stands for a linear projection.

3 Problem definition

In this section, we first describe the task of information extraction for semi-structured documents, and we briefly discuss how the task was approached in the past as a sequence tagging problem. Then we formulate it as a spatial dependency parsing problem. In Section 4, we show how we design our model for the newly formulated problem.

3.1 Semi-structured document IE

Document IE is often defined as the extraction of structured information (e.g. key-value pairs) in documents. For semi-structured documents, the task becomes more challenging, mainly due to two factors: (1) complex spatial layout and (2) hierarchical information structure. In the simplest case, both of the two factors are minimally present, where the text is strictly a linear sequence, and the desired output is simply a list of fields, similar to Named Entity Recognition (NER) task. However, the problem becomes more difficult when at least one of the factors is significant. In name cards, spatial relationship can be tricky; Fig. 1d shows an example where a naïve left-to-right serialization would fail because the `company_name` ("Physics Company") is tilted. In receipts, their hierarchical information structure complicates the problem. For example, in Fig. 1a), words "volcano" (box 5), "iced" (box 6), and "coffee" (box 10) together form a single field `menu_name`, and the field constitutes another group in the second hierarchical layer with the `count` field (box7), `unit_price` field (box 8), and `price` field (box 9). Other conceptual examples are shown in Fig. 1e); documents that have triple information layers (left), multiple columns (middle), and a table (right).

3.2 Previous formulation: Sequence tagging

As mentioned, IOB sequence tagging is appropriate for document IE when the layout and the information structure are simple (Ramshaw and Marcus, 1995; Lample et al., 2016; Chiu and Nichols, 2016; Ma and Hovy, 2020). When one of the factors is present, however, one has to adopt an ad-hoc solution to detour the inherent limitation of IOB.

In the case of complex spatial relationship (e.g., name card), an advanced, dedicated serialization method can be considered. However, it may require layout-specific manual engineering, which becomes more difficult for documents such as name cards that exhibit diverse layouts.

In the case of complex information structure (e.g., receipt), one can consider augmenting each IOB tag with higher-layer information. For instance, in a typical IOB setting, the `menu_name` field will require two tags, namely `menu_name_B` and `menu_name_I`. To model the second layer information (inter-grouping of fields), `menu_name_B` can be augmented into two, namely `B2_menu_name_B`, `I2_menu_name_B`, where `B2` and `I2` indicate the beginning and the inside of the hierarchy's second layer. While effective for some applications, this method would not generalize well to an arbitrary depth as it requires more tags for each additional layer.

3.3 Our formulation: Spatial dependency parsing

To better model spatial relationship and hierarchical information structure in semi-structured documents, we formulate the IE problem as "spatial dependency parsing" task by constructing a dependency graph with tokens and fields as the graph nodes (node per token and field type). This is demonstrated in Fig. 1, where empty blue circles are text nodes, and filled blue circles are field nodes.

Although the spatial layout of semi-structured documents is diverse, it can be considered as the realization of mainly two abstract properties between each pair of nodes, (1) `rel-s` for the ordering and grouping of tokens belonging to the same information category (blue arrows in Fig. 1b), and (2) `rel-g` for the inter-group relation between grouped tokens or groups (orange arrows in the same figure). Connecting a field node to a text node indicates that the text is classified into the field. For example, "volcano iced coffee" in Fig. 1a) is classified as a menu name by being attached to the `menu_name` field node with blue arrows, and it is connected with "x4", "@1,000", and "4,000" with orange arrows to indicate the hierarchical information among the groups. The dependency graphs of name cards and other conceptual examples are also shown in Fig. 1d and e.

4 Model

To perform the spatial dependency parsing task introduced in the previous section in an end-to-end fashion, we propose SPADE♤ that consists of (1) spatial text encoder, (2) graph generator, and (3) graph decoder. Spatial text encoder and graph generator are trained jointly. Graph decoder is a deterministic function (without trainable parameters) that maps the graph to a valid parse of the output structure.

4.1 Spatial text encoder

Spatial text encoder is based on 2D Transformer architecture. Unlike the original Transformer (Vaswani et al., 2017), there is no order among the input tokens, making the model invariant under the permutation of the input tokens. Inspired by Transformer XL (Dai et al., 2019), the attention weights (between each key and query vector) is computed by

$$q_i^T k_j + q_i^T r_{ij} + (b_i^{key})^T k_j + (b_i^{rel})^T r_{ij} \qquad (1)$$

where q_i is the query vector of the i-th input token, k_j is the key vector of the j-th input token, r_{ij} is the relative spatial vector of the j-th token with respect to the i-th token, and $b_i^{key|rel}$ is a bias vector. In (original) Transformer, only the first term of Equation 1 is used.

The relative spatial vector r_{ij} is constructed as follows (Fig. 2c). First, the relative coordinates between each pair of tokens are computed.[2] Next, the coordinates are quantized into integers and embedded using `sin` and `cos` functions (Vaswani et al., 2017). The physical distance and the relative angle between each pair of the tokens are also embedded in a similar way. Finally, the four embedding vectors are linearly projected (with a trainable projection matrix) and concatenated at each encoder layer.

4.2 Graph generator

As discussed in Section 3.3 and shown in Fig. 1, every token corresponds to a node and each pair of the nodes forms one of the two relations (or no relation): (1) `rel-s` for serializing tokens within the same field, and (2) `rel-g` for inter-grouping between fields. The dependency graph can be represented by using a binary matrix $M^{(r)}$ for each relation type r (Fig. 2b) where $M_{ij}^{(r)} = 1$ if their exists a directed edge from the i-th token to the j-th token and 0 otherwise. Each $M^{(r)}$ consists of $n_{\text{field}} + n_{\text{text}}$ number of rows and n_{text} number of columns where n_{field} and n_{text} represent the number of field types and the number of tokens, respectively. The graph generation task now becomes predicting the binary matrix.

We obtain $M^{(r)}$ as follows. The probability that there exists a directed edge $i \xrightarrow{r} j$ is computed by

$$
\begin{aligned}
h_i^{(r)} &= \begin{cases} u_i^{(\text{field})}, & \text{for } i \leq n_{\text{field}} \\ \mathcal{W}_h^{(r)} v_i & \text{otherwise} \end{cases} \\
d_j^{(r)} &= \mathcal{W}_d^{(r)} v_j \\
s_{0,ij}^{(r)} &= (h_i^{(r)})^T \mathcal{W}_0^{(r)} d_j^{(r)} \\
s_{1,ij}^{(r)} &= (h_i^{(r)})^T \mathcal{W}_1^{(r)} d_j^{(r)} \\
p_{ij}^{(r)} &= \frac{\exp(s_{1,ij}^{(r)})}{\exp(s_{0,ij}^{(r)}) + \exp(s_{1,ij}^{(r)})},
\end{aligned}
\qquad (2)
$$

where $u_i^{(\text{field})}$ represents the trainable embedding vector of the i-th field type node (filled blue circles in Fig. 1), $\{v_i\}$ is a set of vectors of contextualized tokens from the enoder, $\mathcal{W}$ stands for affine transformation, h is the embedding vector of the head token, and d is that of the dependent token.

$M_{ij}^{(r)}$ is obtained by binarizing $p_{ij}^{(r)}$ as follows.

$$
M_{ij}^{(r)}(p_{ij}^{(r)}) = \begin{cases} 1 \text{ for } (r{=}\texttt{s}, i \text{ is field type node}, p_{ij}^{(r)} \geq p_{th}) \\ 1 \text{ for } (r{=}\texttt{s}, i \text{ is text node}, p_{ij}^{(r)} \geq p_{th}, \\ \qquad j = \arg\max_k p_{ik}^{(r)}) \\ 1, \text{ for } (r{=}\texttt{g}, i \text{ is text node}, p_{ij}^{(r)} \geq p_{th}) \\ 0, \text{ otherwise.} \end{cases} \qquad (3)
$$

The recall rate of edges can be controlled by varying the threshold value p_{th}. Here, we set $p_{th} = 0.5$.

Tail collision avoidance algorithm Each node in spatial dependency graphs has a single incoming edge per relation except some special documents such as table (Fig. 1e). Based on this property, we apply the following simple yet powerful tail collision avoidance algorithm: (1) at each tail node having multiple incoming edges, all edges are trimmed except the one with the highest linking probability; (2) at each head node of the trimmed edges, the new tail node is found by drawing the next probable edge whose probability is larger than p_{th} and belongs to the top three; (3) go back to Step 1 and repeat the routine until the process becomes self-consistent or the max iteration limit is reached (set to 20 in this paper). The algorithm prevents loops and token redundancy in parses.

4.3 Graph decoder

We decode the generated graph into the final parse through the following three stages: (1) `SEEDING`, (2) `SERIALIZATION`, and (3) `GROUPING` (Table 1). In `SEEDING`, field type nodes (filled circles in Fig. 1) are linked to multiple text nodes (seeds) by `rel-s`. In `SERIALIZATION`, each seed node found in the previous stage generates a directed edge (`rel-s`) to the next text node (i.e. serialization) recursively until there is no further node to be linked. Finally, in `GROUPING`, the serialized texts are grouped iteratively, constructing information layers from the top to the bottom. The total number of iterations is equal to "the number of information layers-1". To group texts using directed edges, we define a special representative field for each information layer. Then, the first token of the representative field generates directed edges to the first token of other fields that belong to the same group using `rel-g` (for example, `menu_name` ("volcano iced coffee") in Fig. 1a) generates directed edges to other member fields (`count` ("x4"), `unit_price` ("@1,000") and `price` ("4,000")).

---

[2] For example, if "token1" is at ($x_1 = 1, y_1 = 10$) and "token2" is at ($x_2 = 3, y_2 = 4$), the relative coordinate of "token2" with respect to "token1" is $(x_2', y_2') = (3-1, 4-10) = (2, -6)$.

The process generates an *arborescence*[3] for each field (`rel-s`) and group (`rel-g`). The resulting set of graphs has a one-to-one correspondence with the parse through detokenization. The use of beam search in `SERIALIZATION` does not introduce noticeable difference in `rel-s` probably due to the short decoding length of the graph (mostly less than 30). The development of a more advanced decoding algorithm that generates globally optimal multiple arborescences remains as future work.

Although undirected edges can be employed for the inter-grouping of fields, the use of directed edges has the following merits: (1) an arbitrary depth of information hierarchy can be described without increasing the number of relation types (Fig. 1e) under a unified framework and (2) a parse can be generated in a straightforward manner by iteratively selecting dependent nodes.

Table 1: A formal description of the parse decoding process. `s` and `g` stand for `rel-s` and `rel-g` respectively.

Action	Input node	Graph at time $t+1$
`INITIALIZATION`		$G_{t=0}$ = empty set
`SEEDING`(μ)	$\mu \in$ field nodes	$G^{(\text{seed})} = \{\mu \xrightarrow{\text{s}} j \mid M^{(\text{s})}_{\mu j} = 1\}$
`SERIALIZATION`(i)	$i \in G^{(\text{seed})} \cup G_t$	$G_{t+1} = G_t \cup \{i \xrightarrow{\text{s}} j \mid M^{(\text{s})}_{ij} = 1\}$
`GROUPING`(i)	$i \in G^{(\text{seed})} \cup G_t$ i linked to representer fields	$G_{t+1} = G_t \cup \{i \xrightarrow{\text{g}} j \mid M^{(\text{g})}_{ij} = 1\}$
`MERGE`		$G_t = G_t \cup G^{(\text{seed})}$

5 Experimental Setup

5.1 Optical character recognition

To extract the visually embedded texts from an image, we use our in-house OCR system that consists of CRAFT text detector (Baek et al., 2019b) and Comb.best text recognizer (Baek et al., 2019a). The OCR models are finetuned on each of the document IE datasets. The output tokens and their spatial information on the image are used as the inputs to SPADE♤.

5.2 Training

We use 12 layers of 2D Transformer encoder (Section 4.1). The parameters are initialized from `bert-multilingual` (Devlin et al., 2018) [4]. ADAM optimizer (Kingma and Ba, 2015) is used with the following learning rates: 1e-5 for the encoder, 1e-4 for the graph generator, and 2e-5 for S+BERT+IOB$_2$ and S$_{\text{ADV}}$+BERT+IOB$_2$. The decay rates are set to $\beta_1 = 0.9, \beta_2 = 0.999$. The batch size is chosen between 4 and 12. SPADE♤ is trained by using one to eight NVIDIA V100 or P40 GPUs for two to seven days, depending on the tasks. The dev sets are used to pick the best model except FUNSD task in which the model is trained in two steps. First, the 25 examples from training set are sampled and used for a model validation. Next, the model is further trained using entire training set and stopped after 1000 epochs. The training dataset is augmented by randomly rotating the text coordinates by a degree of -10° to +10°, (2) by distorting the whole coordinates randomly using a trigonometric function, and (3) by randomly deleting or inserting a single token with 3.3% probability each. Also, 1–2 random tokens from training is attached at the end of the text segments from OCR bounding box with 1.7% probability each. In NAMECARD task, the tokens are not augmented. The identical augmentation algorithm are applied to S+BERT+IOB$_2$, S$_{\text{ADV}}$+BERT+IOB$_2$ and SPADE♤.

5.3 Evaluation metric

To evaluate the predicted parses that consist of hierarchically organized key-value pairs (e.g. Fig. 3, Fig. 4, 5, 6 in Appendix) we use F_1 score based on exact match. First the group of key-value pairs between predictions and ground truth (gt) are matched based on their string edit distance. Each key-value pairs in the predicted parse is counted as true positive if same key-value pair exists within the corresponding group in gt. Otherwise it is counted as false positive. The unmatched key-value pairs in gt are counted as false negative. The accuracy of dependency parsing is evaluated by computing F_1 of predicted edges. For FUNSD dataset, entity labeling and entity linking scores are computed following the original paper (Jaume et al., 2019). See Appendix A.2 for more details.

5.4 Data statistics

We summarize the data statistics in Table 2, 6. The property of each dataset and their collection process is described in Appendix A.1.

6 Experimental Results

The main focus of SPADE♤ is to handle the two challenging factors of semi-structured document information extraction—complex spatial relationships and highly structured information—in a gen-

eralizable way. We first show that our model can handle hierarchical structure in documents by evaluating the model on two datasets CORD (Park et al., 2019) and Receipt-idn that consist of (Indonesian) receipt images. We then show SPADE♤ can perform well on tasks that require modeling the complex spatial relationship in documents by reporting the performance on name card IE where the spatial layout is more complex than receipts. Then the evaluation on the invoice dataset shows the advantage of SPADE♤ when both of the two challenging factors are simultaneously present. Finally, we show that SPADE♤ can handle even more types of documents by evaluating the model on a form understanding dataset, FUNSD (Jaume et al., 2019). Table 3 summarizes the performance of several baseline models and SPADE♤ in various semi-structured document information extraction tasks.

Handling hierarchical structure in documents CORD consists of receipt images without creases or warping. SPADE♤ initially achieves 91.5% and 87.4% in F_1 with and without the oracle (ground truth OCR results), respectively (Table 3, 1st row, co). Their dependency parsing score is also shown in Table 7 in Appendix (1st panel, co). To push the performance further, we notice that individual text nodes have a single incoming edge for each relation except in special documents like table (Fig. 1). Using this property, we integrate Tail Collision Avoidance algorithm (tca) that iteratively trims the tail-sharing-edges and generate new edges until the process becomes self-consistent (Section 4.2). F_1 increases by +1.0% and +0.8% with and without the oracle upon the integration (2nd row, co).

Importance of generating hierarchical structure in receipt IE In receipt IE task, the intergrouping of fields is critical due to multiple appearance of same field types such as `menu_name` and `price` (Fig. 3a). Without the field grouping, the maximum achievable score is 58.1 F_1 (Table 3, 6th row, UB-flat). Generating hierarchical parses from the semi-structured documents is relatively new and thus the direct comparison to previous state-of-the-art methods are not feasible without considerable modification. General confidential issue related to industrial documents and multi-lingual properties of our task also hinder the comparison. In this regard, we build our own baselines consisting of the manually engineered serializer and BERT-based double IOB taggers (S+BERT+IOB$_2$[5]).

BERT-tagger The serializer generates pseudo-1D-text from the input tokens distributed in 2D and groups them line-by-line based on their height differences. BERT+IOB$_2$ predicts the boundary between the fields and between the groups of the fields (see Section 3.2 for the detail). In CORD, S+BERT+IOB$_2$ shows comparable performance with SPADE♤ with the oracle (-0.1 F_1) but shows +1.9 F_1 on the test set (2nd and 3rd rows, CO). The relatively lower score of SPADE♤ on the test set may originate from the small size of the training set (800, Table 2) as SPADE♤ needs to handle the text serialization in a data-driven way. Indeed, when both models are trained using RECEIPT-IDN that consists of 9508 training examples, SPADE♤ outperforms by +1.0 F_1 on the test set (2nd and 3rd rows, RECEIPT-IDN).

Inflexibility of tagging model in handling complex spatial relationships Next, we prepare CORD+ and CORD++, which are more challenging setups where the images are warped or tilted as often seen in real-world applications (Fig. 3). SPADE♤ significantly outperforms S+BERT+IOB$_2$ (+13.4% F_1 in CORD+, +31.1% F_1.b in CORD++). This is due to the failure in the serialization in S+BERT+IOB$_2$ resulting in line-mixing (Fig. 3b, c and Fig. 5, 6 in Appendix). To understand how much improvement can be achieved through further manual engineering, we prepare S$_{ADV}$+BERT+IOB$_2$ which is equipped with the advanced serializer where polynomial fitting is employed to group tokens placed on curvy line. The result shows although there is a large improvement in CORD+ and CORD++ task compared to S+BERT+IOB$_2$, SPADE♤ still shows the better performance (+2.0% in CORD+, +18.3% in CORD++, 1st and 4th rows). This shows the limitation of a serializer-based method that it cannot be easily generalized to handle document images in wild and the performance can be bottlenecked by the serialization step regardless of how advanced tagging models are. The competent performance of SPADE♤ on CORD-M, a dataset generated by concatenating two receipt images from CORD into a single image (Fig. 4 in Appendix), further highlights the flexibility of SPADE♤.

Handling documents having complex layout We further evaluate SPADE♤ on name card IE task. Unlike receipts, no inter-grouping between fields is necessary for name card IE. However, name cards often have a complex layout such as non-horizontal alignment of text or multi column even without tilting and warping (Fig. 1d). Our model achieves +1.1% F_1 compared to S$_{ADV}$+BERT+IOB$_2$ on the test set (Table 3, NC).

Handling documents having both hierarchical structure and complex layout To fully explore the capability of SPADE♤, we further evaluate the model on invoice IE task. Typical invoices have a hierarchical structure where some fields need to be grouped together, such as `item_name`, `count`, and `price` that correspond to one same item. In addition, invoices also have a relatively complex layout, having multiple tables or columns. SPADE♤ achieves +1.9 F_1 compared to S$_{ADV}$+BERT+IOB$_2$ (Table. 3, INV).

Handling general documents In order to see if SPADE♤ can handle more general kinds of documents, we use the FUNSD form understanding dataset (Jaume et al., 2019) where document IE is performed under a more abstract setting by finding general key-value pairs and their inter-grouping (Section A.1.6). The performance is measured on two OCR-independent subtasks (Jaume et al., 2019): (1) "entity-labeling (ELB)" which predicts the information category of the serialized words, and (2) "entity-linking (ELK)" which measures the score for key-value pair link prediction. The evaluation reveals that SPADE♤ achieves the state of the art on ELK, outperforming the previous baseline by 37.3% F_1 (Table 4, rightmost column). In ELB, SPADE♤ achieves +11.5% F_1 absolute improvement with respect to BERT-Base Tagger. Both models use BERT-Base as a backbone. Although the F_1 scores of LayoutLM are higher than our model, their contributions are orthogonal to ours since they focus on making a better pretrained model. Also, it cannot perform ELK. We emphasize that SPADE♤ solves the three subtasks–ELB, ELK, and word serialization–simultaneously, while other tagger models need to use the perfectly serialized input text and solve only entity labeling. The stable performance of SPADE♤ over randomly rotated documents (ELB-R) or shuffled tokens (ELB-S) supports this highlighting the merit of the serializer-

---

[5] S stands for the serializer.

free architecture.

Table 4: F_1 scores for two FUNSD subtasks: entity labeling (ELB, ELB-R, and ELB-S) and entity linking (ELK). "Need `S`" means the input tokens should be serialized. "# of `D`" indicates the number of documents used for layout pretraining.

Model	Need `S`	# of `D`	ELB	ELB-R	ELB-S	ELK

$ The separation of long input text (> 512) into multiple independent inputs introduces small difference in F_1.

†Five encoder layers are used for computational efficiency.

Ablation study We probe the role of each component of SPADE♤ via ablation study (Table 5). The performance drops dramatically upon the removal of the relative coordinate information of tokens in the self-attention layer, highlighting its importance in the serializer-free encoder (2nd row). When the absolute coordinates are used in the input instead of the relative coordinates, F_1 drops by 6.9% (3rd row). Finally, 2.6% drop in F_1 is observed upon the removal of the data augmentation during training (4th row).

Table 5: Ablation study on CORD dataset.

Model	F_1
SPADE♤†	84.5
(-) relative coordinate	10.5 (-74.0)
(-) relative coordinate (+) absolute coordinate	78.6 (-6.9)
(-) data augmentation	81.9 (-2.6)

† Five encoder layers are used for computational efficiency.

7 Conclusion

We present SPADE♤, a spatial dependency parser that can extract highly structured information from documents that have complex layouts. By formulating document IE as a spatial dependency graph construction problem, we provide a powerful unified framework that can extract hierarchical information without feature engineering. We empirically demonstrate the effectiveness of our model over various real-world documents—receipts, name cards, and invoices—and in a popular form understanding task.

Acknowledgments

A Appendices

A.1 Dataset

A.1.1 Dataset collection

The internal datasets Receipt-idn, namecard and Invoice are annotated by the crowd through an in-house web application following (Park et al., 2019; Hwang et al., 2019). First, each text segment is labeled (bounding box and the characters inside) for the OCR task. The text segments are further grouped according to their field types by the crowds. For Receipt-idn and Invoice, additional group-ids are annotated to each field for inter-grouping of them. The text segments placed on the same line are also annotated through row-ids. For quality assurance, the labeled documents are cross-inspected by the crowds.

A.1.2 CORD, CORD+, CORD++, and CORD-M for receipt IE

CORD and their variant consist of 30 information categories such as `menu_name`, `count`, `unit_price`, `price`, and `total_price` (Table 6). The fields are further grouped and forms the information layer at a higher level.

A.1.3 Receipt-idn for receipt IE

Receipt-idn is similar to CORD but includes more diverse information categories (50) such as `store_name`, `store_address`, and `payment_time` (Table 6).

A.1.4 namecard for name card IE

namecard consists of 12 field types, including `name`, `company_name`, `position`, and `address` (Table 6). The task requires grouping and ordering of tokens for each field. Although there is only a single information layer (field), the careful handling of complex spatial relations is required due to the large degree of freedom in the layout.

A.1.5 Invoice for invoice IE

Invoice consists of 62 information categories such as `item_name`, `count`, `price_with_tax`, `item price_without_tax`, `total_price`, `invoice_number`, `invoice_date`, `vendor_name`, and `vendor_address` (Table 6). Similar to receipts, their hierarchical information is represented via inter-field grouping.

A.1.6 FUNSD for general form understanding

FUNSD form understanding task consists of two sub tasks: entity labeling (ELB) and entity linking (ELK). In ELB, tokens are classifed into one of four fields–header, question, answer, and other–while doing serialization of tokens within each field. Both subtasks assume that the input tokens are perfectly serialized with no OCR error. To emphasize the importance of correct serialization in the real-world, we prepare two variant of ELB tasks: ELB-R and ELB-S. In ELB-R, the whole documents are randomly rotated by a degree of -20°–20° and the input tokens are serialized using rotated y-coordinates. In ELB-S task, the input tokens are randomly shuffled. In both tasks, the relative order of the input tokens within each field remain unchanged. In ELK task, tokens are linked based on their key-value relations (inter-grouping between fields). For example, each "header" is linked to the corresponding "question", and "question" is paired with the corresponding "answer".

Table 6: The representative fields of the datasets.

Dataset	representative fields and their numbers
CORD,CORD+, CORD++,CORD-M	`menu_name` (2572), `count` (2357), `unit_price` (737), `price` (2559), `total_price` (974)
Receipt-idn	`menu_name` (28832), `munu_count` (27132), `menu_unitprice` (11530), `menu_price` (28028), `total_price` (10284), `store_name` (9413), `payment_time` (9817)
namecard	`name` (25917), `company_name` (24386), `position` (22848), `address` (26018)
Invoice	`item_name` (2761), `count` (1950), `price_with_tax`(781), `price_without_tax` (2230), `total_price` (844), `invoice_number` (803), `invoice_date` (987), `vendor_name` (993), `vendor_address` (993),
FUNSD^a	`header` (563), `question` (4343), `answer` (3623), `other` (1214)

[a] From (Jaume et al., 2019).

A.2 Evaluation metric

During calculation of F_1 for parses, the difference between prediction and ground truth is not counted in `store_name`, `menu_name`, and `item_name` fields in receipt and invoice when the edit distance (ED) is less then 2 or when the ED/gt-string-length ≤ 0.4. Also, in Japanese documents, white spaces are ignored.

In the FUNSD form understanding task, we measure entity labeling (ELB) and entity linking (ELK) scores following (Jaume et al., 2019). ELB measures the field classification accuracy of already "perfectly" serialized tokens of each field (words group), whereas ELK measures the inter-grouping accuracy between word groups. As SPADE♤ does both the serialization of the fields and grouping between fields simultaneously, we do not feed the serialized tokens into SPADE♤ but only use the oracle information to indicate the first text node of each field from the predicted graph. These text nodes effectively represent entire fields and are used for the evaluation.

A.3 The score for the dependency relation prediction

Table 7: The score for the dependency relation prediction. `s` and `g` stand for `rel-s` and `rel-g`.

		Precision					Recall					F_1

Abstract

Current open-domain question answering systems often follow a Retriever-Reader architecture, where the retriever first retrieves relevant passages and the reader then reads the retrieved passages to form an answer. In this paper, we propose a simple and effective passage reranking method, named Reader-guIDEd Reranker (RIDER), which does not involve training and reranks the retrieved passages solely based on the top predictions of the reader before reranking. We show that RIDER, despite its simplicity, achieves 10 to 20 absolute gains in top-1 retrieval accuracy and 1 to 4 Exact Match (EM) gains without refining the retriever or reader. In addition, RIDER, without any training, outperforms state-of-the-art transformer-based supervised rerankers. Remarkably, RIDER achieves 48.3 EM on the Natural Questions dataset and 66.4 EM on the TriviaQA dataset when only 1,024 tokens (7.8 passages on average) are used as the reader input after passage reranking.[1]

1 Introduction

Current open-domain question answering (OpenQA) systems often follow a Retriever-Reader (R2) architecture, where the retriever first retrieves relevant passages and the reader then reads the retrieved passages to form an answer. Since the retriever retrieves passages from a large candidate pool (*e.g.*, millions of Wikipedia passages), it often fails to rank the most relevant passages at the very top. One line of work (Mao et al., 2020; Karpukhin et al., 2020) aims to improve the retriever and shows that significantly better QA performance can be achieved when the retrieval results are improved.

An alternative solution is to rerank the initial retrieval results via a reranker, which is widely used in information retrieval (Nogueira and Cho, 2019; Qiao et al., 2019) and explored in early OpenQA systems (Wang et al., 2018a; Lee et al., 2018). However, current state-of-the-art OpenQA systems (Karpukhin et al., 2020; Izacard and Grave, 2020b) do not distinguish the order of the retrieved passages and instead equally consider a large number of retrieved passages (*e.g.*, 100), which could be computationally prohibitive as the model size of the readers becomes larger (Izacard and Grave, 2020b).

We argue that a Retriever-Reranker-Reader (R3) architecture is beneficial in terms of both model effectiveness and efficiency: passage reranking improves the retrieval accuracy of the retriever at top positions and allows the reader to achieve comparable performance with fewer passages as the input. However, one bottleneck of R3 is that the reranker, previously based on BiLSTM (Wang et al., 2018a; Lee et al., 2018) and nowadays typically BERT-based cross-encoder (Nogueira and Cho, 2019; Qiao et al., 2019), is often costly to train and its slow inference delays the whole pipeline as well.

Can we achieve better performance without the bother of training an expensive reranker or refining the retriever (reader)? In this paper, we propose a simple and effective passage reranking method, named **R**eader-gu**IDE**d **R**eranker (RIDER), which does not require any training and reranks the retrieved passages solely based on their lexical overlap with the top predicted answers of the reader before reranking. Intuitively, the top predictions of the reader are closely related to the ground-truth answer and even if the predicted answers are partially correct or incorrect, they may still provide useful signals suggesting which passages may contain the correct answer (Mao et al., 2020).

We conduct experiments on the Natural Questions (NQ) (Kwiatkowski et al., 2019) and Triv-

iaQA (Trivia) (Joshi et al., 2017) datasets. We demonstrate that R3 with RIDER, without any additional training, achieves 10 to 20 absolute gains in top-1 retrieval accuracy, and 1 to 4 gains in Exact Match (EM) compared to the R2 architecture. RIDER also outperforms two state-of-the-art transformer-based supervised reranking models that require expensive training and inference. Notably, using only 1,024 tokens (7.8 passages on average) as the input of a generative reader, RIDER achieves EM=47.5/63.5 on NQ/Trivia when the predictions of the same generative reader (EM=45.3/62.2 in R2) are used for reranking, and EM=48.3/66.4 on NQ/Trivia when the predictions of an extractive reader (EM=43.8/62.7 in R2) are used for reranking.

Contributions. (1) We propose Reader-guIDEd Reranker (RIDER), a simple and effective passage reranking method for OpenQA, which reranks the retriever results by the reader predictions without additional training and can be easily applied to existing R2 systems for performance improvements. (2) We demonstrate that the passages reranked by RIDER achieve significantly better retrieval accuracy and consequently lead to better QA performance without refining the retriever or reader. (3) Notably, RIDER achieves comparable or better performance than state-of-the-art methods on two benchmark datasets when only 1,024 tokens are used as the reader input after passage reranking.

2 Method

2.1 Task Formulation

We assume that an OpenQA system with an R2 architecture is available. We denote the initially retrieved passages of the retriever as $\mathbf{R}$. We denote the top-N predictions of the reader on the top-k passages of $\mathbf{R}$ (denoted as $\mathbf{R}^{[:k]}$) as $\mathbf{A}^{[:N]}$. The goal of RIDER is to rerank $\mathbf{R}$ to $\mathbf{R}'$ using $\mathbf{A}^{[:N]}$ such that the retrieval accuracy is improved and better end-to-end QA results are achieved when $\mathbf{R}'^{[:k]}$ is used as the reader input instead of $\mathbf{R}^{[:k]}$.

2.2 Passage Reranking

Given an initially retrieved passage list $\mathbf{R}$ and top-N predictions of the reader $\mathbf{A}^{[:N]}$, RIDER forms a reranked passage list $\mathbf{R}'$ as follows. RIDER scans $\mathbf{R}$ from the beginning of the list and appends to $\mathbf{R}'$ every passage $p \in \mathbf{R}$ if p contains any reader prediction $a \in \mathbf{A}^{[:N]}$ after string normalization (removing articles and punctuation) and tokenization. Then, the remaining passages are appended to $\mathbf{R}'$ according to their original order.

Intuitively, if the reader prediction is perfect, the retrieval accuracy after reranking is guaranteed to be optimal. Specifically, if the reader prediction is correct, it is guaranteed that the retrieval accuracy after reranking is better, since RIDER moves all passages containing the correct answer to the top (or at least the same if those passages are *all* at the top before reranking). If the reader prediction is wrong, RIDER could still be better if the predicted answer co-occurs with the correct answer, the same, or worse if the predicted answer is misleading. In practice, if the reader performs reasonably well, RIDER is also likely to rerank passages well. Overall, we observe quantitatively that RIDER leads to consistent gains in terms of both retrieval accuracy and QA performance without refining the retriever (reader) or even any training itself despite the noise in reader predictions.

2.3 Passage Reading

We consider a scenario where the number of passages that can be used for QA is limited (sometimes deliberately) due to reasons such as insufficient computational resources, the limit of model input length, or requirement for faster responses. We use a generative reader initialized by BART-large (Lewis et al., 2019), which concatenates the question and top-10 retrieved passages, trims them to 1,024 tokens (7.8 passages are left on average) as the input, and learns to generate the answer in a seq2seq manner (Mao et al., 2020; Min et al., 2020). We further add a simple shuffle strategy during reader training, which randomly shuffles the top retrieved passages before concatenation. In this way, the reader appears to be more robust to the reranked passages during inference and achieves better performance after reranking.

3 Experiment Setup

Datasets. We conduct experiments on the open-domain version of two widely used QA benchmarks – Natural Questions (NQ) (Kwiatkowski et al., 2019) and TriviaQA (Trivia) (Joshi et al., 2017), whose statistics are listed in Table 2.

Evaluation Metrics. Following prior studies (Mao et al., 2020; Karpukhin et al., 2020), we use top-k retrieval accuracy to evaluate the retriever and Exact Match (EM) to evaluate the reader. *Top-k retrieval accuracy* is the proportion of questions for

Data Input	NQ					Trivia				
	Top-1	Top-5	Top-10	Top-20	Top-100	Top-1	Top-5	Top-10	Top-20	Top-100
$\mathbf{R}$	46.8	70.7	77.0	81.5	88.9	53.2	73.1	77.0	80.4	85.7
$\mathbf{R}'$ by $\mathbf{G}$ (N=1)	**58.6**	71.4	76.9	81.6	88.9	**68.8**	74.8	77.5	80.4	85.7
$\mathbf{R}'$ by $\mathbf{G}$ (N=10)	56.4	**72.2**	**77.3**	81.6	88.9	66.9	**75.3**	**77.9**	**80.8**	85.7
$\mathbf{R}'$ by $\mathbf{E}$ (N=1)	**60.4**	72.1	77.3	81.7	88.9	**71.9**	77.5	79.8	81.8	85.7
$\mathbf{R}'$ by $\mathbf{E}$ (N=5)	53.5	**75.2**	**80.0**	83.2	88.9	63.2	**77.9**	**80.7**	82.8	85.7
$\mathbf{R}'$ by $\mathbf{E}$ (N=10)	50.3	74.3	80.0	**84.2**	88.9	59.8	77.1	80.5	**82.9**	85.7

Table 1: **Top-k retrieval accuracy on the test sets before and after reranking**. $\mathbf{G}$ and $\mathbf{E}$ denote generative and extractive readers, respectively, whose top predictions are used for reranking.

Dataset	Train / Val / Test	Q-len	A-len	#-A
NQ	79,168 / 8,757 / 3,610	12.5	5.2	1.2
Trivia	78,785 / 8,837 / 11,313	20.2	5.5	13.7

Table 2: **Dataset statistics** that show the number of samples, the average question (answer) length, and the average number of answers for each question.

which the top-k retrieved passages contain at least one answer span. It is an upper bound of how many questions are answerable by an extractive reader. *Exact Match (EM)* is the proportion of the predicted answer spans being exactly the same as one of the ground-truth answers, after string normalization such as article and punctuation removal.

Source of R. Following Mao et al. (2020), we take the top 100 retrieved passages of GAR (Mao et al., 2020) on Trivia and its combination with DPR (Karpukhin et al., 2020) on NQ as the initial retrieval results $\mathbf{R}$ for reranking.

Source of $\mathbf{A}^{[:N]}$. To obtain the top-N predicted answers, we first take the predictions of the generative reader ($\mathbf{G}$) in Sec. 2.3, which is trained on the passages without reranking and used for final passage reading in R3. It represents an apple-to-apple comparison to R2 without any additional information but higher-quality input. We also experiment with an extractive reader ($\mathbf{E}$) that has access to all retrieved passages, where the goal is to study whether we can rerank passages via other signals and further improve $\mathbf{G}$ such that it outperforms both $\mathbf{G}$ and $\mathbf{E}$ when they are in R2. We use the extractive reader in Mao et al. (2020) with BERT-base (Devlin et al., 2019) representation and span voting.

For the generative reader, we either take its top-1 prediction with greedy decoding or sample 10 answers with decoding parameters as follows. We set sampling temperature to 5/2 and the top probability in nucleus sampling to 0.5/0.5 on NQ/Trivia, respectively. Note that there are duplicate samples and on average $\bar{N} = 6$. We set the max input length to 1,024 and max output length to 10. For the extractive reader, the top predictions are the text spans with the highest scores and we set $N = 1, 5, 10$.

4 Experiment Results

4.1 Quality of Reranking Signals

We first analyze the EM of the top-N reader predictions $\mathbf{A}^{[:N]}$. We consider a question correctly answered as long as one of the top-N predictions matches the ground-truth answer. The standard EM is a special case with $N = 1$. As listed in Table 3, the reader EM can be improved by up to 24.0 on NQ and 15.8 on Trivia if we consider the top-10 predictions instead of only the first prediction, suggesting that there is significant potential if we use multiple predicted answers for reranking. That said, using more reader predictions also introduces more noise, *i.e.*, incorrect answers, which could be misleading at times.

Dataset	Top-1	Top-3	Top-5	Top-10
NQ	43.8 (45.3)	57.4	62.6	67.8 (54.2)
Trivia	62.7 (62.2)	72.6	75.5	78.5 (67.7)

Table 3: **EM of top-N predictions of the reader.** Results are mostly on reader $\mathbf{E}$. Only top-1 and top-10 EM are shown (in the brackets) for reader $\mathbf{G}$, as its 10 predictions are sampled without particular order.

4.2 RIDER for Passage Retrieval

We list the top-k retrieval accuracy before and after passage reranking in Table 1. RIDER significantly improves the retrieval accuracy at top positions (especially top-1) without refining the retriever. In particular, we observe that when taking more reader predictions (*i.e.*, larger N), the top-k retriever accuracy tends to improve more at a larger k and less at a smaller k. For example, an improvement of about 3 points is achieved for top-5 and top-10 accuracy when increasing N from 1 to 5 on NQ for reader $\mathbf{E}$, but the top-1 retrieval accuracy also drops significantly (although still better than without reranking), which again suggests that there is a trade-off between answer coverage and noise. Note that the top-100 retrieval accuracy is unchanged after reranking since we rerank the top-100 passages.

4.3 RIDER for Passage Reading

Comparison w. the state-of-the-art. We show the QA performance comparison between RIDER and state-of-the-art methods in Table 4. We observe that RIDER improves GAR (or GAR+DPR) on both datasets by a large margin, despite that they use the same generative reader and no further model training is conducted. Such results indicate that RIDER provides higher-quality input for the reader and better performance can be achieved with the same input length. Moreover, the results of RIDER are better than most of the existing methods that take more passages as input, except for FID-large (Izacard and Grave, 2020b) that reads 100 passages and also has more model parameters.

	Method	**NQ**	**Trivia**
Extractive	Hard EM (Min et al., 2019a)	28.1	50.9
	Path Retriever (Asai et al., 2019)	32.6	-
	ORQA (Lee et al., 2019)	33.3	45.0

	RIDER (GAR+DPR)	**48.3**	-

Table 4: **End-to-end QA comparison of state-of-the-art methods**. RIDER results in up to 4.2 EM gains.

Data Input	**NQ**	**Trivia**
$\mathbf{R}$	45.3	62.2
$\mathbf{R}'_1$ by $\mathbf{G}$ (N=1)	(45.3+1.1) 46.4	(62.2+0.7) 62.9
$\mathbf{R}'_2$ by $\mathbf{G}$ (N=10)	(45.3+2.1) **47.4**	(62.2+0.9) **63.1**
$\mathbf{R}''$ by $\mathbf{R}'_1$	(46.4+1.1) **47.5**	(62.9+0.6) **63.5**
$\mathbf{R}'$ by $\mathbf{E}$ (N=1)	(43.8+3.2) 47.0	(62.7+3.4) **66.1**
$\mathbf{R}'$ by $\mathbf{E}$ (N=5)	(43.8+4.5) **48.3**	(62.7+2.5) 65.2
$\mathbf{R}''$ by best $\mathbf{R}'$	(48.3+0) **48.3**	(66.1+0.3) **66.4**

Table 5: **Comparison of RIDER in EM when different reranking signals are used**. The numbers in the brackets represent the performance of the reader used for reranking and relative gains.

Method	**Top-1**	**Top-5**	**Top-10**	**Top-20**
$\mathbf{R}$	46.8	70.7	77.0	81.5
$\mathbf{R}'$ by BERT reranker	51.4	67.6	75.7	82.4
$\mathbf{R}'$ by BART reranker	55.2	73.5	78.5	82.2
$\mathbf{R}'$ by $\mathbf{G}$ (N=10)	**56.4**	72.2	77.3	81.6
$\mathbf{R}'$ by $\mathbf{E}$ (N=5)	53.5	**75.2**	**80.0**	**83.2**

Table 6: **Comparison with supervised rerankers in top-k retrieval accuracy on NQ**. RIDER outperforms expensive transformer-based models without training.

Ablation Study. A detailed analysis of RIDER with different reranking signals is shown in Table 5. By reranking based on the prediction of the generative reader $\mathbf{G}$ (with input $\mathbf{R}^{[:k]}$), RIDER generally achieves 1 to 2 gains in EM, which shows that RIDER can improve end-to-end QA performance without any additional information. By iterative reranking ($\mathbf{R}''$) using the reader predictions after first reranking, the performance of RIDER is further improved. Conducting more than two iterations of reranking does not appear to bring additional gains.

RIDER achieves even better performance when using the predictions of the extractive reader $\mathbf{E}$ (with input $\mathbf{R}$) for reranking, which is consistent with the results on retrieval. It is also encouraging to see that RIDER significantly outperforms $\mathbf{E}$, which is more computationally expensive and has access to much more passages.

4.4 Comparison w. Supervised Reranking

Finally, we compare RIDER with two state-of-the-art supervised reranking models. The first reranker is a BERT-base cross-encoder (Nogueira and Cho, 2019), which is popularly used for passage reranking in information retrieval. The cross-encoder concatenates the query and passage, and makes a binary relevance decision for each query-passage pair. The second one generates relevance labels as target tokens in a seq2seq manner (Nogueira et al., 2020). We use BART-large as the base model and "YES/NO" as the target tokens.

As listed in Table 6, RIDER, without any training, outperforms the two transformer-based supervised rerankers on retrieval accuracy. Also, for QA performance, the best EM we obtain using the supervised rerankers is merely 46.3 on NQ. Such results further demonstrate the effectiveness of RIDER, which has the advantage of utilizing information from multiple passages (when the reader makes predictions), while the other rerankers consider query-passage pairs independently.

4.5 Runtime Efficiency

The reranking step of RIDER only involves string processing, which can be easily paralleled and reduced to within seconds. We use Nvidia V100 GPUs for reader training and inference. The training of the generative reader takes 8 to 10 hours with 1 GPU, while it takes 12 to 16 hours with 8 GPUs for the DPR reader (Karpukhin et al., 2020). Due to fewer input passages, the inference of the generative reader is also very efficient – it takes around 3.5/11 min to generate answers on the NQ/Trivia test set with 1 GPU. In comparison, the DPR reader takes about 14/40 min with 8 GPUs.

5 Related Work

Reranking for OpenQA. Reranking has been widely used in information retrieval to refine the initial retrieval results. Early effort on passage reranking for OpenQA uses supervised (Lee et al., 2018) or reinforcement learning (Wang et al., 2018a) based on BiLSTM. More recently, BERT-based rerankers that treat the query and passage as a sentence pair (*i.e.*, cross-encoders) achieve superior performance (Nogueira and Cho, 2019; Qiao et al., 2019). However, the training of cross-encoders is rather costly. Moreover, the representations of cross-encoders cannot be pre-computed and matched via Maximum Inner Product Search (MIPS) as in bi-encoders (Karpukhin et al., 2020) but measured online between the query and each passage, which results in slower inference as well.

Another line of work (Das et al., 2018; Qi et al., 2020) reranks the passages by updating the query and often involves a complicated learning process such as R2 interactions. Alternatively, some prior studies (Wang et al., 2018b; Iyer et al., 2020) directly rerank the top predicted answers instead of the passages using either simple heuristics or additional training. In contrast, RIDER utilizes downstream signals (*i.e.*, the predictions of a reader) to rerank the passages without any training.

Reader Distillation. Recent studies (Izacard and Grave, 2020a; Yang and Seo, 2020) show that distillation from the preference of the reader can improve the retriever performance, where the reader preference is measured by the attention scores of the reader over different passages and the retriever is refined by learning to approximate the scores. RIDER, to some extent, can also be seen as one way to distill the reader. However, RIDER is much simpler in that no further training is involved for either the retriever or reader, and explicit reader predictions instead of latent attention scores are leveraged to improve the retriever results directly.

6 Conclusion

In this work, we propose RIDER, a simple and effective passage reranking method for OpenQA, which does not involve additional training or computationally expensive inference, and outperforms state-of-the-art supervised rerankers that involve both. RIDER can be easily integrated into existing R2 systems for performance improvements. Without fine-tuning the retriever or reader, RIDER improves the retrieval accuracy and the QA results on two benchmark datasets significantly. Notably, RIDER achieves comparable or better performance than state-of-the-art methods with less reader input and allows for more efficient OpenQA systems. For future work, we will explore other simple and effective reranking strategies with no (minimal) training or external supervision.

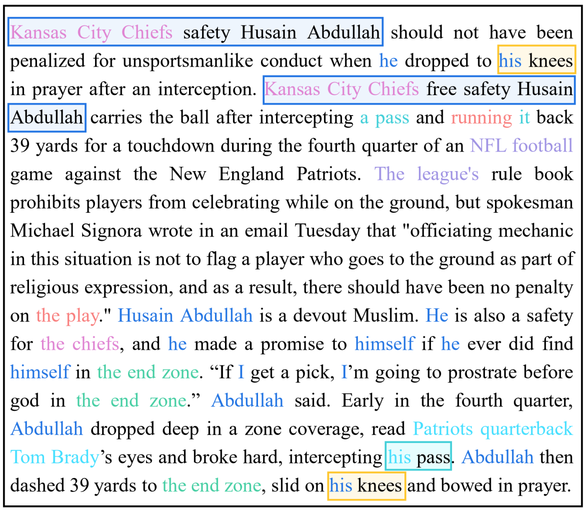
Abstract

Entities and their mentions convey significant semantic information in documents. In multi-document summarization, the same entity may appear across different documents. Capturing such cross-document entity information can be beneficial – intuitively, it allows the system to aggregate diverse useful information around the same entity for better summarization. In this paper, we present EMSum, an entity-aware model for abstractive multi-document summarization. Our model augments the classical Transformer-based encoder-decoder framework with a heterogeneous graph consisting of text units and entities as nodes, which allows rich cross-document information to be captured. In the decoding process, we design a novel two-level attention mechanism, allowing the model to deal with saliency and redundancy issues explicitly. Our model can also be used together with pre-trained language models, arriving at improved performance. We conduct comprehensive experiments on the standard datasets and the results show the effectiveness of our approach.

1 Introduction

Multi-document summarization aims at generating a short and informative summary across a set of topic-related documents. It is a task that can be more challenging than single-document summarization due to the presence of diverse and potentially conflicting information (Ma et al., 2020).

While significant progress has been made in single-document summarization, the mainstream sequence-to-sequence models, which can perform well on single-document summarization, often struggle with extracting salient information and handling redundancy in the presence of multiple, long documents. Thus, simply adopting models that were shown effective for single-document summarization to the multi-document setup may not lead to ideal results (Lebanoff et al., 2018; Zhang et al., 2018; Baumel et al., 2018).



Kansas City Chiefs safety Husain Abdullah should not have been penalized for unsportsmanlike conduct when he dropped to his knees in prayer after an interception. Kansas City Chiefs free safety Husain Abdullah carries the ball after intercepting a pass and running it back 39 yards for a touchdown during the fourth quarter of an NFL football game against the New England Patriots. The league's rule book prohibits players from celebrating while on the ground, but spokesman Michael Signora wrote in an email Tuesday that "officiating mechanic in this situation is not to flag a player who goes to the ground as part of religious expression, and as a result, there should have been no penalty on the play." Husain Abdullah is a devout Muslim. He is also a safety for the chiefs, and he made a promise to himself if he ever did find himself in the end zone. "If I get a pick, I'm going to prostrate before god in the end zone." Abdullah said. Early in the fourth quarter, Abdullah dropped deep in a zone coverage, read Patriots quarterback Tom Brady's eyes and broke hard, intercepting his pass. Abdullah then dashed 39 yards to the end zone, slid on his knees and bowed in prayer.

Figure 1: A sample article from MultiNews. We show the results of co-reference resolution. Mentions of the same entity are highlighted with the same color.

Several previous research efforts have shown that modeling cross-document relations is essential in multi-document summarization (Liu and Lapata, 2019a; Li et al., 2020). Such relations were shown useful in identifying the salient and redundant information from long documents, and can thus guide the summary generation process. However, while effective empirically, such approaches do not focus on explicitly modeling the underlying semantic information across documents.

Entities and their mentions convey rich semantic information, and can be significant in summarization, especially when a specific entity is the topic under discussion for a set of documents. As shown in Figure 1, entity mentions frequently appear in the input article, and are playing unique roles that contribute towards the coherence and conciseness of the text. We believe that entities can be regarded

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 351–362
August 1–6, 2021.

as the indicator of saliency and can be used to reduce redundancy. This motivates us to propose an entity-aware abstractive multi-document summarization model that effectively encodes relations across documents with the help of entities, and explicitly solve the issues of saliency and redundancy.

Inspired by Wang et al. (2020a), we build a heterogeneous graph that consists of nodes that represent documents and entities. The entity nodes can serve as bridges that connect different documents – we can model the relations across documents through entity clusters. We apply the graph attention network (GAT) (Veličković et al., 2017) to enable information flow between nodes and iteratively update the node representations. In the decoding process, we design a novel two-level attention mechanism. The decoder first attends to the entities. Next, the attention weights of entities are incorporated with graph edge weights to guide the attention to the documents. Intuitively, the first stage indentifies the salient content in each decoding step. By considering the global interactions between entities and documents in the graph, the second stage is able to handle the redundancy issue. Experiments show that our model significantly improves the performance on several multi-document datasets. Further improvements can be made when our model is used together with the pre-trained language models.

Our contributions are as follows:

- We construct a heterogeneous graph network for multi-document summarization. The graph consists of document-level and entity-level nodes. To the best of our knowledge, we are the first to model the relations between documents and entities in one heterogeneous graph. Experiments show that exploiting entity nodes as the intermediary between documents can be more effective than exploiting other semantic units (e.g., words).
- We propose a novel two-level attention mechanism during the decoding process, solving the issues of saliency and redundancy explicitly. The mechanism can also reduce the computational cost, making it easier to process long inputs.
- Our model achieves state-of-the-art results on WikiSum and MultiNews. Extensive analysis including ablation studies show the effectiveness of our model.[1]

2 Related Work

2.1 Abstractive Document Summarization

Abstractive summarization is often regarded as the ultimate goal of document summarization research. Extractive summarization methods produce summaries that are semantically similar to the original documents. Thus, they may be able to achieve relatively high ROUGE scores (Lin, 2004). However, sentence-level extraction lacks flexibility and tends to produce redundant information. By contrast, the process of abstractive summarization is more similar to the human summarization process and requires more sophisticated natural language understanding and generation techniques. Traditional approaches to abstractive summarization can be divided into sentence fusion-based (Barzilay and McKeown, 2005; Filippova and Strube, 2008; Banerjee et al., 2015), paraphrasing-based (Bing et al., 2015; Cohn and Lapata, 2009) and information extraction-based (Li, 2015; Wang and Cardie, 2013; Pighin et al., 2014).

With the development of neural-based methods, abstractive methods achieved promising results on single document summarization (See et al., 2017; Paulus et al., 2018; Gehrmann et al., 2018; Li et al., 2018). More recently, due to the excellent performance on various text generation tasks, transformer-based methods become the mainstream approach for abstractive multi-document summarization, as well as pre-trained language models. Liu and Lapata (2019b) propose BertSUM for both extractive and abstractive summarization. Zhang et al. (2019) build low-level and high-level Berts for sentence and document understanding, respectively. Moreover, several general purpose sequence-to-sequence pre-trained models are proposed, such as T5 (Raffel et al., 2020) and BART (Lewis et al., 2019). They are further fine-tuned for the summarization task. Zhang et al. (2020) propose PEGASUS, in which they design a pre-training objective tailored for abstractive text summarization. Zou et al. (2020) present three sequence-to-sequence pre-training objectives by reinstating source text for abstractive summarization.

2.2 Graph-based Document Summarization

Graph-based methods have long been utilized for extractive summarization. Text units on graphs are ranked and selected as the most salient ones to be included in the summary. LexRank (Erkan and Radev, 2004) computes sentence salience based on

---

[1] Our code is at https://github.com/Oceandam/EMSum

the eigenvector centrality in the connectivity graph of inter-sentence cosine similarity. Wan (2008) further incorporate the document-level information and the sentence-to-document relationship into the graph-based ranking process. Christensen et al. (2013) build multi-document graphs to approximate the discourse relations across sentences based on indicators including discourse cues, deverbal nouns, co-reference and more.

For recent methods based on graph neural networks, Tan et al. (2017) propose a graph-based attention mechanism to identify salient sentences. Yasunaga et al. (2017) construct an approximate discourse graph based on discourse markers and entity links, then apply graph convolutional networks over the relation graph. Fan et al. (2019) construct a local knowledge graph, which is then linearized into a structured input sequence so that models can encode within the sequence-to-sequence setting. Huang et al. (2020) further design a graph encoder, which improves upon graph attention networks, to maintain the global context and local entities complementing each other. Li et al. (2020) utilize homogeneous graphs to capture cross-document relations and guide the summary generation process. However, Wang et al. (2020a) are the first to introduce different granularity levels of text nodes to construct heterogeneous graphs for extractive summarization. Our work is partly similar to theirs, but we construct heterogeneous graphs composed of text unit nodes and entity nodes for abstractive multi-document summarization.

2.3 Summarization with Additional Features

In addition to the direct application of the general sequence-to-sequence framework, researchers attempted to incorporate various features into summarization. Cao et al. (2018) extract actual fact descriptions from the source text and propose a dual-attention mechanism to force the generation conditioned on both the source text and the extracted fact descriptions. Sharma et al. (2019) take a pipeline method for single-document summarization which is composed of an entity-aware content selection module and a summary generation module. By contrast, our EMSum model is an end-to-end method for multi-document summarization. Gunel et al. (2020) inject structural world knowledge from Wikidata to a transformer-based model, enabling the model to be more fact-aware. Zhu et al. (2020) extract factual relations from the source texts to build a local knowledge graph and integrated it into the transformer-based model.

Apart from entity or fact information, there are several works that incorporate topic information into summarization model. Narayan et al. (2018) recommend an encoder associating each word with a topic vector capturing whether it is representative of the document's content, and a decoder where each word prediction is conditioned on a document topic vector. Zheng et al. (2019) propose to mine cross-document subtopics. In their work, sentence salience is estimated in a hierarchical way with subtopic salience and relative sentence salience. Perez-Beltrachini et al. (2019) explicitly model the topic structure of summaries, and utilize it to guide a structured convolutional decoder. Wang et al. (2020b) rearrange and further explore the semantics of the topic model and develope a friendly topic assistant for transfomer-based abstractive summarization models.

3 Model

Our model is illustrated in Figure 2, which follows the transformer-based encoder-decoder architecture (Vaswani et al., 2017). We modify the encoder with graph neural networks, so we can incorporate entity information and graph representations at the same time. We design a novel two-level decoding process to explicitly deal with the problem of saliency and redundancy.

3.1 Entity Cluster Extraction

Wang et al. (2020a) use words as semantic units in addition to sentence nodes, acting as the intermediary to enrich the relationships between sentences. However, we argue that word-level semantic units are too fine and will bring huge computational costs. For multi-document summarization, models are usually required to process tens of documents. The total number of words will be vast, which further causes a hindrance for the graph construction and message passing process. Therefore, we use entity clusters as more advanced semantic units. We utilize the co-reference resolution tool (Lee et al., 2017) from AllenNLP (Gardner et al., 2018) to extract entity clusters. Note that we perform extraction globally, which means we concatenate all the documents into one long document. We denote the extracted entity clusters as $\mathcal{C} = \{C_1, C_2, \ldots, C_m\}$, where $C_i = \{mention_1, mention_2, \ldots, mention_l\}$, and l is

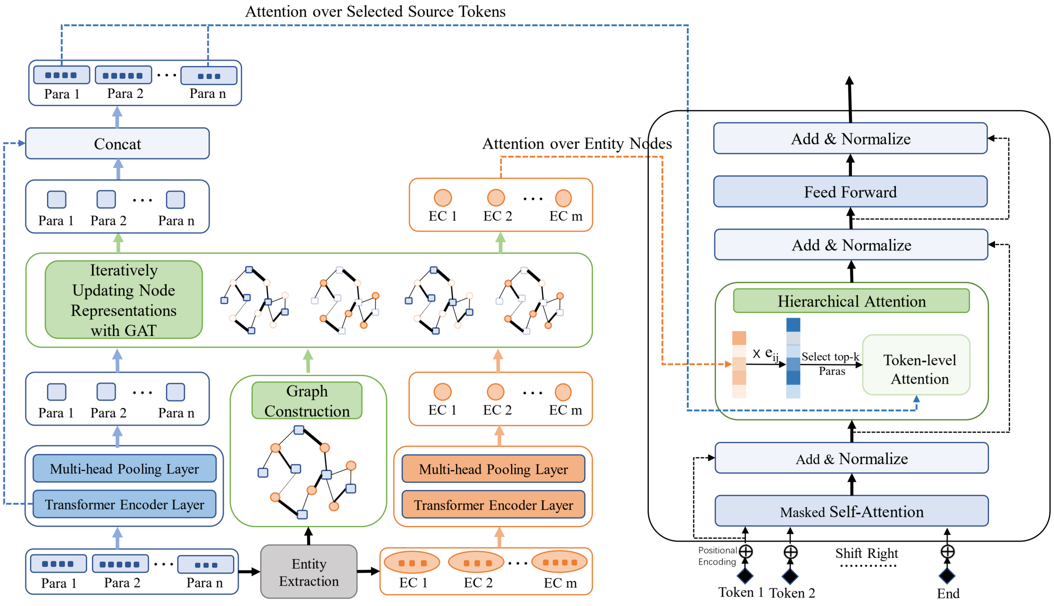

Figure 2: Overall architecture of our model.

the number of entity mentions in cluster C_i.

3.2 Graph Construction

Given a source document cluster $\mathcal{D}$, we firstly divide them into smaller semantic units $\mathcal{P} = \{P_1, P_2, \ldots, P_n\}$, such as paragraphs and sentences, depending on the characteristics of datasets. We then construct a heterogeneous graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$. $\mathcal{V}$ includes paragraph nodes $\mathcal{V}_p$ and entity cluster nodes $\mathcal{V}_c$. $\mathcal{E}$ represents undirected edges between nodes. There exists no edge inside paragraph nodes or entity cluster nodes, but only between them. An edge which connects P_i and C_j means paragraph P_i contains an entity mention in C_j.

We would like to include more information in the graph. We get an occurrence matrix $\mathbf{E} \in \mathbb{R}^{m \times n}$ after extraction, where $e_{ij} \neq 0$ indicates P_i contains entity mentions in C_j for e_{ij} times. Based on $\mathbf{E}$, we further calculate the TF-IDF value matrix $\tilde{\mathbf{E}} \in \mathbb{R}^{m \times n}$ to model the importance of relationships between entity clusters and paragraphs.

3.3 Document Encoder

Paragraph Encoder Several token-level transformer encoding layers are stacked to encode contextual information within each paragraph. The transformer layer is the same as the vanilla transformer layer (Vaswani et al., 2017). Let x_w^0 be the input token vector. For the l-th transformer layer, the input is x_w^{l-1}, the hidden state is h_w^l, and the output is x_w^l.

$$h_w^l = \text{LayerNorm}(x_w^{l-1} + \text{MHAttn}(x_w^{l-1})) \quad (1)$$

$$x_w^l = \text{LayerNorm}(h_w^l + \text{FFN}(h_w^l)) \quad (2)$$

LayerNorm is the layer normalization operation (Ba et al., 2016). MHAttn is multi-head attention from Vaswani et al. (2017). FFN is a feed-forward network with ReLU as activation function. We take the output of last layer as token-level features. We use $\mathbf{H_{p_w}} \in \mathbb{R}^{n_w \times d_w}$ to denote the token-level feature matrix, where n_w is the total number of tokens in all paragraphs and d_w is the dimension of token embedding.

Multi-Head Pooling To obtain fixed length paragraph representations, we follow Liu and Lapata (2019a) to apply a weighted-pooling operation. The multi-head pooling mechanism calculates the weight distributions over tokens, allowing the model to flexibly encode paragraphs in different representational subspace by different head.

$$\mathbf{h_p} = \text{MHPool}(h_{w1}, h_{w2}, \ldots) \quad (3)$$

We use $\mathbf{H_p} \in \mathbb{R}^{n \times d_h}$ to denote the paragraph level feature matrix, where n is the number of paragraphs, d_h is the hidden size.

Entity Cluster Encoder We perform the same encoding process as the paragraph encoder to get entity clusters' representation, but without sharing parameters between the two encoders. We choose this method rather than additional entity embedding methods because we seek to model the relationship between paragraphs and entities in a unified semantic space. Note that we firstly remove pronouns and stopwords in entity mention clusters, which are common in co-reference resolution results but render little benefit for our semantic modeling. We use $\mathbf{H_{c_w}} \in \mathbb{R}^{m_w \times d_w}$ and $\mathbf{H_c} \in \mathbb{R}^{m \times d_h}$ to denote the token level feature matrix and cluster level feature matrix, respectively.

3.4 Graph Encoder

We use graph attention networks (GAT) (Veličković et al., 2017) to update the representations of semantic nodes. We use $i, j \in \{1, ..., (m+n)\}$ to denote an arbitrary node in graph, use $\mathbf{h}_i, \mathbf{h}_j \in \mathbb{R}^{d_h}$ to denote the node representations, and use $\mathcal{N}_i$ to denote the set of neighboring nodes of node i. The GAT layer is designed as follows:

$$z_{ij} = \text{LeakyReLU}(\mathbf{W}_a[\mathbf{W}_q\mathbf{h}_i; \mathbf{W}_k\mathbf{h}_j]) \quad (4)$$

$$\tilde{z}_{ij} = \tilde{e}_{ij} \times z_{ij} \quad (5)$$

$$\alpha_{ij} = \frac{\exp(\tilde{z}_{ij})}{\sum_{l \in \mathcal{N}_i} \exp(\tilde{z}_{il})} \quad (6)$$

$$\mathbf{u_i} = \sigma\left(\sum_{j \in \mathcal{N}_i} \alpha_{ij}\mathbf{W}_v\mathbf{h}_j\right) \quad (7)$$

where $\mathbf{W}_a$, $\mathbf{W}_q$, $\mathbf{W}_k$, $\mathbf{W}_v$ are trainable weights, σ is the sigmoid function, $\tilde{e}_{ij}$ is the edge weight derived from TF-IDF value matrix $\tilde{\mathbf{E}}$.

We basically follow Wang et al. (2020a) to iteratively update node representations. They infuse the scalar edge weight $\tilde{e}_{ij}$ by simply discretizing the real values into integers, and then learn embeddings for such integers. That is how they map the weights to the multi-dimensional embedding space $\mathbf{e_{ij}} \in \mathbb{R}^{d_e}$. In this way, the information contained in the values needs to be learned by an additional embedding matrix. However, we argue that TF-IDF values themselves indicate the closeness between an entity cluster and a paragraph. Therefore, we directly incorporate the raw TF-IDF information into the GAT mechanism by modifying the attention weights using Equation 5.

We combine GAT with multi-head operation. We also add a residual connection to avoid gradient vanishing after several iterations:

$$\tilde{\mathbf{h}}_i = \mathbf{h}_i + \mathbf{u}_i \quad (8)$$

We use the above GAT layer and position-wise feed-forward layer to iteratively update the node representations. Each iteration contains a paragraph-to-entity and a entity-to-paragraph updating process. After iterating for t times, we concatenate $\tilde{\mathbf{H}}_\mathbf{p}$ to each corresponding input token vector, arriving at $\tilde{\mathbf{H}}_{\mathbf{p_w}} \in \mathbb{R}^{n_w \times (d_w + d_h)}$.

3.5 Entity-Aware Decoder with Two-level Attention

Under the setting of multi-document summarization, the input source documents may involve an extremely large number of word tokens. If the decoder needs to compute attention weights over all tokens, the cost would be very high and the attention could be dispersed. Our two-level decoding process firstly focuses on several centering entity cluster nodes, which can be regarded as indicators of saliency. The indicator restricts the token-level attention only to some of the paragraphs, which can further reduce redundancy than naively attending to all tokens. Different from Section 3.4, we use i and j to denote the entity node and paragraph node, respectively.

Attending the Entity Cluster Nodes At each decoding step, the state of decoder is $\mathbf{s}$, we compute attention scores over entity cluster nodes $\mathbf{c}_i$.

$$z_i = \mathbf{u}_0^T \text{LeakyReLU}([\mathbf{W}_{z_1}\mathbf{s}; \mathbf{W}_e\mathbf{c}_i]) \quad (9)$$

The entity nodes act as the intermediary between paragraph nodes. We incorporate z_i with edge weights $\tilde{e}_{ij}$ to enable the information flow between entity nodes and paragraph nodes by:

$$\tilde{z}_j = \sum_{i=1}^{m} z_i \times \tilde{e}_{ij} \quad (10)$$

$$\beta_j = \frac{\exp(\tilde{z}_j)}{\sum_{l=1}^{m} \exp(\tilde{z}_l)} \quad (11)$$

Attending the Paragraph Tokens We select the top-k paragraph nodes with the highest attention score β_j. Then we apply the attention mechanism over the T_w tokens in the selected paragraphs.

$$z_{w_i} = \mathbf{u}_1^T \text{LeakyReLU}([\mathbf{W}_{z_2}\mathbf{s}_t; \mathbf{W}_w\tilde{h}_{w_i}]) \quad (12)$$

$$\gamma_{w_i} = \frac{\exp(z_{w_i})}{\sum_{l=1}^{T_w} \exp(z_{w_l})} \quad (13)$$

For token w_i in paragraph P_j, we further modify γ_{w_i} by

$$\hat{\gamma}_{w_i} = \beta_j \times \gamma_{w_i} \tag{14}$$

Then the context vector $\mathbf{v}_t$ can be computed by:

$$\mathbf{v}_t = \sum_i \hat{\gamma}_{w_i} \tilde{h}_{w_i} \tag{15}$$

Token Prediction Context vectors, treated as salient contents summarized from sources, are concatenated with the decoder hidden state $\mathbf{s}_t$ to produce the vocabulary distribution:

$$P_{vocab} = \mathrm{Softmax}(\mathbf{W}_o[\mathbf{s}_t; \mathbf{v}_t]) \tag{16}$$

We use the weight-sharing strategy between the input embedding matrix and the matrix $\mathbf{W}_o$ to reuse linguistic knowledge (Paulus et al., 2018). We further add a copy mechanism as proposed by See et al. (2017).

3.6 Training

Our training process follows that of the traditional sequence-to-sequence modeling, with maximum likelihood estimation that minimizes:

$$\mathcal{L}_{seq} = -\frac{1}{|D|} \sum_{(\mathbf{y},\mathbf{x}) \in D} \log p(\mathbf{y}|\mathbf{x}; \theta) \tag{17}$$

where $\mathbf{x}$ and $\mathbf{y}$ are document-summary pairs from training set D, and θ are parameters to be learned.

3.7 Pre-trained LMs as Document Encoder

Our document encoder illustrated in section 3.3 can be replaced by a pre-trained language model such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019). Pre-trained language models can be more effective on short inputs than training stacked transformer layers from scratch. We feed input tokens to a pre-trained language model and take the last layer output as token embeddings. Then a single-layer bidirectional LSTM is employed over token embeddings, producing token features. Finally, we perform the same multi-head pooling strategy to obtain paragraph representations.

4 Experiments

We use ROUGE scores to evaluate summarization quality automatically (Lin, 2004). We report different versions of the metric, based on overlaps of unigrams (ROUGE-1, R-1), bigrams (ROUGE-2, R-2) and the longest common subsequences (ROUGE-L, R-L).

4.1 Experimental Setup

We conduct experiments on two major datasets used in the literature of multi-document summarization, namely WikiSum (Liu et al., 2018) and MultiNews (Fabbri et al., 2019).

WikiSum Dataset Liu et al. (2018) treat the generation of Wikipedia section titles as a supervised multi-document summarization task. Liu and Lapata (2019a) crawled Wikipedia articles and source reference documents through the provided urls. They further split the long and messy source documents into multiple paragraphs by line-breaks and select the top-40 paragraphs as input for summarization systems. However, the top-40 dataset is quite heavy for entity extraction and co-reference resolution. Experiment shows that the ROUGE-L recall of top-20 paragraphs against the gold target text is 53.84, and top-40 is 60.42. So we choose to use the top-20 version of WikiSum dataset in order to find a balance between computational cost and the coverage of input content. We get 300,000 instances for training, 38,144 for validation and 38,205 for test. On average, each paragraph has 70.1 tokens, and target sumamry has 139.4 tokens. We then perform entity cluster extraction on the top-20 WikiSum dataset. For each instance, we get 23.7 clusters on average and each cluster has 10.2 tokens on average.

MultiNews Dataset Introduced by Fabbri et al. (2019), MultiNews consists of news articles and hand-written summaries. The source articles come from a diverse set of news sources, over 1,500 sites. Following their experimental settings, we get 44,972 instances for training, 5,622 for validation and 5,622 for test. Different from the WikiSum dataset, each source article only contains 2.8 paragraphs and 21.6 sentences on average, thus we choose to build graph on sentence level rather than paragraph level for this dataset. For each instance, we get 13.3 clusters on average and each cluster has 9.9 tokens on average.

Hyperparameters We set the number of our vanilla Transformer encoding layers as 6, the hidden size as 256 and the number of heads as 8, while the hidden size of feed-forward layers is 1,024. We truncate the length of input paragraphs and entity clusters to 100 and 50 tokens, respectively. In the multi-head pooling layer, the number of heads is 8. In the graph encoding process, each layer has 8 heads and the hidden size is 256. We select the

Table 1: Evaluation Results on WikiSum using ROUGE scores. The results of models with '†' are taken from Li et al. (2020). '$*$' indicates the results are obtained by running the released code. Model name with suffix '+R' means RoBERTa is used. 'Ext' means extractive methods, 'Abs' means abstractive methods.

number of iterations $t = 2$ based on the performance. We use dropout with probability 0.1 before all linear layers and label smoothing (Szegedy et al., 2016) with smoothing factor 0.1. We train our model for 200,000 steps with gradient accumulation every four steps. During decoding we apply beam search with beam size 5 and length penalty (Wu et al., 2016) with factor 0.4.

For models with pre-trained LMs, we choose the base version of RoBERTa. We follow Liu and Lapata (2019b), employing two Adam optimizers (Kingma and Ba, 2015) for the pre-trained part and other parts, with $\beta_1 = 0.9$, $\beta_2 = 0.998$. For the pre-trained part, the learning rate and warmup steps are set as 0.002 and 20,000, while for other parts are 0.2 and 8,000, respectively.

4.2 Baseline Models

We choose a series of Transformer-based models for comparison due to their excellent performance. Flat Transformer (**FT**) is a 6-layer encoder-decoder model. The title and ranked paragraphs were concatenated and truncated to 800 tokens. Transformer Decoder with Memory Compressed Attention model (**T-DMCA**) is proposed by Liu et al. (2018) with the WikiSum dataset. They use a Transformer decoder but apply a convolutional layer to compress the key and value in self-attention. Moreover, we choose Hierarchical Transformer (**HT**) proposed by Liu and Lapata (2019a), **GraphSum** proposed by Li et al. (2020), and **HeterSumGraph** proposed by Wang et al. (2020a) for comparisons. We have introduced them in Section 2.

Table 2: Evaluation Results on MultiNews using ROUGE scores. The results of models with '†' are taken from Li et al. (2020) or Wang et al. (2020a). '*' indicates the results are obtained by running the released code.

4.3 Results

Results on WikiSum Table 1 summarizes the evaluation results on the WikiSum dataset. The first block shows the baseline model Lead and LexRank (Erkan and Radev, 2004), which are extractive methods. The second block shows the results of abstractive models introduced in Section 4.2. We report their results following Li et al. (2020). The last block shows the results of some abstractive models and our model, but such models are fed with 20 top-ranked paragraphs as input.

The results show that if we limit the number of input paragraphs to 20, ROUGE score of all models will drop by about 2 points. We believe this is because the lower-ranked paragraphs can still provide information anyway.

Our model EMSum performs the best under the top-20 setting. Compared to the reported results of GraphSum (which used top 40 documents), EMSum achieves improvements on ROUGE-2 and ROUGE-L, even though EMSum takes shorter source documents as input. The gap between EMSum and GraphSum on ROUGE-1 score is 0.23 (42.40 vs 42.63). Considering all these three metrics together, the results show the effectiveness of our model.

For models combined with pre-trained LMs, the results show that EMSum+RoBERTa further improves the summarization performance on all metrics over EMSum. The improvements over GraphSum+RoBERTa are 0.28 on ROUGE-2 and 0.83 on ROUGE-L, also showing the effectiveness of our model even in the presence of pre-trained LMs.

Results on MultiNews Table 2 summarizes the evaluation results on the MultiNews dataset. Similarly, the first block shows two extractive baselines LexRank, and HeterSumGraph. The second block shows the abstractive methods. We report the results of FT, HT and GraphSum following Li et al. (2020). The last block shows the results of our models. We can see that EMSum outperforms GraphSum and EMSum+RoBERTa outperforms GraphSum+RoBERTa. HeterSumGraph is a extractive method so it achieves better ROUGE-L score. However, our model still achieves higher ROUGE-1 and ROUGE-2 scores than HeterSumGraph. Overall, the results demonstrate the effectiveness of our model on different types of corpora.

4.4 Analysis

We further conduct experiments to analyze the effects of the number of iterations and the number of paragraphs selected for attention. We also conduct ablation studies to validate the effectiveness of different components of our model.

The Number of Iterations We investigate how the number of iterations t influences the performance of our model. To this end, we conduct experiments on WikiSum dataset when $t = 1, 2, 3, 4$. The first block in Table 3 shows the results. Intuitively, the more iterations the graph is updated, the more information is flowed across the nodes. However, the results show us that $t = 3, 4$ outperforms $t = 2$ on ROUGE-L and the overall performance $\tilde{R}$ fluctuates very little. We argue the performance is limited by the number of introduced parameters. Therefore we choose $t = 2$ finally.

The Number of Paragraphs Selected for Attention At each decoding step, our two-level attention mechanism firstly computes weights over entity nodes to identify the most salient parts of source documents. The attention weights over the entire long token sequence may be sparse. So we need to figure out how much salient information is enough for our model, namely the proper value of k. We conduct experiments on WikiSum dataset when $k = 5, 10, 15, 20$. As the results in the second block of Table 3 show, when $k = 5$, the number of attended paragraphs is relatively small thereby degrading performance heavily. When $k = 20$, that means we do not perform any cut-off but only modify the paragraph attention weights with the entity attention weights, so the performance is also reduced. When $k = 10, 15$, the cut-off strategy works and boosts the performance. Finally, we choose $k = 10$ because it performs the best.

k	t	R-1	R-2	R-L	R̃
10	1	41.61	27.74	37.59	35.65
	2	42.93	28.11	38.19	**36.20**
	3	42.58	27.29	38.50	36.12
	4	42.51	27.18	38.76	36.15
5	2	37.75	21.87	31.44	30.35
10		42.93	28.11	38.19	**36.20**
15		42.26	27.36	38.28	35.97
20		40.33	26.17	36.40	34.30

Table 3: Results on different number of iterations t and different number of paragraphs k for attention on WikiSum dataset. R̃ is the mean of R-1, R-2 and R-L.

Model	R-1	R-2	R-L
EMSum	42.40	27.97	37.28
w/o graph enc	39.47	25.18	29.93
w/o two-level attn	40.51	25.31	31.21

Table 4: Ablation study of our model on WikiSum.

Ablation Study To validate the effectiveness of individual components such as graph encoder module and two-level attention module, we conduct experiments of ablation studies. For experiments without graph encoder module, we simply fix the entity cluster representation and paragraph representation after the multi-head pooling layer. For experiments without two-level attention, we apply token-level attention directly, but attend to the entity cluster representation additionally, which is a naive way to incorporate entity information. Table 4 shows the results. The results show the effectiveness of our new introduced module. Incorporating entity information to construct a heterogeneous graph network enables better information flowing between text nodes, and our design of the novel two-level attention mechanism in this task is indeed playing an important role towards the overall effectiveness of our approach.

4.5 Human Evaluation

We further employ human evaluation to assess model performance. We randomly sampled 20 documents-summary pairs from the WikiSum test set and 20 from the MultiNews test set, and invited 3 participants to assess the outputs of different models independently. Following criteria used by previous work (Liu and Lapata, 2019a), the evaluation score takes three aspects into account: (1) Informativeness: does the summary include salient

Dataset	Model	Rating
WikiSum	FT	-0.517
	T-DMCA	-0.117
	HT	0.250
	EMSum	0.383
MultiNews	FT	-0.650
	T-DMCA	-0.033
	HS	0.317
	EMSum	0.367

Table 5: Human evaluation results on summary quality rating. FT, T-DMCA, HT, HS are baseline models explained in Section 4.2.

parts of the input? (2) Fluency: Is the summary fluent and grammatical? (3) Succinctness: does redundancy occur in the summary? We used Best-Worst Scaling (Louviere et al., 2015) because it has been shown to produce more reliable results than rating scales (Kiritchenko and Mohammad, 2017). Annotators are presented with the gold summary and summaries generated from 3 out of 4 systems and decide which summary is the best and which is the worst based on the criteria mentioned above. The rating of each system was computed as the percentage of times it was chosen as best minus the times it was selected as worst. Ratings range from -1 (worst) to 1 (best).

On the WikiSum dataset, we choose FT, T-DMCA, HT, EMSum and conduct human evaluation to compare their performance. On the MultiNews dataset, we choose FT, T-DMCA, HS, together with EMSum. The results are shown in Table 5. These results show that our EMSum model is able to generate summaries of higher quality than other models and further show the effectiveness of our proposed approach.

5 Conclusion

In this paper, we propose an entity-aware multi-document summarization model. We introduce entity nodes in addition to text unit nodes to construct a heterogeneous graph, helping our model capture complicated relations between text units. We also introduce a decoder with a two-level attention mechanism, which firstly attends to the entity nodes, where the attention weights are then subsequently utilized to guide the attention to the text units. With such a novel design, our model is able to deal with the problems of saliency and redundancy explicitly. Moreover, like other Transformer-based models, our model can be easily integrated with pre-trained language models for improved results. Experiments on standard datasets show the effectiveness of our model.

In the future, we would like to explore other approaches such as reinforcement learning based methods (Sharma et al., 2019) to further improve the summary quality in the context of multi-document summarization. We would also like to apply our method to other tasks such as multi-document question answering (Joshi et al., 2017).

Abstract

Fixed length summarization aims at generating summaries with a preset number of words or characters. Most recent researches incorporate length information with word embeddings as the input to the recurrent decoding unit, causing a compromise between length controllability and summary quality. In this work, we present an effective length controlling unit Length Attention (LenAtten) to break this trade-off. Experimental results show that LenAtten not only brings improvements in length controllability and ROGUE scores but also has great generalization ability. In the task of generating a summary with the target length, our model is 732 times better than the best-performing length controllable summarizer in length controllability on the CNN/Daily Mail dataset. [1]

1 Introduction

Automatic text summarization aims at generating a short and coherent summary from one or multiple documents while preserving the main ideas of the original documents. Building upon the conventional summarization task, fixed length text summarization (FLS) demands extra focus on controlling the length of output summaries. Specifically, it requires generating summaries with a preset number of characters or words.

FLS is a rising research topic required in many scenarios. For example, in order to get universal user experiences on multiple platforms and devices, titles and abstracts for news articles are expected to have different numbers of characters. Instead of manually rewriting summaries, FLS can automatically generate required summaries by simply inputting the desired output length. Besides, FLS can help news editors to reduce post-editing time (Makino et al., 2019) and further improve summary quality (Liu et al., 2018; Makino et al., 2019). Last but not least, as shown in Table 1, with FLS, users can get customizable summaries by setting different desired lengths.

Source document	
egyptian president hosni mubarak arrived here friday morning to discuss the latest developments of iraqi crisis with his turkish counterpart suleyman demirel .	
Reference summary	
egyptian president to discuss iraqi crisis with turkish counterpart	
Model	***Summary***
PAULUS	egyptian president arrives in ankara
PAULUS+LA2 (GT)	mubarak arrives in ankara for talks on iraqi crisis with turkish pm
PAULUS+LA2 (30)	egyptian president arrives in ankara
PAULUS+LA2 (50)	egyptian president arrives in ankara for talks on iraq crisis
PAULUS+LA2 (70)	mubarak arrives in ankara for talks on iraqi crisis with turkish president demirel

Table 1: Output examples from the proposed method Length Attention (LA) on the Annotated English Gigaword dataset. Numbers in the parentheses represent different desired lengths. (GT) means the desired length is equal to the number of characters in the reference summary. PAULUS (Paulus et al., 2018).

Despite the benefits that could be brought, previous studies on FLS are very limited. Recent researches in FLS apply length information to either (i) the decoder (Kikuchi et al., 2016; Liu et al., 2018; Takase and Okazaki, 2019) or (ii) the optimization objective function (Makino et al., 2019). Though these systems are promising, they have to make a compromise between length controllability and summary quality. Kikuchi et al. (2016); Makino et al. (2019) can generate high-quality summaries, but perform inadequately at controlling length. Liu et al. (2018); Takase and Okazaki (2019) control the output length accurately, but these models suffer from producing summaries with low ROUGE scores.

In this paper, we present an effective length controlling unit, Length Attention (LenAtten). With LenAtten, summarizers can generate high-quality summaries with a preset number of characters, successfully breaks the trade-off between length controllability and summary quality.

Our contributions in this work are as follows: (1) A novel length controlling unit with great generalization capability is proposed to make summarizers generate high-quality summaries with a preset number of characters. (2) Experimental results show that LenAtten can break the trade-off between length controllability and summary quality. The length controllability of the proposed method is the new state-of-the-art on the examined datasets, to our knowledge.

2 Related Work

There are two types of approaches for text summarization: the extractive approach and the abstractive approach. Extractive approaches generate summaries by extracting words or sentences from the original text (Dorr et al., 2003; Nallapati et al., 2017; Liu and Lapata, 2019; Zhong et al., 2020), while abstractive approaches produce novel words or phrases (Rush et al., 2015; Chopra et al., 2016; Nallapati et al., 2016; Gu et al., 2016; See et al., 2017; Fan et al., 2018; Liu and Lapata, 2019).

Derived from the works in general text summarization, two approaches have been developed for FLS: (1) Incorporating length information into the decoder. LenInit proposed in Kikuchi et al. (2016) introduced length information into the initialization stage of a LSTM decoder. Liu et al. (2018) follows a similar approach as LenInit, but it's based on a CNN sequence-to-sequence architecture. Other studies exploit length information in each decoding step. LenEmb introduced in Kikuchi et al. (2016) generates a learnable embedding for each target length, and uses it as an additional input to its decoder. Takase and Okazaki (2019) extended Transformer's sinusoidal positional encoding (Vaswani et al., 2017) to make summarizers take account of stepwise remaining length during prediction. (2) Leveraging length information in global optimization methods. Makino et al. (2019) proposed a global optimization method named GOLC. GOLC incorporates length information with the minimum risk training (MRT) optimization method.

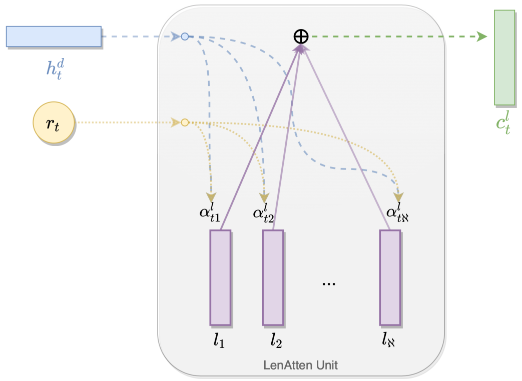

Figure 1: Illustration of the Length Attention Unit. Firstly, decoder hidden state (blue) and remaining length (yellow) are employed to compute the attention weights a^l. Then, the length context vector c_t^l (green) is produced by calculating the weighted sum between attention weights and pre-defined length embeddings (purple). Better viewed in color.

3 Our Approach: Length Attention

The motivation of LenAtten is to separate length information from the input of the recurrent decoding unit and to exploit proper length information based on the stepwise remaining length. As shown in Figure 1, at each decoding step, a length context vector is generated by calculating the weighted sum of a set of pre-defined embedding vectors l_*. Then, the length context vector is concatenated with the decoder hidden state and other attention vectors and fed to the input of the word prediction layer (details are shown in §4.2), so that summarizers can take the remaining length into account. The length context vector c_t^l at t-th decoding step is defined as follows:

$$c_t^l = \sum_{j=1}^{\aleph} \alpha_{tj}^l \, l_j \tag{1}$$

$$\alpha_{tj}^l = \frac{exp(e_{tj}^l)}{\sum_{k=1}^{\aleph} exp(e_{tk}^l)} \tag{2}$$

$$e_t^l = V_l^T \, tanh(W_l \, h_t^d + w_r \, r_t + b_l), \tag{3}$$

where $e_t^l \in \mathbb{R}^{\aleph \times 1}$, α_{tj}^l is the length attention score on the j-th length embedding at the t-th decoding step, h_t^d is the decoder hidden state, and V_l, W_l, w_r, b_l are learnable parameters. r_t is a scalar representing the remaining length at the current decoding step and $\aleph$ is a hyperparameter indicating the number of pre-defined length embeddings.

For length embeddings, we adopt the positional encoding proposed in Vaswani et al. (2017). We keep the embeddings fixed to remove the bias brought by the length distribution of data. The j-th length embedding l_j is defined as follows:

$$l_j = \begin{cases} 0 & j = 1 \\ PE(j-1) & otherwise, \end{cases} \quad (4)$$

where $PE(\,\cdot\,)$ is the positional encoding.

At the t-th decoding step, the remaining length r_t is updated by subtracting the length of the previously generated token. For the first decoding step, r_1 is initialized with desired output length. Following equations are used when $t > 1$:

$$r_t = \begin{cases} 0 & r_{t-1} - L(y_{t-1}) \leq 0 \\ r_{t-1} - L(y_{t-1}) & otherwise \end{cases} \quad (5)$$

where $L(y_{t-1})$ returns the number of characters in the output word y_{t-1}.

4 Experiment

4.1 Experimental Settings

We evaluate LenAtten on the CNN/Daily Mail dataset (See et al., 2017) to compare it with previous studies. In addition, we test LenAtten with short articles and summaries on the Annotated English Gigaword dataset (Rush et al., 2015). By default, all models are trained with maximum likelihood estimation (MLE) on a NVIDIA TITAN RTX GPU.[2]

For evaluation metrics, we adopt the standard F1 score of ROUGE-1, ROUGE-2, and ROUGE-L (Lin, 2004) to evaluate summary quality. For evaluating models' ability to control the output sequence length, we follow (Makino et al., 2019) to compute (1) character-level length variance Var between reference summaries and generated summaries and (2) over-length ratio $\%over$, which measures how many of the generated summaries are longer than their reference summaries. The length variance Var is computed as follows:

$$Var = 0.001 * \frac{1}{n}\sum_{i=1}^{n} |len(y_i) - len(y_i')|^2 \quad (6)$$

where y_i is the reference summary, y_i' is the generated summary, and $len(\cdot)$ returns the number of characters in the given summary. For the FLS task, the length variance Var is expected to be zero as it indicates the lengths of output summaries are exactly the desired summary lengths.

4.2 Methods to be compared

We compare the proposed Length Attention unit with following methods:

LEAD-3 extracts the first three sentences of source articles as the summary.

PG is the standard pointer-generator network proposed in See et al. (2017).

MASS (Song et al., 2019) is a sequence to sequence pre-trained model based on Transformer.

LenAtten is also compared with length controllable summarization methods. For a fair comparison, we choose methods that also aim at generating summaries with a preset number of characters in a word-by-word manner.

LE is the LenEmb method proposed in Kikuchi et al. (2016).

GOLC is a global optimization method introduced in Makino et al. (2019).

We apply LenAtten to three summarization models:

S2S (RNN-based Seq2Seq Model) is a vanilla encoder-decoder summarizer. Specifically, we adopt a Bi-LSTM as the encoder and a unidirectional LSTM as the decoder. To integrate LenAtten, the length context vector c_t^l is added to the input of the word prediction layer to produce the vocabulary distribution P_{vocab}:

$$P_{vocab} = softmax\Big(W[h_t^d||c_t^l||y_{t-1}||C] + b\Big) \quad (7)$$

where W, b are learnable parameters, h_t^d is the decoder hidden state, y_{t-1} is the word embedding of the last generated token, "||" is the vector concatenation operator. C is the last encoder hidden state, which is known as the fixed context vector.

PAULUS (Copying Mechanism) follows the design of Paulus et al. (2018), which incorporates two attention modules and the copying mechanism into a Seq2seq summarizer. To integrate LenAtten, the vocabulary distribution P_{vocab} is calculated using:

$$P_{vocab} = softmax\Big(W[h_t^d||c_t^l||c_t^e||c_t^d] + b\Big) \quad (8)$$

where c_t^e and c_t^d are the context vectors generated from the encoder and decoder attention units.

ATTENTION (Attention-based model) is implemented by removing copying mechanism from **PAULUS**. For the above-mentioned three models, we remove the length context vector c_t^l in the ablation study and keep other components unchanged.

---

[2] Detailed model configurations are provided in the Appendix.

4.3 Experimental Results [3]

Reference Summary Lengths In this experiment, we evaluate our model by comparing it with previous works. The desired length is set as the number of characters in corresponding reference summaries. Table 2 shows that LenAtten has superior length controllability and higher ROUGE scores on both datasets. Specifically, the length variance (Var) of LenAtten is 732 times better than the best-performing length controllable method PG+LE(GOLC) in the CNN/DM dataset. Besides, adding LenAtten can boost ROUGE scores by 1-3 points. We believe the improvement in the ROUGE scores comes from the introduction of length information (i.e. the desired length information). The desired length information can be viewed as an inductive bias, which helps summarizers prefer some of the outputs over others. Under the same context, by conditioning on the desired output length, summarizers may prefer candidate summaries with output lengths similar to the desired length. Thus, summarizers can learn a better alignment with the reference summaries during training and outputs summaries with higher ROUGE scores in inference.

In addition, previous length controllable methods control the output lengths at the cost of damaging the ROUGE scores. The ROUGE scores of PG and PAULUS drop after adding LenEmb (i.e. PG + LE(MLE) and PAULUS + LE). In comparison, LenAtten not only performs better at reducing the length variance Var but also significantly improves ROUGE scores. This suggests that LenAtten can break the trade-off between summary quality and length controllability.

After integrating with LenAtten, the $\%over$ ratio of summarizers rises. This suggests that more of the generated summaries ended up being longer than the references. We believe this is because when the remaining length is small (e.g. 4 characters) but not 0, instead of stopping the generation process, summarizers with LA tend to generate more tokens to meet the length requirement. Since summarizers output a word at each inference step, they may select a word that's longer than the remaining length. Thus, the generated summaries may end up being longer than the references.

Perplexity To figure out how LenAtten affects the performance of the language model, we examine the log-perplexity of models on the test sets. Perplexity is a commonly-used metric for evaluating language models. A lower perplexity score indicates better language model performance. In this experiment, the desired length is set to the reference summary length. As shown in Table 3, after adding LenAtten, log-perplexity drops consistently on both datasets. This suggests that the adding of LenAtten can boost language model performance.

Various Preset Lengths In this experiment, we test the generalization ability of LenAtten under various desired lengths. For the AEG dataset, most reference summaries contain 30-75 characters, and

---

[3] For all the experiments, the number following LA (the LenAtten unit) represents the number of length embeddings (i.e. the value of $\aleph$).

AEG	30	50	75	100	120
R-1 F	37.89	42.67	41.13	39.03	37.45
R-2 F	18.87	21.01	18.99	17.16	16.00
R-L F	33.64	38.76	35.27	31.95	29.84
Var	0.0027	0.0024	0.0026	0.0030	0.0040

CNN/DM	100	200	400	800	1600
R-1 F	30.88	37.90	39.52	37.25	34.23
R-2 F	13.31	16.26	16.58	15.08	13.50
R-L F	23.17	32.95	33.99	29.34	24.54
Var	0.0067	0.0063	0.0058	0.0054	0.0051

Table 4: ROUGE scores and Length Variance Var of PAULUS+LA2 under different desired lengths.

few of them are more than 100 characters. For the CNN/DM dataset, most reference summaries are 100-750 characters. Thus, the desired length is set as 30, 50, 75, 100, and 120 for the AEG dataset and 100, 200, 400, 800, and 1600 for the CNN/DM dataset. We add the LenAtten unit to PAULUS and exploit full reference summaries to get ROUGE scores.

As shown in Table 4, on the AEG dataset, for frequently appeared lengths (30, 50, 75), and lengths that are exceptionally long (100, 120), LenAtten demonstrates great length controllability along with good ROUGE scores. Same conclusions can be drawn on the CNN/DM dataset. This shows that LenAtten has great generalization ability under various desired lengths.

Exploring Hyperparameter $\aleph$ In this experiment, we analyze how different $\aleph$ (the number of pre-defined length embeddings) affect the performance of LenAtten on the AEG dataset. Desired lengths are set to the lengths of reference summaries. Figure 2 shows the length controllability becomes better as the increase of $\aleph$, with no harm to the ROUGE-L scores.

5 Conclusions

In this paper, we present a novel length controlling unit, LenAtten, to help summarization models generate quality summaries with a preset number of characters. On the examined datasets, LenAtten outperforms length controllable summarization baselines steadily in terms of length controllability and demonstrates great generalization ability. LenAtten also breaks the trade-off between length controllability and summary quality. To our knowledge, in the task of generating summaries with target lengths, LenAtten is the new state-of-the-art on the CNN Daily Mail dataset.

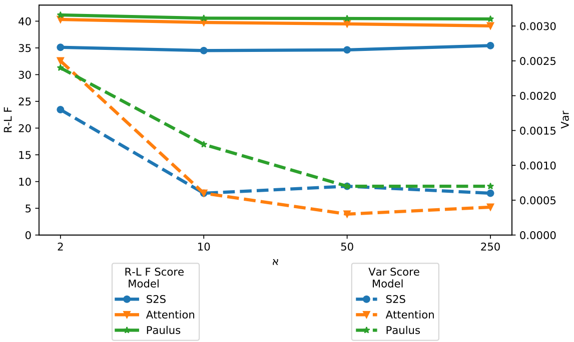

Figure 2: Examining hyperparameter $\aleph$ on the AEG dataset. ROUGE-L F1 scores and Length Variance Var of different models under different $\aleph$ are shown ($\aleph = 2, 10, 50, 250$).

A Appendix

A.1 Experimental settings

Model Configuration In our experiments, the dimension of LSTM hidden state is set as 256, and the vocabulary size is 100,000. Word embeddings are fixed 300-dimensional GloVe vectors[4]. If a word is not covered in the GloVe, a random 300-dimensional vector is used. During training, Adam optimizer is applied with $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 10^{-8}$ and learning rate $\alpha = 0.001$. Besides, we set a 25% probability of choosing the previously generated token instead of the ground-truth token as y_{t-1} to reduce exposure bias. At test time, summaries are produced using beam search with beam size 4. We use a fully python implemented library[5] to obtain the ROUGE score.

Dataset Distribution We plot the length distribution of reference summaries in the AEG (Figure 3) and the CNN/DM (Figure 4) dataset.

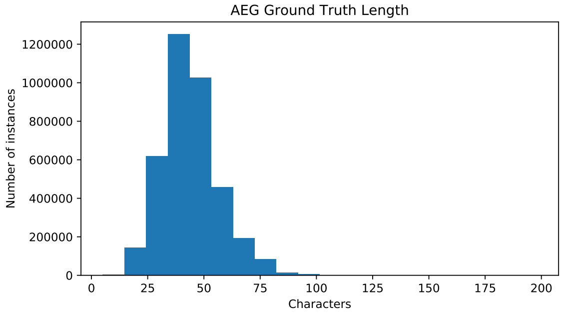

Figure 3: Length distribution of reference summaries on the Annotated English Gigaword dataset. Summaries with 30 to 75 characters cover the majority cases.

A.2 Additional Experiments

Semantic Similarity Another automatic evaluation metric *BertScore* (Zhang et al., 2019) recall score is used to measure the semantic similarity between system outputs and reference summaries. As shown in Figure 5, models with Length Attention module (LA2) outperform baselines (FREE) on both datasets.

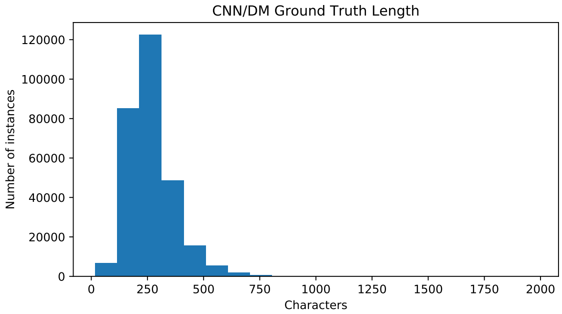

Figure 4: Length distribution of reference summaries on the CNN/Daily Mail dataset. Summaries exceed 2000 characters are ignored, since they only cover 0.009% of the dataset.

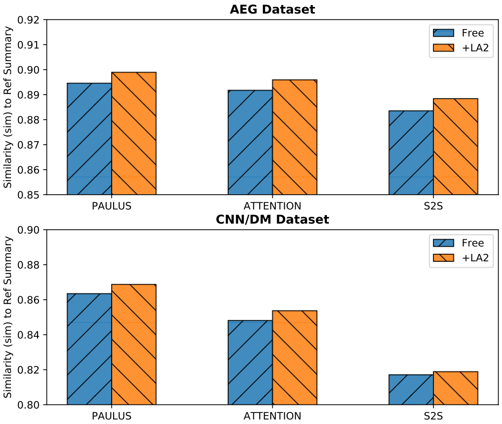

Figure 5: Semantic similarity between model outputs and reference summaries. Desired length is set as reference summary length.

Human Evaluation Correctness (CORR), completeness (COMP), and fluency (FLUE) of system outputs are assessed through 2 human evaluations. We randomly select 10 samples from each dataset. 30 skilled English speakers are presented with the original article and two summaries. One of the summaries is from the model without LenAtten, and the other one is from the same model plus LenAtten (e.g., S2S and S2S+LA2). The evaluation process is well-designed to prevent participants from knowing the source of the presented summaries. Models without LenAtten generate summaries without length restriction, and models with LenAtten are required to output summaries with desired lengths. There are 467 feedbacks collected for the first experiment and 160 for the second.

In the first experiment (Table 5), participants are asked to choose a better one from two given summaries. The desired length is set as the length of the reference summary.

In the second experiment (Table 6), we only examine PAULUS and PAULUS+LA2. The desired

Paulus+LA2 (250)	3.451	**3.483**	**3.419**
Paulus+LA2 (350)	**3.827**	3.482	3.172

Table 6: Results of the second human evaluation. "(Free, avg_len)": model generates summaries freely. The average length of the generated summaries is also listed.

length is set as (30, 50, 70) on the AEG dataset and (150, 250, 350) on the CNN/DM dataset. Participants need to rate each summary from 0 to 5. In order to guarantee the accuracy and credibility of results, each article is presented once to each participant.

As shown in Table 5, models with LenAtten have better completeness and correctness scores on both datasets, along with a few improvements on the fluency. In the second experiment, Table 6 shows that (1) the completeness and correctness scores increase as the desired length increases. This trend is reasonable, since more information should be included in the final summary, as the summary length gets longer. This also suggests that, as the desired length gets longer, models with LenAtten can generate meaningful words instead of simply repeating one or two words. (2) When comparing the results of Paulus (Free, 57.46; 285.5) and Paulus+LA2 (50; 250), Paulus+LA2 outperforms the Paulus (Free) on all metrics. In other words, when the desired length gets smaller (but not too small), LenAtten can help summarization models to use concise words and phrases while maintaining summary quality.

Synonym substitution When examining generated summaries, we find adding LenAtten can make summarizers replace long/short words with synonyms to meet the length requirement. Examples are showcased in Table 7.

XeroAlign: Zero-Shot Cross-lingual Transformer Alignment

Milan Gritta and **Ignacio Iacobacci**
Huawei Noah's Ark Lab, London, UK
`{milan.gritta,ignacio.iacobacci}@huawei.com`

Abstract

The introduction of transformer-based cross-lingual language models brought decisive improvements to multilingual NLP tasks. However, the lack of labelled data has necessitated a variety of methods that aim to close the gap to high-resource languages. Zero-shot methods in particular, often use translated task data as a training signal to bridge the performance gap between the source and target language(s). We introduce **XeroAlign**, a simple method for task-specific alignment of cross-lingual pretrained transformers such as XLM-R. XeroAlign uses translated task data to encourage the model to generate similar sentence embeddings for different languages. The XeroAligned XLM-R, called XLM-RA, shows strong improvements over the baseline models to achieve state-of-the-art zero-shot results on three multilingual natural language understanding tasks. XLM-RA performs on par with state-of-the-art models on a cross-lingual adversarial paraphrasing task and its text classification accuracy exceeds that of XLM-R trained with labelled data.

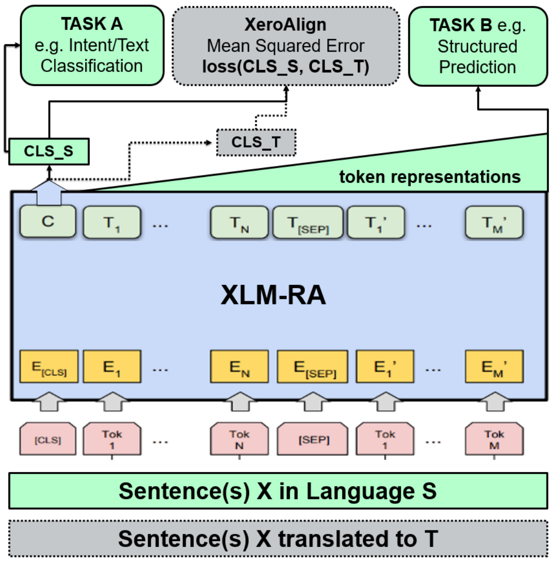

Figure 1: The XeroAligned XLM-R model (XLM-RA) for cross-lingual NLU. XeroAlign is added to the training loop to encourage embeddings in different languages to be similar, enabling a zero-shot classifier transfer.

1 Introduction

Recently, large transformer-based (Vaswani et al., 2017) pretrained language models have achieved state-of-the-art (SOTA) performance on several monolingual and multilingual NLP tasks (Wang et al., 2019a; Hu et al., 2020b). Transfer learning enabled the self-supervised pretraining on unlabelled datasets to learn linguistic features such as syntax and semantics in order to improve tasks with limited training data (Wang et al., 2019b). Pretrained cross-lingual language models (PXLMs) have soon followed to learn general linguistic features and properties of dozens of languages (Lample and Conneau, 2019; Xue et al., 2020). For multilingual tasks in particular, adequate labelled data is usually only available for a few well-resourced languages such as English. Zero-shot approaches were introduced to transfer the knowledge to languages without the requisite training data. To this end, we introduce **XeroAlign**, a conceptually simple and efficient method for task-specific alignment of sentence embeddings generated by PXLMs, aimed at effective zero-shot cross-lingual transfer. XeroAlign is an auxiliary training objective, which uses translated data to bring the performance in the target language closer to the source (labelled) language, as illustrated in Figure 1. We apply our proposed method to the publicly available XLM-R transformer (Conneau et al., 2020) but instead of pursuing large-scale model alignment with general parallel corpora such as Europarl (Koehn, 2005), we show that a simplified, task-specific model alignment is an effective and efficient approach to zero-shot transfer for cross-lingual natural language understanding (XNLU).

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 371–381
August 1–6, 2021.

We evaluate XeroAlign on four datasets (two different tasks) that cover 11 unique languages. The XeroAligned XLM-R model (XLM-RA) achieves SOTA scores on three XNLU datasets, exceeds the text classification performance of XLM-R trained with labelled data and performs on par with SOTA models on an adversarial paraphrasing task.

2 Background

We first outline the necessary background on Contrastive Learning (Becker and Hinton, 1992) and transformer-based PXLMs. Contrastive learning (CL) is a framework designed for self-supervised representation learning. Recent examples include Momentum Contrast (MoCo) (He et al., 2020) and SimCLR (Chen et al., 2020), both of which achieved strong improvements on image classification. The essence of CL is to generate representations that are similar for positive examples and dissimilar for negative examples. CL-based methods in cross-lingual NLP replace negative samples (formerly augmented images) with random sentences in the target language, typically thousands of them. Positive examples comprise sentences translated into the target language. While CL is applicable to task-agnostic model alignment, large batches of random negative samples are infeasible for small datasets. Negative samples drawn randomly from a small dataset can result in duplicates (false negatives), which is why our alignment uses only positive samples. The CL-based alignments in section 2.1 aim to improve generic cross-lingual representations with large (parallel) datasets. In contrast, we align the PXLM only with translated task data, making our approach simpler and more efficient, showing a strong zero-shot transfer.

Transformer-based PXLMs For transformer-based PXLMs, two basic types of representations are commonly used: 1) A sentence embedding for tasks such as text classification (Conneau et al., 2018) or sentence retrieval (Zweigenbaum et al., 2018), which use the `[CLS]` representation of the full input sequence, and 2) Token embeddings, which are used for structured prediction (Pan et al., 2017) or Q&A (Lewis et al., 2020), requiring each token's contextualised representation for a per-token inference. While our method uses the `[CLS]` embedding, other approaches based on Contrastive Learning have used both types of representations to obtain a sentence embedding.

2.1 Related Work

In order to cluster prior work, we formulate a taxonomy (Table 1) for the purposes of positioning our method in the appropriate context. The relevant zero-shot transfer approaches can be grouped by a) whether the alignment is targeted at each task, i.e. is task-specific [TS] or is task-agnostic [TA] and b) whether the alignment is applied to the model [MA] or data [DA]. Our paper falls mostly into the [MA,TS] category although methodological similarities are also found in the [MA,TA] group.

Groups	*Task-Specific*	*Task-Agnostic*
Data Align	[DA,TS]	No relevant work
Model Align	[MA,TS]	[MA,TA]

Table 1: An approximate taxonomy of prior work.

[MA,TA] Hu et al. (2020a) have proposed two objectives for cross-lingual zero-shot transfer a) sentence alignment and b) word alignment. While CL is not mentioned, the proposed sentence alignment closely resembles contrastive learning with one encoder (e.g. SimCLR). Taking the average of the contextualised token representations as the input representation (as an alternative to the `[CLS]` token), the model predicts the correct translation of the sentence within a batch of negative samples. An improvement is observed for text classification tasks and sentence retrieval but not structured prediction. The alignment was applied to a 12-layer multilingual BERT and the scores are comparable to the translate-train baseline (translate data and train normally). Instead, we use one of the best publicly available models, XLM-R from Huggingface, as our starting point since an improvement in a weaker baseline is not guaranteed to work in a stronger model that may have already subsumed those upgrades. Contrastive alignment based on MoCo with two PXLM encoders was proposed by Pan et al. (2020). Using an L2 normalised `[CLS]` token with a non-linear projection as the input representation, the model was aligned on 250K to 2M parallel sentences with added Translation Language Modelling (TLM) and a code-switching augmentation. No ablation for MoCo was provided to estimate its effect although the combination of all methods did provide improvements with multilingual BERT as the base learner. Another model inspired by CL is InfoXLM (Chi et al., 2020). InfoXLM is pretrained with TLM, multilingual

Masked Language Modelling and Cross-lingual Contrastive Learning called XLCo. Like MoCo, they employ two encoders that use the `[CLS]` token (or the uppermost layer average) as the sentence representation, taken from layers 8 (base model) and 12 (large model). Ablation showed a 0.2-0.3 improvement in accuracy for XNLI and MLQA (Lewis et al., 2020). Reminiscent of earlier work on cross-lingual alignment (Hermann and Blunsom, 2014), the task-agnostic sentence embedding model (Feng et al., 2020) called LaBSe (Language-agnostic BERT sentence embeddings) uses the `[CLS]` representations of two BERT encoders (compared to our single encoder) with a margin loss and 6 billion parallel sentences to generate multilingual representations. While similarities exist, our multi-task alignment is an independently devised, more efficient, task-specific and a simplified version of the aforementioned approaches.

[DA,TS] Zero-shot cross-lingual models often make use of machine translation to provide a training signal. This is an uncomplicated transformation for text classification tasks given that adequate machine translation models exist for many language pairs. However, for structured prediction tasks such as Slot Filling or Named Entity Recognition, the non-trivial task of *aligning token labels* can lead to an improved cross-lingual transfer. One of the most commonly used word alignment methods is fastalign (Dyer et al., 2013). Frequently used as a baseline, it involves aligning the word indices in parallel sentences in an unsupervised manner, prior to regular supervised learning. In some scenarios, fastalign can approach SOTA scores for slot filling (Schuster et al., 2019), however, the quality of alignment varies between languages and can even degrade performance (Li et al., 2021) below baseline. An alternative data alignment approach called CoSDA (Qin et al., 2020) uses code-switching as data augmentation. Random words in the input are translated and replaced to make model training highly multilingual, leading to improved cross-lingual transfer. Attempts were also made to automatically learn how to code-switch (Liu et al., 2020). While improvements were reported, it's uncertain how much SOTA models would benefit.

[MA,TS] Continuing with label alignment for slot filling, Xu et al. (2020) tried to predict and align slot labels jointly during training instead of modifying data labels explicitly before fine-tuning. While soft-align improves on fastalign, the difficulty of label alignment makes it challenging to improve on the SOTA. For text classification tasks such as Cross-lingual Natural Language Inference (Conneau et al., 2018), an adversarial cross-lingual alignment was proposed by Qi and Du (2020). Adding a self-attention layer on top of multilingual BERT (Devlin et al., 2019) or XLM (Lample and Conneau, 2019), the model learns the XNLI task while trying to fool the language discriminator in order to produce language-agnostic input representations. While improvements over baselines were reported, the best scores were around 2-3 points behind the standard XLM-R model.

3 Methodology

We introduce **XeroAlign**, a conceptually simple and efficient method for task-specific alignment of sentence embeddings generated by PXLMs, aimed at effective zero-shot cross-lingual transfer. XeroAlign is an auxiliary training objective that is jointly optimised with the primary task, e.g. text classification and/or slot filling, as shown in Figure 1. We use standard architecture for each task and only add the minimum required number of new parameters. For text classification tasks, we use the `[CLS]` token of the PXLM as our pooled sentence representation. A linear classifier (hidden size x number of classes) is learnt on top of the `[CLS]` embedding using cross-entropy as the loss function (TASK A in Figure 1). For slot filling, we use the contextualised representations of each token in the input sequence. Once again, a linear classifier (hidden size x number of slots) is learnt with a cross-entropy loss (TASK B in Figure 1).

Algorithm 1 shows a standard training routine augmented with XeroAlign. Let $PXLM$ be a pre-trained cross-lingual transformer language model, X be the standard English training data and U be the machine translated utterances (from X). The English utterances were translated into each target language using our internal machine translation service. A public online translator e.g. Google Translate can also be used. For the PAWS-X task, we use the public version of the translated data[1]. We then obtain the CLS_S and CLS_T embeddings by taking the first token of the $PXLM$ output sequence for the source x_s and target x_t sentences respectively. Using a Mean Squared Error loss

---

[1] https://github.com/google-research-datasets/paws

Algorithm 1 The XeroAlign algorithm.

```
$PXLM \leftarrow$ Pretrained Cross-lingual LM
$X \leftarrow$ Training data tuples in English
$U \leftarrow$ Utterances translated into Target Lang.
$sim \leftarrow$ similarity function e.g. MSE

# training loop
for $(x_s, y), x_t \in X, U$ do
    $task\_loss \leftarrow task\_loss\_fn(x_s, y)$
    $CLS_S \leftarrow PXLM(x_s)$
    $CLS_T \leftarrow PXLM(x_t)$
    $align\_loss \leftarrow sim(CLS_S, CLS_T)$
    $total\_loss \leftarrow task\_loss + align\_loss$
    # update model parameters
end for
```

function as our similarity function sim, we compute the distance/loss between CLS_S and CLS_T. The sum of the losses ($total\_loss$) is then backpropagated normally. We have conducted all XeroAlign training as multi-task learning for the following reason. When the $PXLM$ is aligned first, followed by primary task training, the $PXLM$ exhibits poor zero-shot performance. Similarly, learning the primary task first, followed by XeroAlign fails as the primary task is partially unlearned during alignment. This is most likely due to the catastrophic forgetting problem (Goodfellow et al., 2013).

3.1 Experimental Setup

In order to make our method easily accessible and reproducible[2], we use the publicly available XLM-R transformer from Huggingface (Wolf et al., 2019) built on top of PyTorch (Paszke et al., 2019). We set a single seed for all experiments and a similar learning rate for each dataset. No hyperparameter sweep was conducted to ensure a robust, low-resource, real-world deployment and to make a fair comparison with SOTA models. XLM-R was XeroAligned over 10 epochs and optimised using Adam (Kingma and Ba, 2015) and a OneCycleLR (Smith and Topin, 2019) scheduler.

3.2 Datasets

We evaluate XeroAlign with four datasets covering 11 unique languages (en, de, es, fr, th, hi, ja, ko, zh, tr, pt) across two tasks (intent classification + slot filling, paraphrase detection).

PAWS-X (Yang et al., 2019) is a multilingual version of PAWS (Zhang et al., 2019), a binary classification task for identifying paraphrases. Examples were sourced from Quora Question Pairs[3] and Wikipedia, chosen to mislead simple 'word overlap' models. PAWS-X contains random examples drawn from PAWS (just under 4K for the development and test set) covering seven languages (en, de, es, fr, ja, ko, zh) and totalling almost 28,000 human translated paraphrases. Each train set contains approximately 49.5K machine translated examples.

MTOD is a Multilingual Task-Oriented Dataset provided by Schuster et al. (2019). It covers three domains (alarm, weather, reminder) and three languages of different sizes: English (43K), human-translated Spanish (8.3K) and Thai (5K). MTOD comprises two correlated NLU tasks, intent classification and slot filling. The SOTA scores are reported by Li et al. (2021) and Schuster et al. (2019).

MTOP is a Multilingual Task-Oriented Parsing dataset provided by Li et al. (2021) that covers interactions with a personal assistant (intent recognition and slot filling tasks). We use the standard flat version, which has the SOTA reported by Li et al. (2021). A compositional version of the data designed for nested queries is also provided. MTOP contains 100K+ human translated examples in 6 languages (en, de, es, fr, th, hi) and 11 domains.

MultiATIS++ by Xu et al. (2020) is an extension of the multilingual version of ATIS (Upadhyay et al., 2018), initially translated into Hindi and Turkish. Six new human-translated[4] languages (de, es, fr, zh, ja, pt) were added with ∼4 times as many examples each (around 6K per language) for 9 languages. These datasets are based on the English-only ATIS (Price, 1990) featuring users interacting with an information service. Once again, intent recognition and slot filling are evaluated.

3.3 Metrics

We use standard evaluation metrics, that is, accuracy for paraphrase detection and intent classification, F-Score[5] for slot filling.

[3] `https://www.quora.com/q/quoradata/First-Quora-Dataset-Release-Question-Pairs`

[4] We have encountered some minor issues with slot annotations. Around 60-70 entities across 5 languages (fr, zh, hi, ja, pt) had to be corrected as the number of slot tags did not agree with the number of tokens in the sentence. However, this only concerns a tiny fraction of the ∼400k+ tokens covered.

Table 2: MTOP results as Intent Classification Accuracy / Slot Filling F-Score. Best English score: 97.3 / 93.9.

4 Results and Analysis

We use 'XLM-R Target' to refer to models trained on each labelled target language. We also provide zero-shot scores denoted 'XLM-R 0-shot', the 'XLM-RA' results and the reported SOTA figures. For PAWS-X, we provide a second baseline called 'Translate-Train', which comprises the union of Target and English train data. Scores are given for the large[6] model unless specified otherwise.

The XeroAligned XLM-R attains SOTA scores on 3 XNLU datasets. The intent classification (+1.1) and slot filling (+2.4) scores, averaged over 5 MTOP languages and shown in Table 2, improved on an XLM-R model with translated utterances, slot label projection and distant supervision (Li et al., 2021). For the MultiATIS++ dataset (Table 5), XLM-RA shows an improved intent accuracy (+1.1) and F-Score (+3.2) over 8 languages, compared to a large multilingual BERT with translated utterances and slot label softalign (Xu et al., 2020). The MTOD classification accuracy (+1.3) and slot tagging F-Score (+5.0) have improved over an XLM-R with translated utterances, slot label projection and distant supervision (Li et al., 2021). MTOD is the only dataset where the base model outperforms (albeit marginally) the large transformer, as seen in Table 6. Finally, we compare our intent classification accuracy (+8.1) and slot filling F-Score (+8.7) for MTOD to a BiLSTM with translated utterances and slot label projection (Schuster et al., 2019), which had the SOTA F-Score for Thai.

On the adversarial paraphrase task (PAWS-X, Table 3), averaged over 7 languages, XLM-RA scores marginally higher (+0.1 accuracy) than VECO (Luo et al., 2020), a variable cross-lingual encoder-decoder and marginally lower (-0.2 accuracy) than FILTER (Fang et al., 2020), an enhanced cross-lingual fusion model, which was the SOTA until 01/2021. We now turn our attention to the improvements over the XLM-R 0-shot model.

4.1 Text Classification

The intent classification accuracy of XLM-RA exceeds that of an XLM-R trained with labelled data, averaged across three task-oriented XNLU datasets (Tables 2, 5, 6). Starting from a competitive baseline model, XeroAlign improves intent accuracy by ∼5-10 points (similar for the base model, see Table 7 in Section 4.4). The benefits of cross-lingual alignment are particularly evident in low-resource languages (tr, hi, th), which is encouraging for applications with limited resources. Paraphrase detection is another instance of text classification. We report average XLM-RA accuracy in Table 3, which exceeds both Target and the Translate-Train scores by over 1 point and by almost 3 points over XLM-R 0-shot (even larger improvements for the base model).

Note that the amount of labelled data is comparable for XeroAlign and Target (except Thai, Spanish in MTOD and Turkish, Hindi in MultiATIS++) hence there is no more than a negligible advantage from the additional data. As the English scores show the highest performance (∼1.5 points higher on average) compared to the Target languages, we hypothesise that transferring this advantage from a high-resource language via XeroAlign is the primary reason behind its effectiveness compared to using target data directly. Given that Target performance has recently been exceeded with MoCo (He et al., 2020) and the similarities between contrastive learning and XeroAlign, our finding seems in line with recent work, which is subject to ongoing research (Zhao et al., 2020).

4.2 Structured Prediction

While XLM-RA is able to exceed Target accuracy for text classification tasks, even our best F-Scores

Table 3: PAWS-X results as Paraphrase Classification Accuracy.

for slot filling are between 8 and 19 points behind the Target model. This is despite a strong average improvement of +4.1 on MTOP, +5.7 on MultiATIS++ and +5.2 on MTOD (a greater benefit for the base model). We think that the gap is primarily down to the difficulty of the sequence labelling task. That is, zero-shot text classification is ‘easier’ than zero-shot slot filling, which is manifested by a ∼10-20 point gap between scores. Sentences in various languages have markedly different input lengths and token order thus word-level inference in cross-lingual settings becomes significantly more challenging than sentence-level prediction because syntax plays a less critical role in sequence classification.

Another reason, related to XeroAlign’s architecture and training, is our choice to align the PXLM on the `[CLS]` embedding, which is subsequently used ‘as is’ for text classification tasks. Aligning individual token representations through the `[CLS]` embedding improves structured prediction as well, however, as the token embeddings are not directly used, the Multi-Head Attention parameters in the uppermost transformer layer never receive any gradient updates from XeroAlign. Closing this gap is a challenging opportunity, which we reserve for future work. Once again, the languages with lower NLP resources (th, hi, tr) tend to benefit the most from cross-lingual alignment.

4.3 XeroAlign Generalisation

In this subsection, we briefly investigate the generalisation of XeroAlign to unseen languages, taking the PAWS-X task as our use case. We are interested in finding out whether aligning on *just one language* has any zero-shot benefits for other languages. Table 4 shows the XLM-RA results when aligned on a single language (rows) and tested on other languages (columns).

-	EN	DE	ES	FR	JA	KO	ZH	AVE
DE	**96.0**	**92.9**	92.3	92.6	84.0	84.5	86.5	89.8
ES	95.9	92.6	**93.0**	93.1	83.9	84.1	86.4	89.9
FR	95.9	92.5	92.9	**93.9**	83.9	84.1	86.9	90.0
JA	**96.0**	92.6	91.8	93.1	**87.1**	**87.4**	87.9	**90.8**
KO	95.7	92.6	92.0	92.7	80.6	87.1	87.3	90.5
ZH	95.5	92.0	92.6	92.7	86.3	86.2	**88.9**	90.6
EU	96.2	92.5	93.0	94.1	84.9	85.2	87.1	90.4
AS	96.0	93.0	92.1	92.7	85.9	87.6	88.4	90.8

Table 4: XLM-RA aligned on one PAWS-X language (rows), evaluated on others (columns). AVE = average. EU = European languages, AS = Asian languages.

We can see that aligning on Asian languages (Japanese in particular) attains the best average improvement compared to aligning with European languages. This seems to reflect the known performance bias of XLM-R towards (high-resource) European languages, all of which show a strong improvement, regardless of language. Aligning only on European languages (de, es, fr) improves the average to 90.4 but aligning on Asian languages (zh, ko, ja) does not improve over Japanese (90.8). In any case, it is notable that the XLM-R model XeroAligned on *just a single language* is able to carry this advantage well beyond a single language thus improve average accuracy by 1.5-2.5 points over baseline (88.3) from Table 3. This effect is even stronger for MTOP (+4 accuracy, +3 F-Score).

4.4 Smaller Language Models

The XeroAligned XLM-R base model shows an even greater relative improvement than its larger counterpart with 24 layers and 550M parameters. To this end, we report the results for the XLM-

Model	**DE**	**ES**	**FR**	**TR**	**HI**	**ZH**	**PT**	**JA**	**AVE**

Table 6: MTOD results as Intent Classification Accuracy / Slot Filling F-Score. Our best English score: 99.3/96.6, (B) = Base, (L) = Large, § = XLM-R model.

RA base model (12 layers, 270M parameters) in Table 7 as the average scores over all languages for MTOP, PAWS-X, MTOD and MultiATIS++. We use a relative % improvement over XLM-R 0-shot to compare the models fairly. We observe that the paraphrase detection accuracy improves by 3.3% for the large PXLM versus 6.5% for the base model. Across three XNLU datasets, the large XeroAligned XLM-R improves over the XLM-R 0-shot by 9.5% versus 14.2% for the base model on slot filling and by 7.1% (large) versus 19.8% (base) on text/intent classification.

Model	**MTOP**	**PAWS-X**	**M-ATIS**	**MTOD**
§ Target	94.0/88.1	85.2	89.0/86.3	97.6/92.2
§ 0-shot	80.8/68.9	81.7	76.9/65.0	80.1/64.8
XLM-RA	93.3/78.9	87.0	93.0/73.4	98.5/74.7

Table 7: The XLM-R(A) base model averages as intent classification accuracy / slot filling F-Score (or paraphrase accuracy for PAWS-X). § = XLM-R model.

This lets applications with lower computational budgets achieve competitive performance with our efficient cross-lingual alignment method for transformed-based PXLMs. In fact, the XLM-RA base model is able to reach up to 90-95% of the performance of its larger sibling using significantly lower computational resources.

4.5 Discussion

XLM-RA's intent classification accuracy is on average within ∼1.5 points of English accuracy across three XNLU datasets. However, the PAWS-X paraphrase detection accuracy is almost 5 points below English models, which is the case for other state-of-the-art PXLMs in Table 3. Why does the XLM-R struggle to generalise more on this task for languages other than English? A combination of several factors is likely at play. Minor translation errors may account for some of this deficit since the training is done using the publicly available machine-translated data. XeroAlign also leverages this data to align the multilingual representations of the PXLM. It is the nature of the dataset makes translation errors more likely for PAWS-X than for the task-oriented XNLU as the differences between paraphrased sentences are very subtle and challenging to discern (and to translate accurately). With that said, we think that the greater than expected deficit may be primarily caused by 1) a domain/topic shift within the dataset and 2) a possible data leakage for English. The original PAWS data (Zhang et al., 2019) was sourced from Quora Question Pairs and Wikipedia with neither being limited to any particular domain. As the English Wikipedia provides a large portion (relative to other languages) of the training data for XLM-R, it is possible that some of the English PAWS sentences may have been seen in training, which could explain the smaller generalisation gap for English.

In order to find out whether the accuracy gap will diminish, we artificially remove the hypothetical domain shift by using the parallel utterances (but not task labels) from the development and test sets. We thus XeroAlign the XLM-R on an extended vocabulary that may not be present in the train set. We observe that the (Exp) model in Table 3 shows an average improvement of over 2 points compared to the best XLM-RA and other SOTA models. This suggests that the increased generalisation gap may be caused by a domain shift for non-English languages on this task. When that topic shift gets (perhaps artificially) removed, the model is able to bring accuracy back within ∼2 points of the English model (in line with XNLU tasks). Note that this gap can be masked for English due to the language biases in data used for pretraining.

In section 2, we outlined the most conceptually similar methods that conducted large-scale model pretraining with task-agnostic sentence alignment as part of the training routine (Hu et al., 2020a; Feng et al., 2020; Pan et al., 2020; Chi et al., 2020). Where ablation studies were provided, the average improvement attributed to contrastive alignment was ∼0.2-0.3 points (though the tasks were slightly different). While we do not directly compare XeroAlign to contrastive alignment, it seems that a task-specific alignment may be a more effective and efficient technique to improve zero-shot transfer, given the magnitude of our results. This leads us to conclude that the effectiveness of our method comes primarily from cross-lingual alignment of the task-specific vocabulary. Language is inherently ambiguous, the semantics of words and phrases shift somewhat from topic to topic, therefore, a cross-lingual alignment of sentence embeddings *within the context of the target task* should lead to better results. Our simplified, lightweight method only uses translated task utterances, a single encoder model and positive samples, the alignment of which is challenging enough without arbitrary negative samples. In fact, this is the main barrier for applying contrastive alignment in task-specific NLP scenarios, i.e. the lack of carefully constructed negative samples. For smaller datasets, random negative samples would mean that the task is either too easy to solve, resulting in no meaningful learning or the model would receive conflicting signals by training on false positive examples, leading to degenerate learning.

4.6 Future Work

Our recommendations for avenues of promising follow-up research involve any of the following: i) aligning additional tasks such as Q&A, Natural Language Inference, Sentence Retrieval, etc. ii) including additional languages, especially low-resource ones (Joshi et al., 2020) and iii) evaluating large-scale, task-agnostic alignment of PXLMs followed by task-specific alignment, which is reminiscent of the common transfer learning paradigm of pretraining with Masked Language Modelling before fine-tuning on the target task. To that end, there is already some emergent work on monolingual fine-tuning with an additional contrastive loss (Gunel et al., 2020). For the purposes of multilingual benchmarks (Hu et al., 2020b; Liang et al., 2020) or other pure empirical pursuits, an architecture or a language-specific hyperparameter search should optimise XLM-RA for significantly higher performance as the large transformer does not always outperform its smaller counterpart and because our hyperparameters remained fixed for all languages. Most importantly, the follow-up work needs to improve zero-shot transfer for cross-lingual *structured prediction* such as Named Entity Recognition (Pan et al., 2017), POS Tagging (Nivre et al., 2016) or Slot Filling (Schuster et al., 2019), which is still lagging behind Target scores.

5 Conclusions

We have introduced **XeroAlign**, a conceptually simple and efficient method for task-specific alignment of multilingual sentence embeddings generated by PXLMs, aimed at effective zero-shot cross-lingual transfer. XeroAlign is an auxiliary training objective that is easily integrated into the unaltered primary task/model. XeroAlign leverages translated training data to bring the sentence embeddings in different languages closer together. We evaluated the XeroAligned XLM-R models (named XLM-RA) on zero-shot cross-lingual text classification, adversarial paraphrase detection and slot filling tasks, achieving SOTA (or near-SOTA) scores across four datasets covering 11 unique languages. Our ultimate vision is a level of zero-shot performance at or near that of Target models. The XeroAligned XLM-R partially achieved that goal by exceeding the intent classification and paraphrase detection accuracies of XLM-R trained with labelled data. We hope our work will inspire further progress in cross-lingual transfer learning.

Acknowledgements

We would like to thank the reviewers for their thoughtful comments and constructive feedback. We also want to thank the MindSpore[7][8] team for the technical support.

Using Word Embeddings to Analyze Teacher Evaluations: An Application to a Filipino Education Non-Profit Organization

Francesca Vera
Stanford University
Stanford, CA 94305
`fvera@alumni.stanford.edu`

Abstract

Analysis of teacher evaluations is crucial to the development of robust educational programs, particularly through the validation of desirable qualities being reflected on in the text. This research applies Natural Language Processing techniques on a real-world dataset from a Filipino education non-profit to explore insights from analyzing evaluations written by Teacher Fellows who assess their own progress. Prior to this research, only qualitative assessment had been conducted on the text. Inspired by the use of word embedding similarities to capture semantic alignment, we utilize GloVe embeddings to determine to what extent these evaluations reflect concepts critical to measuring the competency of Teacher Fellows and upholding the organization's Vision and Mission. As Fellows' quantitative ratings improved, so too did their demonstration of competency in the text. Further, Teacher Fellow language was consistent with the organization's Vision and Mission. This research therefore showcases the possibilities of NLP in education, improving our understanding of Teacher Fellow evaluations, which can lead to advances in program operations and education efforts.

1 Introduction

Applying Natural Language Processing (NLP) techniques to improve the quality of education programs is a crucial step in ensuring the NLP community's contributions to Social Good. Utilizing NLP unlocks the potential of computationally examining texts that were once only qualitatively analyzed or overlooked because of the difficulty in assessing the text. Textual data is plentiful in an educational setting, ranging from comments about student experiences to teacher evaluations and reflections. We look at applying NLP processes to teacher evaluations, which are a basis for documenting teacher growth and performance – components that will impact the quality of the education students receive.

The main contribution of this paper is that it introduces a computational framework through which teacher evaluations can be analyzed, so that insights gained can enhance educational programs. Applied on a real-world dataset from a Filipino education non-profit organization, word embedding similarities reveal which desirable traits within teachers are contained in these Teacher Fellow (a term used by the organization to describe its teachers in training) evaluations and their alignment with the organization's Vision and Mission. The motivation behind this work was to determine what qualities Teacher Fellows embody at different stages, as well as determining if their self-reflection was calibrated with manager (those training Teacher Fellows) evaluations. The organization was also curious if certain competencies emerged more than others.

With this application, we hope to improve the organization's teacher development efforts. Program changes that this piece of work inspired included refinement of the organization's evaluation tools and prompts, reflection on their competency definitions, greater discussions between Teacher Fellows and managers, alignment of interventions provided to Teacher Fellows, and increased support in the overall journey. We envision that this research can be scaled and flexibly applied to other bodies of textual data to serve future educational and Social Good purposes.

2 Related Work

2.1 NLP in Education

The uses of NLP in the education space include: to better understand natural language learning; to improve teaching materials; to develop learning applications; and to enhance student output, as out-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 382–389
August 1–6, 2021.

lined by Dr. Alhawiti (2014) in a survey of the state of NLP applications in education. Relevant to teacher evaluations, research by Rajput et al. (2016) implements a lexicon-based sentiment analysis tool on these evaluations to gain more insight on student feedback. Not only did the tool prove highly correlated with quantitative ratings, but also it provided clearer understanding of teacher performance through its sentiment score. Further, Tzacheva et al. (2019) present a model that detects multiple emotions within student comments on teacher performance in order to increase positivity in student emotions and improve student experience in the classroom. Our research differs from past NLP explorations in that it is mostly concerned with teacher self-evaluation and employs the use of word embeddings to derive a set of pre-defined concepts reflected in the text.

2.2 Word Embedding Similarities

Word embeddings are vector representations of words that capture their semantic features. These vectors can be assessed in relationship to one another through Euclidean distance or cosine similarity, used interchangeably to measure the semantic similarity (Pennington et al., 2014) between the words whose corresponding vectors are being compared. Embedding similarity to affirm the semantic alignment in language is a common technique in NLP. In exploring the semantic similarity between two texts, Kenter and de Rijke (2015) propose the proximity between embeddings as related to semantic proximity. To quantify gender and ethnic stereotypes using embeddings, Garg et al. (2017) computed the Euclidean distance between group words and neutral words to measure the strength of association between the two sets. Similarity can also be calculated on a sentence level, even when the structure of the sentence is ignored, but the associated embeddings of the words within the sentence are considered by averaging. (Faruqui et al., 2014; Yu et al., 2014) We adopt a combination of these past uses of word embeddings by calculating the similarity of sets of words to determine semantic proximity between them, where one of the sets contains sentences for which an associated embedding must be assigned.

3 Dataset

This paper applies NLP techniques on a real-world dataset from a Filipino education non-profit organization since the data consisted of many textual entries. The organization continues to conduct qualitative assessment on this particular dataset, but this paper explores the first application of quantitative analysis on it.

The dataset was made up of Summer Institute (SI) reflections, mid-year Competency Based Evaluations (CBE's), and end-year Competency Based Evaluations. CBE's allow a Teacher Fellow the opportunity to reflect on their progress, as well as provide a formal space for an instructional coach's assessment. Split into four domains: Personal Leadership, Servant Leadership, Change Management, and Critical Learning, CBE's prompt the Fellow to write on "Critical Incidents, Strengths, and Areas of Growth" and give themselves a rating out of 4.0 per domain. A coach repeats the process based on their assessment of the Fellow. Overall, each CBE consists of 8 text entries and 8 ratings. SI reflections differ from CBE's in that the prompts are about high-level, philosophical ideas in education and there are no quantitative ratings.

For the sake of consistency, only Fellows who had SI reflections, mid-, and end-year CBE's were chosen. There were 14 such Fellows. These evaluations were collected in 2019, making it still relevant to the present-day programs of the organization. In total, there were 126 unique text entries: 14 SI reflections, 56 CBE entries by Teacher Fellows, and 56 CBE entries by instructional coaches. Alongside these text entries were 56 ratings by Teacher Fellows and 56 ratings by instructional coaches.

Although the dataset only consisted of 14 Fellows, there were 126 text entries of average length 204 words, which was significant enough to move forward with exploring this application.

4 Method

4.1 Keyword List Development

The organization developed keyword lists to encapsulate the ideas that it was interested in analyzing. A Data and Impact Assessment Manager created these lists based on three important aspects: Competencies, Core Values, and Mission. These Competencies are the listed "indicators" that Fellows should develop throughout the duration of the program and after completion. They were defined by the organization's Fellowship Program team, who have years of experience and pivotal knowledge of the Fellows' impact on students and communities. The "indicators" were condensed into lists of Competency keywords by careful selection of words that carried the most meaning. A similar process was done to create Core Values and Mission lists, which represent the organization's Vision and Mission. Core Values were also embedded in the "indicators," so keywords were extracted from there. The Mission keyword list came directly from the organization's Mission statement. Because the Data and Impact Assessment Manager was not on the Program team that wrote the "indicators," keyword selection was relatively objective, ensuring that certain concepts were not favored nor dismissed.

Although there may be subjectivity within keyword choices, common NLP tasks exist where keywords are grouped by theme into sets (e.g. determining which occupation words are neutral in gender bias embedding explorations (Garg et al., 2017)). The method of having an internal expert choose keywords that represented competencies based on pre-defined qualities that Teacher Fellows should achieve most closely mirrors methods for past NLP datasets where experts from other fields have hand-labeled entries (e.g. cross-validating entries in hate speech datasets (Jha and Mamidi, 2017)) – despite the subjectivity in this exercise. Most importantly, the organization fealt confident that the keywords chosen accurately reflected its desired competencies, core values, and mission.

4.2 Embedding Similarity Calculation

Inspired by the concept that cosine similarity between embeddings measures semantic similarity between words, we calculate the similarity between the keyword lists and teacher evaluations.

For each keyword, we find the keyword embedding. If the keyword was present in the predefined embeddings, we used that embedding. In some cases, however, there were multiple words that made up a keyphrase; for these items, we took the average of embeddings for every word in the keyphrase and assigned that as the embedding. Next, we find the embedding for the teacher evaluations, which we will refer to as the evaluation embedding. Each evaluation was treated as a single document of text with only one assigned embedding. In the pre-processing of this text, punctuation was stripped, spelling was checked through Microsoft Word, and documents were tokenized. Similar to what was done with keyphrases, we averaged the embeddings of every token, and this average was taken as the evaluation embedding.

Competency Domain	Mid-Year Similarity	End-Year Similarity
Personal Leadership	0.498	0.523
Servant Leadership	0.603	0.608
Change Management	0.531	0.532
Critical Learning	0.599	0.600

Table 1: Fellow Competency Similarity Scores

Competency Domain	Mid-Year Similarity	End-Year Similarity
Personal Leadership	0.519	0.523
Servant Leadership	0.632	0.634
Change Management	0.557	0.560
Critical Learning	0.631	0.629

Table 2: Coach Competency Similarity Scores

After finding the keyword embedding and the evaluation embedding, we calculate their cosine similarity, which becomes their similarity score. This process was repeated for every evaluation and keyword. To find the overall score for Competencies, Core Values, or Mission, we average across all Fellow-keyword similarity scores per list.

4.3 Experiments

The following experiments were conducted on the dataset with GloVe 50-dimensional embeddings. A similarity score was calculated for each Fellow across the organization's Competency domains: Personal Leadership, Servant Leadership, Change Management, and Critical Learning, which had unique keyword lists each. This process was repeated for Fellows' and coaches' mid-year and end-year CBE entries, resulting in 16 similarity scores (tables 1 and 2). We also include the Fellows' and coaches' quantitative ratings out of 4.0 from the CBE's (tables 3 and 4) for later comparison. The Competency keywords with the highest similarities are listed out (tables 5 and 6). We calculated the similarity between Fellow evaluations and the Core Values and Mission lists to measure alignment with Vision and Mission. This was done on the Fellows' SI reflections, mid-year CBE's, and end-year CBE's (table 7). We also list the top keywords for Core Values and Mission (table 8).

Competency Domain	Mid-Year Score	End-Year Score
Personal Leadership	2.619	2.833
Servant Leadership	2.381	2.524
Change Management	2.214	2.393
Critical Learning	2.250	2.536

Table 3: Fellow CBE Ratings

Competency Domain	Mid-Year Score	End-Year Score
Personal Leadership	2.500	2.786
Servant Leadership	2.191	2.548
Change Management	2.143	2.446
Critical Learning	2.321	2.750

Table 4: Coach CBE Ratings

5 Discussion of Results

Cosine similarity has maximum score 1.0, which occurs when perfect similarity is achieved; higher cosine similarity indicates higher semantic similarity. Thresholds differ according to vector space and can be calculated through a variety of methods. We employ a cutoff of > 0.37 (Orkphol and Yang, 2019) to indicate similarity based on a predictive model validated by human perception of relevance, as human intuition of similarity is fundamental to how our application would be used in practice. However, we acknowledge that to achieve a truly appropriate cutoff, we would have to replicate the empirical study with our own relevant prompts to generalize for this task.

Fellow and coach mid-year and end-year CBE's display Competency similarity scores above our chosen threshold, indicating that their essence was present in the evaluations. We also notice an improvement in all Competency domains from mid-year to end-year evaluations for Fellows and coaches. This upward trend mirrors the increase in quantitative ratings, suggesting that as Fellows improve in practice, their reflections become more aligned with the domain concepts. The domain with highest similarity was Servant Leadership, while the lowest was Personal Leadership, although the differences between similarities are minimal. It is important distinguish what is reflected on in the evaluations from how the Fellows are rated in practice: for example, Personal Leadership ratings were among the highest out of 4.0, but the similarity scores were the lowest, meaning there may be inconsistencies between what is written and how Fellows are rated. Coaches produced higher similarity scores than Fellows did, which is expected due to coaches who speak more explicitly in terms of the Fellow's competency.

Clear themes emerge from looking at the top keywords for Competency domains. Personal Leadership focuses on life skills that Fellows may improve upon. For Servant Leadership, there is emphasis on the relationship aspects of teaching. Because Change Management is concerned with executing plans for the larger community, the top keywords express big picture thinking. In Critical Learning, the topics cover knowledge and lesson formation.

Personal Leadership	Servant Leadership
Manages Time	Relationship Building
Personal Development	Strong Relationships
Work Habits	Common Goals
Improve	Shared Goals
Describes Drives	Positive Relationships

Table 5: Top 5 Competency Keywords pt. 1

Change Management	Critical Learning
Higher Order Thinking	Working Knowledge
Effective Plans	Lesson Plan
Systems Thinking	Subject Matter
Big Picture	Deliver Lessons
Considering	Subject Content

Table 6: Top 5 Competency Keywords pt. 2

Since the Core Values and Mission keyword lists captured the Vision and Mission of the organization, the significant similarity scores across SI reflections, mid-year, and end-year CBE's indicate that the Vision and Mission was expressed in the Fellows' writing. The top 3 keywords for Core Values are especially salient, as "get the job done" was consistent with the Critical Learning Competency domain, and "working with others" and "working as a team" directly related to Servant Leadership.

5.1 Debrief with the Organization

We set up a formal discussion with the organization's Fellowship Program team, whose expertise in the program, evaluations, and Fellow performance led us to further insights. They endorsed the outcome that Servant Leadership produced the highest similarity scores. They theorized that the interpersonal and community aspects of Servant Leadership were already strong within this cohort of Fellows. When looking at the top 5 keywords for Servant Leadership, the themes of fostering relationships and shared goals were unsurprising to them. The second highest scoring domain, Criti-

Keyword List	SI	Mid-Year CBE	End-Year CBE
Core Values	0.686	0.677	0.679
Mission	0.637	0.620	0.623
Competency	0.565	0.577	0.566

Table 7: Core Values and Mission Similarity Scores

Core Values	Mission
Get the Job Done	Programs
Working with Others	Life Skills
Working as a Team	Developing Students

Table 8: Top 3 Core Values and Mission Keywords

cal Learning, also lined up with their expectations; because this domain is specifically concerned with pedagogical knowledge, Critical Learning tends to be discussed at length, as would be typical in standard teacher evaluations. Further, they said it made sense that coaches produced higher similarity scores than Fellows did since coaches are not only more familiar with concepts, but are also given templates for being explicit in their writing.

The Program team appreciated the conceptual alignment between the evaluations and the Core Values and Mission, claiming that throughout the training process, coaches encourage Fellows to incorporate these components in their practice. After looking at the top 3 Mission keywords, the Program team emphasized that Fellows are coached on “life skills” and “developing students” – two of the most important components of the program.

They noted that one area of improvement that would be easily implemented in future applications of this process would be to update keyword lists as the “indicators” themselves get updated. Because this project inspired reflection within the organization regarding what qualities it is evaluating teachers on, any further analysis should consider appropriate changes in competencies.

It may also be important to note that the Fellowship Program team’s enthusiasm for this project meant that we received dynamic feedback during the entire process.

6 Conclusion

We present an application of word embedding similarities to evaluate how Teacher Fellow evaluations align with requirements for Competency and a non-profit’s Vision and Mission. This analysis adds a new element to the interpretation of textual data that would have otherwise been only qualitatively examined. Moving forward, the organization aims to apply this method to other batches of Fellows. Other members of the organization, such as Admissions and Alumni Program teams, also conduct evaluations on which the method could be applied. A comparison may be conducted to see what certain cohorts were more willing to reflect on in the text and how their focuses differ. More sophisticated models, including Tf-idf weighting and a higher level of pre-processing, are possible, and further validation through correlation with quantitative ratings can help clarify the value of this model. Having demonstrated that Fellows’ evaluations captured ideas contained within Competency, Core Values, and Mission keywords, we are confident that the organization can incorporate this analysis to achieve its goal of providing children access to high quality education across the Philippines.

Acknowledgments

I would like to acknowledge the Filipino education non-profit organization that provided the project scope and dataset that shaped this paper. In particular, Gaby, Ed, and Jo – who offered valuable collaboration, insights, and guidance.

Ethics and Positive Impact Considerations

NLP for Positive Impact aims to promote innovative ways NLP research will positively impact society, and this paper presents a case study of an NLP application for the social good cause of education. We consider the impact of this paper as positive because the improvements to the non-profit's programs (due to this research) will advance the organization's mission to provide Filipino children with the highest standard of education possible. This paper may also inspire positive impact in other situations where similar applications of NLP could be used for social good.

There is also an opportunity to incorporate the UN theme for International Women's Day, "Women in Leadership," because of the relationship between education and empowering women. It is worth noting that in the Philippines, teachers are mostly women, so this research could inform their professional leadership journey, including how to better train and support them. We envision many possibilities for this application in a profession dominated by women in the Philippines.

For context, the Filipino education non-profit focuses on improving teacher quality and addressing system-level educational challenges. This organization that provided the data allowed the submission of this paper. We focus on its Fellowship Program that trains Teacher Fellows to significantly improve student learning outcomes. Because the Fellowship Program is concerned with the growth of Teacher Fellows in their ability to deliver lessons of high quality and create positive change in educational communities, analyzing their evaluations is a worthwhile task in continuing the efficacy of this program. The Fellowship Program reaches over 10,000 public school students in the Philippines annually. Since the organization would be the main beneficiary of this technology, this technology has the potential to improve the Fellowship Program, which in turn will impact the Teacher Fellows and their students. A secondary beneficiary would be other similar non-profit organizations or operations teams that run educational programs.

The dataset used in this application was directly provided to us by the organization's Data and Impact Assessment team. The handover of data was formally documented and a non-disclosure agreement was signed. Further, we met with the Instructional Coaching Team to confirm the consent of the original authors of the texts. With regards to dataset privacy considerations, per the request of the organization and to protect the privacy of the Teacher Fellows and instructional coaches, the evaluations were completely anonymized. For the same reasons, the data cannot be submitted for review or replication. We chose not to include direct quotations from the evaluations (which could have been used to strengthen discussion of results) to ensure the authors' privacy.

An overall evaluation of using word embeddings for similarity tasks was considered. (Faruqui et al., 2016) Further, word embeddings have been shown to carry biases (e.g. gender and ethnic stereotypes) (Garg et al., 2017), so these biases may manifest in the outcomes. Because the similarity threshold was defined by a model based on human perception, the biases of the human participants may also factor into the resulting value. We acknowledge that the research was conducted in English, which may exclude other languages where word embeddings in those languages cannot be applied in a similar way.

`saintfe@mail.ustc.edu.cn, hchen@ustc.edu.cn`

Abstract

Relation classification aims to predict a relation between two entities in a sentence. The existing methods regard all relations as the candidate relations for the two entities. These methods neglect the restrictions on candidate relations by entity types, which leads to some inappropriate relations being candidate relations. In this paper, we propose a novel paradigm, RElation Classification with ENtity Type restriction (RECENT), which exploits entity types to restrict candidate relations. Specially, the mutual restrictions of relations and entity types are formalized and introduced into relation classification. Besides, the proposed paradigm, RECENT, is model-agnostic. Based on two representative models GCN and SpanBERT respectively, $\text{RECENT}_{\text{GCN}}$ and $\text{RECENT}_{\text{SpanBERT}}$ are trained in RECENT[1]. Experimental results on a standard dataset indicate that RECENT improves the performance of GCN and SpanBERT by 6.9 and 4.4 F1 points, respectively. Especially, $\text{RECENT}_{\text{SpanBERT}}$ achieves a new state-of-the-art on TACRED.

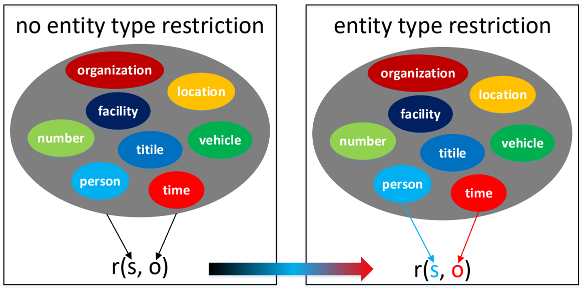

Figure 1: A relation restricts entities with appropriate types. In the figure, r is *who-is-born-when*. Different colored ellipses represent entities with different types.

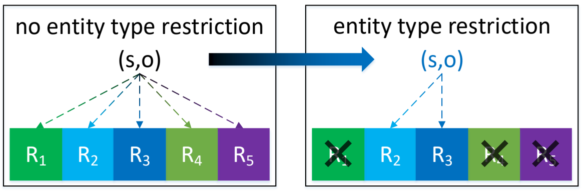

Figure 2: Entity type restriction for relation classification. According to entity type restriction, the number of candidate relations reduces from 5 (left) to 2 (right).

1 Introduction

Relation classification, a supervised version of relation extraction, aims to predict a relation between two entities in a sentence. Relation classification is an important step to construct knowledge bases from a large number of unstructured texts (Trisedya et al., 2019), which benefits many natural language processing applications, such as natural language generation (Kang and Hashimoto, 2020) and question answering (Zhao et al., 2020).

Recently, the majority of methods make use of various neural network architectures to learn a fixed-size representation for a sentence and its entities with various language features, such as part of speech (POS), entity types, and dependency trees. Dependency trees that are parsed from sentences are exploited by GCN (Kipf and Welling, 2017) to model sentences (Zhang et al., 2018; Guo et al., 2019). As a sequence of words, a sentence is modeled by LSTM (Hochreiter and Schmidhuber, 1997) and its entity positions are involved with the attention mechanism (Zhang et al., 2017). More recently, pretrained language models (Devlin et al., 2019; Baldini Soares et al., 2019; Joshi et al., 2020) achieve good performance in relation classification since they are pretrained on massive corpora.

To recap, these methods utilize an encoder architecture (Badrinarayanan et al., 2017) to obtain a representation for a sentence. In other words, they only focus on the modeling of sentences and

August 1–6, 2021.

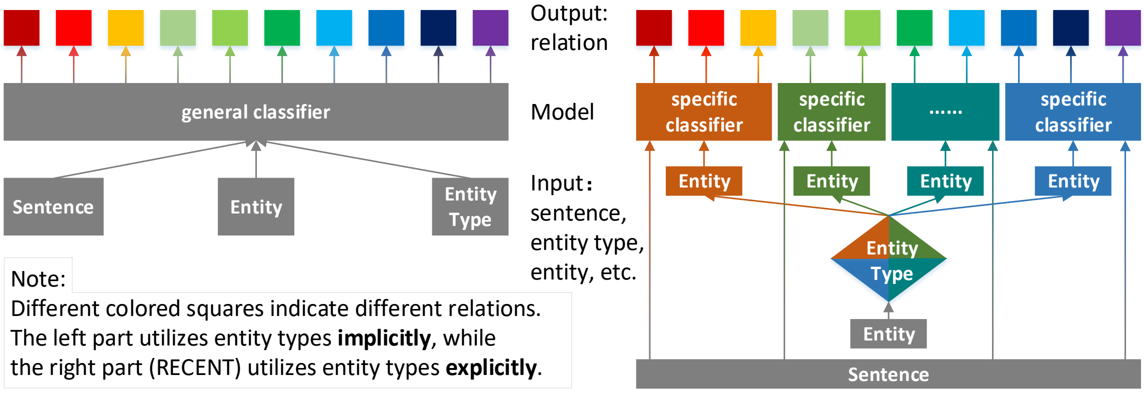

Figure 3: Relation classification with entity type restriction. The left part does not consider the restriction of entity types on relations and only feeds entity types as features into a general classifier. The right part explicitly utilizes entity types to restrict candidate relations and learns a specific classifier for each pair of entity types.

treat relations as labels[2] to be classified. However, in this process, these methods inevitably lose the semantics of relations. Take the mutual restrictions between a relation and entity types as an example. In Figure 1, the relation *who-is-born-when* restricts its first entity to be a person and the second one to be a time. Conversely, entity types can also restrict candidate relations in relation classification. As illustrated in Figure 2, some inappropriate relations can be discarded from candidate relations by entity type restriction. However, the current methods neglect the restriction of entity types on relations so that some inappropriate relations are regarded as candidate relations, which further hurts their performance.

To solve the above problem, a novel paradigm, RElation Classification with ENtity Type restriction (RECENT), is proposed to exploit entity types to restrict candidate relations. As the basis of the paradigm, the mutual restrictions of relations and entity types are formalized. With the entity type restriction, some inappropriate relations are discarded from the candidate relations of a specific pair of entity types, as illustrated in Figure 2. A specific classifier with a specific set of candidate relations is individually learned for each pair of entity types (Figure 3). Therefore, the proposed paradigm, RECENT, can eliminate the interference from inappropriate candidate relations.

The contributions are summarized as follows:

- The mutual restrictions of relations and entity types are formalized.
- A novel paradigm, RECENT, is proposed to exploit entity types to restrict candidate relations in relation classification.
- A new state-of-the-art is achieved on TACRED.

2 Proposed Paradigm

Before introducing the proposed paradigm RECENT, the mutual restrictions between a relation and a pair of entities are formalized as the basis of RECENT.

2.1 Relation Function

When a binary relation is considered as a function, this relation has two entities as its two arguments. Formally, this relation is formalized as $r(s, o)$, where r denotes the <u>r</u>elation and s, o denote the first (<u>s</u>ubject) entity and the second (<u>o</u>bject) entity, respectively. The range of this relation contains two discrete values $\{0, 1\}$:

$$r(s,o) = \begin{cases} 1 & r \text{ holds between } s \text{ and } o, \\ 0 & \text{otherwise.} \end{cases} \tag{1}$$

In a broad sense, the domain of this relation can be any pair of entities. However, when a pair of entities with inappropriate types is fed into a specific relation, the relation can directly return 0, no need to consider the compositional semantics of the relation and the pair of entities. For example, a specific relation *who-is-born-when* expects the first argument to be a person and the second one to be a time. Therefore, (*apple*, *Steven Jobs*) is a pair of inappropriate entities for this relation so that *who-is-born-when(apple, Steven Jobs)* returns 0 without considering the compositional semantics,

---

[2] Specifically, these meaningful relations are treated as meaningless numbers, such as 0, 1, 2.

since *apple* may refer to either a kind of fruit or a company (not a person) and *Steven Jobs* may refer to a famous person (not a time).

Only when a relation receives a pair of appropriate entities whose types match it, the combination of the relation and the entities might make sense (i.e., the function defined in Eq. 1 may return 1). In this case, it is meaningful to further verify the correctness of the compositional semantics. From this perspective, in a narrow sense, the domain (denoted by D_r) of a relation (r) is defined as follows:

$$D_r = \{(s, o) | ts \in S(r) \text{ and } to \in O(r)\}, \tag{2}$$

where ts and to denote the **t**ypes of the subject entity (s) and the object entity (o), respectively. $S(r)$ and $O(r)$ are the appropriate types of r on the subject entity (s) and the object entity (o), respectively.

2.2 Entity Type Restriction

In the previous subsection, the narrow domain of a relation restricts entities whose types need to match the relation. Conversely, given a pair of entities whose types are known, the candidate relations of the entities are also restricted, since the match between relations and entity types is mutual.

Formally, given a pair of entities (s, o) and their types (ts, to), its candidate relations (denoted by $R_{(ts,to)}$) are restricted into a limited set:

$$\begin{aligned} R_{(ts,to)} &= \{r \in R | (s, o) \in D_r\} \\ &= \{r \in R | ts \in S(r) \text{ and } to \in O(r)\}, \end{aligned} \tag{3}$$

where R denotes all possible relations. When the types (ts, to) of a pair of entities (s, o) are explicitly utilized to restrict its candidate relations, the candidate relations reduce from all possible relations R into a rather smaller set $R_{(ts,to)}$.

2.3 Relation Classification

Unlike traditional methods that classify a sentence and its entities on all candidate relations R (the left part of Figure 3), the proposed paradigm, RECENT learns a specific classifier with smaller and more precise candidate relations for each pair of entity types (the right part of Figure 3), based on entity type restriction in the previous subsection.

The procedure of RECENT is summarized in Algorithm 1. In the learning phase, all sentences are first grouped by types of their entities (line 1). For each group (marked as g) with a specific pair of entity types (ts,to), the candidate relations $R_{(ts,to)}$ for the group g are obtained by aggregating the relations in the group g (line 3). Then, a specific classifier (marked by f_g) that maps sentences and their entities in g to $R_{(ts,to)}$, is learned for the group g (line 4). In the prediction phase, given a new sample (se, s, o, ts, to), a group (marked as $g^{'}$) is matched by the entity types (ts, to) (line 6). Then, the classifier $f_{g^{'}}$ learned on the group $g^{'}$ is utilized to predict a relation according to the input (se, s, o) (line 7).

From the 4th line of Algorithm 1, the proposed paradigm RECENT is model-agnostic, which means that RECENT is theoretically compatible with many relation classification models.

Algorithm 1 RECENT

```
Learning Phase:
    Input: $\mathcal{D} = \{(se_i, s_i, o_i, ts_i, to_i, r_i) | i = 1, 2, ..., N\}$ where the subscript $i$ indicates the
    $i$th sample, $se$ is sentence, $s$ is subject entity, $o$ is object entity, $ts$ is type of subject entity, $to$
    is type of object entity, $r$ is relation.
    Output: Multiple classifiers.
 1: Group sentences by entity types.
 2: for each group $g$ (enity types ($ts$, $to$) ) do
 3:     aggregate relations in the group as candidate relations $R_{(ts,to)}$ defined in Eq. 3.
 4:     learn a classifier (marked as $f_g$) on the group that maps $\{(se_i, s_i, o_i) \in g\}$ to $R_{(ts,to)}$.
 5: end for
Prediction Phase:
    Input: A new sample $\{se, s, o, ts, to\}$, each specific classifier for each pair of entity types.
    Output: A relation.
 6: match the sample to a group (marked as $g^{'}$) according to the entity types ($ts$, $to$).
 7: Use the classifier ($f_{g^{'}}$) learned on the group to map ($se$, $s$, $o$) to a relation.
 8: return the relation.
```

3 Experiments

3.1 Dataset

The proposed paradigm RECENT is evaluated on TACRED[3] (Zhang et al., 2017). TACRED contains 41 semantic relations and a special *no_relation* over 106,264 sentences. The subject entities in TACRED are classified into two types: *PERSON* and

---

[3] https://catalog.ldc.upenn.edu/LDC2018T24

ORGANIZATION while the object entities are categorized into 16 fine-grained types, such as *LOCATION* and *TIME*. Namely, entity types are known. By convention, the micro-averaged F1 score (abbreviated as F1) is reported on TACRED.

3.2 Experimental Setup

Since *no_relation* is a candidate relation of each pair of entity types in TACRED, a binary classifier is first learned to distinguish between 41 semantic relations and *no_relation*. In this way, each pair of entity types reduces one candidate relation (i.e. *no_relation*) in RECENT. If the binary classifier predicts *no_relation* for a pair of entities, then the final relation for them is *no_relation*. Otherwise, their specific semantic relation is further predicted in RECENT.

Base Models The proposed paradigm RECENT is model-agnostic. Two representative models that are GCN (Zhang et al., 2018) and SpanBERT (Joshi et al., 2020) are selected as base models (line 4 in Algorithm 1). For a fair comparison with a base model, all classifiers (including the binary classifier) in RECENT are trained by the base model. The corresponding models in the paper are denoted as $\text{RECENT}_{\text{GCN}}$ and $\text{RECENT}_{\text{SpanBERT}}$.

Hyperparameters For $\text{RECENT}_{\text{GCN}}$, the path-centric pruning K is set to 1 as GCN (Zhang et al., 2018). The learning rates for all classifiers in $\text{RECENT}_{\text{GCN}}$ are set to 0.3. For $\text{RECENT}_{\text{SpanBERT}}$, the learning rates for all classifiers are chosen from {5e-6, 1e-5, 2e-5, 3e-5, 5e-5} as SpanBERT.

Compared Models Extensive models in relation classification are regarded as comparison models. They include PA-LSTM (Zhang et al., 2017), C-GCN (Zhang et al., 2018), AGGCN (Guo et al., 2019), C-AGGCN (Guo et al., 2019), MTB (Baldini Soares et al., 2019), KnowBert (Peters et al., 2019), SpanBERT-ALT (Lyu et al., 2020), KEPLER (Wang et al., 2020b), K-Adapter (Wang et al., 2020a), and LUKE (Yamada et al., 2020). To save space, please refer to the original papers of these models for details.

3.3 Experimental Results

The experimental results are presented in Table 1. $\text{RECENT}_{\text{GCN}}$ achieves a significant performance increase on the F1 score above its base model GCN. The absolute increase reaches 6.9 from 64.0 to 70.9. The main contribution for the F1 increase is the improved precision that greatly increases from 69.8 to 88.3. The great increase in precision, which might result from the restriction on candidate relations by entity types in RECENT, indicates the effectiveness of the proposed paradigm RECENT. Besides, $\text{RECENT}_{\text{GCN}}$ suppresses the compared models that do not include pretrained language models.

Model	P	R	F1
PA-LSTM † (Zhang et al., 2017)	65.7	64.5	65.1
C-GCN † (Zhang et al., 2018)	69.9	63.3	66.4
AGGCN † (Guo et al., 2019)	69.9	60.9	65.1
C-AGGCN † (Guo et al., 2019)	71.8	66.4	69.0
GCN † (Zhang et al., 2018)	69.8	59.0	64.0
$\text{RECENT}_{\text{GCN}}$ (ours)	88.3	59.3	70.9
SpanBERT-ALT † (Lyu et al., 2020)	69.0	73.0	70.9
MTB † (Baldini Soares et al., 2019)	-	-	71.5
KnowBert † (Peters et al., 2019)	71.6	71.4	71.5
KEPLER †* (Wang et al., 2020b)	71.5	72.5	72.0
K-Adapter †* (Wang et al., 2020a)	70.14	74.04	72.04
LUKE † (Yamada et al., 2020)	70.4	**75.1**	72.7
SpanBERT † (Joshi et al., 2020)	70.8	70.9	70.8
$\text{RECENT}_{\text{SpanBERT}}$ (ours)	**90.9**	64.2	**75.2**

Table 1: Results on the TACRED dataset. P and R indicate precision and recall, respectively. Bold marks the highest values among models. † marks results reported in the original papers. * marks results from preprint papers.

Similarly, $\text{RECENT}_{\text{SpanBERT}}$ overtakes its base model SpanBERT by absolute 4.4 points on F1. The great soar (absolute 20.1 points) on precision contributes the superior F1 of $\text{RECENT}_{\text{SpanBERT}}$. Unfortunately, the decline in recall limits the further improvement of F1. This might be due to sample imbalance of candidate relations, which will be further studied in future work. On the whole (i.e. F1), $\text{RECENT}_{\text{SpanBERT}}$ outperforms all the compared models. Especially, $\text{RECENT}_{\text{SpanBERT}}$ exceeds the state-of-the-art LUKE model[4] by 2.5 F1 points and achieves a new state-of-the-art.

3.4 Error Analysis of GCN

This subsection analyzes the influence of a baseline model (i.e. GCN) that neglects the restriction of entity types on relations. We retrain a GCN model and the model achieves 68.4 precision, 60.2 recall, and 64.1 F1 (Table 2), which are similar to the

---

[4] LUKE achieves the state-of-the-art (72.7) on the published papers. Cohen et al. (2020) report a new state-of-the-art (74.8) in the preprint way. Anyway, $\text{RECENT}_{\text{SpanBERT}}$ achieves a new state-of-the-art (75.2).

Model	P	R	F1	FP	FP(ET)
GCN	68.4	60.2	64.1	1,323	144

Table 2: Results of our trained GCN on the TACRED dataset. P and R indicate precision and recall, respectively. FP indicates the number of false positives and FP(ET) indicates the number of false positives that break the entity type restriction.

results in its reported paper (Zhang et al., 2018). Observing the prediction results of the model, we find that 1) 1,323 examples are false positives in the test set of TACRED, 2) 144 (about 11%) false positives among them break the entity type restriction. Namely, GCN can make about 89% of false positives meet the entity type restriction, by implicitly using entity types. However, about 11% of false positives still break the restriction. The false positives broken down by relations are counted in Appendix A. In details, false positives broken down by relations are weakly negatively correlated with the amount of training data of relations, where the correlation coefficient is -0.39. This infers that fewer training examples of relations may lead to more false positives of relations.

4 Conclusion

In the paper, a novel paradigm, RECENT, is proposed by entity type restriction. RECENT reduces candidate relations for each pair of entity types by the mutual restrictions between relations and entity types. RECENT is model-agnostic. $\text{RECENT}_{\text{GCN}}$ and $\text{RECENT}_{\text{SpanBERT}}$ that are based on two representative models GCN and SpanBERT respectively, outperform their counterparts on the standard dataset TACRED, which empirically indicates the effectiveness of the proposed paradigm RECENT. Especially, $\text{RECENT}_{\text{SpanBERT}}$ achieves a new state-of-the-art on TACRED.

Link Prediction on N-ary Relational Facts: A Graph-based Approach

Quan Wang, Haifeng Wang, Yajuan Lyu, Yong Zhu
Baidu Inc., Beijing, China
`{wangquan05,wanghaifeng,lvyajuan,zhuyong}@baidu.com`

Abstract

Link prediction on knowledge graphs (KGs) is a key research topic. Previous work mainly focused on binary relations, paying less attention to higher-arity relations although they are ubiquitous in real-world KGs. This paper considers link prediction upon n-ary relational facts and proposes a graph-based approach to this task. The key to our approach is to represent the n-ary structure of a fact as a small heterogeneous graph, and model this graph with edge-biased fully-connected attention. The fully-connected attention captures universal inter-vertex interactions, while with edge-aware attentive biases to particularly encode the graph structure and its heterogeneity. In this fashion, our approach fully models global and local dependencies in each n-ary fact, and hence can more effectively capture associations therein. Extensive evaluation verifies the effectiveness and superiority of our approach. It performs substantially and consistently better than current state-of-the-art across a variety of n-ary relational benchmarks. Our code is publicly available.[1]

1 Introduction

Web-scale knowledge graphs (KGs), such as Freebase (Bollacker et al., 2008), Wikidata (Vrandečić and Krötzsch, 2014), and Google Knowledge Vault (Dong et al., 2014), are useful resources for many real-world applications, ranging from Web search and question answering to recommender systems. Though impressively large, these modern KGs are still known to be greatly incomplete and missing crucial facts (West et al., 2014). Link prediction which predicts missing links in KGs has therefore become an important research topic.

Previous studies mainly consider link prediction upon binary relational facts, which encode binary relations between pairs of entities and are usually represented as $(subject, relation, object)$ triples. Nevertheless, besides binary relational facts, n-ary relational facts that involve more than two entities are also ubiquitous in reality, e.g., *Marie Curie received Nobel Prize in Physics in 1903 together with Pierre Curie and Antoine Henri Becquerel* is a typical 5-ary fact. As pointed out by Wen et al. (2016), more than $1/3$ of the entities in Freebase actually participate in n-ary relational facts.

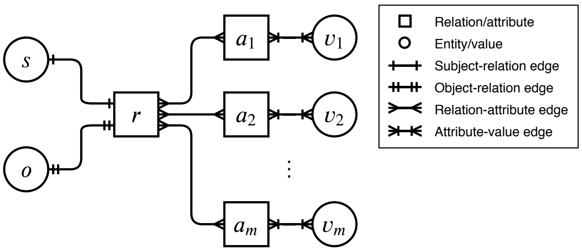

Figure 1: An n-ary fact as a heterogenous graph, with relations/attributes and entities/values as vertices, and four types of edges designed between the vertices.

Despite the ubiquitousness, only a few studies have examined link prediction on n-ary relational facts. In these studies, an n-ary fact is typically represented as a set of peer attributes (relations) along with their values (entities), e.g., {*person: Marie Curie*, *award: Nobel Prize in Physics*, *point-in-time: 1903*, *together-with: Pierre Curie*, *together-with: Antoine Henri Becquerel*}. Link prediction then is achieved by learning the relatedness either between the values (Zhang et al., 2018; Liu et al., 2020; Fatemi et al., 2020) or between the attribute-value pairs (Guan et al., 2019; Liu et al., 2021). This representation inherently assumes that attributes of a same n-ary fact are equally important, which is usually not the case. To further discriminate importance of different attributes, Rosso et al. (2020) and Guan et al. (2020) later proposed to represent an n-ary fact as a primary triple coupled with auxiliary attribute-value descriptions, e.g., in the above 5-ary

fact, (*Marie Curie*, *award-received*, *Nobel Prize in Physics*) is the primary triple and *point-in-time: 1903*, *together-with: Pierre Curie*, *together-with: Antoine Henri Becquerel* are auxiliary descriptions. Link prediction then is achieved by measuring the validity of the primary triple and its compatibility with each attribute-value pair. These attribute-value pairs, however, are modeled independently before a final aggregation, thus ignoring intrinsic semantic relatedness in between.

This work in general follows Rosso et al. (2020) and Guan et al. (2020)'s expressive representation form of n-ary facts, but takes a novel graph learning perspective for modeling and reasoning with such facts. Given an n-ary fact represented as a primary subject-relation-object triple (s, r, o) with auxiliary attribute-value pairs $\{(a_i : v_i)\}$, we first formalize the fact as a heterogenous graph. This graph, as we illustrate in Figure 1, takes relations and entities (attributes and values) as vertices, and introduces four types of edges, i.e., subject-relation, object-relation, relation-attribute, and attribute-value, to denote distinct connectivity patterns between these vertices. In this fashion, the full semantics of the given fact will be retained in the graph. Then, based on this graph representation, we employ a fully-connected attention module to characterize inter-vertex interactions, while further introducing edge-aware attentive biases to particularly handle the graph structure and heterogeneity. This enables us to capture not only local but also global dependencies within the fact. Our approach directly encodes each n-ary fact as a whole graph so as to better capture rich associations therein. In this sense, we call it GRAph-based N-ary relational learning (GRAN).

The most similar prior art to this work is STARE (Galkin et al., 2020), which uses a message passing based graph encoder to obtain relation (attribute) and entity (value) embeddings, and feeds these embeddings into a Transformer (Vaswani et al., 2017) decoder to score n-ary facts. Our approach is more neatly designed by (1) excluding the computational-heavy graph encoder which, according to a contemporaneous study (Yu and Yang, 2021), may not be necessary given an expressive enough decoder, and (2) modeling the full n-ary structure of a fact during decoding which enables to capture not only global but also local dependencies therein.

We evaluate our approach on a variety of n-ary link prediction benchmarks. Experimental results reveal that GRAN works particularly well in learning and reasoning with n-ary relational facts, consistently and substantially outperforming current state-of-the-art across all the benchmarks. Our main contributions are summarized as follows:

- We present a novel graph-based approach to learning and reasoning with n-ary facts, capable of capturing rich associations therein.
- We demonstrate the effectiveness and superiority of our approach, establishing new state-of-the-art across a variety of benchmarks.

2 Problem statement

This section formally defines n-ary relational facts and the link prediction task on this kind of data.

Definition 1 (N-ary relational fact) An n-ary relational fact $\mathcal{F}$ is a primary subject-relation-object triple (s, r, o) coupled with m auxiliary attribute-value pairs $\{(a_i : v_i)\}_{i=1}^m$, where $r, a_1, \cdots, a_m \in \mathcal{R}$ and $s, o, v_1, \cdots, v_m \in \mathcal{E}$, with $\mathcal{R}$ and $\mathcal{E}$ being the sets of relations and entities, respectively. We slightly abuse terminology here by referring to the primary relation and all attributes as relations, and referring to the subject, object, and values as entities unless otherwise specified. The arity of the fact is $(m+2)$, i.e., the number of entities in the fact.

Definition 2 (N-ary link prediction) N-ary link prediction aims to predict a missing element from an n-ary fact. The missing element can be either an entity $\in \{s, o, v_1, \cdots, v_m\}$ or a relation $\in \{r, a_1, \cdots, a_m\}$, e.g., to predict the primary subject of the incomplete n-ary fact $\big((?, r, o), \{(a_i : v_i)\}_{i=1}^m\big)$.

3 Graph-based n-ary relational learning

This section presents GRAN, our graph-based approach to n-ary link prediction. There are two key factors of our approach: graph representation and graph learning. The former represents n-ary facts as graphs, and the latter learns with these graphs to perform inference on n-ary facts.

3.1 Graph representation

We elaborate the first key factor: graph representation of n-ary facts. Given an n-ary fact defined as $\mathcal{F} = \big((s, r, o), \{(a_i : v_i)\}_{i=1}^m\big)$, we reformulate it equivalently as a heterogeneous graph $\mathcal{G} = (\mathcal{V}, \mathcal{L})$. The vertex set $\mathcal{V}$ consists of all entities and relations in the fact, i.e., $\mathcal{V} = \{r, s, o, a_1, \cdots, a_m, v_1, \cdots, v_m\}$. The link set $\mathcal{L}$ consists of $(2m+2)$ undirected edges of four types between the vertices, i.e.,

- 1 subject-relation edge (s, r),
- 1 object-relation edge (o, r),
- m relation-attribute edges $\{(r, a_i)\}_{i=1}^{m}$,
- m attribute-value edges $\{(a_i, v_i)\}_{i=1}^{m}$.

The graph heterogeneity is reflected in that the vertices and links are both typed, with type mapping functions $\phi\colon \mathcal{V} \rightarrow \{\textit{entity}, \textit{relation}\}$ and $\psi\colon \mathcal{L} \rightarrow \{$ *subject-relation*, *object-relation*, *relation-attribute*, *attribute-value*$\}$, respectively. Figure 1 provides a visual illustration of this heterogenous graph.

As we can see, the graph representation retains the full semantics of a given fact. It also enables us to model the fact as a whole and capture all possible interactions therein, which, as we will show later in our experiments, is crucial for learning with n-ary relational facts.

3.2 Graph learning

The second key factor is learning with heterogeneous graphs to perform inference on n-ary facts. Given an incomplete n-ary fact with a missing element, say $\big((?, r, o), \{(a_i : v_i)\}_{i=1}^{m}\big)$, which is represented as a heterogeneous graph, we feed the graph into an embedding layer, a stack of L successive graph attention layers, and a final prediction layer to predict the missing element, say s. This whole process is sketched in Figure 2 (left).

The input embedding layer maps the elements of the input n-ary fact or, equivalently, the vertices of the input graph, to their continuous vector representations (the missing element is denoted by a special token [MASK]). The L graph attention layers then repeatedly encode the graph and update its vertex representations. Our graph attention generally inherits from Transformer (Vaswani et al., 2017) and its fully-connected attention which captures universal inter-vertex associations, but further introduces edge-aware attentive biases to particularly handle graph structure and heterogeneity. As such, we call it edge-biased fully-connected attention. After the graph encoding process, we use the representation of the special token [MASK] to predict the missing element. In the rest of this section, we emphasize the edge-biased fully-connected attention, and refer readers to (Vaswani et al., 2017) and Appendix A for other modules of our graph attention layer.

Edge-biased fully-connected attention We are given an input graph $\mathcal{G} = (\mathcal{V}, \mathcal{L})$, with vertex type mapping function ϕ and link type mapping function ψ. Vertices are associated with hidden states $(\mathbf{x}_1, \cdots, \mathbf{x}_{|\mathcal{V}|}) \in \mathbb{R}^{d_x}$ generated by previous layers. The aim of this attention is to aggregate information from different vertices and update vertex representations, by taking into account the graph structure and its heterogeneity. We employ multi-head attention with H heads, each applied independently to the input $(\mathbf{x}_1, \cdots, \mathbf{x}_{|\mathcal{V}|}) \in \mathbb{R}^{d_x}$ to generate updated vertex representations $(\mathbf{z}_1^h, \cdots, \mathbf{z}_{|\mathcal{V}|}^h) \in \mathbb{R}^{d_z}$ for $h = 1, \cdots, H$. These updated vertex representations are concatenated and linearly transformed to generate final attention output. We set $d_x = d$ and $d_z = \frac{d}{H}$ for all layers and heads. Below we describe the specific design of each head, and we drop the head index h for notational brevity.

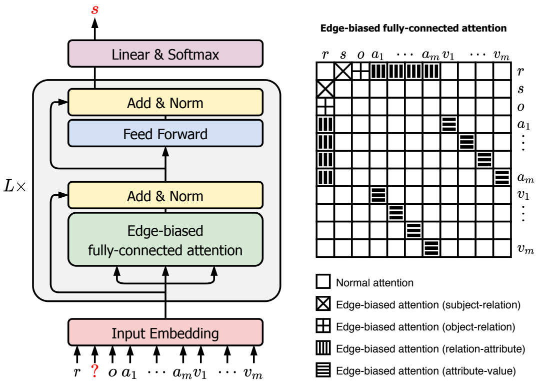

Figure 2: Overview of the graph learning process, with edge-biased fully-connected attention illustrated.

Our attention follows the traditional query-key-value attention (Vaswani et al., 2017). Specifically, for each input $\mathbf{x}_i$, we project it into a triple of query, key, and value as $(\mathbf{W}^Q\mathbf{x}_i, \mathbf{W}^K\mathbf{x}_i, \mathbf{W}^V\mathbf{x}_i) \in \mathbb{R}^{d_z}$, using parameters $\mathbf{W}^Q, \mathbf{W}^K, \mathbf{W}^V \in \mathbb{R}^{d_z \times d_x}$, respectively. Then we measure the similarity between each pair of vertices, say i and j, as a scaled dot product of i's query and j's edge-biased key:

$$\alpha_{ij} = \frac{(\mathbf{W}^Q\mathbf{x}_i)^\top(\mathbf{W}^K\mathbf{x}_j + \mathbf{e}_{ij}^K)}{\sqrt{d_z}}. \tag{1}$$

After we obtain the similarity scores α_{ij}, a softmax operation is applied, and the edge-biased values are aggregated accordingly to generate the updated representation for each vertex i:

$$\mathbf{z}_i = \sum_{j=1}^{|\mathcal{V}|} \frac{\exp(\alpha_{ij})}{\sum_{k=1}^{|\mathcal{V}|}\exp(\alpha_{ik})}(\mathbf{W}^V\mathbf{x}_j + \mathbf{e}_{ij}^V). \tag{2}$$

We call this attention fully-connected as it takes into account similarity between any two vertices i and j. We call it edge-biased as it further introduces attentive biases $\mathbf{e}_{ij}^K, \mathbf{e}_{ij}^V \in \mathbb{R}^{d_z}$ to encode the typed edge between i and j, one to generate edge-biased key (cf. Eq. (1)) and the other edge-biased value (cf. Eq. (2)). Introducing $\mathbf{e}_{ij}^K$ enables our attention to encode not only global dependencies that universally exist between any pair of vertices, but also local dependencies that are particularly indicated by typed edges. Introducing $\mathbf{e}_{ij}^V$ further propagates edge information to the attention output. If there is no edge linking i and j we set $\mathbf{e}_{ij}^K = \mathbf{e}_{ij}^V = \mathbf{0}$, which, at this time, degenerates to the conventional fully-connected attention used in Transformer (Vaswani et al., 2017). As the attentive biases $\mathbf{e}_{ij}^K, \mathbf{e}_{ij}^V$ can be designed freely to meet any desired specifications, this attention is in essence quite flexible, capable of modeling arbitrary relationships between the input elements. This idea has actually been applied, e.g., to model relative positions between words within sentences (Shaw et al., 2018; Wang et al., 2019a), or to model various kinds of mention dependencies for relation extraction (Xu et al., 2021).

Edge-aware attentive biases We now elaborate how $\mathbf{e}_{ij}^K$ and $\mathbf{e}_{ij}^V$ are specifically designed for n-ary facts. Recall that given an n-ary fact represented as a heterogeneous graph $\mathcal{G} = (\mathcal{V}, \mathcal{L})$, there are 4 distinct types of edges in the graph: *subject-relation*, *object-relation*, *relation-attribute*, *attribute-value*. To each we assign a pair of key and value biases. The attentive biases between vertices i and j are then defined as the biases associated with the type of the edge linking i and j:

$$(\mathbf{e}_{ij}^K, \mathbf{e}_{ij}^V) = \begin{cases} (\mathbf{0}, \mathbf{0}), & \text{if } (i,j) \notin \mathcal{L}, \\ (\mathbf{e}_1^K, \mathbf{e}_1^V), & \text{if } \psi(i,j) = \textit{subject-relation}, \\ (\mathbf{e}_2^K, \mathbf{e}_2^V), & \text{if } \psi(i,j) = \textit{object-relation}, \\ (\mathbf{e}_3^K, \mathbf{e}_3^V), & \text{if } \psi(i,j) = \textit{relation-attribute}, \\ (\mathbf{e}_4^K, \mathbf{e}_4^V), & \text{if } \psi(i,j) = \textit{attribute-value}. \end{cases} \quad (3)$$

Here $\mathbf{e}_k^K, \mathbf{e}_k^V \in \mathbb{R}^{d_z}$ for $k = 1, 2, 3, 4$ are the key and value biases corresponding to the 4 edge types, shared across all layers and heads. In this way, the graph structure (whether there is an edge between two vertices) and its heterogeneity (which type the edge is between two vertices) can be well encoded into the attentive biases, and then propagated to the final attention output. Figure 2 (right) visualizes the edge-biased attention between pairs of vertices in an n-ary fact.

3.3 Model training

We directly use n-ary link prediction as our training task. Specifically, given an n-ary fact $\mathcal{F} = \big((s, r, o), \{(a_i : v_i)\}_{i=1}^m\big)$ in the training set we create $(2m + 3)$ training instances for it, each to predict a missing element (either an entity or a relation) given other elements in the fact, e.g., $\big((?, r, o), \{(a_i : v_i)\}_{i=1}^m\big)$ is to predict the primary subject and the answer to which is s. Here and in what follows we denote a training instance as $\widetilde{\mathcal{F}}$, with the missing element indicated by a special token [MASK]. This training instance is reformulated as a heterogeneous graph $\widetilde{\mathcal{G}}$ with vertices $(x_1, \cdots, x_k)$, where $k = 2m + 3$ is the total number of vertices therein. The label is denoted as y. We have $y \in \mathcal{E}$ for entity prediction and $y \in \mathcal{R}$ for relation prediction.

Each training instance $\widetilde{\mathcal{F}}$ or, equivalently, the corresponding graph $\widetilde{\mathcal{G}}$ is fed into the embedding, graph attention, and final prediction layers to predict the missing element, as we introduced above. Suppose after the successive graph attention layers we obtain for the vertices $(x_1, \cdots, x_k)$ their hidden states $(\mathbf{h}_1, \cdots, \mathbf{h}_k) \in \mathbb{R}^d$. The hidden state corresponding to [MASK], denoted as $\mathbf{h}$ for brevity, is used for the final prediction. The prediction layer is constructed by two linear transformations followed by a standard softmax operation:

$$\mathbf{p} = \textsc{Softmax}\big(\mathbf{W}_2^\top (\mathbf{W}_1 \mathbf{h} + \mathbf{b}_1) + \mathbf{b}_2\big). \quad (4)$$

Here, we share $\mathbf{W}_2$ with the weight matrix of the input embedding layer, and $\mathbf{W}_1, \mathbf{b}_1, \mathbf{b}_2$ are freely learnable. The final output $\mathbf{p}$ is a probability distribution over entities in $\mathcal{E}$ or relations in $\mathcal{R}$, depending on the type of the missing element.

We use the cross-entropy between the prediction and the label as our training loss:

$$L = \sum\nolimits_t y_t \log p_t, \quad (5)$$

where p_t is the t-th entry of the prediction $\mathbf{p}$, and y_t the t-th entry of the label $\mathbf{y}$. As a one-hot label restricts each prediction task to a single answer, which might not be the case in practice, we employ label smoothing to lessen this restriction. Specifically, for entity prediction, we set $y_t = 1 - \epsilon^{(e)}$ for the target entity and $y_t = \frac{\epsilon^{(e)}}{|\mathcal{E}|-1}$ for each of the other entities, where $\epsilon^{(e)}$ is a small entity label smoothing rate. For relation prediction y_t is set in a similar way, with relation label smoothing rate $\epsilon^{(r)}$. The loss is minimized using Adam optimizer (Kingma and Ba, 2015). We use learning rate warmup over the first 10% training steps and linear decay of the learning rate. We also use batch normalization and dropout after each layer and sub-layer to regularize, stabilize, and speed up training.

Unlike previous methods which score individual facts and learn from positive-negative pairs (Rosso et al., 2020; Guan et al., 2020), our training scheme bears two advantages: (1) Directly using n-ary link prediction as the training task can effectively avoid training-test discrepancy. (2) Introducing a special token [MASK] enables us to score a target element against all candidates simultaneously, which accelerates convergence during training and speeds up evaluation drastically (Dettmers et al., 2018).

4 Experiments and results

We evaluate GRAN in the link prediction task on n-ary facts. This section presents our experiments and results.

4.1 Datasets

We consider standard n-ary link prediction benchmarks including:

JF17K (Zhang et al., 2018)[2] is collected from Freebase. On this dataset, an n-ary relation is predefined by a set of attributes, and facts of this relation should have all corresponding values completely given. Take *music.group_membership* as an example. All facts of this relation should get three values w.r.t. the predefined attributes, e.g., (*Guitar*, *Dean Fertita*, *Queens of the Stone Age*). The maximum arity of the relations there is 6.

WikiPeople (Guan et al., 2019)[3] is derived from Wikidata concerning entities of type *human*. On this dataset, n-ary facts are already represented as primary triples with auxiliary attribute-value pairs, which is more tolerant to data incompleteness. The maximum arity there is 9. As the original dataset also contains literals, we follow (Rosso et al., 2020; Galkin et al., 2020) and consider another version that filters out statements containing literals. This filtered version is referred to as **WikiPeople**$^-$, and the maximum arity there is 7.

JF17K-3, **JF17K-4**, **WikiPeople-3**, and **WikiPeople-4** (Liu et al., 2020)[4] are subsets of JF17K and WikiPeople, consisting solely of 3-ary and 4-ary relational facts therein, respectively.

For JF17K and its subsets, we transform the representation of an n-ary fact to a primary triple coupled with auxiliary attribute-value pairs. We follow (Rosso et al., 2020; Galkin et al., 2020) and directly take the values corresponding to the first and second attributes as the primary subject and object, respectively. Other attributes and values are taken as auxiliary descriptions. Facts on each dataset are split into train/dev/test sets, and we use the original split. On JF17K which provides no dev set, we split 20% of the train set for development. The statistics of these datasets are summarized in Table 1.

4.2 Baseline methods

We compare against the following state-of-the-art n-ary link prediction techniques:

RAE (Zhang et al., 2018) represents an n-ary fact as an $(n+1)$-tuple consisting of the predefined relation and its n values. It generalizes a binary link prediction method TransH (Wang et al., 2014) to the higher-arity case, which measures the validity of a fact as the compatibility between its n values.

NaLP (Guan et al., 2019) and **RAM** (Liu et al., 2021) represent an n-ary fact as a set of attribute-value pairs. Then, NaLP employs a convolutional neural network followed by fully connected neural nets to model the relatedness of such attribute-value pairs and accordingly measure the validity of a fact. RAM further encourages to model the relatedness between different attributes and also the relatedness between an attribute and all involved values.

HINGE(Rosso et al., 2020) and **NeuInfer**(Guan et al., 2020) regard an n-ary fact as a primary triple with auxiliary attribute-value pairs. Then they deploy neural modules to measure the validity of the primary triple and its compatibility with each auxiliary description, and combine these modules to obtain the overall score of a fact. As different auxiliary descriptions are modeled independently before aggregation, these two methods show limited ability to model full associations within n-ary facts.

STARE (Galkin et al., 2020) is a recently proposed method generalizing graph convolutional networks (Kipf and Welling, 2017) to n-ary relational KGs. It employs a message passing based graph encoder to obtain entity/relation embeddings, and feeds these embeddings to Transformer decoder to score n-ary facts. **Hy-Transformer** (Yu and Yang, 2021) replaces the graph encoder with light-weight embedding processing modules, achieving higher efficiency without sacrificing effectiveness. These two methods employ vanilla Transformer decoders, ignoring specific n-ary structures during decoding.

n-CP, **n-TuckER**, and **GETD** (Liu et al., 2020) are tensor factorization approaches to n-ary link prediction. They all follow RAE and represent each n-ary fact as an $(n+1)$-tuple. A whole KG can thus be represented as a binary valued $(n+1)$-way ten-

Table 1: Dataset statistics, where the columns respectively indicate the number of all facts, n-ary facts with $n > 2$, entities, relations, facts in train/dev/test sets, and all possible arities.

sor $\mathcal{X} \in \{0,1\}^{|\mathcal{R}|\times|\mathcal{E}|\times\cdots\times|\mathcal{E}|}$, where $x = 1$ means the corresponding fact is true and $x = 0$ otherwise. $\mathcal{X}$ is then decomposed and approximated by a low-rank tensor $\hat{\mathcal{X}}$ that estimates the validity of all facts. Different tensor decomposition strategies can be applied, e.g., n-CP generalizes CP decomposition (Kruskal, 1977) and n-TuckER is built on TuckER (Balazevic et al., 2019). As the tensor representation inherently requires all facts to have the same arity, these methods are not applicable to datasets of mixed arities, e.g., JF17K and WikiPeople.

4.3 GRAN variants

We evaluate three variants of GRAN to investigate the impact of modeling graph structure and heterogeneity, including:

GRAN-hete is the full model introduced above. It uses edge representations defined in Eq. (3), which encode both graph structure (whether there is an edge) and heterogeneity (which type the edge is).

GRAN-homo retains graph structure but ignores heterogeneity. There are only two groups of edge attentive biases: $(\mathbf{e}_{ij}^K, \mathbf{e}_{ij}^V) = (\mathbf{0}, \mathbf{0})$ or $(\mathbf{e}_{ij}^K, \mathbf{e}_{ij}^V) = (\mathbf{e}^K, \mathbf{e}^V)$. The former is used if there is no edge between vertices i and j, while the latter is employed whenever the two vertices are linked, irrespective of the type of the edge between them. This in essence views an n-ary fact as a homogeneous graph where all edges are of the same type.

GRAN-complete considers neither graph structure nor heterogeneity. It simply sets $(\mathbf{e}_{ij}^K, \mathbf{e}_{ij}^V) = (\mathbf{0}, \mathbf{0})$ for all vertex pairs. The edge-biased attention thus degenerates to the conventional one used in Transformer, which captures only global dependencies between vertices. This in essence regards an n-ary fact as a complete graph in which any two vertices are connected by an (untyped) edge. STARE and Hy-Transformer are most similar to this variant.

We use the following configurations for all variants of GRAN: $L = 12$ graph attention layers, $H = 4$ attention heads, hidden size $d = 256$, batch size $b = 1024$, and learning rate $\eta = 5e{-}4$, fixed across all the datasets. Besides, on each dataset, we tune entity/relation label smoothing rate $\epsilon^{(e)}/\epsilon^{(r)}$, dropout rate ρ, and training epochs τ in their respective ranges. The optimal configuration is determined by dev MRR. We leave the tuning ranges and optimal values of these hyperparameters to Appendix B. After determining the optimal configuration on each dataset, we train with a combination of the train and dev splits and evaluate on the test split, as practiced in (Galkin et al., 2020).

4.4 Evaluation protocol and metrics

During evaluation, we distinguish between entity prediction and relation prediction. Take entity prediction as an example. For each test n-ary fact, we replace one of its entities (i.e., subject, object, or an auxiliary value) with the special token [MASK], feed the masked graph into GRAN, and obtain a predicted distribution of the answer over all entities $\in \mathcal{E}$. Then we sort the distribution probabilities in descending order and get the rank of the correct answer. During ranking, we ignore facts that already exist in the train, dev, or test split. We repeat this whole procedure for all specified entities in the test fact, and report MRR and Hits@k for $k = 1, 10$ aggregated on the test split. MRR is the average of reciprocal rankings, and Hits@k is the proportion of top k rankings (abbreviated as H@k). The same evaluation protocol and metrics also apply to relation prediction, where a relation can be either the primary relation or an auxiliary attribute.

4.5 Results on datasets of mixed arities

Table 2 presents entity prediction results on JF17K and the two versions of WikiPeople, which consist of facts with mixed arities.[5] We consider two set-

---

[5] Tensor factorization based approaches which require all facts to have the same arity are not applicable here.

Table 3: Relation prediction results on JF17K and WikiPeople. Baseline results for predicting all relations taken from (Guan et al., 2019, 2020), and those for predicting the primary relation taken from (Rosso et al., 2020). Best scores are highlighted in bold, and "–" denotes missing scores.

tings: (1) predicting all entities $s, o, v_1, \cdots, v_m$ in an n-ary fact and (2) predicting only the subject s and object o. This enables us to make a direct comparison to previous literatures (Guan et al., 2020; Rosso et al., 2020; Galkin et al., 2020). From the results, we can see that (1) The optimal setting of our approach offers consistent and substantial improvements over all the baselines across all the datasets in almost all metrics, showing its significant effectiveness and superiority in entity prediction within n-ary facts. (2) All the variants, including the less expressive GRAN-homo and GRAN-complete, perform quite well, greatly surpassing the competitive baselines in almost all cases except for the WikiPeople$^-$ dataset. This verifies the superior effectiveness of modeling n-ary facts as whole graphs so as to capture global dependencies between all relations and entities therein. (3) Among the variants, GRAN-hete offers the best performance. This demonstrates the necessity and superiority of further modeling specific graph structures and graph heterogeneity, so as to capture local dependencies reflected by typed edges linking relations and entities.

Table 3 further shows relation prediction results on these datasets. Again, to make direct comparison with previous literatures, we consider two settings: (1) predicting all relations including the primary relation r and auxiliary attributes $a_1, \cdots, a_m$ and (2) predicting only the primary relation r. Here, on each dataset, GRAN models are fixed to their respective optimal configurations (see Appendix B) determined in the entity prediction task.[6] The results show that GRAN variants perform particularly well in relation prediction. Among these variants, GRAN-hete performs the best, consistently outperforming the baselines and achieving extremely high performance across all the datasets. This is because relation prediction is, by nature, a relatively easy task due to a small number of candidate answers.

---

[6] Relation prediction typically requires much less training epochs than entity prediction according to our initial experiments. But we did not conduct hyperparameter searching for relation prediction, as the configurations we used, though not optimal, perform well enough in this task.

Table 5: Breakdown performance of the GRAN variants in entity prediction task on JF17K and WikiPeople. Only MRR scores are reported.

4.6 Results on datasets of a single arity

Table 4 presents entity prediction results on the four subsets of JF17K and WikiPeople, which consist solely of 3-ary or 4-ary facts. Here, an entity means either the subject, the object, or an attribute value. On these four single-arity subsets, tensor factorization based approaches like n-CP, n-TuckER, and GETD apply quite well and have reported promising performance (Liu et al., 2020). From the results, we can observe similar phenomena as from Table 2. The GRAN variants perform particularly well, all surpassing or at least performing on par with the baselines across the datasets. And GRAN-hete, again, offers the best performance in general among the three variants.

4.7 Further analysis

We further look into the breakdown entity prediction performance of the GRAN variants on different arities. More specifically, we group the test split of each dataset into binary ($n = 2$) and n-ary ($n > 2$) categories. Entity prediction means predicting the subject/object for the binary category, or predicting an attribute value in addition for the n-ary category. Table 5 presents the breakdown MRR scores in all these different cases on JF17K, WikiPeople, and WikiPeople$^-$, with the GRAN variants set to their respective optimal configurations on each dataset (see Appendix B). Among the variants GRAN-hete performs best in all cases, which again verifies the necessity and superiority of modeling n-ary facts as heterogeneous graphs. Ignoring the graph heterogeneity (GRAN-homo) or further graph structures (GRAN-complete) always leads to worse performance, particularly when predicting auxiliary attribute values in higher-arity facts.

5 Related work

Link prediction on binary relational data Most previous work of learning with knowledge graphs (KGs) focused on binary relations. Among different binary relational learning techniques, embedding based models have received increasing attention in recent years due to their effectiveness and simplicity. The idea there is to represent symbolic entities and relations in a continuous vector space and measure the validity of a fact in that space. This kind of models can be roughly grouped into three categories: translation distance based (Bordes et al., 2013; Wang et al., 2014; Sun et al., 2019), semantic matching based (Trouillon et al., 2016; Balazevic et al., 2019), and neural network based (Dettmers et al., 2018; Schlichtkrull et al., 2018), according to the design of validity scoring functions. We refer readers to (Nickel et al., 2016; Wang et al., 2017; Ji et al., 2021) for thorough reviews of the literature.

Link prediction on n-ary relational data Since binary relations oversimplify the complex nature of the data stored in KGs, a few recent studies have started to explore learning and reasoning with n-ary relational data ($n > 2$), in particular via embedding based approaches. Most of these studies represent n-ary facts as tuples of pre-defined relations with corresponding attribute values, and generalize binary relational learning methods to the n-ary case, e.g., m-TransH (Wen et al., 2016) and RAE (Zhang et al., 2018) generalize TransH (Wang et al., 2014), a translation distance based embedding model for binary relations, while n-CP, n-TuckER, and GETD (Liu et al., 2020) generalize 3-way tensor decomposition techniques to the higher-arity case. NaLP (Guan et al., 2019) and RAM (Liu et al., 2021) are slightly different approaches which represent n-ary facts directly as groups of attribute-value pairs and then model relatedness between such attributes and values. In these approaches, however, attributes of an n-ary fact are assumed to be equally important, which is often not the case in reality. Rosso et al. (2020) and Guan et al. (2020) therefore proposed to represent n-ary facts as primary triples coupled with auxiliary attribute-value pairs, which naturally discriminates the importance of different attributes. The overall validity of a fact is then measured by the validity of the primary triple and its compatibility with each attribute-value pair. STARE (Galkin et al., 2020) follows the same representation form of n-ary facts, and generalizes graph convolutional networks to n-ary relational KGs to learn entity and relation embeddings. These embeddings are then fed into a Transformer decoder to score n-ary facts. Nevertheless, during the decoding process STARE takes into account solely global dependencies and ignores the specific n-ary structure of a given fact.

Transformer and its extensions Transformer (Vaswani et al., 2017) was initially devised as an encoder-decoder architecture for machine translation, and quickly received broad attention across all areas of natural language processing (Radford et al., 2018; Devlin et al., 2019; Yang et al., 2019). Transformer uses neither convolution nor recurrence, but instead is built entirely with (self-) attention layers. Recently, there has been a lot of interest in modifying this attention to further meet various desired specifications, e.g., to encode syntax trees (Strubell et al., 2018; Wang et al., 2019c), character-word lattice structures (Li et al., 2020), as well as relative positions between words (Shaw et al., 2018; Wang et al., 2019a). There are also a few recent attempts that apply vanilla Transformer (Wang et al., 2019b) or hierarchical Transformer (Chen et al., 2020) to KGs, but mainly restricted to binary relations and deployed with conventional attention. This work, in contrast, deals with higher-arity relational data represented as heterogeneous graphs, and employs modified attention to encode graph structure and heterogeneity.

6 Conclusion

This paper studies link prediction on higher-arity relational facts and presents a graph-based approach to this task. For each given n-ary fact, our approach (1) represents the fact as a heterogeneous graph in which the semantics of the fact are fully retained; (2) models the graph using fully-connected attention with edge-aware attentive biases so as to capture both local and global dependencies within the given fact. By modeling an n-ary fact as a whole graph, our approach can more effectively capture entity relation associations therein, which is crucial for inference on such facts. Link prediction results on a variety of n-ary relational benchmarks demonstrate the significant effectiveness and superiority of our approach.

As future work, we would like to (1) verify the effectiveness of GRAN on newly introduced benchmarks such as WD50K (Galkin et al., 2020) and FB-AUTO (Fatemi et al., 2020); (2) investigate the usefulness of specific modules, e.g., positional embeddings and various forms of attentive biases in GRAN; and (3) integrate other types of data in a KG, e.g., entities's textual descriptions, for better n-ary link prediction.

A Graph attention layers

After the input embedding layer, we employ a stack of L identical graph attention layers to encode the input graph before making final predictions. These graph attention layers generally follow the design of Transformer encoder (Vaswani et al., 2017), each of which consists of two sub-layers, i.e., an edge-biased fully-connected attention sub-layer followed by an element-wise feed-forward sub-layer. The attention sub-layer, as illustrated in Section 3.2, relates different vertices of the input graph to update its vertex representations. It computes attention in an edge-biased fully-connected fashion, which thus is able to capture both global and local dependencies within the graph. The feed-forward sub-layer is composed of two linear transformations with a GELU activation (Hendrycks and Gimpel, 2016) in between, applied to each element/vertex separately and identically. We further introduce residual connections (He et al., 2016) and layer normalization (Ba et al., 2016) around each graph attention layer and its sub-layers. To facilitate these residual connections, all the layers and their sub-layers produce outputs of the same dimension d.

B Hyperparameter settings

We use the following hyperparameter settings for GRAN: $L=12$ graph attention layers, $H=4$ attention heads, hidden size $d=256$, batch size b=1024, and learning rate $\eta=5e-4$. These configurations are fixed across all the datasets. Besides, on each dataset we tune the following hyperparameters in their respective ranges:

- entity label smoothing rate $\epsilon^{(e)} \in \{.0, .1, .2, .3, .4, .5, .6, .7, .8, .9\}$;
- relation label smoothing rate $\epsilon^{(r)} \in \{.0, .1, .2, .3, .4, .5\}$;
- dropout rate $\rho \in \{.1, .2, .3, .4, .5\}$;
- training epochs τ from 20 to 200 in steps of 20 on all the datasets.

We determine the optimal configuration for GRAN-hete by dev MRR of entity prediction on each dataset. And then we directly set GRAN-homo and GRAN-complete to the same configuration. Table 6 presents the optimal configuration on each dataset.

	$\epsilon^{(e)}$	$\epsilon^{(r)}$	ρ	τ
JF17K	.9	.0	.2	160
WikiPeople	.2	.2	.1	200
WikiPeople$^-$	.2	.1	.1	160
JF17K-3	.8	.2	.2	180
JF17K-4	.8	.0	.3	160
WikiPeople-3	.8	.4	.3	100
WikiPeople-4	.8	.4	.3	100

Table 6: Optimal configuration of the GRAN variants on each dataset.

C Infrastructure and runtime

We train all the GRAN variants on one 16G V100 GPU. With the hyperparameter settings specified in Appendix B, it takes about 3 hours to finish training and evaluation on JF17K, 17 hours on Wikipeople, 10 hours on Wikipeople$^-$, 1 hour on JF17K-3, 0.5 hour on JF17K-4, Wikipeople-3, and WikiPeople-4. This runtime covers the whole training and evaluation process. Compared to previous methods like HINGE (Rosso et al., 2020) and NeuInfer (Guan et al., 2020) which score individual facts and learn from positive-negative pairs, GRAN directly scores each target answer against all candidates in a single pass and drastically speeds up evaluation. GRAN is also much more efficient than STARE (Galkin et al., 2020), which is a graph encoder plus Transformer decoder architecture. By eliminating the computational heavy graph encoder, GRAN requires significantly less running time but still achieves better performance than STARE, e.g., GRAN-hete achieves .617 MRR within 3 hours while STARE takes about 10 hours to achieve .574 MRR on JF17K; GRAN-hete achieves .503 MRR within 10 hours but STARE takes about 4 days to achieve a similar MRR on Wikipeople$^-$ (which is 9-10 times slower).

GLGE: A New General Language Generation Evaluation Benchmark

Abstract

Multi-task benchmarks such as GLUE and SuperGLUE have driven great progress of pretraining and transfer learning in Natural Language Processing (NLP). These benchmarks mostly focus on a range of Natural Language Understanding (NLU) tasks, without considering the Natural Language Generation (NLG) models. In this paper, we present the **G**eneral **L**anguage **G**eneration **E**valuation (**GLGE**), a new multi-task benchmark for evaluating the generalization capabilities of NLG models across eight language generation tasks. For each task, we continue to design three subtasks in terms of task difficulty (**GLGE-Easy**, **GLGE-Medium**, and **GLGE-Hard**). This introduces 24 subtasks to comprehensively compare model performance. To encourage research on pretraining and transfer learning on NLG models, we make GLGE publicly available and build a leaderboard with strong baselines including MASS, BART, and ProphetNet[1].

1 Introduction

Pretrained language models, such as BERT (Devlin et al., 2019) and other advanced pretrained models (Raffel et al., 2020; Yang et al., 2019; Liu et al., 2019; Alberti et al., 2019; Brown et al., 2020; Clark et al., 2020) have made great progress in a host of Natural Language Understanding (NLU) tasks. Meanwhile, the development of general evaluation benchmarks has also helped drive the progress of these models. These benchmarks usually use an overall score to evaluate the performance of models across a wide range of NLU tasks. In addition to GLUE (Wang et al., 2019b) and SuperGLUE (Wang et al., 2019a) which are general language understanding evaluation benchmarks for English, several general language understanding evaluation benchmarks for other languages are proposed, such as CLUE (Xu et al., 2020) for Chinese, FLUE (Le et al., 2020) for French, and IndoNLU (Wilie et al., 2020) for Indonesian. Furthermore, the multilingual multi-task benchmarks such as XTREME (Hu et al., 2020) and XGLUE (Liang et al., 2020) are proposed for cross-lingual evaluation.

In addition to NLU tasks, an increasing number of pretrained language models designed for Natural Language Generation (NLG) tasks have recently been proposed, such as MASS (Song et al., 2019), BERT-share (Rothe et al., 2020), BART (Lewis et al., 2020), ProphetNet (Qi et al., 2020), and ERINE-GEN (Xiao et al., 2020). However, the generalization capabilities of the language generation of these models are usually evaluated with different tasks, datasets, and metrics, which cannot provide a coherent and comprehensive evaluation. Although there are several general evaluation benchmarks as we mentioned above, none of them are particularly designed for general language generation evaluation.

To fill the gap of the NLG evaluation benchmark, we introduce the **G**eneral **L**anguage **G**eneration **E**valuation (**GLGE**) benchmark, a new multi-task benchmark for evaluating the generalization capabilities of NLG in English language. It contains eight English language generation tasks, covering text summarization, question generation, generative question answering, and dialogue. We select six pre-existing popular datasets and introduce two new datasets selected from real-world scenarios. Moreover, in order to provide more diversified difficulty challenges, we employ two simple but effective strategies to build three NLG evaluation benchmarks (called **GLGE-Easy**, **GLGE-Medium**, and **GLGE-Hard**) in terms of task difficulty.

---

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 408–420
August 1–6, 2021. ©2021 Association for Computational Linguistics

To better understand the challenges posed by GLGE, we conduct experiments with existing widely used non-pretrained models (e.g., vanilla LSTM Seq2Seq (Bahdanau et al., 2015), vanilla Transformer (Vaswani et al., 2017)), and pretrained models (e.g., MASS (Song et al., 2019), BART (Lewis et al., 2020), and ProphetNet (Qi et al., 2020)). We further analyze the n-gram diversity of the output samples. The experimental results show that there is a large performance gap between the pretrained models and the non-pretrained models. However, on the GLGE-hard task, the performance of the pretrained models still has great room for improvement.

In summary, the contributions of this work are five-fold: (1) a new multi-task NLG evaluation benchmark consisting of eight distinct datasets across four kinds of typical NLG tasks, (2) three NLG evaluation benchmarks of different difficulty levels, (3) standardized evaluation metrics and scripts for model evaluation and comparison, (4) open-sourced baselines and a public leaderboard[2] for the benchmark, (5) a thorough comparative study on existing widely used non-pretrained models and pretrained models with a detailed analysis of the results.

2 GLGE Benchmark

2.1 Design Principles

For the GLGE benchmark, we design and select the NLG tasks based on the following principles:

2.1.1 Task Diversity

The tasks in GLGE focus on evaluating the generalization capabilities of a NLG model, varying the task, the length of the input text, the length of the output text, the type of generated text, and the size of the dataset.

2.1.2 Task Difficulty

The tasks in GLGE should be challenging but solvable, which can encourage researchers to design better NLG models. Furthermore, we aim to provide benchmarks of different difficulty levels like GLUE (Wang et al., 2019b) and SuperGLUE (Wang et al., 2019a), which allows researchers to comprehensively evaluate the models. Researchers can also select the benchmark with moderate difficulty according to the size of the model and the scale of the used pretraining corpus for comparison.

2.1.3 Ease of Evaluation

The tasks in GLGE should be easily evaluated automatically. For some unconditional, open-ended, and weak conditional language generation tasks (e.g., answer-agnostic question generation, single-turn chit-chat response generation, and story generation), reasonable generation results are diverse. Due to the limited number of references in the automatic evaluation of text generation tasks, it is more difficult for automatic evaluation of those tasks. Therefore, instead of selecting unconditional and weak conditional language generation tasks, we tend to select language generation tasks with stronger conditions (e.g., answer-aware question generation), which makes the automatic evaluation more convincing.

2.1.4 Task Popularity

Most tasks in GLGE should use widely-used NLG datasets, which have been implicitly agreed upon by the NLG community as challenging and meaningful. Since GLGE is mainly designed for the generalization capabilities evaluation of the English NLG pretrained model, the choice of task also refers to several related works of NLG pretraining model, such as MASS (Song et al., 2019), BART (Lewis et al., 2020), ProphetNet (Qi et al., 2020), and ERNIE-GEN (Xiao et al., 2020).

Based on the above principles, we invite 10 NLG experts[3] to discuss and vote on existing widely-used NLG datasets. Note that since the GLGE is designed for evaluating the generalization capabilities of NLG in English language, we do not include the cross-lingual NLG tasks, such as machine translation and cross-lingual text summarization (Liang et al., 2020). Finally, we select 6 existing popular NLG datasets. Besides, we also introduce two new datasets selected from real-world scenarios for the GLGE benchmark, which makes GLGE have more practical values. Unlike the existing datasets, the test sets of these new two datasets are hidden, which further ensures the fairness of the evaluation results. The input sequence and output sequence of the selected tasks are all well-defined. We preprocess them and provide the input and output sequence pairs directly, which benefits researchers to focus on model improvements.

2.2 Tasks and Datasets

GLGE contains eight English NLG tasks, covering text summarization, question generation, generative question answering, and dialogue. Descriptions and statistics of these tasks are shown in Table 1, with concrete examples shown in Appendix.

2.2.1 Abstractive Text Summarization

As a typical NLG task, abstractive text summarization aims to generate a short and fluent summary of a long text document. GLGE contains four abstractive text summarization tasks. As discussed in Bhandari et al. (2020), we use ROUGE-1, ROUGE-2, and ROUGE-L (Lin, 2004) as the metrics for these tasks.

CNN/DailyMail (Hermann et al., 2015) dataset contains 220K articles from the Daily Mail newspapers and 93K articles from the CNN. Each article contains a bullet point summary. GLGE uses the non-anonymized variant See et al. (2017). After the pre-processing, there are 311,971 ⟨article, summary⟩ pairs, where the source input is the article, and the target output is the summary which consists of multiple sentences.

Gigaword (Rush et al., 2015) contains 4M examples extracted from the news articles of the Gigaword corpus (Graff et al., 2003). After the pre-processing, there are 3,995,559 ⟨passage, summary⟩ data pairs, where the source input is the first sentence of the article, and the target output is the headline that usually contains a single sentence.

XSum (Narayan et al., 2018) consists of 227K online articles from the British Broadcasting Corporation (BBC), which contains professionally written single-sentence summaries. After the pre-processing, there are 226,677 ⟨article, summary⟩ data pairs, where the source input is the news article, and the target output is a single-sentence summary.

MSNews **M**icro**S**oft **News** headline generation (**MSNews**) is a new News headline generation dataset we collected for GLGE. We random select 151K online news articles from 2012-01-01 to 2020-09-01 from a real-world news search engine. Each article contains a professionally written single-sentence headline. After the pre-processing, there are 151,140 ⟨article, headline⟩ data pairs, where the source input is the news article, and the target output is a news headline.

2.2.2 Answer-aware Question Generation

The question generation task is another typical NLG task, which aims to generate a question based on a given text passage or document. Compared with answer-agnostic question generation tasks that can generate lots of reasonable questions, answer-aware question generation (Zhou et al., 2017) is asked to generate a question asks towards the given answer span based on a given text passage or document. In order to facilitate automatic evaluation, GLGE selects two answer-aware question generation tasks:

SQuAD 1.1 (Rajpurkar et al., 2016) dataset contains over 100K crowd-worker created questions with the corresponding answer spans in 536 Wikipedia articles. Since the original hidden test set of the SQuAD 1.1 is hidden, we follow (Du et al., 2017; Zhao et al., 2018) to re-split the dataset with the examples from the original training set and development set. After the pre-processing, there are 98,169 ⟨answer, passage, question⟩ data triples, in which the source input is a Wikipedia passage along with an answer span, and the target output is a question. ROUGE-L, BLEU-4 (Papineni et al., 2002), and METEOR (Banerjee and Lavie, 2005) are used as the metrics.

MSQG **M**icro**S**oft **Q**uestion **G**eneration (**MSQG**) is another dataset we collected, which is a new challenge dataset, the questions in this dataset are freely edited by daily users. For MSQG, we collect 220K passages from a real world search engine. Each passage contains a highlight span and a related query, we regard the queries as questions in this dataset. After the pre-processing, there are 220,088 ⟨highlight span, passage, question⟩ data triples, where the source input is a news passage along with highlight span, and the target output is a user question. ROUGE-L, BLEU-4, and METEOR are used as the metrics.

2.2.3 Conversational Question Answering

Conversational question answering is a classic and popular generative question answering task. Compared with the extractive question answering, such as SQuAD (Rajpurkar et al., 2016), conversational question answering requires the model to answer the question based on a running conversation history and the given passage.

CoQA (Reddy et al., 2019) dataset contains 127K questions with answers, obtained from 8K conversations about text passages from seven diverse domains. After the pre-processing, there are 116,630 ⟨conversation history, passage, question, answer⟩ data 4-tuples, where the source input is a sequence of conversation history along with a given question and a given passage, and the target output is a free-form answer text. F1-Score (Rajpurkar et al., 2016) is used as the metric.

2.2.4 Personalized Dialogue

Conversational AI is an important topic in NLG. Compared with text summarization, the responses of single-turn conversations are diverse and might lack of specification, and thus it is hard to use the single ground-truth for automatic evaluation. We select the personalizing dialogue task, which is a challenging multi-turn conversation task. In addition to the conversation history, this task gives the profile information as an additional condition to facilitate specific response generation.

PersonaChat (Zhang et al., 2018) dataset consists of about 160K utterances, which requires the model to generate responses according to given multi-turn conversations and persona profile. After pre-processing, there are 151,157 ⟨persona profile description text, conversation history, response⟩ data triples, where the source input is a sequence of conversation history along with several sentences of persona profile description information, and the target output is a response. BLEU-1, BLEU-2, Distinct-1, and Distinct-2 (Li et al., 2016) are used as the evaluation metrics.

2.3 Overall Score

Similar to GLUE (Wang et al., 2019b) and SuperGLUE (Wang et al., 2019a), we seek to give an overall system performance over all GLGE tasks by aggregating the scores of all tasks. We follow GLUE to adopt a simple approach that weighs each task equally. For the tasks with multiple metrics, we firstly average those metrics to get a task score. Besides, because the values of the original Distinct-1 (D-1) and Distinct-2 (D-2) (Li et al., 2016) scores which are used as the metrics for dialogue task are usually quite small (less than 0.01), we re-scale them by 100.0 so that these score values are in the same order of magnitude as other scores.

2.4 Challenges of Three Difficulty Levels

As discussed in § 2.1.2, GLGE provides three levels of difficulty for each task, called **GLGE-Easy**, **GLGE-Medium**, and **GLGE-Hard**. The original 8 task datasets as described in § 2.2 constitute the GLGE-Easy. Based on GLGE-Easy, we employ two strategies to further increase the task difficulty.

Low-resource. We increase the difficulty of GLGE by simulating low-resource scenarios. For each task, we keep the test and development sets of GLGE-Easy and randomly reduce the scale of the training data to 50% of the original train set. The dataset of 8 tasks under this setting is regarded as GLGE-Medium.

Low-frequency. In order to further evaluate the generalization capability of the NLG model, we increase the difficulty of GLGE by reducing the word overlap rate between the output of the training set and the output of the test set. The motivation is that a good NLG model should be able to generate a fluent target output based on the input information, even if the target output may contain some low-frequency words. For the test set and development sets of GLGE-Hard, we still use those in GLGE-

Easy. For the training set of GLGE-Hard, we first count the frequency of each token in the target sentence of the test set. Then we remove the stop words of the target sentence of each training sample in GLGE-Easy, ranking them by calculating their word frequency score of the test set. This can be formulated as

$$\text{Score}(y) = \frac{\sum_{w_y \in y} \text{TF}(w_y)}{|y|}, \tag{1}$$

where y is a target sentence without stop words, w_y is a token in y, $\text{TF}(w_y)$ denotes the word frequency of the token w_y in the target sentences of the whole test set, and $|y|$ denotes the token length of y. Instead of reducing the training data scale randomly as in GLGE-Medium, we select the top 25% training data with minimum word frequency score of the test set from the original training set as the training set of each dataset. The dataset of 8 tasks under this setting is regarded as GLGE-Hard.

3 Experiments

3.1 Baselines

For the baselines, we first evaluate two widely-used non-pretrained models: vanilla LSTM based Seq2Seq (Bahdanau et al., 2015) and vanilla Transformer (Vaswani et al., 2017). Besides, we evaluate several widely used pretrained NLG models, including MASS (Song et al., 2019), BART (Lewis et al., 2020), and ProphetNet (Qi et al., 2020). To further evaluate the performance of the pretrained NLG models of different model sizes and the different scales of the pretraining corpus, we compare the $\text{MASS}_{\text{base}}$, $\text{ProphetNet}_{\text{base}}$, $\text{MASS}_{\text{middle}}$, $\text{BART}_{\text{large}}$, and $\text{ProphetNet}_{\text{large}}$ on GLGE.

3.2 Implementation Details

Vanilla LSTM (Bahdanau et al., 2015). The hyper-parameters and implementation of LSTM-Seq2Seq are based on the *LSTM* register model of Fairseq[4], where the word embedding dimension, the hidden size, the number of the encoder layer, and the number of the decoder layer are 512, 512, 1, and 1, respectively. For each task in GLGE, we use Adam (Kingma and Ba, 2015) with an initial learning rate of between 0.0001 and 0.0003, and train the LSTM-Seq2Seq for a maximum of 100 epochs.

Vanilla Transformer (Vaswani et al., 2017). The hyper-parameters and implementation of Transformer are based on the *transformer_vaswani_wmt_en_de_big* register model of Fairseq[5], which contains a 6-layer encoder and a 6-layer decoder with 1024 embedding/hidden size and 4096 feed-forward filter size. For each task in GLGE, we use Adam with the initial learning rate of between 0.0003 and 0.001, and train the Transformer for a maximum of 20 epochs.

$\text{MASS}_{\text{base}}$ (Song et al., 2019). The hyper-parameters and implementation of MASS are based on their source code[6]. $\text{MASS}_{\text{base}}$ contains a 6-layer encoder and a 6-layer decoder with 768 embedding/hidden size and 3072 feed-forward filter size. The $\text{MASS}_{\text{base}}$ is pretrained on BookCorpus (Zhu et al., 2015) and English Wikipedia (16GB in total). For each task in GLGE, we fine-tune $\text{MASS}_{\text{base}}$ with the same hyper-parameters used in their source code[7] for a maximum of 25 epochs.

$\text{MASS}_{\text{middle}}$ (Song et al., 2019) which contains a 6-layer encoder and a 6-layer decoder with 1024 embedding/hidden size and 4096 feed-forward filter size. The $\text{MASS}_{\text{middle}}$ is also pretrained on BookCorpus and English Wikipedia (16GB in total). For each task in GLGE, we use the same hyper-parameters as used in $\text{MASS}_{\text{base}}$.

$\text{ProphetNet}_{\text{base}}$ (Qi et al., 2020). The hyper-parameters and implementation of ProphetNet are based on their source code[8]. $\text{ProphetNet}_{\text{base}}$ contains a 6-layer encoder and a 6-layer decoder with 768 embedding/hidden size and 3072 feed-forward filter size. Similar to MASS, the $\text{ProphetNet}_{\text{base}}$ is pretrained on BookCorpus and English Wikipedia (16GB in total) with 125K steps. For each task in GLGE, we fine-tune $\text{ProphetNet}_{\text{base}}$ with the same hyper-parameters used in their source code for a maximum of 10 epochs.

$\text{ProphetNet}_{\text{large}}$ (Qi et al., 2020). It contains a 12-layer encoder and 12-layer decoder with 1024 embedding/hidden size and 4096 feed-forward filter size. The $\text{ProphetNet}_{\text{large}}$ is pretrained on the 160GB English language corpora of news, books, stories, and web text for 14 epochs. For each task in

Table 2: Overall results of baselines on all GLGE tasks. We use the color to highlight the overall score. R-1: ROUGE-1. R-2: ROUGE-2. R-L: ROUGE-L. B-4: BLUE-4. MTR: METEOR. D-1: Distinct-1. D-2: Distinct-2. Note that as discussed in § 2.3, the values of Distinct-1 and Distinct-2 are multiplied by 100.

GLGE, we fine-tune ProphetNet$_{\text{large}}$ with the same hyper-parameters used in their source code for a maximum of 10 epochs.

BART$_{\text{large}}$ (Lewis et al., 2020). The hyper-parameters and implementation of BART$_{\text{large}}$ are based on the source code[9]. BART$_{\text{large}}$ contains a 12-layer encoder and 12-layer decoder with 1024 embedding/hidden size and 4096 feed-forward filter size. The pretraining of BART$_{\text{large}}$ uses the same pretraining data as Liu et al. (2019), consisting of 160GB of news, books, stories, and web text. For each task in GLGE, we fine-tune BART$_{\text{large}}$ with the same hyper-parameters used in their source code[10] for a maximum of 20000 iterations.

Except BART, all the baselines adopt BERT-uncased tokenizer. We fine-tune all baselines on each individual task with 4×16GB NVIDIA V100 GPUs. We evaluate the best model checkpoint based on the loss on the development set. During inference, we use beam search (Och and Ney, 2004) with beam size 4 or 5 and remove the duplicated trigrams in beam search (Fan et al., 2018) to obtain the generated results.

3.3 Results and Analysis

Overall results. The main results are presented in Table 2. From the overall scores (highlighted in color), we can observe the fairly consistent gains moving from LSTM to Transformer, and then to pretrained base models and pretrained large models, such as ProphetNet$_{\text{base}}$ and ProphetNet$_{\text{large}}$. The performance gap between the pretrained model and non-pretrained model is obvious. The difference in terms of overall score is about absolute 15% on the three levels GLGE benchmarks (GLGE-Easy, GLGE-Medium, and GLGE-Hard). As expected, the pretrained large models (ProphetNet$_{\text{large}}$ and BART$_{\text{large}}$) achieve the best overall scores.

From the results of each model on the three levels GLGE benchmarks, we can see that each model has a significant drop in performance from GLGE-Easy to GLGE-Medium and GLGE-Hard benchmarks. For both the non-pretrained model and pretrained models, there is a nearly 2% drop in terms of overall score from GLGE-Easy to GLGE-Medium, and about 4%-8% drop from GLGE-Easy to GLGE-Hard. These results illustrate the diversified difficulty of GLGE. We recommend that researchers choose a GLGE benchmark with moder-

Table 3: Overall results of baselines across the tasks of GLGE-Medium + Low-frequency strategy. We use the color to highlight the overall score. R-1: ROUGE-1. R-2: ROUGE-2. R-L: ROUGE-L. B-4: BLUE-4. MTR: METEOR. D-1: Distinct-1. D-2: Distinct-2.

ate difficulty based on the model size of the pretrained model and the scale size of the pretrained corpus. At the same time, researchers can also perform more comprehensive evaluation of model performance on GLGE benchmarks at all difficulty levels.

Low-frequency strategy analysis. To further verify the effectiveness of the low-frequency strategy as described in § 2.4. We build the GLGE-Medium + low-frequency benchmark and evaluate the models on it. Both GLGE-Medium and GLGE-Medium + low-frequency retain 50% of the training samples in the GLGE-Easy training set. The only difference between them is that GLGE-Medium uses random sampling to retain 50% training samples, while GLGE-Medium + low-frequency uses the low-frequency strategy as used in GLGE-Hard to select 50% training samples. We use the same baselines with the same settings in § 3.2 to compare the model performance on GLGE-Medium and GLGE-Medium + low-frequency. The results are shown in Table 3. We can see that after the introduction of the low-frequency strategy, the performance of the models has dropped significantly. These results demonstrate that the low-frequency strategy can effectively improve the difficulty of the benchmark.

Output diversity analysis. We further compare the output diversity of each model on all the tasks of GLGE-Easy. We report the mean of the Distinct bigram (Distinct-2) (Li et al., 2016) ratios of the generated samples to the golden references. Note that if the bigram diversity of the generated samples is close to that of the real samples, the distinct bigram ratio is close to 1. The results are shown in Figure 1. In general, output bigram diversity of the pretrained model is higher than non-pretrained models. For the tasks of CNN/DailyMail (CNN/DM), Gigaword, and MSNews, the bigram diversity of the generated samples are close to that of the real samples. However, for the tasks of XSUM, SQuAD 1.1, MSQG, CoQA, and PersonaChat, the bigram diversity of the non-pretrained model is significantly lower than that of the pretrained model. For these tasks, the non-pretrained model tends to generate universal responses (Li et al., 2016) or outputs. Moreover, there is still a huge gap between the bigram diversity of pretrained models and real samples (golden) on the task of XSUM, MSQG, and PersonaChat. Obviously, there exists great room for future improvement of the pretrained models in terms of output diversity.

4 Related Works

Benchmarks Recently, the development of general natural language understanding (NLU) evaluation benchmarks has helped drive the progress of pretraining and transfer learning in NLP. Conneau and Kiela (2018) propose a toolkit, SentEval, for evaluating the quality of universal sentence representations. DecaNLP (McCann et al., 2018) casts ten diversified NLP tasks as a general question-answering format for evaluation. Wang et al. (2019b) propose a widely-used multi-task benchmark, GLUE, for NLU in the English language. There are nine NLU tasks in GLUE, including two single-sentence tasks, three similarity and paraphrase tasks, and four natural language inference tasks. After that, SuperGLUE (Wang et al., 2019a) is proposed as a harder counterpart of GLUE. Besides sentence- and sentence-pair classification tasks used in GLUE, SuperGLUE extends the task formats by introducing coreference resolution and question answering tasks. More recently, A new NLU benchmark called DialoGLUE (Mehri et al., 2020) for task-oriented dialogue is proposed. It consists of seven task-oriented dialogue datasets

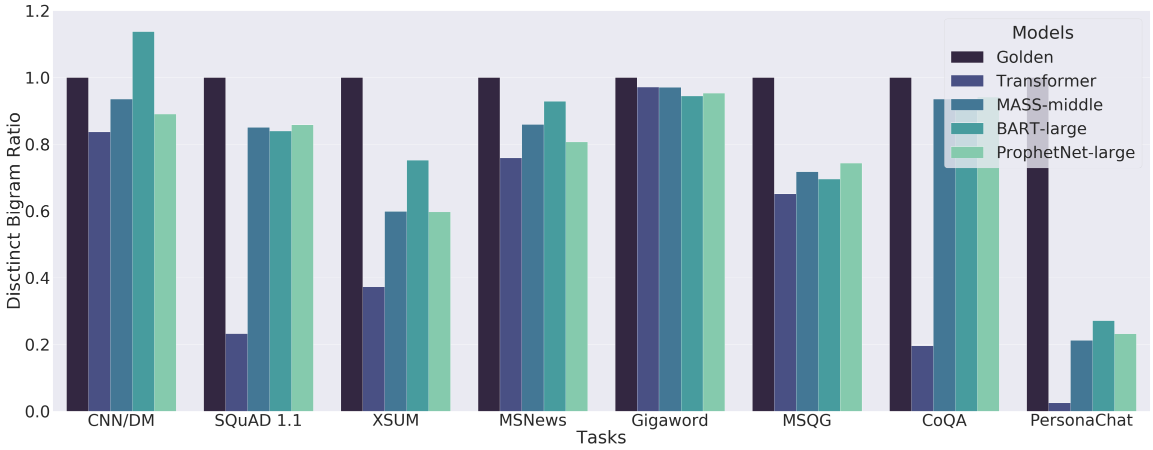

Figure 1: Distinct bigram ratios of the generated samples to the golden references on GLGE-Easy.

covering four kinds of NLU tasks: intent prediction, slot tagging, semantic parsing, and dialogue state tracking.

In addition to the English NLU evaluation benchmark, there has been an increasing amount of new benchmarks in other languages. For example, CLUE (Xu et al., 2020) is a Chinese NLU benchmark that consists of eight diverse Chinese NLU tasks, including single-sentence, sentence-pair, and machine reading comprehension tasks. FLUE (Le et al., 2020) is proposed for the French language, which is a French NLU benchmark that includes several NLU tasks, such as text classification, paraphrasing, language inference, parsing, POS tagging, and word sense disambiguation. IndoNLU (Wilie et al., 2020) is a new benchmark for evaluating Indonesian language understanding, which introduces twelve tasks, ranging from single sentence classification to pair-sentences sequence labeling. Furthermore, the multilingual multi-task benchmarks are proposed for cross-lingual evaluating. Hu et al. (2020) introduce XTREME benchmark which is a multi-task benchmark for evaluating the cross-lingual generalization capabilities of multilingual representations across forty languages and nine tasks. Almost at the same time, XGLUE (Liang et al., 2020) is proposed which is a new multilingual multi-task benchmark for cross-lingual pretraining, understanding, and generation. There are eleven cross-lingual tasks including nine NLU tasks and two NLG tasks in XGLUE, each task provides labeled data in multiple languages.

The above benchmarks mostly focus on NLU which provides a range of language understanding tasks. However, to our best knowledge, there is no benchmark designed specifically for general NLG evaluation. To fill this gap, we introduce GLGE, a new multi-task benchmark for evaluating the generalization capabilities of NLG across eight language generation tasks.

Pretrained NLG Models In recent years, pretrained language models (Devlin et al., 2019; Raffel et al., 2020; Yang et al., 2019; Liu et al., 2019; Alberti et al., 2019; Brown et al., 2020; Clark et al., 2020) have achieved state-of-the-art results in several NLU benchmarks. Besides, more and more pretraining based models which are designed for NLG tasks are proposed. Rothe et al. (2020) adopt the Transformer-based sequence-to-sequence (seq2seq) model and leverage the checkpoints of the pretrained NLU models for sequence generation tasks. MASS (Song et al., 2019) pretrains the seq2seq model by dropping a continuous token span to corrupt the text and learns to reconstruct it. Raffel et al. (2020) investigate several model structures and pretraining tasks, and further propose a unified text-to-text transformer called T5. Similarly, BART (Lewis et al., 2020) adopts the encoder-decoder structure and is pretrained with randomly sentence order reconstruction and text in-filling tasks.

More recently, Qi et al. (2020) propose, ProphetNet, which introduces the future n-gram prediction mechanism for language generation. ENRINE-GEN (Xiao et al., 2020) introduces the infilling generation mechanism, noise-aware generation, and span-by-span generation task for NLG model pretraining. In addition to general NLG tasks, some task-specific pretrained NLG models are proposed. For dialogue and conversation, a dialogue generative pretrained transformer called DialoGPT (Zhang et al., 2020c) is proposed for conversational response generation, which is pretrained on a large-scale conversation-like exchange corpus. Furthermore, PLATO (Bao et al., 2020) is a dialogue generation pretraining framework for chit-chat, knowledge grounded dialogues, and conversational question answering. PLATO introduces discrete latent variables to tackle the one-to-many mapping problem in response generation. For text summarization, Zhang et al. (2020a) propose PEGASUS, which design the pretraining objectives called gap sentence generation tailored for abstractive text summarization.

5 Conclusion

To facilitate the development, evaluation, and comparison of new NLG models, we introduce GLGE, a multi-task evaluation benchmark for NLG with three difficulty levels. To the best of our knowledge, GLGE is the first comprehensive NLG evaluation benchmark. We evaluate several baselines on GLGE and analyze their results. The GLGE benchmark is hosted publicly and we invite the research community to submit to the leaderboard.

In future work, we will try to introduce other automatic evaluation metrics, such as BERTscore (Zhang et al., 2020b) and BLEURT (Sellam et al., 2020). Besides, we will compare the correlation between these metrics and human judgment.

AMBERT: A Pre-trained Language Model with Multi-Grained Tokenization

Xinsong Zhang, Pengshuai Li, Hang Li
ByteDance AI Lab
{zhangxinsong.0320, lipengshuai.1204, lihang.lh}@bytedance.com

Abstract

Pre-trained language models such as BERT have exhibited remarkable performances in many tasks in natural language understanding (NLU). The tokens in the models are usually fine-grained in the sense that for languages like English they are words or sub-words and for languages like Chinese they are characters. In English, for example, there are multi-word expressions which form natural lexical units and thus the use of coarse-grained tokenization also appears to be reasonable. In fact, both fine-grained and coarse-grained tokenizations have advantages and disadvantages for learning of pre-trained language models. In this paper, we propose a novel pre-trained language model, referred to as AMBERT (A Multi-grained BERT), on the basis of both fine-grained and coarse-grained tokenizations. For English, AMBERT takes both the sequence of words (fine-grained tokens) and the sequence of phrases (coarse-grained tokens) as input after tokenization, employs one encoder for processing the sequence of words and the other encoder for processing the sequence of the phrases, utilizes shared parameters between the two encoders, and finally creates a sequence of contextualized representations of the words and a sequence of contextualized representations of the phrases. Experiments have been conducted on benchmark datasets for Chinese and English, including CLUE, GLUE, SQuAD and RACE. The results show that AMBERT can outperform BERT in all cases, particularly the improvements are significant for Chinese. We also develop a method to improve the efficiency of AMBERT in inference, which still performs better than BERT with the same computational cost as BERT.

1 Introduction

Pre-trained models such as BERT, RoBERTa, and ALBERT (Devlin et al., 2018; Liu et al., 2019; Lan et al., 2019) have shown great power in natural language understanding (NLU). The Transformer-based language models are first learned from a large corpus in pre-training, and then learned from labeled data of a downstream task in fine-tuning. With Transformer (Vaswani et al., 2017), pre-training technique, and big data, the models can effectively capture the lexical, syntactic, and semantic relations between the tokens in the input text and achieve state-of-the-art performance in many NLU tasks, such as sentiment analysis, text entailment, and machine reading comprehension.

In BERT, for example, pre-training is mainly conducted based on masked language modeling (MLM) in which about 15% of the tokens in the input text are masked with a special token [MASK], and the goal is to reconstruct the original text from the masked tokens. Fine-tuning is separately performed for individual tasks as text classification, text matching, text span detection, etc. Usually, the tokens in the input text are fine-grained; for example, they are words or sub-words in English and characters in Chinese. In principle, the tokens can also be coarse-grained, that is, for example, phrases in English and words in Chinese. There are many multi-word expressions in English such as 'New York' and 'ice cream' and the use of phrases also appears to be reasonable. It is more sensible to use words (including single character words) in Chinese, because they are basic lexical units. In fact, all existing pre-trained language models employ single-grained (usually fine-grained) tokenization.

Previous work indicates that the fine-grained approach and the coarse-grained approach have both pros and cons. The tokens in the fine-grained approach are less complete as lexical units but their representations are easier to learn (because there are less token types and more tokens in training data), while the tokens in the coarse-grained approach are more complete as lexical units but their

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 421–435
August 1–6, 2021.

representations are more difficult to learn (because there are more token types and less tokens in training data). Moreover, for the coarse-grained approach there is no guarantee that tokenization (segmentation) is completely correct. Sometimes ambiguity exists and it would be better to retain all possibilities of tokenization. In contrast, for the fine-grained approach tokenization is carried out at the primitive level and there is no risk of 'incorrect' tokenization.

For example, (Li et al., 2019) observe that fine-grained models consistently outperform coarse-grained models in deep learning for Chinese language processing. They point out that the reason is that low frequency words (coarse-grained tokens) tend to have insufficient training data and tend to be out of vocabulary, and as a result the learned representations are not sufficiently reliable. On the other hand, previous work also demonstrates that masking of coarse-grained tokens in pre-training of language models is helpful (Cui et al., 2019; Joshi et al., 2020). That is, although the model itself is fine-grained, masking on consecutive tokens (phrases in English and words in Chinese) can lead to learning of a more accurate model. In Appendix A, we give examples of attention maps in BERT to further support the assertion.

In this paper, we propose A Multi-grained BERT model (AMBERT), which employs both fine-grained and coarse-grained tokenizations. For English, AMBERT extends BERT by simultaneously constructing representations for both words and phrases in the input text using two encoders. Specifically, AMBERT first conducts tokenization at both word and phrase levels. It then takes the embeddings of words and phrases as input to the two encoders with the shared parameters. Finally it obtains a contextualized representation for the word and a contextualized representation for the phrase at each position. Note that the number of parameters in AMBERT is comparable to that of BERT, because the parameters in the two encoders are shared. There are only additional parameters from multi-grained embeddings. AMBERT can represent the input text at both word-level and phrase-level, to leverage the advantages of the two approaches of tokenization, and create richer representations for the input text at multiple granularity.

AMBERT consists of two encoders and thus its computational cost is roughly doubled compared with BERT. We also develop a method for improving the efficiency of AMBERT in inference, which only uses one of the two encoders. One can choose either the fine-grained encoder or the coarse-grained encoder for a specific task using a development dataset.

We conduct extensive experiments to make a comparison between AMBERT and the baselines as well as alternatives to AMBERT, using the benchmark datasets in English and Chinese. The results show that AMBERT significantly outperforms single-grained BERT models with a large margin in both Chinese and English. In English, compared to Google BERT, AMBERT achieves 2.0% higher GLUE score, 2.5% higher RACE score, and 5.1% more SQuAD score. In Chinese, AMBERT improves average score by over 2.7% in CLUE. Furthermore, AMBERT with only one encoder can preform much better than the single-grained BERT models with a similar amount of inference time.

We make the following contributions.

- Study of multi-grained pre-trained language models,
- Proposal of a new pre-trained language model called AMBERT as an extension of BERT,
- Empirical verification of AMBERT on the English and Chinese benchmark datasets GLUE, SQuAD, RACE, and CLUE,
- Proposal of an efficient inference method for AMBERT.

2 Related work

There has been a large amount of work on pre-trained language models. ELMo (Peters et al., 2018) is one of the first pre-trained language models for learning contextualized representations of words in the input text. Leveraging the power of Transformer (Vaswani et al., 2017), GPTs (Radford et al., 2018, 2019) are developed as unidirectional models to make predictions on the input text in an auto-regressive manner, and BERT (Devlin et al., 2018) is developed as a bidirectional model to make predictions on the whole or part of the input text. Masked language modeling (MLM) and next sentence prediction (NSP) are the two tasks in pre-training of BERT. Since the inception of BERT, a number of new models have been proposed to further enhance the performance of it. XLNet (Yang et al., 2019) is a permutation language model which can improve the accuracy of MLM. RoBERTa (Liu et al., 2019) represents a new way of training more reliable BERT with a very large amount of data. ALBERT (Lan et al., 2019) is a light-weight version of BERT, which shares parameters across layers. StructBERT (Wang et al., 2019) incorporates word and sentence structures into BERT to learn better representations of tokens and sentences. ERNIE2.0 (Sun et al., 2020) is a variant of BERT pre-trained on multiple tasks with coarse-grained tokens masked. ELECTRA (Clark et al., 2020) has a GAN-style architecture for efficiently utilizing all tokens in pre-training.

It has been found that the use of coarse-grained tokens is beneficial for pre-trained language models. (Devlin et al., 2018) point out that 'whole word masking' is effective for training of BERT. It is also observed that whole word masking is useful for building a Chinese BERT (Cui et al., 2019). In ERNIE (Sun et al., 2019b), entity level masking is employed as a strategy for pre-training and proved to be effective for language understanding tasks (see also (Zhang et al., 2019)). In SpanBERT (Joshi et al., 2020), text spans are masked in pre-training and the learned model can substantially enhance the accuracies of span selection tasks. It is indicated that word segmentation is especially important for Chinese and a BERT-based Chinese text encoder is proposed with n-gram representations (Diao et al., 2019). All existing work focuses on the use of single-grained tokens in learning and utilization of pre-trained language models. In this work, we propose a general technique of exploiting multi-grained tokens for pre-trained language models and apply it to BERT.

3 Our Method: AMBERT

In this section, we present the model, pre-training, and fine-tuning of AMBERT. We also present a discussion on alternatives to AMBERT.

3.1 Model

Figure 1 gives an overview of AMBERT. AMBERT takes a text as input. Tokenization is conducted on the input text to obtain a sequence of fine-grained tokens and a sequence of coarse-grained tokens. AMBERT has two encoders, one for processing the fine-grained token sequence and the other for processing the coarse-grained token sequence. Each of the encoders has exactly the same architecture as that of BERT (Devlin et al., 2018). The two encoders share the same parameters at each corresponding layer, except that each has its own token embedding parameters. The fine-grained encoder generates contextualized representations from the sequence of fine-grained tokens through its layers. In parallel, the coarse-grained encoder generates contextualized representations from the sequence of coarse-grained tokens through its layers. AMBERT outputs a sequence of contextualized representations for the fine-grained tokens and a sequence of contextualized representations for the coarse-grained tokens.

AMBERT is expressive in that it learns and utilizes contextualized representations of the input text at both fine-grained and coarse-grained levels. The model retains all possibilities of tokenizations and learns the attention weights (importance) of representations of multi-grained tokens. AMBERT is also efficient through sharing of parameters between the two encoders. The parameters represent the same ways of combining representations, no matter whether representations are those of fine-grained tokens or coarse-grained tokens.

3.2 Pre-Training

Pre-training of AMBERT is mainly conducted on the basis of masked language modeling (MLM), at both fine-grained and coarse-grained levels. Next sentence prediction (NSP) is not essential as indicated in many studies after BERT (Lan et al., 2019; Liu et al., 2019). We only use NSP in our experiments for comparison purposes. Let $\hat{\mathbf{x}}$ denote the sequence of fine-grained tokens with some of them being masked, and $\bar{\mathbf{x}}$ denote the masked fine-grained tokens. Let $\hat{\mathbf{z}}$ denote the sequence of coarse-grained tokens with some of them being masked, and $\bar{\mathbf{z}}$ denote the masked coarse-grained tokens. Pre-training is defined as optimization of the following function,

$$\min_{\theta} \; -\log p_{\theta}(\bar{\mathbf{x}}, \bar{\mathbf{z}}|\hat{\mathbf{x}}, \hat{\mathbf{z}}) \approx$$

$$\min_{\theta} -\sum_{i=1}^{M} m_i \log p_{\theta}(x_i|\hat{\mathbf{x}}) - \sum_{j=1}^{n} n_j \log p_{\theta}(z_j|\hat{\mathbf{z}}),$$

where m_i takes 1 or 0 as values and $m_i = 1$ indicates that fine-grained token x_i is masked, m denotes the total number of fine-grained tokens; n_j takes 1 or 0 as values and $n_j = 1$ indicates that coarse-grained token z_j is masked, n denotes the total number of coarse-grained tokens; and θ denotes parameters.

3.3 Fine-Tuning

In fine-tuning of AMBERT for classification, the fine-grained encoder and coarse-grained encoder

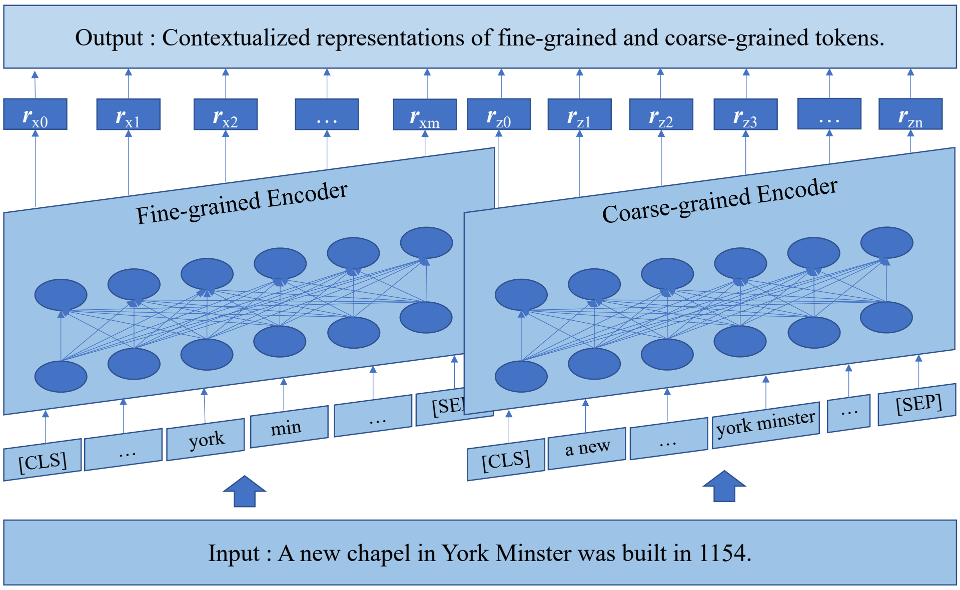

Figure 1: An overview of AMBERT, showing the process of creating multi-grained representations. The input is a sentence in English and output is the overall representation of the sentence. There are two encoders for processing the sequence of fine-grained tokens and the sequence of coarse-grained tokens respectively. The final contextualized representations of fine-grained tokens and coarse-grained tokens are denoted as $\boldsymbol{r}_{x0}, \boldsymbol{r}_{x1}, \cdots, \boldsymbol{r}_{xm}$ and $\boldsymbol{r}_{z0}, \boldsymbol{r}_{z1}, \cdots, \boldsymbol{r}_{zn}$ respectively.

create special [CLS] representations, and both representations are used for classification. Fine-tuning is defined as optimization of the following function, which is a regularized loss of multi-task learning, starting from the pre-trained model,

$$\begin{aligned} &\min_{\theta} \; -\log p_{\theta}(\boldsymbol{y}|\mathbf{x}) \\ &= \min_{\theta} -\log p_{\theta}(\boldsymbol{y}|\boldsymbol{r}_{x0}) - \log p_{\theta}(\boldsymbol{y}|\boldsymbol{r}_{z0}) \\ &- \log p_{\theta}(\boldsymbol{y}|[\boldsymbol{r}_{x0}, \boldsymbol{r}_{z0}]) + \lambda \|\tilde{\boldsymbol{y}}_x - \tilde{\boldsymbol{y}}_z\|_2, \end{aligned}$$

where $\mathbf{x}$ is the input text, $\boldsymbol{y}$ is the classification label, $\boldsymbol{r}_{x0}$ and $\boldsymbol{r}_{z0}$ are the [CLS] representations of fine-grained encoder and coarse-grained encoder, $[\boldsymbol{a}, \boldsymbol{b}]$ denotes concatenation of vectors $\boldsymbol{a}$ and $\boldsymbol{b}$, λ is a regularization coefficient, and $\|\|_2$ denotes L2 norm. The last term is based on agreement regularization (Brantley et al., 2019), which forces agreement between the predictions ($\tilde{\boldsymbol{y}}_x$ and $\tilde{\boldsymbol{y}}_z$).

Similarly, fine-tuning of AMBERT for span detection can be carried out, in which the representations of fine-grained tokens are concatenated with the representations of corresponding coarse-grained tokens. The concatenated representations are then utilized in the task.

3.4 Inference

We propose two ways of using AMBERT in inference. One is to utilize the AMBERT itself and the other to utilize only one encoder of AMBERT. The former performs better but needs more computation and the latter performs slightly worse but only needs computation comparable to BERT. One can choose either drop the fine-grained encoder or the coarse-grained encoder in AMBERT through evaluation using a development dataset, which makes the computational cost close to that of BERT.

3.5 Alternatives

We can consider two alternatives to AMBERT, which also rely on multi-grained tokenization. We refer to them as AMBERT-Combo and AMBERT-Hybrid and make comparisons of them with AMBERT in our experiments.

AMBERT-Combo has two individual encoders, an encoder (BERT) working on the fine-grained token sequence and the other encoder (BERT) working on the coarse-grained token sequence, without parameter sharing between them. In learning and inference AMBERT-Combo simply combines the output layers of the two encoders. Its fine-tuning is similar to that of AMBERT.

AMBERT-Hybrid has only one encoder (BERT) working on both the fine-grained token sequence and the coarse-grained token sequence. It creates representations on the concatenation of two sequences and lets the representations of the two

$$

where the notations are the same as in (1). Its fine-tuning is the same as that of BERT.

4 Experiments

We make comparisons between AMBERT and the baselines including fine-grained BERT and coarse-grained BERT, as well as the alternatives including AMBERT-Combo and AMBERT-Hybrid, using benchmark datasets in both Chinese and English. The experiments on the alternatives can also be seen as ablation study on AMBERT. The ablation studies for the regularization term λ are given in the Appendix E.

4.1 Data for Pre-Training

For Chinese, we use a corpus consisting of 25 million documents (57G uncompressed text) from Jinri Toutiao[1]. Note that there is no common corpus for training of Chinese BERT. For English, we use a corpus of 13.9 million documents (47G uncompressed text) from Wikipedia and OpenWebText (Gokaslan and Cohen, 2019)[2].

The characters in the Chinese texts are naturally taken as fine-grained tokens. We conduct word segmentation on the texts and treat the words as coarse-grained tokens. We employ a word segmentation tool based on a n-gram model. Both tokenizations exploit WordPiece embeddings (Wu et al., 2016). There are 21,128 characters and 72,635 words in the vocabulary of Chinese.

The words in the English texts are naturally taken as fine-grained tokens. We perform coarse-grained tokenization on the English texts in the following way. First, we calculate the n-grams in the Wikipedia documents using KenLM (Heafield, 2011). We next build a phrase-level dictionary consisting of phrases whose frequencies are sufficiently high and whose last words highly depend on their previous words. We then employ a left-to-right search algorithm to perform phrase-level tokenization on the texts. There are 30,522 words and 77,645 phrases in the vocabulary of English.

4.2 Experimental setup

We make use of the same parameter settings for the AMBERT and BERT models. All models in this paper are 'base-models' having 12 layers of encoder. It is too computationally expensive for

---

[1] Jinri Toutiao is a popular news app. in China.

[2] Unfortunately, BookCorpus, one of the two corpora in the original paper for English BERT, is no longer publicly available.

us to train the models as 'large models' having 24 layers. To retain consistency, the masked spans in the coarse-grained encoder are also masked in the fine-grained encoder. The details of pre-training and fine-tuning are the same as those in the original BERT paper (Devlin et al., 2018), which are given in Appendix C.

4.3 Chinese Tasks

4.3.1 Benchmarks

We use the benchmark datasets, Chinese Language Understanding Evaluation (CLUE) (Xu et al., 2020) for experiments in Chinese. CLUE contains six classification tasks, that are TNEWS, IFLYTEK and CLUEWSC2020, AFQMC, CSL and CMNLI[3], and three Machine Reading Comprehension (MRC) tasks which are CMRC2018, ChID and C^3. The details of all the benchmarks are shown in Appendix B. Data augmentation is also performed for all models in the tasks of TNEWS, CSL and CLUEWSC2020 to achieve better performance (see Appendix D for detailed explanation).

4.3.2 Experimental Results

We compare AMBERT with the BERT baselines, including the BERT model released from Google, referred to as Google BERT, and the BERT model trained by us, referred to as Our BERT, including fine-grained (character) and coarse-grained (word) models. Case study is given in Appendix F.

Table 1 shows the results of the classification tasks. AMBERT improves average scores of the BERT baselines by about 1.0% and also works better than AMBERT-Combo and AMBERT-Hybrid. The results of MRC tasks are shown in Table 2. AMBERT improves average scores of the BERT baselines by over 3.0%. Our BERT (word) performs poorly in CMRC2018. This is probably because the results of word segmentation are not accurate enough for the task. AMBERT-Combo and AMBERT-Hybrid are on average better than single-grained BERT models. AMBERT further outperforms both of them.

We also compare AMBERT with the state-of-the-art models such as RoBERTa and ALBERT in CLUE benchmark. The base models are trained with different datasets and procedures, and thus the comparisons should only be taken as references. Note that the settings of the base models are the same as that of Xu et al. (2020). Table 3 shows the results. The average score of AMBERT is higher than all the other models. We conclude that multi-grained tokenization is very helpful for pre-trained language models and the design of AMBERT is reasonable.

4.4 English Tasks

4.4.1 Benchmarks

The General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2018) is a collection of nine NLU tasks. Following BERT (Devlin et al., 2018), we exclude the task WNLI for the reason that results of different models on this task are undifferentiated. In addition, three MRC tasks are also included, i.e., SQuAD v1.1, SQuAD v2.0,

---

[3] The task is introduced at the CLUE website.

Table 5: Performances on three English MRC tasks. We use EM and F1 to evaluate the performance of text detection, and report accuracies for RACE, on both development set and test set.

Model	Avg.	SQuAD 1.1		SQuAD 2.0				RACE	
		DEV(EM, F1)		DEV(EM, F1)		TEST(EM, F1)		DEV	TEST
Google BERT	74.0	80.8	88.5	70.1	73.5	73.7	76.3	64.5	64.3
Our BERT (word)	76.7	83.8	90.6	76.6	79.6	77.3	80.3	62.4	62.6

AMBERT‡	194M	**82.8**	60.0	95.2	**88.9**	88.2	**89.5**	87.2	92.6	72.6	**82.5**	**71.2**

and RACE. The details of English benchmarks can be found in Appendix B.

4.4.2 Experimental Results

We compare AMBERT with the BERT models on the tasks in GLUE. The results of Google BERT are from the original paper (Devlin et al., 2018), and the results of Our BERT are obtained by us. From Table 4 we can see the following trends, 1) Multi-grained models, particularly AMBERT, can achieve better results than single-grained models. 2) Among the multi-grained models, AMBERT performs best with fewer parameters and less computation. Case study is given in Appendix F.

We also make comparison on the MRC tasks. The results of Google BERT are either from the papers (Devlin et al., 2018; Yang et al., 2019) or from our runs with the official code. From Table 5 we make the following conclusions. 1) in SQuAD, AMBERT outperforms Google BERT with a large margin. Our BERT (word) generally performs well and Our BERT (phrase) performs poorly in the span detection tasks. 2) In RACE, AMBERT performs best among all the baselines for both development set and test set. 3) AMBERT is the best multi-grained model.

We compare AMBERT with the state-of-the-art models in both GLUE and MRC benchmarks. The results of baselines, in Table 6, are either reported in published papers or re-implemented by us with HuggingFace's Transformer (Wolf et al., 2019). We use the provided implementation in HuggingFace's Transformer, without additional data augmentation, question-answering module[4] and other tricks. Note that AMBERT outperforms all the models on average without using training techniques such as bigger batches and dynamic masking.

4.5 Enhancement of Inference Speed

We also conduct experiments on the efficient inference method of AMBERT on CLUE/GLUE/SQuAD/RACE. We choose the fine-grained encoder for the span detection tasks (CMRC2018 and SQuAD) because it performs much better in the tasks. We choose the coarse-grained encoder for the other Chinese tasks and the fine-grained encoder for the other English tasks because they perform better on average. All the decisions are made based on the results from the Dev datasets. The detailed results are shown in Table 7. We conclude that, a) for the English tasks, AMBERT with one chosen encoder achieves similar results as AMBERT with two encoders and outperforms the single-grained "Our BERT" models with a large margin; b) for the Chinese tasks, AMBERT with one chosen encoder performs slightly worse than AMBERT but performs much better than the single-grained "Our BERT" models. Therefore, in practice, one can train an AMBERT with two encoders and use only one of the encoders in inference.

---

[4] For that reason, we cannot use the results for SQuAD 2.0 in Clark et al. (2020).

Table 7: Performances on the development sets of CLUE, GLUE, SQuAD and RACE with different ways for inference. CN-Models and EN-Models denote Chinese and English pre-trained models respectively. CoLA uses Matthew's Corr. We report EM of CMRC2018 and average EM of SQuAD1.1 and SQuAD2.0. The other metrics are all accuracies. We report the better results among single-grained models as "Our BERT".

CN-Models	Speedup	Avg.	TNEWS	IFLYTEK	CLUEWSC2020	AFQMC	CSL	CMNLI	CMRC2018	ChID	C^3	-
AMBERT	1.0	75.3	68.1	60.1	81.6	74.7	85.6	82.3	68.8	87.2	69.5	-

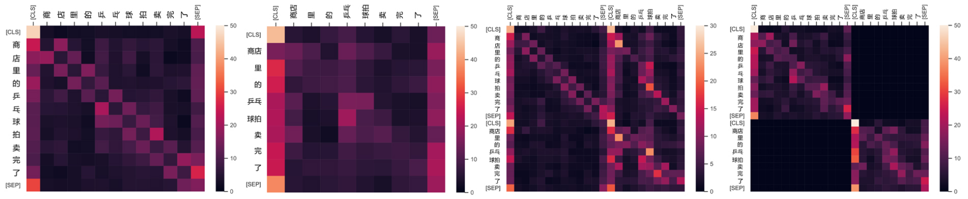
Our BERT (word) Our BERT (phrase) AMBERT-Hybrid AMBERT



Our BERT (char) Our BERT (word) AMBERT-Hybrid AMBERT

Figure 2: Attention weights of first layers of Our BERT (word/phrase), AMBERT-Hybrid and AMBERT, for English and Chinese sentences.

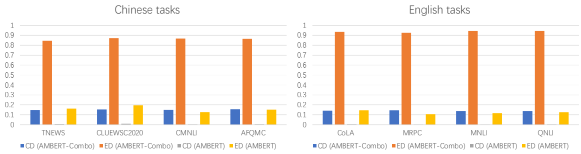


Figure 3: Distances between representations of fine-grained and coarse-grained encoders (representations of [CLS]) in AMBERT-Combo and AMBERT. CD and ED stand for cosine distance (one minus cosine similarity) and normalized Euclidean distance respectively.

4.6 Discussions

We further investigate the reason that AMBERT is superior to AMBERT-Combo. Figure 3 shows the distances between the [CLS] representations of the fine-grained encoder and coarse-grained encoder in AMBERT-Combo and AMBERT after pre-training, in terms of cosine distance (one minus cosine similarity) and normalized Euclidean distance. One can see that the distances in AMBERT-Combo are larger than the distances in AMBERT. We perform the assessment using the data in different tasks and find similar trends. The results indicate that the representations of fine-grained encoder and coarse-grained encoder are closer in AMBERT than in AMBERT-Combo. These are natural consequences of using AMBERT and AMBERT-Combo, whose parameters are respectively shared and unshared across encoders. It implies that the higher performances by AMBERT is due to its parameter sharing, which can learn and represent similar ways of combining tokens no matter whether they are fine-grained or coarse-grained. An intuitive explanation is that the ways of combining representations of fine-grained tokens and the ways of combining representations of coarse-grained tokens "in the same contexts" are exactly the same.

We also examine the reasons that AMBERT works better than AMBERT-Hybrid, while both of them exploit multi-grained tokenization. Figure 2 shows the attention weights of first layers in AMBERT and AMBERT-Hybrid, as well as the single-grained BERT models, after pre-training. In AMBERT-Hybrid, the fine-grained tokens attend more to the corresponding coarse-grained tokens and as a result the attention weights among fine-grained tokens are weakened. In contrast, in AMBERT the attention weights among fine-grained tokens and those among coarse-grained tokens are intact. It appears that attentions among single-grained tokens (fine-grained ones or coarse-grained ones) play important roles in downstream tasks.

To answer the question why the improvements by AMBERT on Chinese are larger than on English in the same pre-training settings, we further make an analysis. We respectively tokenize 10,000 randomly selected Chinese sentences from five tasks in CLUE with our Chinese word tokenizer. The average proportion of words is 51.5%, which indicates that about half of the tokens are fine-grained and half are coarse-grained in Chinese. Similarly, we tokenize 10,000 randomly selected English sentences from five different tasks in GLUE with our English phrase tokenizer. The average proportion of phrases is only 13.1%, which means that there are much less coarse-grained tokens than fine-grained tokens in English. (Please refer to Table 10 in the Appendix for more details of the experiments.) Therefore, we postulate that for Chinese it is necessary for a model to process the language at both fine-grained and coarse-grained levels. AMBERT indeed has the capability.

5 Conclusion

In this paper, we have proposed a novel pre-trained language model called AMBERT, as an extension of BERT. AMBERT employs multi-grained tokenization, that is, it uses both words and phrases in English and both characters and words in Chinese. With multi-grained tokenization, AMBERT learns in parallel the representations of the fine-grained tokens and the coarse-grained tokens using two encoders with shared parameters. We also develop an alternative way of using AMBERT in inference to save computation cost. Experimental results have demonstrated that AMBERT significantly outperforms BERT and other models in NLU tasks in both English and Chinese. AMBERT increases average score of Google BERT by about 2.7% in Chinese benchmark CLUE. AMBERT improves Google BERT by over 3.0% on a variety of tasks in English benchmarks GLUE, SQuAD (1.1 and 2.0), and RACE.

As future work, we plan to study the following issues: 1) to investigate model acceleration methods in learning of AMBERT, such as sparse attention (Child et al., 2019; Kitaev et al., 2020; Zaheer et al., 2020) and synthetic attention (Tay et al., 2020); 2) to apply the technique of AMBERT into other pre-trained language models such as XLNet; 3) to employ AMBERT in other NLU tasks.

Acknowledgments

We thank the teams at ByteDance for providing the Chinese corpus and the Chinese word segmentation tool.

A Attention maps for single-grained models

We construct fine-grained and coarse-grained BERT models for English and Chinese, and examine the attention maps of the models using the BertViz tool (Vig, 2019). Figure 4 shows the attention maps of the first layer of fine-grained models for several sentences in English and Chinese. One can see that there are tokens that improperly attend to other tokens in the sentences. For example, in the English sentences, the words “drawing”, “new”, and “dog” have high attention weights to “portrait”, “york”, and “food”, respectively, which are not appropriate. For example, in the Chinese sentences, the chars “拍”, “北”, “长” have high attention weights to “卖”, “京”, “市”, respectively, which are also not reasonable. (It is verified that the bottom layers at BERT mainly represent lexical information, the middle layers mainly represent syntactic information, and the top layers mainly represent semantic information (Jawahar et al., 2019).) Ideally a token should only attend to the tokens with which they form a lexical unit at the first layer. This cannot be guaranteed in the fine-grained BERT model, however, because usually a fine-grained token may belong to multiple lexical units (i.e., there is ambiguity).

Figure 5 shows the attention maps of the first layer of coarse-grained models for the same sentences in English and Chinese. In the English sentences, the words are combined into the phrases of “drawing room”, “york minister”, and “dog food”. The attentions are appropriate in the first two sentences, but it is not in the last sentence because of the incorrect tokenization. Similarly, in the Chinese sentences, the high attention weights of words “球拍(bat)” and “京城(capital)” are reasonable, but that of word “市长(mayor)” is not. Note that incorrect tokenization is inevitable.

B Detailed descriptions for the benchmarks

B.1 Chinese Tasks

TNEWS is a text classification task in which titles of news articles in TouTiao are to be classified into 15 classes. IFLYTEK is a task of assigning app descriptions into 119 categories. CLUEWSC2020, standing for the Chinese Winograd Schema Challenge, is a co-reference resolution task. AFQMC is a binary classification task that aims to predict whether two sentences are semantically similar. CSL uses the Chinese Scientific Literature dataset containing abstracts and their keywords of papers and the goal is to identify whether given keywords are the original keywords of a paper. CMNLI is based on translation from MNLI (Williams et al., 2017), which is a large-scale, crowd-sourced entailment classification task. CMRC2018 (Cui et al., 2018) makes use of a span-based dataset for Chinese machine reading comprehension. ChID (Zheng et al., 2019) is a large-scale Chinese IDiom cloze test. C^3 (Sun et al., 2019a) is a free-form multiple-choice machine reading comprehension for Chinese.

B.2 English Tasks

CoLA (Warstadt et al., 2019) contains English acceptability judgments drawn from books and journal articles on linguistic theory. SST-2 (Socher et al., 2013) consists of sentences from movie reviews and human annotations of their sentiment. MRPC (Dolan and Brockett, 2005) is a corpus of sentence pairs automatically extracted from online news sources, and the target is to identify whether a sentence pair is semantically equivalent. STS-B (Cer et al., 2017) is a collection of sentence pairs and the task is to predict similarity scores. QQP is a collection of question pairs and requires models to recognize semantically equivalent ones. MNLI (Williams et al., 2017) is a crowd-sourced collection of sentence pairs with textual entailment annotations. QNLI (Wang et al., 2018) is a question-answering dataset consisting of question-paragraph pairs, where one of the sentences in the paragraph contains the answer to the corresponding question. RTE (Bentivogli et al., 2009) comes from a series of annual textual entailment challenges.

C Hyper-parameters

C.1 Hyper-parameters in pre-training

In pre-training of the AMBERT models, in total 15% of the coarse-grained tokens are masked, which is the same proportion for the BERT models. We adopt the standard hyper-parameters of BERT in pre-training of the models except batch sizes which are tuned to make our fine-grained BERT models comparable to the Google BERT models. Table 8 shows the hyper-parameters in our Chinese AMBERT and English AMBERT. Our BERT models and alternatives of AMBERT (AMBERT-Combo and AMBERT-Hybrid) all use the same

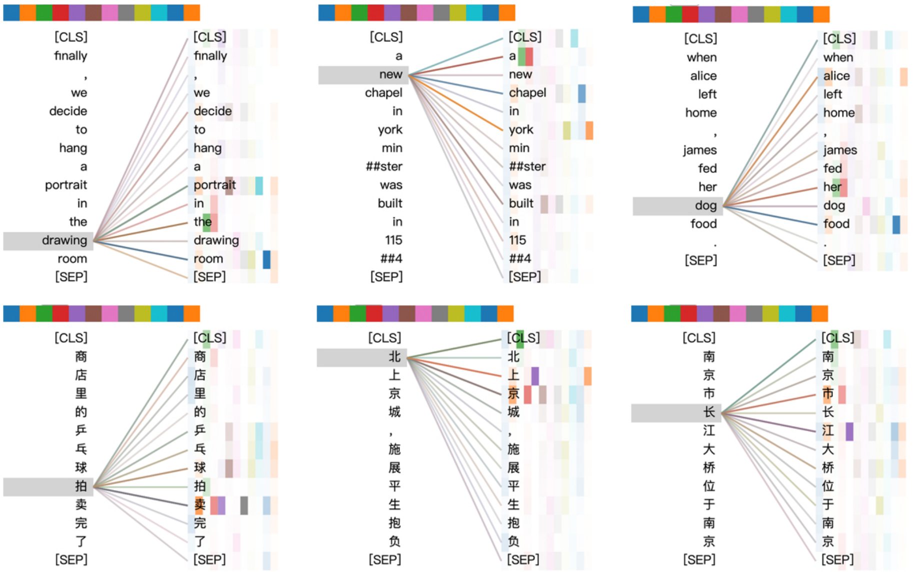

Figure 4: Attention maps of first layers of fine-grained BERT models for English and Chinese sentences. The Chinese sentences are "商店里的乒乓球拍卖完了 (Table tennis bats are sold out in the shop)", "北上京城施展平生报复 (Go north to Beijing to fulfill the dream)", "南京市长江大桥位于南京 (The Nanjing Yantze River bridge is located in Nanjing)". Different colors represent attention weights in different heads and darkness represents weight.

hyper-parameters in pre-training. The optimizer is Adam (Kingma and Ba, 2014). To enhance efficiency, we use mixed precision for all the models. Training is carried out on Nvidia V-100. The numbers of GPUs used for training are from 32 to 64, depending on the model sizes.

Table 8: Hyper-parameters for pre-trained AMBERT.

Hyperparam	Chinese AMBERT	English AMBERT
Number of Layers l	12	12
Hidden Size d	768	768
Sequence Lengh n	512	512
FFN Inner Hidden Size	3072	3072
Attention Heads	12	12
Attention Head Size	64	64
Dropout	0.1	0.1
Attention Dropout	0.1	0.1

Learning Rate Decay	Linear	Linear
Adam ϵ	1e-6	1e-6
Adam β_1	0.9	0.9
Adam β_2	0.999	0.999

C.2 Hyper-parameters in Fine-tuning

For the Chinese tasks, since all the original papers do not report detailed hyper-parameters in fine-tuning of the baseline models, we uniformly use the same hyper-parameters as shown in Table 11 except training epoch, because AMBERT and AMBERT-Combo have more parameters and need more training to get converged. We choose the training epochs for all models when the performances on development sets stop to improve. Table 11 also shows all the hyper-parameters in fine-tuning of the English models. We adopt the best hyper-parameters in the original papers for the baselines. Moreover, for AMBERT‡, we also tune learning rate ([1e-5, 2e-5, 3e-5]) and batch size ([16, 32]) for GLUE with the same method in RoBERTa (Liu et al., 2019).

D Data Augmentation

To enhance the performance, we conduct data augmentation for the three Chinese classification tasks of TNEWS, CSL, and CLUEWSC2020. In TNEWS, we use both keywords and titles. In CSL, we concatenate keywords with a special token "_". In CLUEWSC2020, we duplicate a few instances having pronouns in the training data such as "她 (she)".

E Regularization in Fine-tuning

Table 9 shows the results of using different values as regularization coefficients in fine-tuning on the development sets of CLUE, GLUE and RACE. It appears that for most tasks the use of regularization

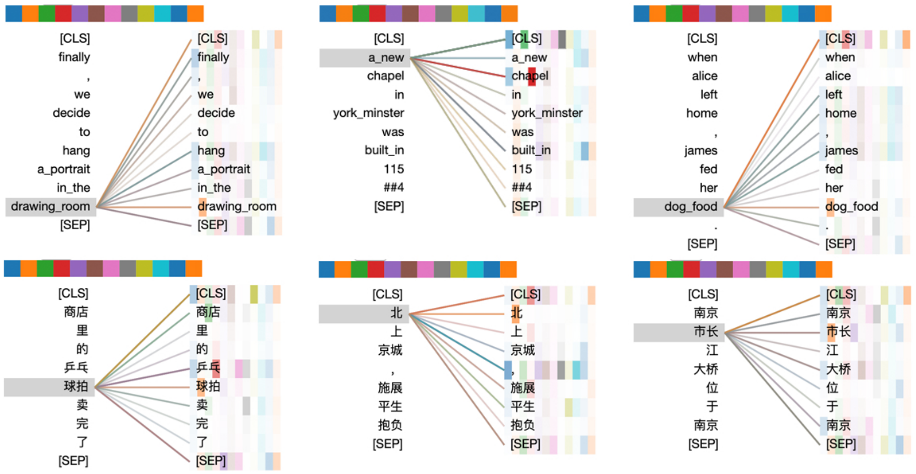

Figure 5: Attention maps of first layers of coarse-grained BERT models for English and Chinese sentences. Note that tokenizations may have errors.

Table 9: Performances on the development sets of CLUE, GLUE and RACE with different regularization coefficients in fine-tuning. CN-Models and EN-Models stand for Chinese and English pre-trained models respectively. CoLA uses Matthew's Corr. The other metrics are accuracies.

CN-Models	λ	TNEWS	IFLYTEK	CLUEWSC2020	AFQMC	CSL	CMNLI	ChID	C^3	-

Avg.	-	-	13.1

is necessary. For simplicity, we did not use the best value of coefficient for each task and instead we adopt 0.0 for RACE and 1.0 for the other tasks.

F Case study

We also qualitatively study the results of BERT and AMBERT, and find that they support our claims (cf., Section 1) very well. Here, we give some random examples from the entailment tasks (QNLI and CMNLI) in Table 12. One can have the following observations. 1) The fine-grained models (e.g., Our BERT word) cannot effectively use complete lexical units such as “Doctor Who” and “打死” (sentence pairs 1 and 5), which may result in incorrect predictions. 2) The coarse-grained models (e.g., Our BERT phrase), on the other hand, cannot effectively deal with incorrect tokenizations, for example, “the blind” and “格式” (sentence pairs 2 and 6). 3) AMBERT is able to make effective use of complete lexical units such as “sister station” in sentence pair 4 and “员工/ 工人” in sentence pair 7, and robust to incorrect tokenizations, such as “used to” in sentence pair 3. 4) AMBERT can in general make more accurate decisions on difficult sentence pairs with both fine-grained and coarse-grained tokenization results.

Multimodal Incremental Transformer with Visual Grounding for Visual Dialogue Generation

Feilong Chen, Fandong Meng, Xiuyi Chen, Peng Li, Jie Zhou
Pattern Recognition Center, WeChat AI, Tencent Inc, Beijing, China
{ivess.chan,hugheren.chan}@gmail.com
{fandongmeng,patrickpli,withtomzhou}@tencent.com

Abstract

Visual dialogue is a challenging task since it needs to answer a series of coherent questions on the basis of understanding the visual environment. Previous studies focus on the implicit exploration of multimodal co-reference by implicitly attending to spatial image features or object-level image features but neglect the importance of locating the objects explicitly in the visual content, which is associated with entities in the textual content. Therefore, in this paper we propose a **M**ultimodal **I**ncremental **T**ransformer with **V**isual **G**rounding, named MITVG, which consists of two key parts: visual grounding and multimodal incremental transformer. Visual grounding aims to explicitly locate related objects in the image guided by textual entities, which helps the model exclude the visual content that does not need attention. On the basis of visual grounding, the multimodal incremental transformer encodes the multi-turn dialogue history combined with visual scene step by step according to the order of the dialogue and then generates a contextually and visually coherent response. Experimental results on the VisDial v0.9 and v1.0 datasets demonstrate the superiority of the proposed model, which achieves comparable performance.

1 Introduction

Recently, there is increasing interest in vision-language tasks, such as image caption (Xu et al., 2015; Anderson et al., 2016, 2018; Cornia et al., 2020) and visual question answering (Ren et al., 2015a; Gao et al., 2015; Lu et al., 2016; Anderson et al., 2018). In the real world, our conversations (Chen et al., 2020b, 2019) usually have multiple turns. As an extension of conventional single-turn visual question answering, Das et al. (2017) introduce a multi-turn visual question answering task named visual dialogue, which aims to explore the ability of an AI agent to hold a meaningful multi-turn dialogue with humans in natural language about visual content.

Caption: there is a frisbee team with their coach taking a team photo

Q1: how many people ?	A1: 7 people
Q2: is anyone holding a frisbee ?	A2: yes
Q3: is the coach on the right ?	A3: yes, on the far right
Q4: are they wearing matching uniforms ?	A4: all except the coach

Figure 1: An example of visual dialogue. The color in text background corresponds to the same color box in the image, which indicates the same entity. Our model firstly associates textual entities with objects explicitly and then gives contextually and visually coherent answers to contextual questions.

Visual dialogue (Agarwal et al., 2020; Wang et al., 2020; Qi et al., 2020; Murahari et al., 2020) requires agents to give a response on the basis of understanding both visual and textual content. One of the key challenges in visual dialogue is how to solve multimodal co-reference (Das et al., 2017; Kottur et al., 2018). Therefore, some fusion-based models (Das et al., 2017) are proposed to fuse spatial image features and textual features in order to obtain a joint representation. Then attention-based models (Lu et al., 2017; Wu et al., 2018; Kottur et al., 2018) are proposed to dynamically attend to spatial image features in order to find related visual content. Furthermore, models based on object-level image features (Niu et al., 2019; Gan et al., 2019; Chen et al., 2020a; Jiang et al., 2020a; Nguyen

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 436–446
August 1–6, 2021.

et al., 2020; Jiang et al., 2020b) are proposed to effectively leverage the visual content for multimodal co-reference. However, as implicit exploration of multimodal co-reference, these methods implicitly attend to spatial or object-level image features, which is trained with the whole model and is inevitably distracted by unnecessary visual content. Intuitively, specific mapping of objects and textual entities can reduce the noise of attention. As shown in Figure 1, the related objects can help the agent to understand the entities (e.g., Q1: "*people*", Q2: "*frisbee*", Q3: "*coach*") for the generation of correct answers. Then when it answers the question Q4 "*are they wearing matching uniforms ?*", the agent has already comprehended "*people*" and "*coach*" from the previous conversation. On this basis, it can learn the entity "*uniforms*" with the corresponding object in the image, and generate the answer "*all except the coach*". To this end, we need to 1) explicitly locate related objects guided by textual entities to exclude undesired visual content, and 2) incrementally model the multi-turn structure of the dialogue to develop a unified representation combining multi-turn utterances with the corresponding related objects. However, previous work overlooks these two important aspects.

In this paper, we thus propose a novel and effective **M**ultimodal **I**ncremental **T**ransformer with **V**isual **G**rounding, named MITVG, which contains two key parts: visual grounding and multimodal incremental transformer. Visual grounding aims to establish specific mapping of objects and textual entities by explicitly locating related objects in the image with the textual entities. By doing so, our model can exclude undesired visual content and reduce attention noise. On the basis of visual grounding, the multimodal incremental transformer is used to model the multi-turn dialogue history combined with the specific visual content to generate visually and contextually coherent responses. As an encoder-decoder framework, MITVG contains a Multimodal Incremental Transformer Encoder (MITE) and a Gated Cross-Attention Decoder (GCAD).

We test the effectiveness of our proposed model on large-scale datasets: VisDial v0.9 and v1.0 (Das et al., 2017). Both automatic and manual evaluations show that our model substantially outperforms the competitive baselines and achieves the new state-of-the-art results on substantial metrics. Our main contributions are as follows:

- To the best of our knowledge, we are the first to leverage visual grounding to explicitly locate related objects in the image guided by textual entities for visual dialogue.
- We propose a novel multimodal incremental transformer to encode the multi-turn dialogue history step by step combined with the visual content and then generate a contextually and visually coherent response.
- We achieve comparable performance on VisDial v0.9 and v1.0 datasets.

2 Approach

2.1 Overview

In this section, we formally describe the visual dialogue task and then proceed to our proposed **M**ultimodal **I**ncremental **T**ransformer with **V**isual **G**rounding (MITVG).

Following Das et al.(2017), a visual dialogue agent is given three inputs, i.e., an image I, a dialogue history (the caption and question-answer pairs) till round $t-1$: $H = (\underbrace{Cap}_{H_0}, \underbrace{(Q_1, A_1)}_{H_1}, \cdots, \underbrace{(Q_{t-1}, A_{t-1})}_{H_{t-1}})$ and the current question Q_t at round t, where Cap is the caption describing the image taken as H_0 and $H_1, \ldots, H_{t-1}$ are concatenations of question-answer pairs. The goal of the visual dialogue agent is to generate a response (or answer) A_t to the question Q_t. Cap, Q_* and A_* are sentences.

Figure 2 shows the framework of MITVG, which aims to explicitly model multi-turn dialogue history step by step based on the explicit modeling relationship between multiple modalities. MITVG firstly locates related objects in the image explicitly guided by the textual entities via visual grounding, then encodes multi-turn dialogue history in the order of the dialogue utterance based on visual grounding via Multimodal Incremental Encoder (MITE), and finally utilizes the outputs of both encoder and visual grounding to generate the response word by word via Gated Cross-Attention Decoder (GCAD).

2.2 Input Representation

Before describing our method, we introduce the input representation.

Image Features. We use a pre-trained Faster R-CNN model (Ren et al., 2015b) to extract object-

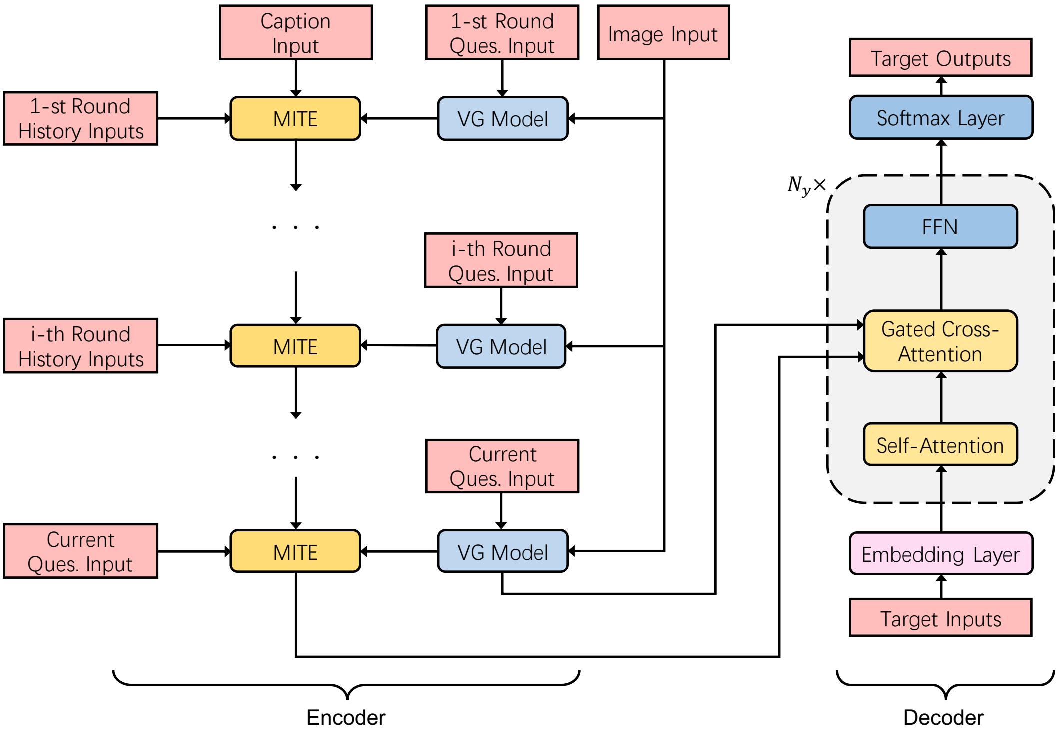

Figure 2: The framework of **M**ultimodal **I**ncremental **T**ransformer with **V**isual **G**rounding (MITVG). "VG Model" indicates visual grounding model (Yang et al., 2019b) (Details are described in Sec. 2.3). "MITE" denotes the multimodal incremental transformer encoder (Details are described in Sec. 2.4.1). MITVG firstly uses the VG model to explicitly model the relationship between the textual content and the visual content, and encodes multi-turn dialogue history in the order of the dialogue based on visual grounding, and finally utilizes the outputs of both encoder and visual grounding to generate the response word by word in the decoding process.

level image features. Specifically, the image features v for an image I are represented by:

$$v = \mathrm{Faster\ R-CNN}(I) \in \mathbb{R}^{K\times V}, \quad (1)$$

where K denotes the total number of the detected objects per image and V denotes the dimension of features for each object.

Language Features. The current (at the t-th round) L-word question features are a sequence of M-dimension word embedding with positional encoding added (Vaswani et al., 2017), as follows:

$$q_t = [s_{t,1}, s_{t,2}, \ldots, s_{t,L}] \in \mathbb{R}^{L\times M}, \quad (2)$$

$$s_{t,j} = w_j + PE(j), \quad (3)$$

where w_j is the word embedding of the j-th word in the question Q_t, and $PE(\cdot)$ denotes positional encoding function (Vaswani et al., 2017). For the dialogue history $H = \{H_0, H_1, \ldots, H_{t-1}\}$ and the answer A_t, the dialogue history features $u = \{u_0, u_1, \ldots, u_{t-1}\}$ and the answer features a_t are obtained in the same way as the question Q_t.

2.3 Visual Grounding

To exclude the needless visual content, we introduce visual grounding, which is defined to ground a natural language query (phrase or sentence) about an image onto a correct region of the image. First of all, we use NeuralCoref[1] for reference resolution. For example, when it processes the question Q4 "*are they wearing matching uniforms ?*" shown in Figure 1, NeuralCoref takes the question Q4 and its history as inputs, and then generates a new question "*are the people wearing matching uniforms ?*" as a new Q4. As shown in Figure 3 (a), visual grounding model (Yang et al., 2019b) takes the i-th question Q_i and the image I as inputs and generates initial visual grounding features, as follows:

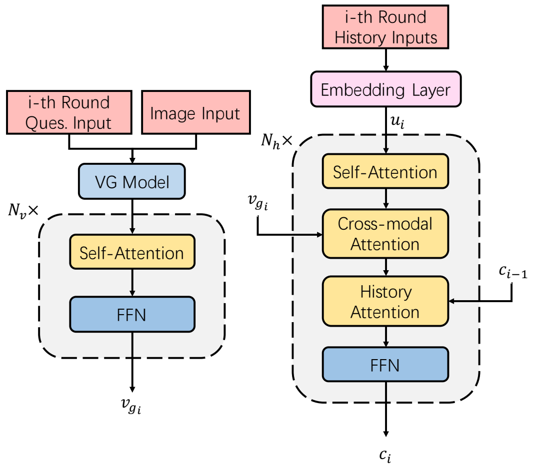
$$v_{g_i}^{(0)} = \mathrm{VGM}(Q_i, I), \quad (4)$$

where $\mathrm{VGM}(\cdot)$ denotes visual grounding model[2]. Then $v_{g_i}^{(0)}$ is sent to the multi-head self-attention

---

[1] Introduction and code of NeuralCoref are available at https://github.com/huggingface/neuralcoref. NeuralCoref is only used for visual grounding.

[2] Introduction and code are available at https://github.com/zyang-ur/onestage_grounding.



(a) (b)

Figure 3: Framework of (a) Visual Grounding and (b) Multimodal Incremental Transformer Encoder (MITE).

layer followed by a position wise feed-forward network (FFN) layer (stacked N_v times) to generate the i-th visual grounding features as follows[3]:

$$\hat{v}_{g_i}^{n} = \text{MultiHead}\left(v_{g_i}^{(n-1)}, v_{g_i}^{(n-1)}, v_{g_i}^{(n-1)}\right), \quad (5)$$

where $n = 1, \ldots, N_v$ and $\text{MultiHead}(\cdot)$ denotes the multi-head self-attention layer (Vaswani et al., 2017), then

$$v_{g_i}^{(n)} = \text{FFN}\left(\hat{v}_{g_i}^{n}\right), \quad (6)$$

where $n = 1, \ldots, N_v$ and $\text{FFN}(\cdot)$ denotes the position wise feed-forward networks (Vaswani et al., 2017). After N_v layers computation, we obtain the final visual grounding features v_{g_i} by:

$$v_{g_i} = v_{g_i}^{(N_v)}, \quad (7)$$

Actually, there are some questions that do not contain any entities in the visual dialogue, such as "*anything else ?*". For such questions, we use the features of the whole image instead, i.e. $v_{g_i} = v$.

2.4 Multimodal Incremental Transformer

Inspired by the idea of incremental transformer (Li et al., 2019) which is originally designed for the single-modal dialogue task, we make an extension and propose a multimodal incremental transformer, which is composed of a Multimodal Incremental Transformer Encoder (MITE) and a Gated Cross-Attention Decoder (GCAD). The MITE uses an incremental encoding scheme to encode multi-turn dialogue history with an understanding of the image. The GCAD leverages the outputs from both the encoder and visual grounding via the gated cross-attention layer to fuse the two modal information in order to generate a contextually and visually coherent response word by word.

2.4.1 MITE

To effectively encode multi-turn utterances grounded in visual content, we design the Multimodal Incremental Transformer Encoder (MITE). As shown in Figure 3 (b), at the i-th round, where $i = 1, 2, ..., t-1$, the MITE takes the visual grounding features v_{g_i}, the dialogue history features u_i and the context state c_{i-1} as inputs, and utilizes attention mechanism to incrementally build up the representation of the relevant dialogue history and the associated image regions, and then outputs the new context state c_i. This process can be stated recursively as follows:

$$c_i = \text{MITE}\left(v_{g_i}, u_i, c_{i-1}\right), \quad (8)$$

where $\text{MITE}(\cdot)$ denotes the encoding function, c_i denotes the context state after the dialogue history features u_i and the visual grounding features v_{g_i} being encoded, and c_0 is the dialogue history features u_0.

As shown in Figure 3 (b), we use a stack of N_h identical layers to encode v_{g_i}, u_i and c_{i-1}, and to generate c_i. Each layer consists of four sub-layers. **The first sub-layer** is a multi-head self-attention for the dialogue history:

$$\mathrm{A}^{(\mathrm{n})} = \text{MultiHead}\left(\mathrm{C}^{(n-1)}, \mathrm{C}^{(n-1)}, \mathrm{C}^{(n-1)}\right), \quad (9)$$

where $n = 1, \ldots, N_h$, $\mathrm{C}^{(n-1)}$ is the output of the last layer N_{n-1}, and $\mathrm{C}^{(0)}$ is the dialog history features u_i. **The second sub-layer** is a multi-head cross-modal attention:

$$\mathrm{B}^{(\mathrm{n})} = \text{MultiHead}\left(\mathrm{A}^{n}, v_{g_i}, v_{g_i}\right), \quad (10)$$

where v_{g_i} is the visual grounding features. **The third sub-layer** is a multi-head history attention:

$$\mathrm{F}^{(\mathrm{n})} = \text{MultiHead}\left(\mathrm{B}^{(n)}, \mathrm{c}_{i-1}, \mathrm{c}_{i-1}\right), \quad (11)$$

where c_{i-1} is the context state after the previous dialogue history features u_{i-1} being encoded. That's why we call this encoder "Multimodal Incremental Transformer". **The fourth sub-layer** is a position wise feed-forward network (FFN):

$$\mathrm{C}^{(\mathrm{n})} = \text{FFN}\left(\mathrm{F}^{(n)}\right). \quad (12)$$

---

[3] For simplicity, we omit the descriptions of layer normalization and residual connection.

We use c_i to denote the final representation at N_h-th layer:

$$c_i = \mathrm{C}^{(N_h)}. \tag{13}$$

The mulitmodal incremental transformer encoder at the current turn t, i.e., the bottom one in Figure 2, has the same structure as all the other MITEs but takes the visual grounding features v_{g_t}, the current question features q_t and the context state c_{t-1} as inputs and generates the final context state c_t.

2.4.2 GCAD

Motivated by the real-world human cognitive process, we design a Gated Cross-Attention Decoder (GCAD) shown in Figure 2, which takes the masked answer features $a_{<z}$ (where $z = 1, 2, ..., Z$ and Z is the length of the answer), encoder outputs c_t and visual grounding features v_{g_t} as inputs, and generates contextually and visually coherent responses grounded in an image. GCAD is composed of a stack of N_y identical layers, each of which has three sub-layers.

The first sub-layer is a multi-head self-attention as follows:

$$\mathrm{J}^{(n)} = \mathrm{MultiHead}\left(\mathrm{R}^{(n-1)}, \mathrm{R}^{(n-1)}, \mathrm{R}^{(n-1)}\right), \tag{14}$$

where $n = 1, \ldots, N_y$, $\mathrm{R}^{(n-1)}$ is the output of the previous layer, and $\mathrm{R}^{(0)}$ is the masked answer features $a_{<z}$.

The second sub-layer is a multi-head gated cross-modal attention layer (GCA) as shown in Figure 4, calculated as:

$$\mathrm{P}^{(n)} = \alpha^{(n)} \circ \mathrm{E}^{(n)} + \beta^{(n)} \circ \mathrm{G}^{(n)}, \tag{15}$$

where $n = 1, \ldots, N_y$, $\circ$ denotes Hadamard product, $\mathrm{E}^{(n)}$ and $\mathrm{G}^{(n)}$ denote the outputs of two cross-attention functions, computed as follows:

$$\begin{aligned} \mathrm{E}^{(n)} &= \mathrm{MultiHead}\left(\mathrm{J}^{(n)}, c_t, c_t\right), & (16) \\ \mathrm{G}^{(n)} &= \mathrm{MultiHead}\left(\mathrm{J}^{(n)}, v_{g_t}, v_{g_t}\right), & (17) \end{aligned}$$

where $\alpha^{(n)}$, $\beta^{(n)}$ are two gates[4]:

$$\begin{aligned} \alpha^{(n)} &= \sigma\left(W_E[\mathrm{J}^{(n)}, E^{(n)}] + b_E\right), & (18) \\ \beta^{(n)} &= \sigma\left(W_G[\mathrm{J}^{(n)}, G^{(n)}] + b_G\right), & (19) \end{aligned}$$

where σ denotes sigmoid function, W_E, W_G, b_E, b_G are learnable parameters, and $[\cdot, \cdot]$ indicates concatenation.

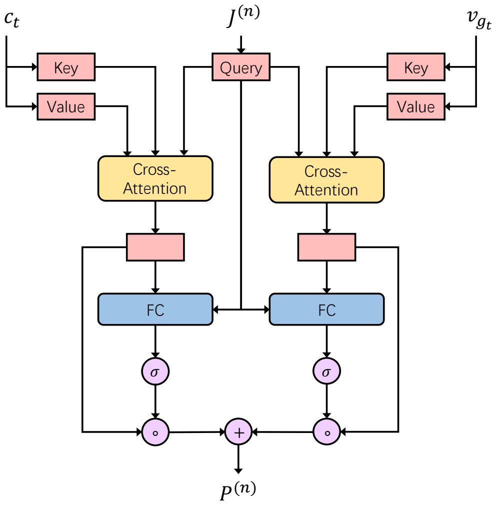


Figure 4: Framework of Gated Cross-Attention (GCA) in the Deocer.

The third sub-layer is a position wise feed-forward network (FFN):

$$\mathrm{R}^{(n)} = \mathrm{FFN}\left(\mathrm{P}^{(n)}\right). \tag{20}$$

We use r_z to denote the final representation at N_y-th layer:

$$r_z = \mathrm{R}^{(N_y)}. \tag{21}$$

Finally, we use softmax to get the word probabilities $\hat{a}_z$:

$$\hat{a}_z = \mathrm{softmax}(r_z). \tag{22}$$

3 Experiments

3.1 Datasets

We conduct experiments on the VisDial v0.9 and v1.0 datasets (Das et al., 2017) to verify our approach. VisDial v0.9 contains 83k dialogs on COCO-train (Lu et al., 2017) and 40k dialogs on COCO-val images as test set, for a total of 1.23M dialog question-answer pairs. VisDial v1.0 dateset is an extension of VisDial v0.9 dateset with additional 10k COCO-like images from Flickr. VisDial v1.0 dateset contains 123k, 2k and 8k images as train, validation and test splits, respectively.

3.2 Implementation and Evaluation

Implementation Details. Following previous work (Das et al., 2017), in order to represent words we firstly lowercase all the texts and convert digits to words, and then remove contractions before tokenization. The captions, questions and answers are further truncated to ensure that they are not longer than 40, 20 and 20 tokens, respectively. We construct the vocabulary of tokens that appear at least

---

Table 2: Performance on VisDial val v1.0 (Das et al., 2017). ‡ denotes that all the models are re-implemented by Gan et al. (2019). Our MITVG outperforms previous work and achieves comparable performance.

5 times in the training split. To represent image regions, we use Faster R-CNN (Ren et al., 2015b) with ResNet-101 (He et al., 2016) finetuned on the Visual Genome dataset (Krishna et al., 2017), thus obtaining a 2048-dimensional feature vector for each region. The layers of our encoder, decoder and visual grounding module are all set to 3. The number of attention heads in multi-head attention is 8 and the filter size is 2048. The word embedding is shared by the history, questions and responses. The dimension of word embedding is set to 512 empirically. We use Adam (Kingma and Ba, 2014) for optimization, following the learning rate scheduling strategy of Vaswani et al. (2017). Our model is implemented using PyTorch v1.0, Python v3.6, and provides out of the box support with CUDA 9 and CuDNN 7. We train our model on TITAN XP with 8 GPUs. For each epoch, we spend about 9,000 seconds on training the model. The total parameters are about 56.79M.

Before we train our model, we use three external tools for image features extracting, reference resolution and visual grounding.

Image Features Extracting We extract image features of VisDial images, using a Faster-RCNN (Ren et al., 2015b) with ResNet-101 (He et al., 2016) pre-trained on Visual Genome (Krishna et al., 2017), introduction and code from https://github.com/peteanderson80/bottom-up-attention.

Reference Resolution we use NeuralCoref v4.0 for reference resolution, which is developed by huggingface. Introduction and code are available at https://github.com/huggingface/neuralcoref.

Visual Grounding We use One-Stage Visual Grounding Model (Yang et al., 2019b) to obtain the visual grounding features. Introduction and code are available at https://github.com/zyang-ur/onestage_grounding.

Automatic Evaluation. We use a retrieval setting to evaluate individual responses at each round of a dialogue, following Das et al. (2017). Specifically, at test time, apart from the image, ground truth dialogue history and the question, a list of 100-candidate answers is also given. The model is evaluated on retrieval metrics: (1) rank of human response (Mean, the lower the better), (2) existence of the human response in $top-k$ ranked responses, i.e., R@k (3) mean reciprocal rank (MRR) of the human response (the higher the better) and (4) normalized discounted cumulative gain (NDCG) for VisDial v1.0 (the higher the better). During evaluation, we use the log-likelihood scores to rank candidate answers.

Human Evaluation. We randomly extract 100 samples for human evaluation according to Wu et al. (2018), and then ask 3 human subjects to guess whether the last response in the dialogue is human-generated or machine-generated. If at least 2 of them agree it is generated by a human, we think it passes the Truing Test (M1). In addition, we record the percentage of responses that are evaluated better than or equal to human responses (M2), according to the human subjects' evaluation.

3.3 Main Results

We compare our proposed model to the state-of-the-art *generative models* developed in previous work. Current encoder-decoder based generative models can be divided into tree facets. (1) Fusion-based models: LF (Das et al., 2017) and HREA (Das et al., 2017) directly encode the multimodal inputs and decode the answer. (2) Attention-based models: HCIAE (Lu et al., 2017), CoAtt (Wu et al., 2018), Primary (Guo et al., 2019a), ReDAN (Gan et al., 2019), DVAN (Guo et al., 2019b) and DMRM (Chen et al., 2020a), DAM, LTMI, KBGN. (3) Visual co-reference resolution models: CorefNMN (Kottur et al., 2018), RvA (Niu et al., 2019). (4) The pretraining model: VDBERT (Wang et al., 2020).

As shown in Table 1 and Table 2, our MITVG, which explicitly locates related objects guided by the textual entities and implements a multimodal incremental transformer to incrementally build the representation of the dialogue history and the image, achieves comparable performance on the VisDial v0.9 and v1.0 datasets. Specifically, our model outperforms previous work by a significant margin both on the VisDial v0.9 dataset (0.87 on MRR, 0.31 on R@1, 1.17 on R@5, 0.75 on R10) and the VisDial v1.0 dataset (0.98 on MRR, 0.76 on R@1, 1.23 on R@5, 1.28 on R10, 0.82 on Mean, and 1.00 on NDCG). The improvement of R@10 is the largest and our method also gains a large increase on MRR and R@1 due to the explicit modeling of multiple modalities (Seeing Sec 3.5 for further quantitative analysis).

	DMRM	MITVG
Method 1 (M1)	0.62	**0.76**
Method 2 (M2)	0.59	**0.70**

Table 3: Human evaluation on 100 sampled responses on VisDial val v1.0. M1: percentage of responses pass the Turing Test. M2: percentage of responses evaluated better than or equal to human responses.

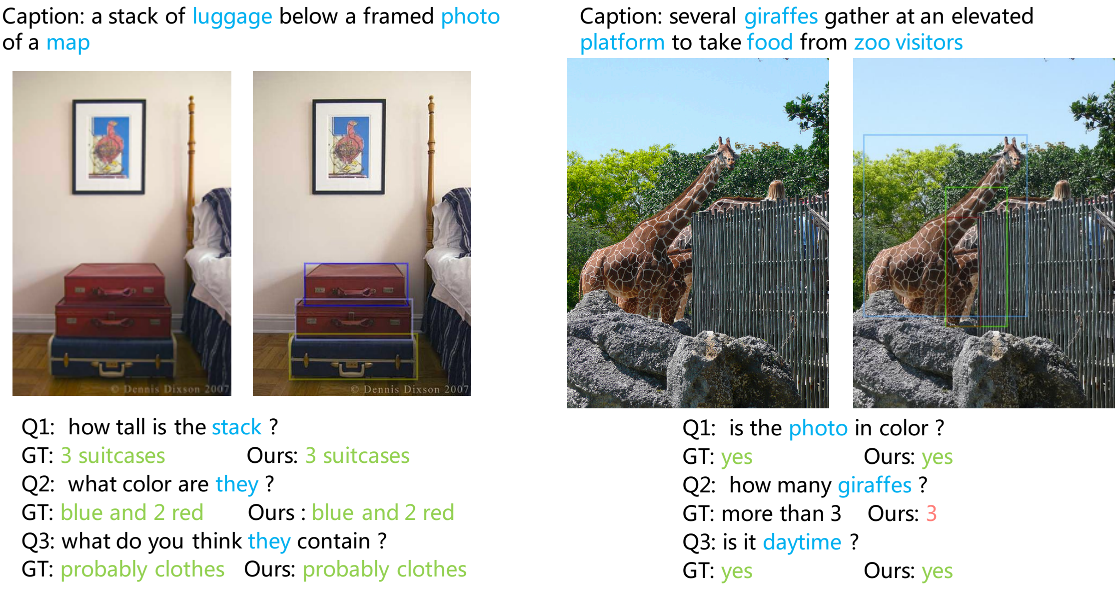
As shown in Table 3, we conduct human study to further prove the effectiveness of our model. Our model achieves the highest scores both on the metric M1 (0.76) and M2 (0.70) compared with the previous model, DMRM (Chen et al., 2020a). These results show that our model can generate a better contextually and visually coherent response.

3.4 Ablation Study

We also conduct an ablation study to illustrate the validity of our proposed Multimodal Incremental Transformer with Visual Grounding. The results are shown in Table 4.

We implement Multimodal Incremental Transformer without Visual Grounding ('MITVG w/o VG') to verify the validity of visual grounding. As shown in Table 4, comparing 'MITVG w/o VG' with MITVG, we find the metrics decrease obviously (0.46 on MRR, 0.60 on R@1, 0.68 on R@5, 0.46 on R@10 and 0.59 on Mean) if visual grounding is deleted from MITVG. This observation demonstrates the validity of visual grounding.

To verify the effectiveness of the incremental transformer architecture, we implement a Multimodal Incremental LSTM without Visual Grounding ('MI-LSTM w/o VG'). A 3-layer bidirectional LSTM (Schuster and Paliwal, 1997) with multi-head attention and a 1-layer LSTM with GCA are applied for encoder and decoder, respectively. All the LSTM hidden state size is 512. Results in Table 4 demonstrate the effectiveness of our incremental transformer architecture (compare 'MITVG w/o VG' with 'MI-LSTM w/o VG'). Results from the comparison between 'MITVG w/o VG' and DMRM (Chen et al., 2020a) also show the validity of our incremental transformer to some extent.



(a) (b)

Figure 5: Case study. The text marked in blue indicates the dialogue topic. The answers marked in green and red indicate the right and wrong answers, respectively. Our MITVG often generates right responses (marked in green) in keeping with human answers.

Model	MRR	R@1	R@5	R@10	Mean
DMRM	50.16	40.15	60.02	67.21	15.19
MITVG	**51.14**	**41.03**	**61.25**	**68.49**	**14.37**
MITVG w/o VG	50.68	40.43	60.57	68.03	14.96
MI-LSTM w/o VG	50.02	39.85	59.86	67.16	15.78

Table 4: Ablation study of our proposed model on VisDial val v1.0. "MI-LISM" indicates Multimodal Incremental LSTM. "VG" indicates visual grounding.

	Train	Validation	Test
VisDial v0.9	2.04	1.95	-
VisDial v1.0	2.05	1.93	1.93

Table 5: Average number of the grounded objects in each question.

3.5 Case Study

As shown in Table 5, we calculate the average number of the objects associated with entities in each question for assistant analysis. As shown in Figure 5 (a), owing to the explicit understanding of visual content via visual grounding and the multimodal incremental transformer architecture, our MITVG generates responses in keeping with human answers. For example, while answering the question Q1 '*'how tall is the stack ?*" and Q2 "*what color are they ?*", our model grounds the three suitcases accurately via visual grounding, thus giving the accurate responses "*3 suitcases*" and "*blue and 2 red*". However, as shown in Figure 5 (b), for questions Q2, MITVG gives a wrong answer because it focuses on wrong number of objects in the question by visual grounding.

4 Related Work

Visual Dialogue. Our work touches two branches of the research in visual dialogue. One is how to leverage image features. Niu et al. (2019) utilize object-level image features as visual attention and refine it by recursively reviewing the dialog history. Gan et al. (2019) and Chen et al. (2020a) regard the object-level image features as visual memory to infer answers progressively through multiple steps. The other is how to model dialogue history. Yang et al. (2019a) propose a new training paradigm inspired by actor-critic policy gradient (Sutton et al., 1999) for history-advantage training. Guo et al. (2020) represent each turn dialogue history with visual content as a node in a context-aware graph neural network. Park et al. (2020) refine history information from both topic aggregation and context matching. Different from these approaches, we explicitly establish specific mapping of objects and textual entities to exclude undesired visual content via visual grounding, and model multi-turn structure of the dialogue based on visual grounding to develop a unified representation combining multi-turn utterances along with the relevant objects.

Incremental Structures. There are some successes on introducing the incremental structure into tasks related to dialog systems (Zilka and Jurcicek, 2015; Coman et al., 2019; Li et al., 2019; Das et al., 2017). In particular, Coman et al. (2019) propose an incremental dialog state tracker which is updated on a token basis from incremental transcriptions. Li et al. (2019) devise an incremental transformer to encode multi-turn utterances along with knowledge in related documents for document grounded conversations. Das et al. (2017) propose a dialog-RNN to produce an encoding for this round and a state for next round. Our model is different from these approaches mainly in two aspects: 1) we explicitly model the relationship between modalities, i.e., textual utterance and image objects, in visual dialogue through visual grounding; 2) based on the explicit association between modalities, our model incrementally encodes the dialogue history and the image with well-designed incremental multimodal architecture to sufficiently understand the dialogue content, thus generating better responses.

5 Conclusion

We propose a novel Multimodal Incremental Transformer with Visual Grounding for visual dialogue, named MITVG, which consists of two key parts: visual grounding and multimodal incremental transformer. Visual grounding aims to explicitly model the relationship between multiple modalities. Based on visual grounding, multimodal incremental transformer aims to explicitly model multi-turn dialogue history in the order of the dialogue. Experiments on the VisDial v0.9 and v1.0 datasets show that our model achieves comparable performance.

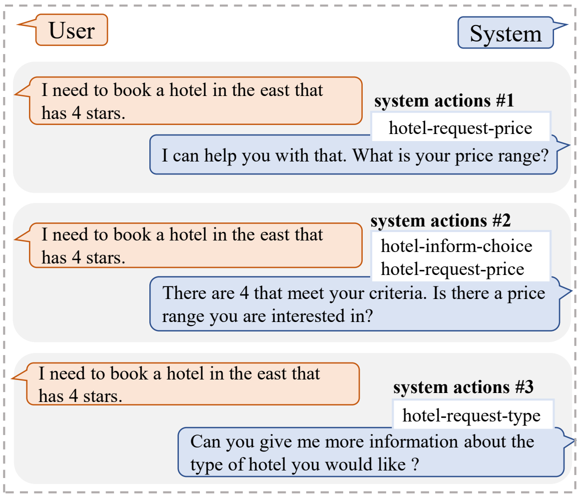
Abstract

Dialogue policy learning, a subtask that determines the content of system response generation and then the degree of task completion, is essential for task-oriented dialogue systems. However, the unbalanced distribution of system actions in dialogue datasets often causes difficulty in learning to generate desired actions and responses. In this paper, we propose a retrieve-and-memorize framework to enhance the learning of system actions. Specially, we first design a neural context-aware retrieval module to retrieve multiple candidate system actions from the training set given a dialogue context. Then, we propose a memory-augmented multi-decoder network to generate the system actions conditioned on the candidate actions, which allows the network to adaptively select key information in the candidate actions and ignore noises. We conduct experiments on the large-scale multi-domain task-oriented dialogue dataset MultiWOZ 2.0 and MultiWOZ 2.1. Experimental results show that our method achieves competitive performance among several state-of-the-art models in the context-to-response generation task.

1 Introduction

Task-oriented dialogue systems communicate with users through natural language conversations to accomplish a wide range of tasks such as restaurant and flight bookings. Recent years have seen a rapid growth of interest in building task-oriented dialogue systems (Budzianowski et al., 2018). Such systems are usually decomposed into several subtasks, including natural language understanding (Gupta et al., 2018), dialogue state tracking (Zhong et al., 2018), system actions (dialogue policy) prediction, and response generation (Wen et al., 2015; Chen et al., 2019; Zhao et al., 2019), where system actions can be viewed as a semantic plan of response generation. One of the main challenges for context-to-response generation in task-oriented dialogue systems comes from the intrinsic one-to-many property in conversations. As shown in Figure 1, there can be multiple valid system actions for the same dialogue context, which means that multiple satisfactory system responses can be generated correspondingly. However, in most collected dialogue datasets, each dialogue context has only one reference, which leads to an unbalanced distribution of system actions and responses in multi-domain dialogue datasets (Zhang et al., 2020). Models trained on such unbalanced datasets tend to overfit high-frequency system actions and underfit low-frequency ones.



I need to book a hotel in the east that has 4 stars.

I can help you with that. What is your price range?

I need to book a hotel in the east that has 4 stars.

There are 4 that meet your criteria. Is there a price range you are interested in?

I need to book a hotel in the east that has 4 stars.

Can you give me more information about the type of hotel you would like ?

Figure 1: An example of the one-to-many property,where there are multiple appropriate system actions and responses given the same dialogue context.

One line of work focuses on the representation of system actions, which alleviates the unbalanced problem to a certain extent. Chen et al. (2019) reconstruct system actions into a compact graph representation. Zhao et al. (2019) treat system actions as latent variables and use reinforcement learning

to optimize them. Wang et al. (2020b) model system actions prediction as a sequence generation problem by treating system actions as a sequence of tokens. On the other hand, Zhang et al. (2020) explicitly modeling the one-to-many property to enrich system action diversity through a rule-based multi-action data augmentation. Specifically, they treat system actions that follow the same dialogue state as alternative valid actions and train them together with the reference system action. However, their data augmentation framework has two shortcomings. First, it enforces a rigid mapping between dialogue state and system actions. Dialogue state, which consists of information such as belief state and user actions, is not flexible enough to represent the whole dialogue context and thus limits the diversity of the mapped system actions. Second, they treat the mapped system actions as gold references during training which may force the model to fit noise in the mapped system actions and ultimately hinder the quality of the generated system actions.

To address the above limitations, we propose to model the one-to-many property more effectively by retrieving multiple candidate system actions and selectively taking the candidates into consideration when generating system action. We design a retrieve-and-memorize framework that consists of a context-aware neural retrieval module (CARM) and a memory-augmented multi-decoder network (MAMD). Specifically, the context-aware retrieval module uses a pre-trained language model to convert the dialogue history as well as belief state into a context representation of each sample. Multiple candidate system actions are retrieved based on the distances between the context vector and the representations of other samples in the latent space. These retrieved candidate actions are more diverse and consistent with the dialogue context since they are obtained based on a more holistic representation. Instead of treating the candidates impartially with the gold references, we encode them into a memory bank and the memory-augmented multi-decoder network can dynamically attend to the memory bank during system actions generation. Additionally, we employ a random sampling mechanism where during training, the memory bank is filled with randomly sampled system actions with a probability, which allows the model to learn to distinguish the quality of the candidates and adaptively adjust its dependence on the candidate actions.

We evaluate our model on MultiWOZ (Budzianowski et al., 2018), a large-scale multi-domain dataset for task-oriented dialogue systems. Extensive experiments and analyses are conducted to demonstrate the effectiveness of our model, and the results show that it significantly outperforms the baseline model. Our main contributions are summarized as follows:

- We propose a context-aware retrieval module that can retrieve multiple appropriate system actions given a dialogue context.
- We propose a memory-augmented multi-decoder network that can generate system actions based on multiple candidate actions.
- Our model outperforms several state-of-the-art baselines on a large-scale multi-domain dataset for task-oriented dialogue systems.

2 Related Work

One line of research focuses on the representation of system actions. A typical approach to encoding system actions is by concatenating the one-hot representation at each level of actions into a flat vector (Wen et al., 2015; Budzianowski et al., 2018). Such sparse representations make the learning of system actions difficult. To overcome the sparsity issue, Chen et al. (2019) compact the one-hot vector representation based on the intrinsic hierarchical structures of system actions, and apply hierarchical disentangled self-attention to generate system response. Zhao et al. (2019) treat system actions as latent variables and use reinforced learning (He et al., 2016) to optimize them. Recently, Wang et al. (2020b) propose a co-generation framework to generate system actions and response sequentially, which achieves a new state of the art in the context-to-response task. Our proposed framework adopts the idea of modeling belief state and system actions (Wang et al., 2020b; Liang et al., 2020) as sequences and generates the belief state, system action, and response sequentially to make better use of the intermediate supervision.

Another line of research uses data augmentation to expand the training data. Gao et al. (2020) use the paraphrase technique (Li et al., 2019; Wang et al., 2019) to generate user utterances and then expand the training set with the augmented user utterances. Zhang et al. (2020) augment system actions with a mapped dialogue state, which consists of belief state, user action, turn domain, and database search result. Such mapping is rule-based and requires user actions for the construction of dialogue state, which takes extra annotations. Both of the above approaches treat the augmented samples as equivalent to the gold ones, which may force the model to fit noises in the augmented data. In this paper, we focus on a better neural retrieval method for the alternative system actions, and instead of directly training on the augmented actions, we encode them in a memory bank as auxiliary information.

3 Methodology

To frame the problem of dialogue policy learning, we use $X_t = \{U_1, .., U_{t-1}, R_{t-1}, U_t\}$ to denote the dialogue history at turn t of a multi-turn conversation, where $U_i = u_1u_2, ...u_{m_i}$ and $R_i = r_1r_2...r_{n_i}$ are the i-th user utterance and system response, respectively. Following previous works (Zhang et al., 2020; Liang et al., 2020), we convert the belief state and system actions from a list of triples to sequences. For example, the belief state "*restaurant-food-Chinese,restaurant-price-expansive*" is converted to "*restaurant [food] Chinese [price] expansive*", and the system actions "*restaurant-inform-price,restaurant-inform-phone*" are converted to "*restaurant [inform] price phone*". We use $B_t = b_1b_2...b_p$ and $A_t = a_1a_2...a_q$ to represent the current belief state and system action, respectively. Our goal is to generate system actions A_t and system response R_t of turn t based on the dialogue context X_t and belief state B_t.

We employ a retrieve-and-memorize framework to generate the system response. First, we use a context-aware retrieve module to retrieve multiple proper candidate system actions from the training set. Then, we encode the candidate actions into a memory bank and propose a memory-augmented module to enhance the action generation.

3.1 Context-Aware Retrieval Module

In order to retrieve alternative system actions that are more comprehensive and context-aware, we utilize the powerful pre-trained language model BERT (Devlin et al., 2019) to obtain distributed representations of the dialogue context. We search in the training corpus for system actions with similar distributed representations and retrieve them as alternative candidate actions. Concretely, we combine the dialogue history $X_t = \{U_1, .., U_{t-1}, R_{t-1}, U_t\}$ and belief state B_t as dialogue context and feed the concatenated dialogue context into a pre-trained BERT encoder:

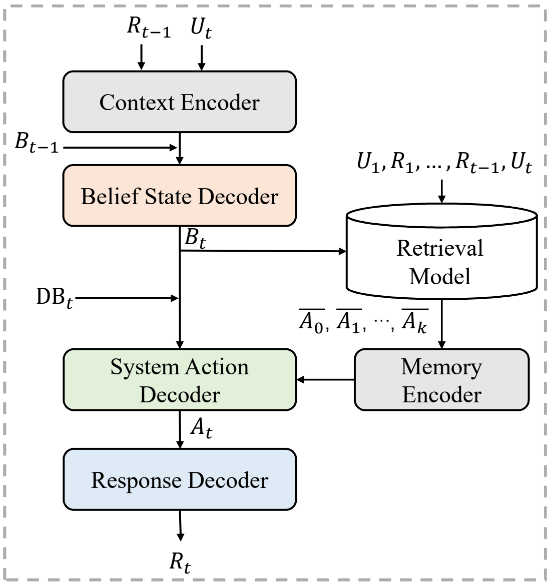

Figure 2: An overview of the proposed model.

$$H = \text{BERT}([CLS] \oplus B_t \oplus [SEP] \oplus X_t), \quad (1)$$

where $\oplus$ is the concatenation operator, $[CLS]$ is a special token that precedes every input sequence of BERT, and $[SEP]$ is a special token used to separate different parts of the input sequence. The BERT model encodes the input dialogue context into a sequence of hidden states $H = \{h^{CLS}, h^1, ..., h^L\}$. We use h^{CLS} to represent the distributed representation of dialogue context, since h^{CLS} is expected to capture the information of the whole sequence. Then we use L_2 distance to measure the similarity between the distributed representations of different dialog contexts:

$$L_2(h_i^{CLS}, h_j^{CLS}) = ||h_i^{CLS} - h_j^{CLS}||_2. \quad (2)$$

Based on the L_2 distance, k most similar dialogue contexts are selected from the training set, and the corresponding system actions constitute a candidate actions set $\{\bar{A}_1, \bar{A}_2, ..., \bar{A}_k\}$.

Pre-training Task Directly applying h^{CLS} from BERT without fine-tuning or further pre-training may not result in desired dialogue context representations that correlate well with system actions. A good dialogue contextual representation should satisfy the property that dialogue contexts with similar semantics are close to each other in the representation space. Therefore, we further pre-train the

BERT model with an actions prediction task:

$$p(y|B_t, X_t) = \text{classifier}(h^{CLS}), \tag{3}$$

where $y \in \mathbb{R}^D$ is a one-hot label of system actions (Chen et al., 2019), D is the dimension of the label space, and *classifier* is a simple linear classifier.

3.2 Memory-Augmented Multi-Decoder Network

We propose a memory-augmented multi-decoder network that jointly generates belief state, system actions, and system response while having access to a memory bank when generating the system action. Given the retrieved candidate system actions, we encode these candidates into the memory bank and enhance the generation of system actions by querying the memory bank during decoding.

Encoding Module We use Bidirectional GRUs (Chung et al., 2014) as our encoders. First, we encode the current user utterance, the previous system response and the previous belief state separately into hidden states:

$$\begin{aligned} H_u &= \text{Encoder}(U_t), \\ H_{pre\_r} &= \text{Encoder}(R_{t-1}), \\ H_{pre\_b} &= \text{Encoder}(B_{t-1}), \end{aligned} \tag{4}$$

Then, another encoder is used to encode the candidate system actions into memory bank:

$$M_t = \text{Encoder}_M(\bar{A}_1 \oplus \bar{A}_2 \oplus ... \oplus \bar{A}_k), \tag{5}$$

where $M_t = \{m_1, ..., m_k\}$.

Belief State Generation The belief state B_t of turn t is generated based on the current user utterance U_t, previous system response R_{t-1} and previous belief state B_{t-1}. The generation of B_t at each time step τ can be formulated as follows:

$$\begin{aligned} s_\tau &= \text{Attn}(h_{\tau-1}, H_u, H_{pre\_r}, H_{pre\_b}), \\ c_\tau &= [s_\tau \oplus e(b_{\tau-1})], \\ p(b_\tau|b_{1:\tau-1}), h_\tau &= \text{Dec}_b(c_\tau, h_{\tau-1}, H_{pre\_b}), \end{aligned} \tag{6}$$

where $Attn$[1] is an attention function, $e(b_{\tau-1})$ is the embedding of the previous token, $h_{\tau-1}$ is the hidden state from the last decoding step, and $h_0 = \mathbf{0}$. Dec_b[1] is the belief state decoder augmented with copy mechanism (Gu et al., 2016), which can copy tokens from the previous belief state. $p(b_\tau|b_{1:\tau-1})$ is a distribution over vocabulary. We use cross entropy between ground truth and the output distribution $\mathcal{L}_b(\theta)$ as the loss of belief state generation. We collect the hidden states $H_b = \{h_0, h_1, ..., h_p\}$ of each step to feed them into the action decoder.

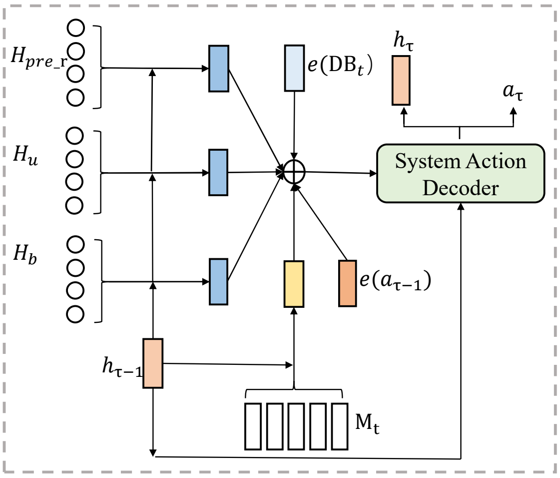

Figure 3: Generation of system actions at time step τ.

Memory-Augmented Action Generation As shown in Figure 3, the system action A_t of turn t is generated based on not only the dialog history and the current belief state, but also the memory bank which encodes the retrieved candidate system actions. For the generation of A_t, at each time step, we first compute the state s_τ:

$$s_\tau = \text{Attn}(h_{\tau-1}, H_u, H_{pre\_r}, H_b). \tag{7}$$

Then, we use the hidden state $h_{\tau-1}$ to query the encoded candidate system actions memory M_t:

$$\begin{aligned} a_\tau^i &= \tanh(W[h_{\tau-1} \oplus m_i]), \\ \alpha_\tau &= \text{Softmax}(a_\tau), \\ v_\tau &= \sum\nolimits_{i=1}^{k} \alpha_\tau^i m_i, \end{aligned} \tag{8}$$

where W are learnable parameters and v_τ contains information from the memory. Now we incorporate v_τ into the generation process:

$$\begin{aligned} c_\tau &= [s_\tau \oplus e(a_{\tau-1}) \oplus e(DB_t) \oplus v_\tau], \\ p(a_\tau|a_{1:\tau-1}), h_\tau &= \text{Dec}_a(c_\tau, h_{\tau-1}, H_b), \end{aligned} \tag{9}$$

where $e(a_{\tau-1})$ is the embedding of the previous token, $e(DB_t)$ is the embedding of the database search result which indicates the number of matched entities. Dec_a is the action decoder augmented with copy mechanism. The cross entropy $\mathcal{L}_a(\theta)$ between the output distribution and ground truth is the loss of actions generation. We

---

[1] Please refer to the appendix for more details.

collect the hidden states $H_a = \{h_0, h_1, ..., h_q\}$ as well to feed it into the system response decoder.

Random Sampling Though the retrieved candidate system actions are considered to be of high quality and suitable given the dialogue context, we would still like our model to avoid taking those candidates for granted and developing excessive dependence on them. To this end, during training, the memory bank is filled with randomly sampled system actions with a probability p, and retrieved candidates with a probability $(1 - p)$. This allows the model to learn to distinguish good candidates from bad candidates.

Response Generation Lastly, we generate the system response conditioned on the hidden states of user utterance H_u, belief state H_b and system actions H_a with the response decoder Dec_r:

$$\begin{aligned} s_\tau &= \text{Attn}(h_{\tau-1}, H_u, H_b, H_a), \\ c_\tau &= [s_\tau \oplus e(r_{\tau-1})], \\ p(r_\tau | r_{1:\tau-1}), h_\tau &= \text{Dec}_r(c_\tau, h_{\tau-1}, H_b), \end{aligned} \tag{10}$$

The response generation loss $\mathcal{L}_r(\theta)$ is the cross entropy between the output and ground truth.

Objective Function The final objective function is the sum of belief state loss, actions generation loss and response generation loss:

$$\mathcal{L}(\theta) = \mathcal{L}_b(\theta) + \mathcal{L}_a(\theta) + \mathcal{L}_r(\theta) \tag{11}$$

4 Experiments

4.1 Dataset and Metrics

We conduct our experiments primarily on MultiWOZ 2.0 (Budzianowski et al., 2018). It consists of 8438 dialogues spanning several domains and topics. Each of the test and validation sets contains 1000 dialogues. As for automatic evaluation, we use *Inform Rate* and *Success Rate* to evaluate dialogue task completion. The former measures whether the system has provided a proper entity and the latter measures whether it has answered all the requested attributes (Budzianowski et al., 2018). Besides, *BLEU* (Papineni et al., 2002) is used to measure the fluency of generated responses. To measure the overall quality, we compute a combined score by $(\textit{Inform}+\textit{Success})\times 0.5 + \textit{BLEU}$ (Mehri et al., 2019).

4.2 Implementation Details

Our model is trained on a 12 GB Nvidia GeForce RTX 2080 Ti with a batch size of 80. Our implementation[2] is based on PyTorch (Paszke et al., 2019). We pre-trained the BERT model based on the open-source library Transformers (Wolf et al., 2020). The dimension of word embeddings is 50 and the hidden size is 100. We use one-layer Bidirectional GRUs (Chung et al., 2014) as context encoders and three GRUs augmented with copy mechanism as decoders. The candidate actions are encoded by another Bidirectional GRU. We use Adam (Kingma and Ba, 2015) optimizer with a learning rate of 0.007. We use greedy search to decode system actions and beam search with a beam size of 5 to decode system responses. We use the ground truth belief states for a fair comparison with other baselines. We train our model for 60 epochs and select the best model on the validation set, and then evaluate it on the test set to get the final results.

4.3 Baselines

We compare our full model MAMD with several baselines on MultiWOZ 2.0: SC-LSTM (Wen et al., 2015), LaRL (Zhao et al., 2019), HDSA (Chen et al., 2019) , DAMD (Zhang et al., 2020), PARG (Gao et al., 2020), SimpleTOD (Hosseini-Asl et al., 2020), MarCo (Wang et al., 2020b), UBAR (Yang et al., 2020), HDNO (Wang et al., 2020a), LAVA (Lubis et al., 2020). Especially, SC-LSTM and HDSA treat system actions as one-hot vectors, and LaRL, HDNO, LAVA treats them as latent variables. Besides, HDSA uses BERT to predict system actions. DAMD, PARG, SimpleTOD, MarCo, and UBAR treat belief state, system actions as sequences and generate them along with system response. Besides, DAMD (aug) means DAMD using rule-based multi-action data augmentation to augment the system actions. Similar to HDSA, MarCo also uses BERT to predict system actions.

4.4 Overall Results

As shown in Table 1, our model significantly outperforms the baseline model DAMD in *Inform Rate*, *Success Rate* and especially *Combined Score*. Besides, our model achieves the best performance in *Combined Score* among all the baseline models. We also observe that models that generate system actions as a sequence generally have superior performance, implying that sequence is a better representation to model the inter-relationships among dialogue actions than one-hot vectors. Besides, our

Table 2: Overall results on the MultiWOZ 2.1 dataset.

model outperforms all the methods with data augmentation, which shows the effectiveness of our proposed retrieve-and-memorize framework.

We also evaluate our model on MultiWOZ 2.1 (Eric et al., 2020), an updated version of MultiWOZ 2.0. As shown in Table 11, the results are consistent with that on MultiWOZ 2.0 in Table 1.

4.5 Performance Across Different Domains

We report the performance of our model on different domains of MultiWOZ 2.0 and compare it with DAMD and DAMD (aug). The results are shown in Figure 4. From the bar chart, we can find that our model achieves the best performance across all domains. Besides, our model achieves significant performance improvements in *taxi* and *attraction* domains, which appear less frequently in the training data than other domains. Our MAMD narrows the performance gaps among different domains.

4.6 Ablation Study

In this section, we conduct experiments to study the contributions of the proposed context-aware retrieval module and memory-augmented module.

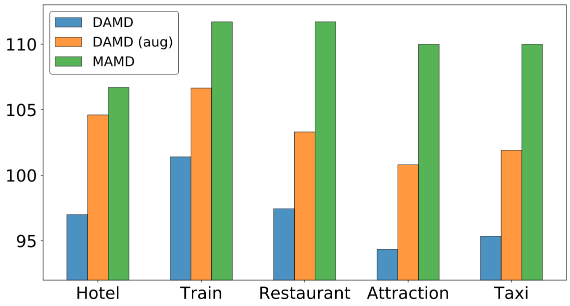

Figure 4: Results of our MAMD and DAMD in combined scores across different domains. If a dialogue involves more than one domain, it is counted into each.

As shown in Table 3, the first group is the baseline directly trained on four types of augmented data, where it treats the augmented actions as equivalent to the golden ones. We observe that the performance drops significantly if the augmented actions are randomly selected, suggesting that the benefit of such data augmentation is strongly subject to the quality of the augmented data. Additionally, the model trained with CARM outperforms the Rule, which indicates the higher quality of our context-aware retrieved candidates and the effectiveness of the proposed CARM. What's more, removing the system actions prediction pre-training task in CARM causes a performance drop, which demonstrates the necessity to adjust the pre-trained model and obtain more task-related representations.

The second group in Table 3 shows the results of the model with the memory-augmented (MA) module trained as well as evaluated with various augmented data. First, with MA, our MAMD is much more robust to random noise, only slightly under-

Method	**Score**	**Δ**
Baseline	98.95	0
+ Random	91.65	-7.30
+ Rule	102.15	+3.20
+ CARM	106.65	+7.70
+ CARM w/o Pt	102.25	+3.30
+ Random + MA	98.10	-0.85
+ Rule + MA	106.75	+7.80
+ CARM + MA	108.70	+9.75
+ CARM + MA + RS	111.20	+12.25

Table 3: Results of ablation study. *Baseline* is MAMD without the memory-augmentation component. *Random* means randomly selected actions, *Rule* is the rule-based augmentation proposed by DAMD, *CARM* is the proposed context-aware retrieval module, and *w/o Pt* means without pre-training before retrieval. *MA* is the proposed memory-augmentation module, and *RS* is the proposed random sampling technique.

performing the baseline. This is because, during training, a model with MA can learn to ignore the noises in the memory and pay less attention to the memory during evaluation. Second, we see more performance gains with MA from both rule-based and context-aware retrieved candidates, which suggests a model with MA can utilize the candidate system actions more effectively. Last but not least, with the random sampling mechanism, the performance of our full model further improves.

4.7 Effect of Random Sampling

To further analyze the effect of random sampling, we adjust the random sampling probability during training from 0 (no random sampling and all candidates are from CARM) to 1 (all candidates are randomly sampled), and evaluate MAMD with retrieved candidates and randomly sampled candidates in the memory bank. As shown in Figure 5, the first thing to notice is that without random sampling, i.e., the random sampling probability p is set to 0, the performance of MAMD with random candidate system actions drops drastically to 66.40. This indicates MAMD trained with all decent-quality candidates has developed excessive dependence on the candidates and in a way treats them as ground truth actions, which is what we try to avoid by introducing random sampling. Once we introduced random sampling, the performance gap between MAMD evaluated with retrieved actions and random actions is significantly narrowed, which suggests MAMD is capable of telling the quality of the candidates in the memory bank.

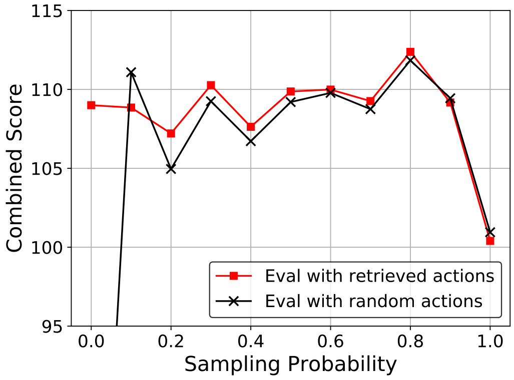

Figure 5: Results of our model trained with different random sampling probabilities and evaluated with different type of candidate actions on the development set.

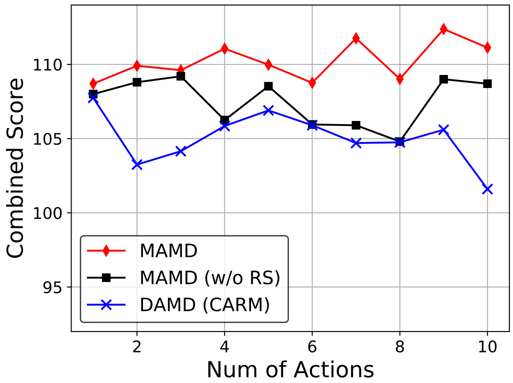

Figure 6: Combined score of three models trained with different numbers of candidate actions retrieved by CARM on the development set, where *MAMD (w/o RS)* means our model without random sampling and *DAMD (CARM)* means DAMD trained with augmented system actions retrieved by CARM.

4.8 Effect of the Number of Candidate Actions

To analyze the effect of the number of candidate actions on our proposed modules, we train three model variations with different numbers of candidate actions retrieved by CARM. As shown in Figure 6, we can see that both MAMD and MAMD (w/o RS) achieve their best performances with 9 candidate actions. Additionally, both our models consistently outperform DAMD, which suggests the effectiveness of the memory-augmented module. What's more, the performance of our full model increases more steadily as the number of candidate actions goes up, while without random sampling, the performance of our model is much more unstable across different numbers of candidate actions, which indicates that random sampling can bring in some desirable regularization.

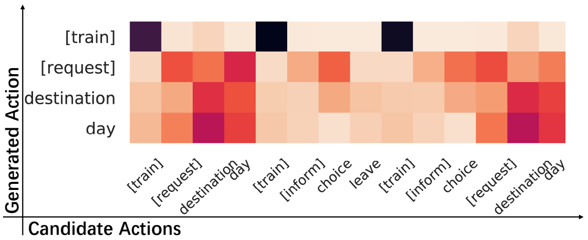

Figure 7: Visualization of the attention from generated system actions to candidate actions. The y-axis is generated system actions and the x-axis is candidate system actions. At each decoding step, the generated system actions selectively attend to the candidate actions. (Dialogue ID:MUL0473)

Context:
Sys: I would recommend the cambridge museum of technology, would you like any information about that?
User: Yes. What is the postcode and phone number?

DAMD:
[attraction] [recommend] postcode phone name type
[attraction] [inform] phone postcode
[attraction] [nooffer] type
......

CARM:
[attraction] [inform] phone postcode
[attraction] [inform] postcode phone [general] [reqmore]

Reference:
[attraction] [inform] postcode phone [general] [reqmore]

Table 4: Comparison of retrieved candidate system actions of DAMD and our CARM.

Context: ... User: Please book tickets and provide me with the total cost of tickets and confirmation number.

DAMD:
The [value_id] is **[value_price]**. The train id is [value_id]. Is there anything else I can help you with?

MAMD:
Booking was successful, the total fee is **[value_price]** payable at the station. Reference number is: **[value_reference]**. Is there anything else I can help you with?

Reference:
It has been booked! Your reference number is **[value_reference]**. The cost is **[value_price]**. Do you need anything else?

Table 5: An example of response generation of DAMD and MAMD.

MAMD vs. DAMD	**Win%**	**Tie%**	**Lose%**
Completion	19.25%	66.54%	14.21%
Readability	3.13%	93.08%	3.79%

MAMD vs. Reference	**Win%**	**Tie%**	**Lose%**
Completion	14.51%	56.11%	29.38%
Readability	2.85%	92.03%	5.11%

Table 6: Results of human evaluation on response quality. *Reference* means ground truth response. *Win*, *Tie* and *Lose* respectively indicate the proportions that our model wins over, ties with or loses to its counterpart.

5 Visualization and Case Study

An illustrative example is shown in Figure 7, the current user utterance is “*I need a train departing cambridge arriving by 20:30*”. The action decoder successfully attends to appropriate actions and ignores the noisy ones like “*[train] [inform] leave*”, as the leaving time has not provided by the user.

Table 4 shows an example of candidate system actions that CARM appropriately retrieved but DAMD failed. The user asks the system to provide the postcode and phone number of the attraction, while DAMD returns “*[attraction][nooffer][type]*”.

We also present an example of response generation in Table 5, where the user asks for the price and reference number. DAMD manages to provide the postcode but fails to provide the reference number, while our MAMD model successfully provides both the postcode and the reference number.

6 Human Evaluation

Finally, we conduct a human study to evaluate our model from the human perspective. We randomly select 30 dialogue sessions (211 dialog turns in total) from the test dataset and have 5 postgraduates as judges to compare two groups of systems: MAMD vs. DAMD and MAMD vs. Reference, in terms of *Readability* and *Completion* (Wang et al., 2020b). *Completion* measures whether a response has correctly answered a user query, including relevance and informativeness. *Readability* measures the fluency and consistency of the response.

We report the human evaluation results in Table 6, from which we can observe that our model outperforms DAMD and beats or ties with Reference nearly 70% of the time in terms of *Completion*. In *Readability*, our model ties more than 92% with DAMD as well as Reference. This may suggest the language of responses lacks diversity and is easy to learn. Overall, our model is superior to DAMD in human evaluation, which demonstrates its competence in a more holistic evaluation other than automatic metrics.

7 Conclusion

In this paper, we proposed a retrieve-and-memorize framework to deal with the unbalanced distribution of system actions in task-oriented dialogue systems. Our framework includes a neural retrieval module that can retrieve multiple candidate system actions given a dialogue context, and a memory-augmented multi-decoder network that can generate system actions conditioned on multiple candidate system actions. Extensive experiments were conducted on a large-scale multi-domain task dialogue dataset and the results demonstrate the effectiveness of our framework. In essence, the whole framework, including its random sampling strategy, can be viewed as an attempt to prevent the systems from overfitting skewed dialogue datasets with an unbalanced distribution of system actions.

A More Details of MAMD

A.1 Attention Function

In MAMD, we use an attention function *Attn* to attend to three groups of hidden states. In this study, $Attn(h, H_a, H_b, H_c)$ is defined as:

$$\begin{aligned} h_a &= \text{CatAttn}(h, H_a), \\ h_b &= \text{CatAttn}(h, H_b), \\ h_c &= \text{CatAttn}(h, H_c), \\ \text{Attn}(h, H_a, H_b, H_c) &= [h_a \oplus h_b \oplus h_c], \end{aligned} \tag{12}$$

where $\oplus$ is the concatenation operator and CatAttn is a simple concat-attention defined as:

$$\begin{aligned} a_i &= \tanh(W[h \oplus H_i]), \\ \alpha_i &= \text{Softmax}(a), \\ \text{CatAttn}(h, H) &= \sum\nolimits_{i=1}^{n} \alpha_i H_i, \end{aligned} \tag{13}$$

where W represents learnable parameters, H is the sequence of encoded hidden states,[3] and n is the number of hidden states in H.

A.2 Decoder with Copy Mechanism

The decoder used to generate the belief state, system action and response is a one-layer GRU augmented with copy mechanism. Each step of the

---

[3] For example, the encoded hidden states of user utterance.

generation in $\text{Dec}(c_t, h_{t-1}, H)$ is defined as follows:

$$\begin{aligned}
h_t &= \text{GRU}(c_t, h_{t-1}), \\
p_{vocab} &= \text{Softmax}(W_v h_t), \\
s_i &= h_t^\top \tanh(W_c H i), \\
p_{copy} &= \text{Softmax}(s), \\
p_{final}(w) &= p_{vocab}(w) + \sum_{i:X(i)=w} p^i_{copy}, \\
\text{Dec}(c_t, h_{t-1}, H) &= p_{final}, h_t,
\end{aligned} \tag{14}$$

where W_v and W_c are learnable weights, and X is the corresponding context of H.

B More implementation Details

B.1 Hyperparameters

In this section, we report the hyperparameter setting in our model. For MAMD, we adopt the default hyperparameters in DAMD, as shown in Table 7. As for the learning rate, the number of candidate actions, and the random sampling probability, we apply grid search to find the best combination on the development set. It takes about 10 hours to train our model on a single 12 GB Nvidia GeForce RTX 2080 Ti. As for CARM's pre-training task, the hyperparameter setting is shown in Table 8.

Parameter	**Values**
batch size	80
learning rate	7e-3
embedding size	50
hidden size	100
dimension of db search result	6
encoder layers	1
decoder layers	1
epoch	60
candidate actions	9
random sampling probability	0.8
beam size	5
random seed	777

Table 7: Hyperparameter setting of MAMD.

B.2 Delexicalization Strategy

For delexicalization, we follow DAMD's domain-adaptive delexicalization strategy. Specially, we use tokens such as [value_name] to represent the same slot name. In this case, the placeholders [hotel_name] and [restaurant_name] will be converted to [value_name]. During the evaluation, we induce the domain of a placeholder from the transition between two adjacent belief states and the generated system actions of the current dialog turn.[4]

Parameter	**Values**
batch size	6
learning rate	5e-5
epoch	20
random seed	42
max sequence length	400
warmup proportion	0.1

Table 8: Hyperparameter setting of CARM.

B.3 Post-Processing of Candidate Action Retrieval

As for candidate action retrieval, we retrieve 50 candidate actions for each sample. Then, we apply post-processing to clean the candidate actions:

- Duplicated actions are merged. For example, the system actions "[attraction] [inform] postcode phone [general] [reqmore]" and "[attraction] [inform] postcode phone [general] [reqmore]" will be combined into "[attraction] [inform] postcode phone [general] [reqmore]".
- Null system actions are removed.
- System actions with different database query results are filtered out.
- System actions that conflict with current belief are filtered, e.g., requesting a slot that is already included in belief states.

C Dataset Details

We provide more information about the MultiWOZ 2.0 dataset. The training set contains 8438 dialogs, 115,424 turns, and 1,520,970 tokens. The average number of turns per dialog is 13.68, and the average number of tokens per turn is 13.18. The number of slots and values are 25 and 4510, respectively. The ontology is shown in Table 9. We also count the numbers of system actions across different domains. As shown in Figure 8, the numbers of system actions in *attraction* and *taxi* are smaller than the other domains, showing the unbalanced distribution of system actions at the domain level.

D More Analyses and Discussions

D.1 Results on Development and Test Sets

We report the results of MAMD on the development and test sets of MultiWOZ 2.0 and MultiWOZ 2.1. As shown in Table 10 and Table 11, the results on the development set are generally consistent with that on the test set on both benchmarks.

D.2 Distribution of Generated System Actions

To further analyze the influence of our model on the generation of system actions, we count the appearance of generated actions. Recall that each dimension of the actions stands for either *domain*, *function* or *slot*, where *domain* defines the domain involved in the conversation, and *function* defines the behavior of system such as informing the user or request certain information. Here we only count the first two dimensions of the actions because the third dimension appears to be less important.

As shown in Figure 9, the distribution of system actions generated by DAMD is proportional to the original distribution in the dataset, and DAMD tends to generate fewer actions than the original distribution. After applying their rule-based multi-action data augmentation, DAMD (aug) can generate more diverse system actions compared with DAMD. Compared with DAMD (aug), MAMD generates more actions. More importantly, MAMD generates more important actions such as “attraction-inform” and “taxi-inform” which are more relevant to task completion, while DAMD (aug) tends to generate less useful actions such as “general-require” and “general-greet”. This phenomenon indicates that the memory-augmented mechanism provides some guidance to our model during system action learning. To sum up, our proposed model can generate more diverse and valuable actions, which demonstrates the effectiveness of our proposed memory-augmented mechanism.

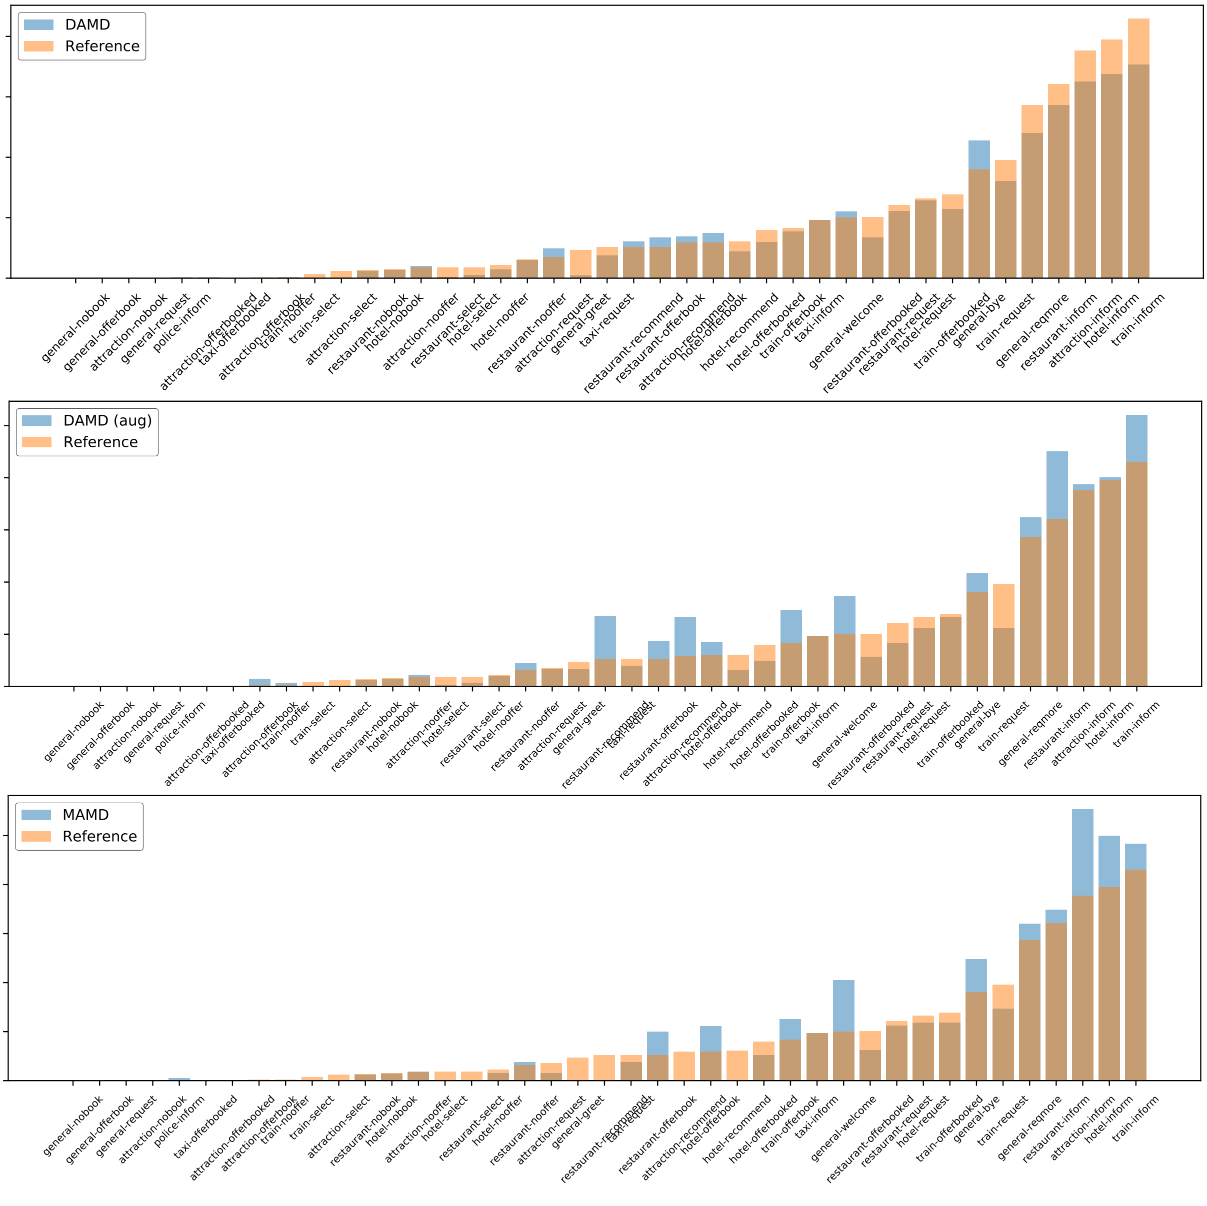

Figure 9: Statistics of generated system actions by DAMD, DAMD (aug) and MAMD, and comparison with reference actions.

Adapt-and-Distill: Developing Small, Fast and Effective Pretrained Language Models for Domains

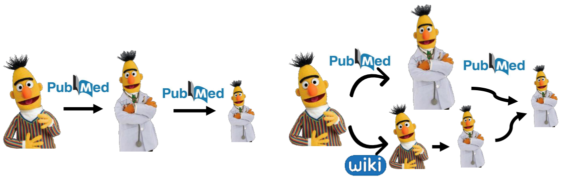
Abstract

Large pretrained models have achieved great success in many natural language processing tasks. However, when they are applied in specific domains, these models suffer from domain shift and bring challenges in fine-tuning and online serving for latency and capacity constraints. In this paper, we present a general approach to developing small, fast and effective pretrained models for specific domains. This is achieved by adapting the off-the-shelf general pretrained models and performing task-agnostic knowledge distillation in target domains. Specifically, we propose domain-specific vocabulary expansion in the adaptation stage and employ corpus level occurrence probability to choose the size of incremental vocabulary automatically. Then we systematically explore different strategies to compress the large pretrained models for specific domains. We conduct our experiments in the biomedical and computer science domain. The experimental results demonstrate that our approach achieves better performance over the $\text{BERT}_{\text{BASE}}$ model in domain-specific tasks while 3.3× smaller and 5.1× faster than $\text{BERT}_{\text{BASE}}$. The code and pretrained models are available at `https://aka.ms/adalm`.

1 Introduction

Pre-trained language models, such as GPT (Radford et al., 2018), BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) and UniLM (Dong et al., 2019) have achieved impressive success in many natural language processing tasks. These models usually have hundreds of millions of parameters. They are pre-trained on a large corpus of general domain and fine-tuned on target domain tasks. However, it is not optimal to deploy these models directly to edge devices in specific domains. First, heavy model size and high latency makes it difficult to deploy on resource-limited edge devices such as mobile phone. Second, directly fine-tuning a general pre-trained model on a domain-specific task may not be optimal when the target domain varies substantially from the general domain. Thirdly, many specialized domains contain their own specific terms, which are not included in pre-trained language model vocabulary.

(a) From scratch (b) Distill-then-Adapt



(c) Adapt-then-Distill (d) Adapt-and-Distill

Figure 1: The four alternatives when distilling BERT into specific domains. All strategies are task-agnostic.

In this paper, we introduce AdaLM, a framework that aims to develop small, fast and effective pretrained language models for specific domains. To address domain shift problem, recent studies (Lee et al., 2020; Gururangan et al., 2020) conduct continual pre-training to adapt a general domain pretrained model to specific domains. However, specific domains contain many common in-domain terms, which may be divided into bite-sized pieces (e.g., *lymphoma* is tokenized into [*l, ##ym, ##ph, ##oma*]). Gu et al.(2020) mentions that domain-specific vocabularies play a vital role in domain adaptation of pre-trained models. Specifically, we propose a domain-specific vocabulary expansion in the adaptation stage, which augments in-domain terms or subword units automatically given in-domain text. Also, it is critical to decide the size of incremental vocabulary. Motivated by subword reg-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 460–470
August 1–6, 2021.

ularization (Kudo, 2018), AdaLM introduces a corpus occurrence probability as a metric to optimize the size of incremental vocabulary automatically.

We systematically explore different strategies to compress general BERT models to specific domains (Figure 1): (a) From scratch: pre-training domain-specific small model from scratch with domain corpus; (b) Distill-then-Adapt: first distilling large model into small model, then adapting it into a specific domain; (c) Adapt-then-Distill: first adapting BERT into a specific domain, then distilling model into small size; (d) Adapt-and-Distill: adapting both the large and small models, then distilling with these two models initializing the teacher and student models respectively.

We conduct experiments in both biomedical and computer science domain and fine-tune the domain-specific small models on different downstream tasks. Experiments demonstrate that Adapt-and-Distill achieves state-of-the-art results for domain-specific tasks. Specifically, the 6-layer model of 384 hidden dimensions outperforms the $\text{BERT}_{\text{BASE}}$ model while 3.3× smaller and 5.1× faster than $\text{BERT}_{\text{BASE}}$.

2 Related Work

Domain adaptation of pre-trained model Most previous work on the domain-adaptation of pre-trained models targets large models. Lee et al. (2020) conduct continual pre-training to adapt the BERT model to the biomedical domain using the PubMed abstracts and the PMC full text. Gururangan et al. (2020) also employ continual pre-training to adapt pre-trained models into different domains including biomedical, computer science and news. However, many specialized domains contain their own specific words that are not included in pre-trained language model vocabulary. Gu et al.(2020) propose a biomedical pre-trained model PubMedBERT, where the vocabulary was created from scratch and the model is pre-trained from scratch. Furthermore, in many specialized domains, large enough corpora may not be available to support pre-training from scratch. Zhang et al. (2020) and Tai et al. (2020) extend the open-domain vocabulary with top frequent in-domain words to resolve this out-of-vocabulary issue. This approach ignores domain-specific sub-word units (e.g., *blasto-*, *germin-* in biomedical domain). These subword units help generalize domain knowledge and avoid unseen words.

Task-agnostic knowledge distillation In recent years, tremendous progress has been made in model compression (Cheng et al., 2017). Knowledge distillation has proven to be a promising way to compress large models while maintaining accuracy (Sanh et al., 2019; Jiao et al., 2020; Sun et al., 2020; Wang et al., 2020). In this paper, we focus on task-agnostic knowledge distillation approaches, where a distilled small pre-trained model can be directly fine-tuned on downstream tasks. DistilBERT (Sanh et al., 2019) employs the soft label and embedding outputs to supervise the student. TinyBERT (Jiao et al., 2020) and MobileBERT (Sun et al., 2020) introduce self-attention distributions and hidden states to train the student model. MiniLM (Wang et al., 2020) avoids restrictions on the number of student layers and employs the self-attention distributions and value relation of the teacher's last transformer layer to supervise the student model. Because this method is more flexible, we implement MiniLM to compress large models in this work. No previous work systematically explores different strategies to achieve an effective and efficient smaller model in specific domains.

3 Methods

3.1 Overview

We systematically explore different strategies to achieve an effective and efficient small model in specific domains. We summarize them into four strategies: from scratch, distill-then-adapt, adapt-then-distill and adapt-and-distill.

Pretrain-from-scratch Domain-specific pretraining from scratch employs a random initialization of a pretrained model and pretrains a small model directly on domain-specific corpus. In this work, we conduct pretraining from scratch on different vocabularies including BERT original vocabulary, from scratch vocabulary, and expanded vocabulary.

Distill-then-adapt These approaches first distill the large general pretrained model which pretrained on Wikipedia and BookCorpus. Then it continues the pretraining process using a domain-specific corpus. In this work, we first distill the BERT model into a small model using task-agnostic knowledge distillation in MiniLM (Wang et al., 2020). Then we initialize the small model with it and conduct continual training with both the BERT original vocabulary and the expanded vocabulary.

Adapt-then-distill In this work, we select different large models as teacher models such as BERT and large models with different vocabularies. We first adapt these models into domain-specific models and then implement MiniLM to compress them to small models.

Adapt-and-distill In the previous part, when doing knowledge distill, we initialized the student model randomly. In order to get a better domain-specific small model, we try to explore the impact of the initialization of the student model. In this part, we adapt large and small models into specific domains separately, then use these two models to initialize the teacher and student model respectively.

3.2 Domain Adaptation

AdaLM contains a simple yet effective domain adaptation framework for a pretrained language model. As shown in Figure 2, it takes a general pretrained language model, original vocabulary and a domain specific corpus as input. Through vocabulary expansion and continual pretraining, AdaLM adapts general models into specific domains.

The core pipeline of domain adaptation consists of the three steps described below:

1. Given original vocabulary and a domain-specific corpus, the vocabulary expansion module aims to augment original vocabulary with domain-specific subword units or terms. We augment domain-specific vocabulary from the target domain, while keeping the original BERT vocabulary unchanged. We describe them in more detail in Section 3.3.
2. Due to the size of the vocabulary having changed, we cannot initialize our model with BERT directly. As illustrated in Figure 3, we initialize the original embedding and Transformer encoder with weights from BERT (the green part in Figure 3). For incremental vocabulary, we first tokenize them into sub-words with the original vocabulary and then use an average pooling of their own sub-words embedding to initialize. As shown in Figure 3, the word '*lymphoma*' is not included in BERT vocabulary. We tokenize it into three sub-words (*lym*, *##pho*, *##ma*). The embedding vector of 'lymphoma' is initialized by the average embedding vector of '*lym*', '*##pho*'and '*##ma*'.
3. After model initialization and data preprocessing, we continually pretrain our model with domain-specific corpus using masked language model loss. Following BERT, we randomly replace 15% of tokens by a special token (e.g., [MASK]) and ask the language model to predict them in continual pretraining.

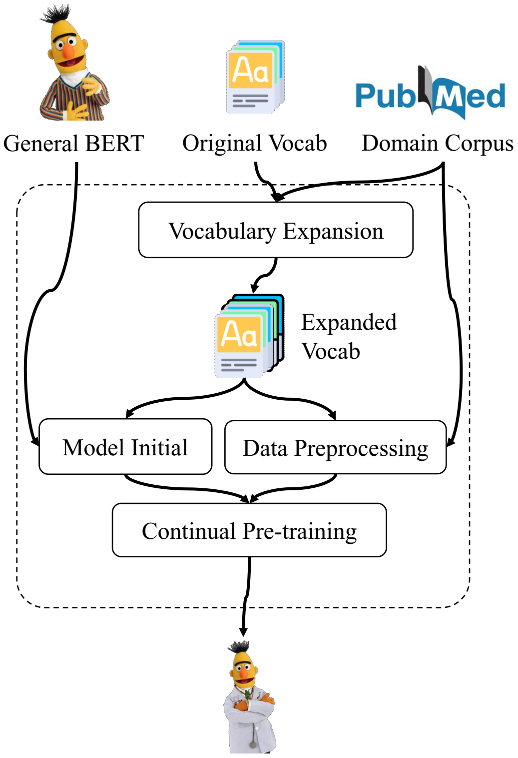

Figure 2: The pipeline of domain adaptation. Here we adapt the BERT model into the biomedical domain with PubMed dataset.

3.3 Vocabulary Expansion

Vocabulary expansion is the core module of AdaLM. It augments domain-specific terms or subword units to leverage domain knowledge. The size of the incremental vocabulary is a vital parameter for vocabulary expansion. Considering that unigram language modeling (Kudo, 2018) aligns more closely with morphology and avoids problems stemming from BPE's greedy construction procedure, as proposed in (Bostrom and Durrett, 2020), we followed Kudo (2018) and introduced a corpus occurrence probability as a metric to optimize the size of incremental vocabulary automati-

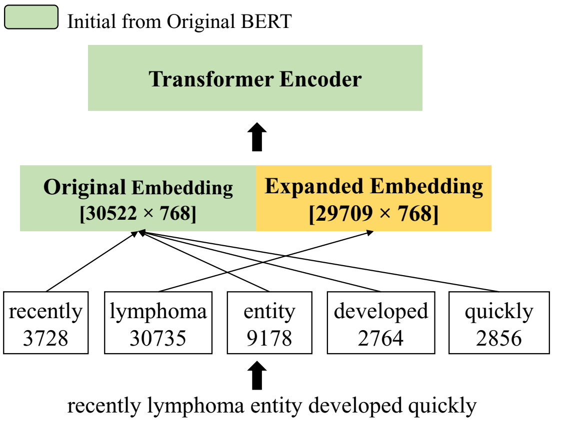

Figure 3: Concatenate original embedding with expanded embedding.

cally. We assume that each subword occurs independently and we assign to each subword in the corpus a probability equal to its frequency in the corpus.

$$\forall i \; x_i \in \mathcal{V}, \quad \sum_{x_i \in \mathcal{V}} p(x_i) = 1, \tag{1}$$

where $\mathcal{V}$ is a pre-determined vocabulary. The probability of a subword sequence $\mathbf{x} = (x_1, \dots, x_M)$ can be computed by the product of the subword appearance probabilities $p(x_i)$. We convert it to logarithmic form:

$$P(\mathbf{x}) = \sum_{i=1}^{M} log(p(x_i)), \tag{2}$$

Given a domain-specific corpus D, the occurrence probability of corpus D is formulated as:

$$P(D) = \sum_{\mathbf{x}}^{|D|} log(P(\mathbf{x})), \tag{3}$$

where $\mathbf{x}$ represents tokenized sentence in corpus D.

We sample 550k sentences from the PubMed corpus and compute the occurrence probability $P(D)$ with different vocabulary sizes. The results are shown in Figure 4. We compare the occurrence probability with BERT and PubMedBERT vocabularies. We observe that $P(D)$ reveals a logarithmic trend with substantial increases at the beginning and little influence after vocabulary size of 70k in the biomedical domain. The PubMedBERT vocabulary performs similarly to the 40k size vocabulary. We present the occurrence probability of different vocabulary sizes in Appendix A.

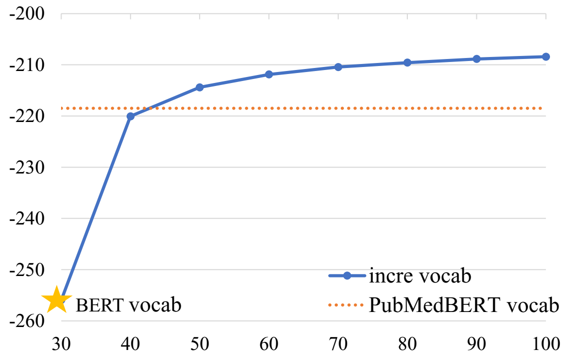

Figure 4: The $P(D)$ of different vocab sizes under biomedical domain. We use the BERT's vocabulary as the 30k vocabulary without vocabulary expanding. The PubMedBERT vocabulary is also 30k.

We propose a simple method to decide the size of the incremental vocabulary. Assume the probability at the time step $i-1$ is $P_{i-1}(D)$ and at the time step i is $P_i(D)$. If the rise $\frac{P_i(D)-P_{i-1}(D)}{P_{i-1}(D)}$ is lower than a threshold δ, we regard the vocabulary size at the time step i as the final size.

```
Algorithm 1: Vocabulary Expansion
  Input: Original vocabulary $raw\_vocab$,
         domain corpora $D$, threshold $\delta$ and
         vocabulary size step $V_\triangle$
  Output: $vocab_{final}$
  $token\_count \leftarrow$ whitespace split from $D$;
  $P_0 \leftarrow$ computed from $raw\_vocab$;
  $V_0 \leftarrow |raw\_vocab|$;
  do
      vocabulary size $V_i \leftarrow V_{i-1} + V_\triangle$;
      $sub\_count \leftarrow$ split token to subwords;
      Sort $sub\_count$ by frequency;
      $incr\_vocab \leftarrow$keep $(V_i - V_0)$ subwords;
      $vocab_i \leftarrow raw\_vocab + incr\_vocab$;
      $P_i \leftarrow$ computed from $vocab_i$
  while $\frac{P_i - P_{i-1}}{P_{i-1}} > \delta$;
  return $vocab_{final} \leftarrow vocab_i$ ;
```

We expand the domain-specific vocabulary with the process shown in Algorithm 1. We implement our vocabulary expansion algorithm referring to SubwordTextBuilder in tensor2tensor[1]. In experiments, we set the threshold δ as 1% and vocabulary size step $V_\triangle$ as 10k. Finally, we obtain the expanded vocabulary size of biomedical as 60k and computer science domain as 50k.

4 Experiment Details

We conduct our experiments in two domains: biomedical and computer science.

4.1 Datasets

Domain corpus: For the biomedical domain, we collect a 16GB corpus from PubMed[2] abstracts to adapt our model. We use the latest collection and pre-process the corpora with the same process as PubMedBERT (we omit any abstracts with less than 128 words to reduce noise.).

For the computer science domain, we use the abstracts text from the arXiv[3] Dataset. We select abstracts in computer science categories, collecting 300M entries for the corpus.

Fine-tuning tasks: For the biomedical domain, we choose three tasks: named entity recognition (NER), evidence-based medical information extraction (PICO), and relation extraction (RE). We perform entity-level F1 in NER task and word-level macro-F1 in the PICO task. The RE task uses the micro-F1 of positive classes evaluation. JNLPBA (Collier and Kim, 2004) NER dataset contains 6,892 disease mentions, which are mapped to 790 unique disease concepts with BIO tagging (Ramshaw and Marcus, 1995). EBM PICO (Nye et al., 2018) datasets annotates text spans with four tags: Participants, Intervention, Comparator and Outcome. ChemProt (Krallinger et al., 2017) dataset consists of five interactions between chemical and protein entities. We list the statistics of those tasks in Table 1.

We fine-tune two downstream tasks in the computer science domain. They are both classification tasks. The ACL-ARC (Jurgens et al., 2018) dataset mainly focuses on analyzing how scientific works frame their contributions through different types of citations. SCIERC (Luan et al., 2018) dataset includes annotations for scientific entities, their relations, and coreference clusters. The statistics are available in Table 2.

4.2 Implementation

We use the uncased version of $\text{BERT}_{\text{BASE}}$ (12 layers, 768 hidden size) as the large model and the MiniLM (6 layers, 384 hidden size) as the small model.

Dataset	Train	Dev	Test
JNLPBA	46,750	4551	8,662
EBM PICO	339,167	85321	16,364
ChemProt	18,035	11268	15,745

Table 1: Biomedical dataset used in our experiment. All selected from BLURB[4]

Dataset	Train	Task	Test	Classes
ACL-ARC	1,688	114	139	6
SCIERC	3,219	455	974	7

Table 2: Computer science dataset used in our experiment. We use the same train, development, and test splits as Gururangan et al. (2020)

To adapt the large model, we set the batch size at 8192 and the training step at 30,000. The peak learning rate was set to 6e-4. To adapt the small model, we set the batch size as 256 and the training step as 200,000. The learning rate is set to 1e-4. The maximum length of the input sequence was 512 and the token masking probability was 15% for both the large model and the small model.

We implement MiniLM to compress large models and follow the setting of MiniLM, where the batch size was set to 256 and peak learning rate as 4e-4. We set the training step as 200,000.

For biomedical tasks, we follow the setting of PubMedBERT (Gu et al., 2020) to fine-tune these three tasks. For computer science tasks, we use the same setting as Gururangan et al. (2020). The concrete parameters are shown in Appendix B.

5 Results

The results of the tasks are shown in the Table 3 and 4. We structure our evaluation by stepping through each of our three findings:

(1) Domain-specific vocabulary plays a significant role in domain-specific tasks and expanding vocabulary with the general vocabulary is better than just using domain-specific vocabulary.

We observe improved results via the expanded vocabulary with both the large and small models. For large model, AdaLM achieves the best results under each domain, where 77.74 on biomedical domain tasks, beating BioBERT and PubMedBERT and 77.76 on the computer science domain tasks.

For small models, in the biomedical domain, whether we train from scratch or distill-then-adapt with small models, incremental vocabulary mod-

	Adapt-and-Distill	Model (f) initial (j)	AdaLM$^\diamondsuit$	**79.04**	**74.91**	72.06	**75.34**

Table 3: Comparison between different strategies on biomedical tasks. The AdaLM$^\diamondsuit$ means we just adapt the large model without distillation. Scores of the methods marked with † are taken from (Gu et al., 2020). Underlined data marks the small models whose performances surpass the BERT model's performance. L and d indicate the number of layers and the hidden dimension of the model.

els always perform better than the general vocabulary or just the domain-specific vocabulary. (When distill-then-adapt with the PubMed vocabulary, we initialize the word embedding in the same way as mentioned in Section 3.2). In addition, with distill-then-adapt, the model (f) (75.10) can surpass the BERT model (74.28).

In the computer science domain, distill-then-adapt models with incremental vocabulary also show great performance. Model (d) achieves a comparable result of 72.91 as BERT and outperforms BERT in the ACL-ARC datasets with 65.93 (+1.01 F1). We also observe that when training from scratch, the results of Model (b) with incremental vocabulary are lower (1.45 lower) than that of model (a). This may be because after vocabulary expansion, a from-scratch model needs to be pretrained with more unlabeled data.

(2) Continual pretraining on domain-specific texts from general language models is better than pretraining from scratch.

Gu et al. (2020) finds that for domains with abundant unlabeled texts, pretraining language models from scratch outperforms continual pretraining of general-domain language models. However, in our experiments, we find that general-domains model can help our model to learn the target domain better. In the biomedical domain, we use MiniLM model to initialize the model (d), (e) and (f) in distill-then-adapt setting. No matter which vocabulary is used, continual pretraining on domain-specific texts from general language models is better than pretraining from scratch. For AdaLM vocabulary, the model (f) gets 75.10, outperforming the model (c) trained from scratch with the same vocabulary by 1.08. On the other hand, for domains that do not have enormous unlabeled texts such as the computer science domain in our experiments, continual pretraining also showed better results. With continual pretraining, model (d) achieves higher results exceeding both model (b) (+5.66 F1) and model (c) (+0.47 F1).

(3) Adapt-and-Distill is the best strategy to develop a task-agnostic domain-specific small pretrained model.

In the Adapt-then-Distill part, our findings supports evidence from previous observations (Wang et al., 2020) that a better teacher model leads to a better student model. Using AdaLM which performs best among large models as the teacher model can yield good results: 75.09 in the biomedical domain and 71.62 in the computer science, better than other domain-specific large models. Furthermore, we find that a better student model for initialization can also help to get a better small model. In the Adapt-and-Distill part, we adapt large and small models into specific domains separately and then compress the adapted large model as the teacher with the adapted small model as initialization. In the biomedical domain, the model (j), initialized from model (i), achieves the best result of 75.34 among the small models. It also

Config	Type	Model	Teacher	ACL-ARC	SCIERC	Average

		Random initial (f)	AdaLM$^\diamondsuit$	66.21	77.04	71.62
	Adapt-and-Distill	Model (d) initial (g)	AdaLM$^\diamondsuit$	**68.74**	78.88	<u>**73.81**</u>

Table 4: Comparison between different strategies on computer science tasks. The AdaLM$^\diamondsuit$ is the adapted large model without compressing. We report averages across five random seeds. Data marked with underlines are the results of small models which outperform the BERT model's. L and d indicate the number of layers and the hidden dimension of the model.

outperforms the BERT model (+1.06 F1). In the computer science domain, model (g), initialized by model (d), is the only small model that outperforms BERT (+0.78 F1).

6 Analysis

6.1 Inference Speed

We compare AdaLM's parameters' size and inference speed with the BERT model in the biomedical domain in Table 5.

Type	Model	#Params	Speedup
Large	BERT	109M	×1.0
	PubMedBERT	109M	×1.0
	AdaLM vocab	132M	×1.07
Small	BERT vocab	22M	×5.0
	AdaLM	34M	×5.1

Table 5: Comparison of model's parameter size and the inference speed. The inference speedup is computed by the classification task ChemProt and evaluated on a single NVIDIA P100 GPU.

First we can find that the vocabulary expansion yields marginal improvements on the model's inference speed. We added about 20M parameters in the embedding weights in the large model using AdaLM vocabulary, but its inference speed is slightly faster than BERT and PubMedBERT. Since most domain-specific terms are shattered into fragmented subwords, the length of the token sequence we get by using the incremental vocabulary is shorter than the length of the sequence got by the original vocabulary, which reduces the computation load. We list the change of the sequence length of the downstream tasks in Appendix C. Meanwhile, in the embedding layers, the model just needs to map the sub-words' id to their dense representations, which is little affected by the parameters' size. The small model shows the same trend.

In addition, the small model AdaLM shows great potential. Compared with the 12-layer model of 768 hidden dimensions, the 6-layer model of 384 hidden dimensions is 3.3x smaller and 5.1x faster in the model efficiency, while performing similarly to or even better than BERT$_{\text{BASE}}$.

6.2 Impact of Training Time

Pre-training often demands lots of time. In this section, we examine the adapted model's performance as a function of training time. Here we use the biomedical domain since its unlabelled texts are abundant and compare the large domain-specific adapted model with BioBERT. For every 24 hrs of continual pre-training, we fine-tuned the adapted model on the downstream tasks. For comparison, we convert the training time of BioBERT to the time it may take with the same computing resource of this work (16 V100 GPUs).

We list the results in Table 6, we denote the large adapted model as AdaLM in the table. AdaLM at 0 hrs means that we fine-tune the initialized model directly without any continual pre-training. We find that BERT is slightly better than 0hr AdaLM and after 24 hrs, AdaLM outperforms BioBERT, which demonstrates that domain-specific vocabulary is very critical for domain adaption of pre-trained model. Our experiments demonstrate promising re-

Model	Training Time	Average
AdaLM	0 hrs	74.25
	24 hrs	76.80
	48 hrs	77.36
	72 hrs	77.74
BERT	0 hrs	74.28
BioBERT	120 hrs	76.22

Table 6: Results with different pre-training time. In the table, AdaLM is the adapted large model without compressing.

sults in the biomedical domain. Under constrained computation, AdaLM achieves better performance compared to BioBERT. More details can be found in Appendix D

6.3 Impact of Vocabulary Size

To understand the impact of the vocabulary size, we conduct some experiments with different vocabulary sizes in the biomedical domain. We select the biomedical large AdaLM model and to reduce the computation load, we set the batch size as 256 and step as 250K in our ablation studies. We show performance of the model with different sizes in Table 7.

	40k	50k	60k	70k	80k
JNLPBA	78.84	**79.02**	78.91	78.94	79.01
PICO	**75.09**	74.81	74.99	74.58	75.00
ChemProt	76.10	76.80	**77.21**	76.40	76.85
Average	76.67	76.87	**77.03**	76.64	76.95

Table 7: The performance of different vocabulary sizes

We observe that the model of 60k achieves the best results in our ablation studies. The result is a bit surprising. Despite having a larger vocabulary, the 70k and 80k model does not show a stronger performance. A possible explanation for these results may be that a larger vocabulary set may contain some more complicated but less frequent words, which cannot be learnt well through continual pre-training. For example, the word *ferrocytochrome* exists in 70k and 80k vocabularies but is split into (*'ferrocy', '##tochrom', '##e'*) in the 60k vocabulary. In our sampled data (about 550k sentences), '*ferrocytochrome*' appears less than 100 times, while the subword '*##tochrom*' appears more than 10k times and '*ferrocy*' appears more than 200 times. The representation of those rare words cannot be learnt well due to the sparsity problem.

6.4 Vocabulary Visualization

The main motivation for using an the expanded vocabulary set is to leverage domain knowledge better. Compared to PubMedBERT which just uses the domain-specific vocabulary and initializes the model randomly, the keep of the general vocabulary and the general language model's weights may help us make good use of the existing knowledge and word embedding.

To assess the importance of the expanded vocabulary, we compute the $L2$-distance of the embedding weights before and after pre-training in our AdaLM model in the biomedical domain in Figure 5.

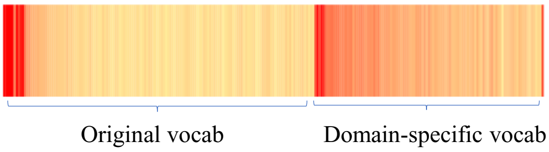

Figure 5: The $L2$-distance of the embedding layer. The deeper the color, the farther the distance.

We observe that the domain-specific vocabulary part changes a lot during the pre-training time, which indicates that our model learns much information about these domain-specific terms. We also observe that there is little change in many original sub-words' embedding weights, which indicates that many general vocabularies can be used directly in continual training.

7 Conclusion

In this paper, we investigate several variations to compress general BERT models to specific domains. Our experiments reveal that the best strategy to obtain a task-agnostic domain-specific pretrained model is to adapt large and small models into specific domains separately and then compress the adapted large model with the adapted small model as initialization. We show that the adapted 6-layer model of 384 hidden dimensions outperforms the BERT$_{\text{BASE}}$ model while 3.3× smaller and 5.0× faster than BERT$_{\text{BASE}}$. Our findings suggest that domain-specific vocabulary and general-domain language model play vital roles in domain adaptation of a pretrained model. In the future, we will investigate more directions in domain adaptation, such as data selection and efficient adaptation.

Abstract

Adversarial debiasing can help to learn fairer models. Previous work has assumed that both main task labels and protected attributes are available in the dataset. However, protected labels are often unavailable, or only available in limited numbers. In this paper, we propose a training strategy which needs only a small volume of protected labels in adversarial training, incorporating an estimation method to transfer private-labelled instances from one dataset to another. We demonstrate the in- and cross-domain effectiveness of our method through a range of experiments.

1 Introduction

Protected attributes such as user gender can act as confounding variables in models, and spurious correlations with task response variables can lead to unfair predictions, as seen in tasks such as part-of-speech tagging (Hovy and Søgaard, 2015), hate speech detection (Huang et al., 2020), and sentiment analysis (Kiritchenko and Mohammad, 2018).

Adversarial methods are a popular method for mitigating bias associated with protected attributes, wherein the encoder attempts to prevent a discriminator from identifying protected attributes (Zhang et al., 2018; Li et al., 2018; Han et al., 2021). An adversarial network consists of a discriminator A and an encoder E. Each input x_i is required to be annotated with both a main task label y_i and protected attribute label g_i, and the discriminator identifies protected information in the representation generated by the encoder ($\hat{g}_i = A(h_i)$). The objective of the encoder training incorporates two parts: (1) predicting the main task label ($\hat{y}_i = C(E(x_i))$); and (2) preventing protected attributes from being identified by the discriminator.

An important limitation of previous adversarial debiasing work is that training instances must be annotated with both main task and protected labels (Li et al., 2018; Wadsworth et al., 2018; Zhang et al., 2018; Wang et al., 2019; Han et al., 2021). However, sourcing protected labels can be difficult, for reasons ranging from privacy regulations/ethical concerns, to only a small subset of users explicitly publicly disclosing protected attributes.

Our contributions are as follows: (1) we present a novel way of training the main task model and the discriminator separately, removing the restriction that every training instance needs to be annotated with protected labels; (2) we conduct in-domain experiments with diminishingly small amounts of protected-labelled data for sentiment analysis and hate speech detection, and show that our method can be successfully applied with remarkably little protected data; and (3) we present preliminary results for cross-domain transfer of protected attributes for sentiment analysis and POS tagging. The source code and data associated with this paper are available at: `https://github.com/HanXudong/Decoupling_Adversarial_Training_for_Fair_NLP`.

2 Methodology

Adversarial Separation Training Intuitively, adversarial supervision can be decoupled from the main task training, i.e., the inputs used for training the main model do not have to be annotated with protected labels. In doing so, we attain flexibility in being able to train the discriminator over only those instances where we have access to the protected attribute, as well as being able to transfer private attributes between datasets. Following the setup of Li et al. (2018), the optimisation objective is:

$$\min_{E,C} \max_{A} \sum_{i \in \mathcal{D}_{\text{main}}} \mathcal{X}(y_i, \hat{y}_i(E, C)) - \lambda_{\text{adv}} \sum_{j \in \mathcal{D}_{\text{adv}}} \mathcal{X}(g_j, \hat{g}_j(E, A)) \,,$$

Algorithm 1: Predictability Estimation

```
Input: Out of domain dataset $D_O = (X_O, G_O)$,
       pretrained main task model $M_I$ in the target
       domain, $\mathcal{M}$, number of folds $k$, number of
       test folds at each step $t$
Output: protected label predictability scores, $\mathcal{P}$
Calculate hidden representations $H_O$ of $X_O$ from $M_I$
Partition $D_O$ into $k$ equi-sized folds as $\{F_1, \ldots, F_k\}$
Create $\binom{k}{t}$ test fold combinations as $T$
for $i \leftarrow$ to $\binom{k}{t}$ do
    Use $T_i$ as $F_{\text{test}}$, remaining folds as $F_{\text{train}}$
    Train $\mathcal{M}$ on $F_{\text{train}}$
    forall $(h_{O,j}, g_{O,j}) \in F_{test}$ do
        Make prediction $\hat{g}_{O,j} = \mathcal{M}(h_{O,j})$
        Accumulate correct predictions
          $\mathcal{P}(j) \mathrel{+}= \delta(\hat{g}_{O,j}, g_{O,j})$
    end
end
return $\mathcal{P}$
```

where $\mathcal{X}$ is cross entropy loss, and λ_{adv} is a tunable hyperparameter. The critical observation of this work is that the two sources of data $\mathcal{D}_{\text{main}}$ and $\mathcal{D}_{\text{adv}}$ need not be the same, but may overlap or be entirely disjoint, as we explore in Section 3.

Filtering Cross-domain Data The inputs used for discriminator training do not have to be annotated with the main task label. Inspired by the domain robustness results of Li et al. (2018) with adversarial training, we examine cross-domain adversarial learning where protected labels are unknown for the target task in two settings: (1) sentiment analysis classification, and (2) part of speech (POS) tagging. In both cases we use external race labels from a hate speech dataset, and ignore any protected attributes in the original dataset.

According to our experiments, one problem associated with using cross-domain protected-labelled data is that some protected labels may not be relevant to the target domain. To address this problem, inspired by adversarial filtering (Le Bras et al., 2020), we conduct preliminary exploration on filtering cross-domain data in adversarial separation training. This method finds out-of-domain instances with the most confident predictions of the protected label, and selects these instances to use as a silver standard in training in-domain adversaries.

To estimate the protected label predictability of a cross-domain instance $(x_{O,i}, g_{O,i})$ in the target domain given a trained main task model in the target domain (M_I) and an estimator $\mathcal{M}$ (a logistic regression classifier), the protected label predictability of each instance is estimated as shown in Algorithm 1. Specifically, for folds k and test folds t, the predictability of each instance is estimated n times (i.e., by n different models) over different training sets. n can be derived from k and t as follows: $n = \frac{(k-1)!}{(k-t)!(t-1)!}$. Note that when $t = 1$, our method equates to k-fold cross-validation, and the predictability of each instance is estimated once. We demonstrate how the estimated predictability $\mathcal{P}$ can be used in Section 3.5.

3 Experiments and Analysis

In this section, we report on experiments under two scenarios: (1) in-domain, where protected labelled data and main labelled data are from the same domain; and (2) cross-domain, where protected labelled data are from a different domain to the main task data.

3.1 GAP

A common way of measuring fairness is GAP: the absolute difference for a metric between data subsets selected by different settings of the protected attribute. For instance, in the binary setting, we can compare the true positive rate (TPR) for male- vs. female-authored documents in the test set; this difference is the TPR-GAP, and is zero for a fair model.

3.2 In-domain: Sentiment Analysis

Data We experiment with the dataset of Blodgett et al. (2016), which contains tweets that are either African American English (AAE)-like or Standard American English (SAE)-like (following Han et al. (2021)). Each tweet is annotated with a binary "race" label (based on AAE or SAE), and a binary sentiment score determined by the (redacted) emoji within it.

We use the train/dev/test splits from Han et al. (2021) of 100k/8k/8k instances, respectively. The full dataset is artificially balanced across the four race–sentiment combinations. To (re)introduce bias into the dataset, previous work has skewed the training data to generate race–sentiment combinations (AAE–happy, SAE–happy, AAE–sad, and SAE–sad) of 40%, 10%, 10%, and 40%, respectively, leaving the dev and test data unbiased.

To examine how much private labelled data is needed, we randomly mask the protected attribute from up to 99% of the training data.

Models We use the same model architecture as Han et al. (2021), in the form of the fixed-parameter DeepMoji encoder (Felbo et al., 2017)

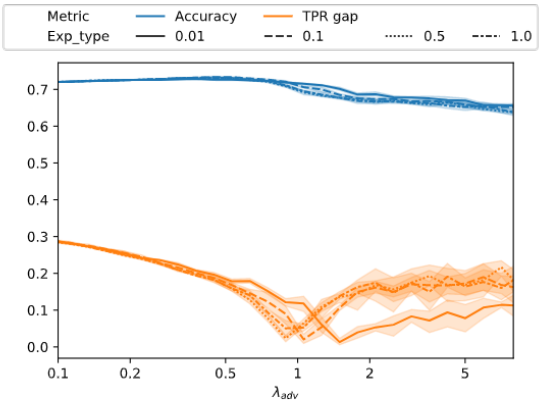

Figure 1: In-domain Sentiment Analysis: main task accuracy and GAP with respect to the trade-off hyperparameter λ_{adv}; shaded areas = 95% CI estimated over 5 runs.

followed by a trainable 3-layer MLP. DeeMoji contains 22.4 million parameters and is pretrained over 1246 million tweets to predict one of 64 common emojis. The discriminator for adversarial training (for all experiments in this paper) is trained to predict the protected attribute from the hidden states of the last hidden layer of the MLP classifier. Full training details are provided in the Appendix.

Results We explore 4 dataset settings where 100%, 50%, 10%, and 1% of the training data is labelled with its private attribute. We tune λ_{adv} log-uniformly under each data setting, using the same case-control training strategies for all experiments in this paper.

As shown in Figure 1, tuning λ_{adv} results in a series of candidate models, and there is a clear inflection point for the TPR GAP under each data setting, at different values of λ_{adv}.

To compare the adversarial training performance across different numbers of private labels, we show the trade-off plot in Figure 2a. Each point reflects the Accuracy and TPR GAP of a candidate model with a given λ_{adv}. The points for the three data settings of 100%, 50%, and 10% are hard to separate, indicating that adversarial training with only 10% of protected labels can achieve similar results to using protected labels for 100% of the data. Even with 1% of private labels, debiasing is evident, but this comes at a lower accuracy for a given TPR GAP level.

3.3 In-domain: Hate Speech Detection

Data Our second in-domain dataset is the English Twitter hate speech detection dataset of Huang et al. (2020), where each tweet is labelled with a binary hate speech label and also contains (binary) demographic indicators for the tweet author: binary gender (female or male), location (U.S. or other), age (older or younger than the median), and race (white or other). We focus on *age*, which has been shown to result in the greatest model unfairness (Huang et al., 2020), and use the train/dev/test splits of Huang et al. (2020). Since age information is not available for all authors, we downsample to get a subset of tweets which are annotated with age, with approximately 31k/6.7k/6.7k in training/dev/test.

Model Huang et al. (2020) compare 4 different model architectures for the hate speech detection task — TF-IDF-weighted feature-based logistic regression, convolutional neural network, an RNN (in the form of a biGRU), and BERT (Devlin et al., 2019) — and found the RNN model to consistently perform best. Based on this, we use the same RNN model, and perform debiasing on top of it.

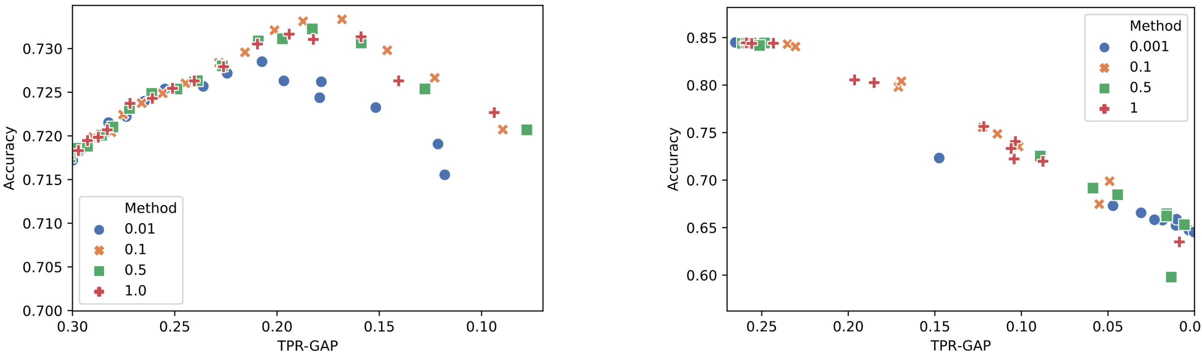
Results Figure 2b shows the trade-off plot with respect to hate speech detection models under similar data conditions as our first experiment (100%, 50%, 10%, and 0.1%). Consistent with our previous observations, there is little distinguishing 100%, 50%, and 10%. In fact, when we further decrease the proportion of protected labels, we observe that even with 0.1% of protected attributes, the trade-off is close to the 100% model.

3.4 Cross-domain: Sentiment Analysis

Next, we turn to the cross-domain setting, in taking protected labelled data from one domain and using it to adversarially debias a sentiment analyser over a different but similar domain.

Data We use the same model architecture and sentiment analysis dataset as in Section 3.2, but source private attributes (in the form of race) from the hate speech dataset from Section 3.3 to train the discriminator. Note that the race labels for the hate speech dataset (white or other) diverge slightly from those in the target domain (SAE or AAE).

Results Figure 3 shows the trade-off plot for the model. To compare the cross- and in-domain settings, we include in-domain adversarial debiasing results (1% data setting). Compared with in-domain results, the trade-off for cross-domain debiasing is worse than the 1% in-domain setting, but substantially better than random.



(a) Sentiment Analysis

(b) Hate Speech Detection

Figure 2: In-domain evaluation showing the accuracy–TPR-GAP trade-off for different fractions of protected-labels in the training dataset. For each data setting, we evaluate predictions for λ_{adv} settings near to that where the model achieves its smallest development TPR GAP. Since there is strong correlation between TPR GAP and TNR GAP, we only include TPR GAP.

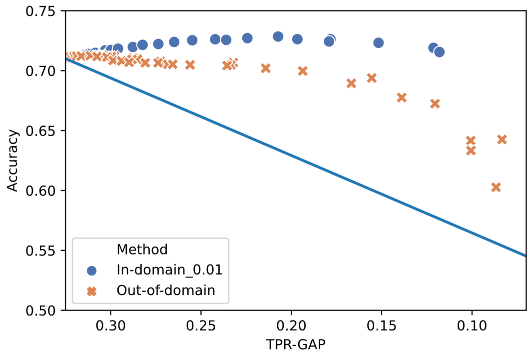


Figure 3: Cross-domain Sentiment Analysis: trade-off plot. The blue solid line denotes baseline debiasing results, based on randomly replacing main task predictions with a Bernoulli r.v. sampled from $p = 0.5$.

In terms of the drop in model accuracy during debiasing, each point in Figure 3 corresponds to a candidate model, and in this cross-domain setting, some models (e.g., for those models with TPR-GAP around 0.2) are able to reduce the bias by about 50% while maintaining performance that is close to the vanilla model. Managing the trade-off relates to model selection and the requirements of a given application scenario, for example, choosing a model that is able to achieve at least a certain fairness level. Overall, at a given bias level, our method doesn't make use of any in-domain protected labels, and consistently outperforms the random baseline.

3.5 Cross-domain: POS tagging

As second cross-domain task, we follow Li et al. (2018) in performing POS tagging.

Data We use three datasets for different purposes: main task training, adversarial training, and out-of-domain evaluation.

Following Li et al. (2018), we train a biLSTM POS tagging model on the English Web Treebank (Bies et al., 2012), comprising 13.5k POS-tagged sentences without protected labels. To evaluate model performance and fairness, we use the TrustPilot English POS-tagged dataset (Hovy and Søgaard, 2015), consisting of 600 sentences with both POS labels and binary author-age labels (over-45-year-old and under-35-year-old).

To train the discriminator, we use unlabelled TrustPilot data (Hovy, 2015), which consists of 156.5k English reviews with author-age labels. Based on protected-label predictability estimation (Algorithm 1), we examine 4 subsampling strategies: (1) "random", based on random-sampling; (2) "largest leakage", select instances with the highest predictability (intuitively the most biased instances); (3) "smallest leakage", select instances where the predictability is below a majority-class baseline; and (4) "absolute leakage", a combination of largest and smallest leakage where equal number of instances from the largest leakage sampling and the smallest leakage sampling are concatenated together.

Results We follow Li et al. (2018), in evaluating fairness via the difference in tagging accuracy between age groups.

Figure 4 shows the trade-off plot with respect to the 4 filtering strategies. Note that the test set only includes 600 instances, so we explore a wider range of the λ_{adv}, and train 5 random initialized

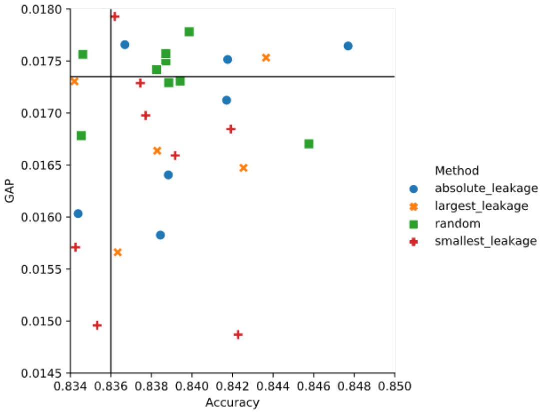

Figure 4: Cross-domain POS Tagging. The vertical line denotes the biased model accuracy, and the horizontal line denotes the biased model Accuracy GAP. Points in the upper-right quadrant are preferable.

	Top P		**Top F**	
	Acc↑	GAP↓	ACC↑	GAP↓
Biased	83.60	1.74	83.60	1.74
Random	83.94	1.73	83.89	1.70
Largest	83.86	1.66	83.63	1.63
Smallest	83.92	1.68	83.53	1.57
Absolute	84.18	1.75	83.84	1.64

Table 1: Evaluation results on the test set, median value over 5 best models. Biased stands for the non-debiasing model. **Top P** = 5 models with best performance, and **Top F** = 5 models with best fairness. "↑" and "↓" indicate that higher and lower performance, resp., is better for the given metric.

models for each λ_{adv} and take the average. Points in the lower-right quadrant are preferable, in that they decrease bias while increasing accuracy.

We report models of each predictability estimation based sampling method, and all models from random sampling (with respect to different λ_{adv}). Compared to the biased model performance and fairness (vertical and horizontal lines, respectively), the random sampling method does not lead to clear improvements, while our proposed methods lead to consistent gains.

We further compare these methods numerically in Table 1 by selecting top 5 best models from what has been shown in Figure 4. Specifically, we select models with top 5 performance (largest accuracy score) or fairness (smallest GAP) separately, and report the median values of accuracy and GAP over the selected models.

Largest and smallest leakage show close results and are safer choices that consistently outperform random and non-debiasing methods. Intuitively, in a binary classification problem, instances within the the smallest leakage group could also be informative as they could be transformed to largest leakage groups by reverting the predictions, i.e., $\hat{g}_{O,j} = 1 - \mathcal{M}(h_{O,j})$, thus using largest leakage sampling is similar to using smallest leakage sampling. Combining largest and smallest leakage instances together, the absolute sampling method achieves slightly better accuracy performance than other sampling strategies and consist better performance-fairness trade-off than the biased model.

4 Conclusion

We propose a novel training strategy for adversarial debiasing which decouples the training of the main task model and discriminator, including the possibility of training on different data. Based on in-domain evaluation over sentiment analysis and hate speech detection, our method performs as well as the standard adversarial method using only 10% of protected labels. Furthermore, experiments in a cross-domain setting demonstrate the potential feasibility of the method in settings where protected labels are not available.

Acknowledgments

We thank Lea Frermann, Shivashankar Subramanian, and the anonymous reviewers for their helpful feedback and suggestions.

Ethical Considerations

This work aims to use less protected-labelled data in adversarial debiasing. Adversarial training in NLP can help to learn fairer models across demographic attributes used. However, due to the lack of protected labels, previous work has had to use identified demographic attributes for adversarial debasing. By reducing the number of protected labels that are needed in adversarial training, using only self-identified characteristics becomes an effective choice.
