Abstract

Data augmentation has recently seen increased interest in NLP due to more work in low-resource domains, new tasks, and the popularity of large-scale neural networks that require large amounts of training data. Despite this recent upsurge, this area is still relatively underexplored, perhaps due to the challenges posed by the discrete nature of language data. In this paper, we present a comprehensive and unifying survey of data augmentation for NLP by summarizing the literature in a structured manner. We first introduce and motivate data augmentation for NLP, and then discuss major methodologically representative approaches. Next, we highlight techniques that are used for popular NLP applications and tasks. We conclude by outlining current challenges and directions for future research. Overall, our paper aims to clarify the landscape of existing literature in data augmentation for NLP and motivate additional work in this area. We also present a GitHub repository with a paper list that will be continuously updated at https://github.com/styfeng/DataAug4NLP.

1 Introduction

Data augmentation (DA) refers to strategies for increasing the diversity of training examples without explicitly collecting new data. It has received active attention in recent machine learning (ML) research in the form of well-received, general-purpose techniques such as UDA (Xie et al., 2020) (3.1) and MixUp (Zhang et al., 2017) (3.2). These are often first explored in computer vision (CV), and DA's adaptation for natural language processing (NLP) seems secondary and comparatively underexplored, perhaps due to challenges presented by the discrete nature of language, which rules out continuous noising and makes it hard to maintain invariance.

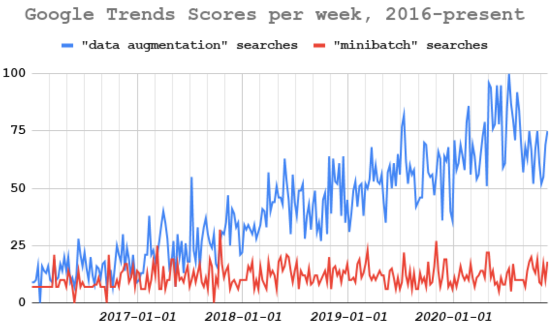

Figure 1: Weekly Google Trends scores for the search term *"data augmentation"*, with a control, uneventful ML search term (*"minibatch"*) for comparison.

Despite these challenges, there has been increased interest and demand for DA for NLP. As NLP grows due to off-the-shelf availability of large pretrained models, there are increasingly more tasks and domains to explore. Many of these are low-resource, and have a paucity of training examples, creating many use-cases for which DA can play an important role. Particularly, for many non-classification NLP tasks such as span-based tasks and generation, DA research is relatively sparse despite their ubiquity in real-world settings.

Our paper aims to sensitize the NLP community towards this growing area of work, which has also seen increasing interest in ML overall (as seen in Figure 1). As interest and work on this topic continue to increase, this is an opportune time for a paper of our kind to (i) give a bird's eye view of DA for NLP, and (ii) identify key challenges to effectively motivate and orient interest in this area. To the best of our knowledge, this is the first survey to take a detailed look at DA methods for NLP.[1]

This paper is structured as follows. Section

---

[*] Equal contribution by the two authors.

[†] AI Resident.

[1] Liu et al. (2020a) present a smaller-scale text data augmentation survey that is concise and focused. Our work serves as a more comprehensive survey with larger coverage and is more up-to-date.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 968–988
August 1–6, 2021.

2 discusses what DA is, its goals and trade-offs, and why it works. Section 3 describes popular methodologically representative DA techniques for NLP—which we categorize into rule-based (3.1), example interpolation-based (3.2), or model-based (3.3). Section 4 discusses useful NLP applications for DA, including low-resource languages (4.1), mitigating bias (4.2), fixing class imbalance (4.3), few-shot learning (4.4), and adversarial examples (4.5). Section 5 describes DA methods for common NLP tasks including summarization (5.1), question answering (5.2), sequence tagging tasks (5.3), parsing tasks (5.4), grammatical error correction (5.5), neural machine translation (5.6), data-to-text NLG (5.7), open-ended and conditional text generation (5.8), dialogue (5.9), and multimodal tasks (5.10). Finally, Section 6 discusses challenges and future directions in DA for NLP. Appendix A lists useful blog posts and code repositories.

Through this work, we hope to emulate past papers which have surveyed DA methods for other types of data, such as images (Shorten and Khoshgoftaar, 2019), faces (Wang et al., 2019b), and time series (Iwana and Uchida, 2020). We hope to draw further attention, elicit broader interest, and motivate additional work in DA, particularly for NLP.

2 Background

What is data augmentation? Data augmentation (DA) encompasses methods of increasing training data diversity without directly collecting more data. Most strategies either add slightly modified copies of existing data or create synthetic data, aiming for the augmented data to act as a regularizer and reduce overfitting when training ML models (Shorten and Khoshgoftaar, 2019; Hernández-García and König, 2020). DA has been commonly used in CV, where techniques like *cropping*, *flipping*, and *color jittering* are a standard component of model training. In NLP, where the input space is discrete, how to generate effective augmented examples that capture the desired invariances is less obvious.

What are the goals and trade-offs? Despite challenges associated with text, many DA techniques for NLP have been proposed, ranging from rule-based manipulations (Zhang et al., 2015) to more complicated generative approaches (Liu et al., 2020b). As DA aims to provide an alternative to collecting more data, an ideal DA technique should be both easy-to-implement and improve model performance. Most offer trade-offs between these two.

Rule-based techniques are easy-to-implement but usually offer incremental performance improvements (Li et al., 2017; Wei and Zou, 2019; Wei et al., 2021b). Techniques leveraging trained models may be more costly to implement but introduce more data variation, leading to better performance boosts. Model-based techniques customized for downstream tasks can have strong effects on performance but be difficult to develop and utilize.

Further, the distribution of augmented data should neither be too similar nor too different from the original. This may lead to greater overfitting or poor performance through training on examples not representative of the given domain, respectively. Effective DA approaches should aim for a balance.

Kashefi and Hwa (2020) devise a KL-Divergence-based unsupervised procedure to *preemptively* choose among DA heuristics, rather than a typical "run-all-heuristics" comparison, which can be very time and cost intensive.

Interpretation of DA Dao et al. (2019) note that *"data augmentation is typically performed in an adhoc manner with little understanding of the underlying theoretical principles"*, and claim the typical explanation of DA as *regularization* to be insufficient. Overall, there indeed appears to be a lack of research on *why* exactly DA works. Existing work on this topic is mainly surface-level, and rarely investigates the theoretical underpinnings and principles. We discuss this challenge more in §6, and highlight some of the existing work below.

Bishop (1995) show training with noised examples is reducible to Tikhonov regularization (subsumes L2). Rajput et al. (2019) show that DA can increase the positive margin for classifiers, but only when augmenting exponentially many examples for common DA methods.

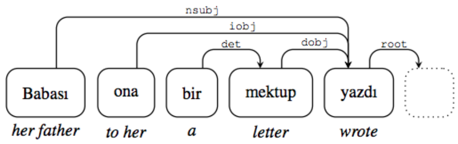
Dao et al. (2019) think of DA transformations as kernels, and find two ways DA helps: averaging of features and variance regularization. Chen et al. (2020d) show that DA leads to variance reduction by averaging over orbits of the group that keep the data distribution approximately invariant.

3 Techniques & Methods

We now discuss some methodologically representative DA techniques which are relevant to all tasks via the extensibility of their formulation.[2]

---

[2] Table 1 compares several DA methods by various aspects relating to their applicability, dependencies, and requirements.



(a) Dependency analysis

(1) Babası yazdı (Her father he-wrote)
(2) Ona yazdı (He-wrote to her)
(3) Bir mektup yazdı (He-wrote a letter)

(b) Sentence Cropping

(1) Babası yazdı bir mektup ona (SVOIO)
(2) Yazdı babası ona bir mektup (VSIOO)
(3) Bir mektup yazdı babası ona (OVSIO)
(4) Ona bir mektup yazdı babası (IOOVS)

(c) Sentence Rotating

Figure 2: *Dependency tree morphing* DA applied to a Turkish sentence, Şahin and Steedman (2018)

3.1 Rule-Based Techniques

Here, we cover DA primitives which use easy-to-compute, predetermined transforms sans model components. *Feature space DA* approaches generate augmented examples in the model's feature space rather than input data. Many few-shot learning approaches (Hariharan and Girshick, 2017; Schwartz et al., 2018) leverage estimated feature space "analogy" transformations between examples of known classes to augment for novel classes (see §4.4). Paschali et al. (2019) use iterative affine transformations and projections to maximally "stretch" an example along the class-manifold.

Wei and Zou (2019) propose EASY DATA AUGMENTATION (EDA), a set of token-level random perturbation operations including *random insertion, deletion*, and *swap*. They show improved performance on many text classification tasks. UDA (Xie et al., 2020) show how supervised DA methods can be exploited for unsupervised data through consistency training on $(x, DA(x))$ pairs.

For paraphrase identification, Chen et al. (2020b) construct a signed graph over the data, with individual sentences as nodes and pair labels as signed edges. They use balance theory and transitivity to infer augmented sentence pairs from this graph. Motivated by image cropping and rotation, Şahin and Steedman (2018) propose *dependency tree morphing*. For dependency-annotated sentences, children of the same parent are swapped (à la rotation) or some deleted (à la cropping), as seen in Figure 2. This is most beneficial for language families with rich case marking systems (e.g. *Baltic* and *Slavic*).

3.2 Example Interpolation Techniques

Another class of DA techniques, pioneered by MIXUP (Zhang et al., 2017), interpolates the inputs and labels of two or more real examples. This class of techniques is also sometimes referred to as *Mixed Sample Data Augmentation* (MSDA). Ensuing work has explored interpolating inner components (Verma et al., 2019; Faramarzi et al., 2020), more general mixing schemes (Guo, 2020), and adding adversaries (Beckham et al., 2019).

Another class of extensions of MIXUP which has been growing in the vision community attempts to fuse raw input image pairs together into a single input image, rather than improve the continuous interpolation mechanism. Examples of this paradigm include CUTMIX (Yun et al., 2019), CUTOUT (DeVries and Taylor, 2017) and COPY-PASTE (Ghiasi et al., 2020). For instance, CUTMIX replaces a small sub-region of Image A with a patch sampled from Image B, with the labels mixed in proportion to sub-region sizes. There is potential to borrow ideas and inspiration from these works for NLP, e.g. for multimodal work involving both images and text (see *"Multimodal challenges"* in §6).

A bottleneck to using MIXUP for NLP tasks was the requirement of continuous inputs. This has been overcome by mixing embeddings or higher hidden layers (Chen et al., 2020c). Later variants propose speech-tailored mixing schemes (Jindal et al., 2020b) and interpolation with adversarial examples (Cheng et al., 2020), among others.

SEQ2MIXUP (Guo et al., 2020) generalizes MIXUP for sequence transduction tasks in two ways - the "hard" version samples a binary mask (from a Bernoulli with a $\beta(\alpha, \alpha)$ prior) and picks from one of two sequences at each token position, while the "soft" version softly interpolates between sequences based on a coefficient sampled from $\beta(\alpha, \alpha)$. The "soft" version is found to outperform the "hard" version and earlier interpolation-based techniques like SWITCHOUT (Wang et al., 2018a).

3.3 Model-Based Techniques

Seq2seq and language models have also been used for DA. The popular BACKTRANSLATION method (Sennrich et al., 2016) translates a sequence into another language and then back into the original language. Kumar et al. (2019a) train seq2seq models with their proposed method DiPS which learns to generate diverse paraphrases of input text using a modified decoder with a submodular objective,

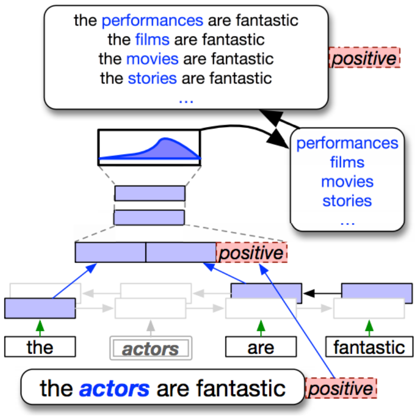


Figure 3: *Contextual Augmentation*, Kobayashi (2018)

and show its effectiveness as DA for several classification tasks. Pretrained language models such as RNNs (Kobayashi, 2018) and transformers (Yang et al., 2020) have also been used for augmentation.

Kobayashi (2018) generate augmented examples by replacing words with others randomly drawn according to the recurrent language model's distribution based on the current context (illustration in Figure 3). Yang et al. (2020) propose G-DAUG^c which generates synthetic examples using pretrained transformer language models, and selects the most informative and diverse set for augmentation. Gao et al. (2019) advocate retaining the full distribution through "soft" augmented examples, showing gains on machine translation.

Nie et al. (2020) augment word representations with a context-sensitive attention-based mixture of their semantic neighbors from a pretrained embedding space, and show its effectiveness for NER on social media text. Inspired by denoising autoencoders, Ng et al. (2020) use a corrupt-and-reconstruct approach, with the corruption function $q(x'|x)$ masking an arbitrary number of word positions and the reconstruction function $r(x|x')$ unmasking them using BERT (Devlin et al., 2019). Their approach works well on domain-shifted test sets across 9 datasets on sentiment, NLI, and NMT.

Feng et al. (2019) propose a task called SEMANTIC TEXT EXCHANGE (STE) which involves adjusting the overall semantics of a text to fit the context of a new word/phrase that is inserted called the *replacement entity (RE)*. They do so by using a system called SMERTI and a masked LM approach. While not proposed directly for DA, it can be used as such, as investigated in Feng et al. (2020).

Rather than starting from an existing example and modifying it, some model-based DA approaches directly estimate a generative process from the training set and sample from it. Anaby-Tavor et al. (2020) learn a label-conditioned generator by finetuning GPT-2 (Radford et al., 2019) on the training data, using this to generate candidate examples per class. A classifier trained on the original training set is then used to select top k candidate examples which confidently belong to the respective class for augmentation. Quteineh et al. (2020) use a similar label-conditioned GPT-2 generation method, and demonstrate its effectiveness as a DA method in an active learning setup.

Other approaches include syntactic or controlled paraphrasing (Iyyer et al., 2018; Kumar et al., 2020), document or story-level paraphrasing (Gangal et al., 2021), augmenting misclassified examples (Dreossi et al., 2018), BERT cross-encoder labeling of new inputs (Thakur et al., 2021), and guided generation using large-scale generative language models (Liu et al., 2020b,c). Models can also learn to combine together simpler DA primitives (Cubuk et al., 2018; Ratner et al., 2017) or add human-in-the-loop (Kaushik et al., 2020, 2021).

4 Applications

In this section, we discuss several DA methods for some common NLP applications.[2]

4.1 Low-Resource Languages

Low-resource languages are an important and challenging application for DA, typically for neural machine translation (NMT). Techniques using external knowledge such as WordNet (Miller, 1995) may be difficult to use effectively here.[3] There are ways to leverage high-resource languages for low-resource languages, particularly if they have similar linguistic properties. Xia et al. (2019) use this approach to improve low-resource NMT.

Li et al. (2020b) use *backtranslation* and self-learning to generate augmented training data. Inspired by work in CV, Fadaee et al. (2017) generate additional training examples that contain low-frequency (rare) words in synthetically created contexts. Qin et al. (2020) present a DA framework to generate multi-lingual code-switching data to finetune multilingual-BERT. It encourages the alignment of representations from source and multiple target languages once by mixing their context information. They see improved performance across 5 tasks with 19 languages.

---

[3] Low-resource language challenges discussed more in §6.

Table 1: Comparing a selection of DA methods by various aspects relating to their applicability, dependencies, and requirements. *Ext.Know*, *KWE*, *tok*, *const*, and *dep* stand for External Knowledge, keyword extraction, tokenization, constituency parsing, and dependency parsing, respectively. *Ext.Know* refers to whether the DA method requires external knowledge (e.g. WordNet) and *Pretrained* if it requires a pretrained model (e.g. BERT). *Preprocess* denotes preprocessing required, *Level* denotes the depth at which data is modified by the DA, and *Task-Agnostic* refers to whether the DA method can be applied to different tasks. See Appendix B for further explanation.

4.2 Mitigating Bias

Zhao et al. (2018) attempt to mitigate gender bias in coreference resolution by creating an augmented dataset identical to the original but biased towards the underrepresented gender (using gender swapping of entities such as replacing *"he"* with *"she"*) and train on the union of the two datasets. Lu et al. (2020) formally propose Counterfactual DA (CDA) for gender bias mitigation, which involves causal interventions that break associations between gendered and gender-neutral words. Zmigrod et al. (2019) and Hall Maudslay et al. (2019) propose further improvements to CDA. Moosavi et al. (2020) augment training sentences with their corresponding predicate-argument structures, improving the robustness of transformer models against various types of biases.

4.3 Fixing Class Imbalance

Fixing class imbalance typically involves a combination of undersampling and oversampling. Synthetic Minority Oversampling Technique (SMOTE) (Chawla et al., 2002), which generates augmented minority class examples through interpolation, still remains popular (Fernández et al., 2018). Multilabel SMOTE (MLSMOTE) (Charte et al., 2015) modifies SMOTE to balance classes for multi-label classification, where classifiers predict more than one class at the same time. Other techniques such as EDA (Wei and Zou, 2019) can possibly be used for oversampling as well.

4.4 Few-Shot Learning

DA methods can ease few-shot learning by adding more examples for novel classes introduced in the few-shot phase. Hariharan and Girshick (2017) use learned analogy transformations $\phi(z_1, z_2, x)$ between example pairs from a non-novel class $z_1 \rightarrow z_2$ to generate augmented examples $x \rightarrow x'$ for novel classes. Schwartz et al. (2018) generalize this to beyond just linear offsets, through their "Δ-network" autoencoder which learns the distribution

$P(z_2|z_1, C)$ from all $y^*_{z_1} = y^*_{z_2} = C$ pairs, where C is a class and y is the ground-truth labelling function. Both these methods are applied only on image tasks, but their theoretical formulations are generally applicable, and hence we discuss them.

Kumar et al. (2019b) apply these and other DA methods for few-shot learning of novel intent classes in task-oriented dialog. Wei et al. (2021a) show that data augmentation facilitates curriculum learning for training triplet networks for few-shot text classification. Lee et al. (2021) use T5 to generate additional examples for data-scarce classes.

4.5 Adversarial Examples (AVEs)

Adversarial examples can be generated using innocuous label-preserving transformations (e.g. paraphrasing) that fool state-of-the-art NLP models, as shown in Jia et al. (2019). Specifically, they add sentences with distractor spans to passages to construct AVEs for span-based QA. Zhang et al. (2019d) construct AVEs for paraphrase detection using word swapping. Kang et al. (2018) and Glockner et al. (2018) create AVEs for textual entailment using WordNet relations.

5 Tasks

In this section, we discuss several DA works for common NLP tasks.[2] We focus on non-classification tasks as classification is worked on by default, and well covered in earlier sections (e.g. §3 and §4). Numerous previously mentioned DA techniques, e.g. (Wei and Zou, 2019; Chen et al., 2020b; Anaby-Tavor et al., 2020), have been used or can be used for text classification tasks.

5.1 Summarization

Fabbri et al. (2020) investigate *backtranslation* as a DA method for few-shot abstractive summarization with the use of a consistency loss inspired by UDA. Parida and Motlicek (2019) propose an iterative DA approach for abstractive summarization that uses a mix of synthetic and real data, where the former is generated from Common Crawl. Zhu et al. (2019) introduce a query-focused summarization (Dang, 2005) dataset collected using Wikipedia called WIKIREF which can be used for DA. Pasunuru et al. (2021) use DA methods to construct two training datasets for Query-focused Multi-Document Summarization (QMDS) called QMDSCNN and QMDSIR by modifying CNN/DM (Hermann et al., 2015) and mining search-query logs, respectively.

5.2 Question Answering (QA)

Longpre et al. (2019) investigate various DA and sampling techniques for domain-agnostic QA including paraphrasing by *backtranslation*. Yang et al. (2019) propose a DA method using distant supervision to improve BERT finetuning for open-domain QA. Riabi et al. (2020) leverage Question Generation models to produce augmented examples for zero-shot cross-lingual QA. Singh et al. (2019) propose XLDA, or CROSS-LINGUAL DA, which substitutes a portion of the input text with its translation in another language, improving performance across multiple languages on NLI tasks including the SQuAD QA task. Asai and Hajishirzi (2020) use logical and linguistic knowledge to generate additional training data to improve the accuracy and consistency of QA responses by models. Yu et al. (2018) introduce a new QA architecture called QANet that shows improved performance on SQuAD when combined with augmented data generated using backtranslation.

5.3 Sequence Tagging Tasks

Ding et al. (2020) propose DAGA, a two-step DA process. First, a language model over sequences of tags and words linearized as per a certain scheme is learned. Second, sequences are sampled from this language model and de-linearized to generate new examples. Şahin and Steedman (2018), discussed in §3.1, use *dependency tree morphing* (Figure 2) to generate additional training examples on the downstream task of part-of-speech (POS) tagging.

Dai and Adel (2020) modify DA techniques proposed for sentence-level tasks for named entity recognition (NER), including label-wise token and synonym replacement, and show improved performance using both recurrent and transformer models. Zhang et al. (2020) propose a DA method based on MIXUP called SEQMIX for active sequence labeling by augmenting queried samples, showing improvements on NER and Event Detection.

5.4 Parsing Tasks

Jia and Liang (2016) propose DATA RECOMBINATION for injecting task-specific priors to neural semantic parsers. A synchronous context-free grammar (SCFG) is induced from training data, and new "recombinant" examples are sampled. Yu et al. (2020) introduce GRAPPA, a pretraining approach for table semantic parsing, and generate synthetic question-SQL pairs via an SCFG. Andreas (2020) use *compositionality* to construct synthetic examples for downstream tasks like semantic parsing. Fragments of original examples are replaced with fragments from other examples in similar contexts.

Vania et al. (2019) investigate DA for low-resource dependency parsing including *dependency tree morphing* from Şahin and Steedman (2018) (Figure 2) and modified *nonce* sentence generation from Gulordava et al. (2018), which replaces content words with other words of the same POS, morphological features, and dependency labels.

5.5 Grammatical Error Correction (GEC)

Lack of parallel data is typically a barrier for GEC. Various works have thus looked at DA methods for GEC. We discuss some here, and more can be found in Table 2 in Appendix C.

There is work that makes use of additional resources. Boyd (2018) use German edits from Wikipedia revision history and use those relating to GEC as augmented training data. Zhang et al. (2019b) explore multi-task transfer, or the use of annotated data from other tasks.

There is also work that adds synthetic errors to noise the text. Wang et al. (2019a) investigate two approaches: token-level perturbations and training error generation models with a filtering strategy to keep generations with sufficient errors. Grundkiewicz et al. (2019) use *confusion sets* generated by a spellchecker for noising. Choe et al. (2019) learn error patterns from small annotated samples along with *POS-specific noising*.

There have also been approaches to improve the diversity of generated errors. Wan et al. (2020) investigate noising through editing the latent representations of grammatical sentences, and Xie et al. (2018) use a neural sequence transduction model and beam search noising procedures.

5.6 Neural Machine Translation (NMT)

There are many works which have investigated DA for NMT. We highlighted some in §3 and §4.1, e.g. (Sennrich et al., 2016; Fadaee et al., 2017; Xia et al., 2019). We discuss some further ones here, and more can be found in Table 3 in Appendix C.

Wang et al. (2018a) propose SWITCHOUT, a DA method that randomly replaces words in both source and target sentences with other random words from their corresponding vocabularies. Gao et al. (2019) introduce SOFT CONTEXTUAL DA that softly augments randomly chosen words in a sentence using a contextual mixture of multiple related words over the vocabulary. Nguyen et al. (2020) propose DATA DIVERSIFICATION which merges original training data with the predictions of several forward and backward models.

5.7 Data-to-Text NLG

Data-to-text NLG refers to tasks which require generating natural language descriptions of structured or semi-structured data inputs, e.g. game score tables (Wiseman et al., 2017). Randomly perturbing game score values without invalidating overall game outcome is one DA strategy explored in game summary generation (Hayashi et al., 2019).

Two popular recent benchmarks are E2E-NLG (Dušek et al., 2018) and WebNLG (Gardent et al., 2017). Both involve generation from structured inputs - meaning representation (MR) sequences and triple sequences, respectively. Montella et al. (2020) show performance gains on WebNLG by DA using Wikipedia sentences as targets and parsed OpenIE triples as inputs. Tandon et al. (2018) propose DA for E2E-NLG based on permuting the input MR sequence. Kedzie and McKeown (2019) inject Gaussian noise into a trained decoder's hidden states and sample diverse augmented examples from it. This sample-augment-retrain loop helps performance on E2E-NLG.

5.8 Open-Ended & Conditional Generation

There has been limited work on DA for open-ended and conditional text generation. Feng et al. (2020) experiment with a suite of DA methods for finetuning GPT-2 on a low-resource domain in attempts to improve the quality of generated continuations, which they call GENAUG. They find that WN-HYPERS (WordNet hypernym replacement of keywords) and SYNTHETIC NOISE (randomly perturbing non-terminal characters in words) are useful, and the quality of generated text improves to a peak at $\approx$ 3x the original amount of training data.

5.9 Dialogue

Most DA approaches for dialogue focus on task-oriented dialogue. We outline some below, and more can be found in Table 4 in Appendix C.

Quan and Xiong (2019) present sentence and word-level DA approaches for end-to-end task-oriented dialogue. Louvan and Magnini (2020) propose LIGHTWEIGHT AUGMENTATION, a set of word-span and sentence-level DA methods for low-resource slot filling and intent classification.

Hou et al. (2018) present a seq2seq DA framework to augment dialogue utterances for dialogue language understanding (Young et al., 2013), including a *diversity rank* to produce diverse utterances. Zhang et al. (2019c) propose MADA to generate diverse responses using the property that several valid responses exist for a dialogue context.

There is also DA work for spoken dialogue. Hou et al. (2018), Kim et al. (2019), Zhao et al. (2019), and Yoo et al. (2019) investigate DA methods for dialogue and *spoken language understanding* (SLU), including generative latent variable models.

5.10 Multimodal Tasks

DA techniques have also been proposed for multimodal tasks where aligned data for multiple modalities is required. We look at ones that involve language or text. Some are discussed below, and more can be found in Table 5 in Appendix C.

Beginning with speech, Wang et al. (2020) propose a DA method to improve the robustness of downstream dialogue models to speech recognition errors. Wiesner et al. (2018) and Renduchintala et al. (2018) propose DA methods for end-to-end *automatic speech recognition* (ASR).

Looking at images or video, Xu et al. (2020) learn a cross-modality matching network to produce synthetic image-text pairs for multimodal classifiers. Atliha and Šešok (2020) explore DA methods such as synonym replacement and contextualized word embeddings augmentation using BERT for *image captioning*. Kafle et al. (2017), Yokota and Nakayama (2018), and Tang et al. (2020) propose methods for *visual QA* including question generation and adversarial examples.

6 Challenges & Future Directions

Looking forward, data augmentation faces substantial challenges, specifically for NLP, and with these challenges, new opportunities for future work arise.

Dissonance between empirical novelties and theoretical narrative: There appears to be a conspicuous lack of research on *why* DA works. Most studies might show empirically that a DA technique works and provide some intuition, but it is currently challenging to measure the goodness of a technique without resorting to a full-scale experiment. A recent work in vision (Gontijo-Lopes et al., 2020) has proposed that affinity (the distributional shift caused by DA) and diversity (the complexity of the augmentation) can predict DA performance, but it is unclear how these results might translate to NLP.

Minimal benefit for pretrained models on in-domain data: With the popularization of large pretrained language models, it has recently come to light that a couple of previously effective DA techniques for certain text classification tasks in English (Wei and Zou, 2019; Sennrich et al., 2016) provide little benefit for models like BERT and RoBERTa, which already achieve high performance on in-domain text classification (Longpre et al., 2020). One hypothesis for this could be that using simple DA techniques provides little benefit when finetuning large pretrained transformers on tasks for which examples are well-represented in the pretraining data, but DA methods could still be effective when finetuning on tasks for which examples are scarce or out-of-domain compared with the training data. Further work could study under which scenarios data augmentation for large pretrained models is likely to be effective.

Multimodal challenges: While there has been increased work in multimodal DA, as discussed in §5.10, effective DA methods for multiple modalities has been challenging. Many works focus on augmenting a single modality or multiple ones separately. For example, there is potential to further explore simultaneous image and text augmentation for image captioning, such as a combination of CUTMIX (Yun et al., 2019) and caption editing.

Span-based tasks offer unique DA challenges as there are typically many correlated classification decisions. For example, random token replacement may be a locally acceptable DA method but possibly disrupt coreference chains for latter sentences. DA techniques here must take into account dependencies between different locations in the text.

Working in specialized domains such as those with domain-specific vocabulary and jargon (e.g. *medicine*) can present challenges. Many pretrained models and external knowledge (e.g. WordNet) cannot be effectively used. Studies have shown that DA becomes less beneficial when applied to out-of-domain data, likely because the distribution of augmented data can substantially differ from the original data (Zhang et al., 2019a; Herzig et al., 2020; Campagna et al., 2020; Zhong et al., 2020).

Working with low-resource languages may present similar difficulties as specialized domains.

Further, DA techniques successful in the high-resource scenario may not be effective for low-resource languages that are of a different language family or very distinctive in linguistic and typological terms. For example, those which are language isolates or lack high-resource cognates.

More vision-inspired techniques: Although many NLP DA methods have been inspired by analogous approaches in CV, there is potential for drawing further connections. Many CV DA techniques motivated by real-world invariances (e.g. many angles of looking at the same object) may have similar NLP interpretations. For instance, *grayscaling* could translate to toning down aspects of the text (e.g. plural to singular, *"awesome"* → *"good"*). Morphing a dependency tree could be analogous to rotating an image, and paraphrasing techniques may be analogous to changing perspective. For example, negative data augmentation (NDA) (Sinha et al., 2021) involves creating out-of-distribution samples. It has so far been exclusively explored for CV, but could be investigated for text.

Self-supervised learning: More recently, DA has been increasingly used as a key component of self-supervised learning, particularly in vision (Chen et al., 2020e). In NLP, BART (Lewis et al., 2020) showed that predicting deleted tokens as a pretraining task can achieve similar performance as the masked LM, and ELECTRA (Clark et al., 2020) found that pretraining by predicting corrupted tokens outperforms BERT given the same model size, data, and compute. We expect future work will continue exploring how to effectively manipulate text for both pretraining and downstream tasks.

Offline versus online data augmentation: In CV, standard techniques such as cropping, color jittering, and rotations are typically done stochastically, allowing for DA to be incorporated elegantly into the training pipeline. In NLP, however, it is unclear how to include a lightweight code module to apply DA stochastically. This is because DA techniques for NLP often leverage external resources (e.g. a word dictionary for token substitution or a translation model for backtranslation) that are not easily transferable across model training pipelines. Thus, a common practice for DA in NLP is simply to generate augmented data offline and store it as additional data to be loaded during training.[4] Future work on a lightweight module for online DA in NLP could be fruitful, though another challenge will be determining when such a module will be helpful, which—compared with CV, where the invariances being imposed are well-accepted—can vary substantially across NLP tasks.

Lack of unification is a challenge for the current literature on data augmentation for NLP, and popular methods are often presented in an auxiliary fashion. Whereas there are well-accepted frameworks for DA for CV (e.g. default augmentation libraries in PyTorch, *RandAugment* (Cubuk et al., 2019)), there are no such "generalized" DA techniques for NLP. Further, we believe that DA research would benefit from the establishment of standard and unified benchmark tasks and datasets to compare different augmentation methods.

Good data augmentation practices would help make DA work more accessible and reproducible to the NLP and ML communities. On top of unified benchmark tasks, datasets, and frameworks/libraries mentioned above, other good practices include making code and augmented datasets publicly available, reporting variation among results (e.g. standard deviation across random seeds), and more standardized evaluation procedures. Further, transparent hyperparameter analysis, explicitly stating failure cases of proposed techniques, and discussion of the intuition and theory behind them would further improve the transparency and interpretability of DA techniques.

7 Conclusion

In this paper, we presented a comprehensive and structured survey of data augmentation for natural language processing (NLP). We provided a background about data augmentation and how it works, discussed major methodologically representative data augmentation techniques for NLP, and touched upon data augmentation techniques for popular NLP applications and tasks. Finally, we outlined current challenges and directions for future research, and showed that there is much room for further exploration. Overall, we hope our paper can serve as a guide for NLP researchers to decide on which data augmentation techniques to use, and inspire additional interest and work in this area. Please see the corresponding GitHub repository at https://github.com/styfeng/DataAug4NLP.

A Useful Blog Posts and Code Repositories

The following blog posts and code repositories could be helpful in addition to the information presented and papers/works mentioned in the body:

- Introduction to popular text augmentation techniques: https://towardsdatascience.com/data-augmentation-in-nlp-2801a34dfc28
- Detailed blog post on various text DA techniques: https://amitness.com/2020/05/data-augmentation-for-nlp/
- Lightweight library for DA on text and audio: https://github.com/makcedward/nlpaug
- `python` framework for adversarial examples: https://github.com/QData/TextAttack

B DA Methods Table - Description of Columns and Attributes

Table 1 in the main body compares a non-exhaustive selection of DA methods along various aspects relating to their applicability, dependencies, and requirements. Below, we provide a more extensive description of each of this table's columns and their attributes.

1. **Ext.Know**: Short for external knowledge, this column is ✓ when the data augmentation process requires knowledge resources which go beyond the immediate input examples and the task definition, such as WordNet (Miller, 1995) or PPDB (Pavlick et al., 2015). Note that we exclude the case where these resources are pretrained models under a separate point (next) for clarity, since these are widespread enough to merit a separate category.

2. **Pretrained**: Denotes that the data augmentation process requires a pretrained model, such as BERT (Devlin et al., 2019) or GPT-2 (Radford et al., 2019).

3. **Preprocess**: Denotes the preprocessing steps, e.g. tokenization (*tok*), dependency parsing (*dep*), etc. required for the DA process. A hyphen (-) means either no preprocessing is required or that it was not explicitly stated.

4. **Level**: Denotes the depth and extent to which elements of the instance/data are modified by the DA. Some primitives modify just the INPUT (e.g. word swapping), some modify both INPUT and LABEL (e.g. negation), while others make changes in the embedding or hidden space (EMBED/HIDDEN) or higher representation layers enroute to the task model.

5. **Task-Agnostic**: This is an approximate, partially subjective column denoting the extent to which a DA method can be applied to different tasks. When we say ✓ here, we don't denote a very rigid sense of the term task-agnostic, but mean that it would possibly easily extend to most NLP tasks as understood by the authors. Similarly, an × denotes being restricted to a specific task (or small group of related tasks) only. There can be other labels, denoting applicability to broad task families. For example, SUBSTRUCTURAL denotes the family of tasks where sub-parts of the input are also valid input examples in their own right, e.g. constituency parsing. SENTENCE PAIRS denotes tasks which involve pairwise sentence scoring such as paraphrase identification, duplicate question detection, and semantic textual similarity.

C Additional DA Works by Task

See Table 2 for additional DA works for GEC, Table 3 for additional DA works for neural machine translation, Table 4 for additional DA works for dialogue, and Table 5 for additional DA works for multimodal tasks. Each work is described briefly.

D Additional Figure

Pedro Domingos
@pmddomingos

Data augmentation is one of the ugliest hacks in ML. If you know what the invariances are, encode them into the architecture. Don't blow up the size of you dataset in order to approximate them.

Paper/Work	**Brief Description**
Lichtarge et al. (2019)	Generate synthetic noised examples of Wikipedia sentences using backtranslation through various languages.
White and Rozovskaya (2020)	Detailed comparative study of the DA for GEC systems UEdin-MS (Grundkiewicz et al., 2019) and Kakao&Brain (Choe et al., 2019).
Foster and Andersen (2009)	Introduces error generation tool called GenERRate which learns to generate ungrammatical text with various errors by using an error analysis file.
Kimn (2020)	Use a set of syntactic rules for common Japanese grammatical errors to generate augmented error-correct sentence pairs for Japanese GEC.
Felice (2016)	Thesis that surveys previous work on error generation and investigates some new approaches using random and probabilistic methods.
Xu et al. (2019)	Noises using five error types: concatenation, misspelling, substitution, deletion, and transposition. Decent performance on the BEA 2019 Shared Task.
Zhang et al. (2019b)	Explore backtranslation and feature discrimination for DA.
Mizumoto et al. (2011)	DA by extracting Japanese GEC training data from the revision log of a language learning SNS.

Table 2: Additional DA works for grammatical error correction (GEC), along with a brief description of each.

Paper/Work	**Brief Description**
Vaibhav et al. (2019)	Present a *synthetic noise induction* model which heuristically adds social media noise to text, and *labeled backtranslation*.
Hassan et al. (2017)	Present a DA method to project words from closely-related high-resource languages to low-resource languages using word embedding representations.
Cheng et al. (2020)	Propose *AdvAug*, an adversarial augmentation method for NMT, by sampling adversarial examples from a new vicinity distribution and using their embeddings to augment training.
Graça et al. (2019)	Investigate improvements to sampling-based approaches and the synthetic data generated by backtranslation.
Bulte and Tezcan (2019)	Propose DA approaches for NMT that leverage information retrieved from a Translation Memory (TM) and using fuzzy TM matches.
Moussallem et al. (2019)	Propose an NMT model KG-NMT which is augmented by knowledge graphs to enhance semantic feature extraction and hence the translation of entities and terminological expressions.
Peng et al. (2020)	Propose dictionary-based DA (DDA) for cross-domain NMT by synthesizing a domain-specific dictionary and automatically generating a pseudo in-domain parallel corpus.
Li et al. (2020a)	Present a DA method using sentence boundary segmentation to improve the robustness of NMT on ASR transcripts.
Nishimura et al. (2018)	Introduce DA methods for multi-source NMT that fills in incomplete portions of multi-source training data.
Sugiyama and Yoshinaga (2019)	Investigate effectiveness of DA by backtranslation for context-aware NMT.
Li and Specia (2019)	Present DA methods to improve NMT robustness to noise while keeping models small, and explore the use of noise from external data (speech transcripts).
Chinea-Ríos et al. (2017)	Propose DA method to create synthetic data by leveraging the embedding representation of sentences.

Abstract

Recent studies report that many machine reading comprehension (MRC) models can perform closely to or even better than humans on benchmark datasets. However, existing works indicate that many MRC models may learn *shortcuts* to outwit these benchmarks, but the performance is unsatisfactory in real-world applications. In this work, we attempt to explore, instead of the expected comprehension skills, why these models learn the *shortcuts*. Based on the observation that a large portion of questions in current datasets have *shortcut* solutions, we argue that larger proportion of *shortcut* questions in training data make models rely on *shortcut* tricks excessively. To investigate this hypothesis, we carefully design two synthetic datasets with annotations that indicate whether a question can be answered using *shortcut* solutions. We further propose two new methods to quantitatively analyze the learning difficulty regarding *shortcut* and challenging questions, and revealing the inherent learning mechanism behind the different performance between the two kinds of questions. A thorough empirical analysis shows that MRC models tend to learn *shortcut* questions earlier than challenging questions, and the high proportions of *shortcut* questions in training sets hinder models from exploring the sophisticated reasoning skills in the later stage of training.

1 Introduction

The task of machine reading comprehension (MRC) aims at evaluating whether a model can understand natural language texts by answering a series of questions. Recently, MRC research has seen considerable progress in terms of model performance, and many models are reported to approach or even outperform human-level performance on different benchmarks. These benchmarks are designed to address challenging features, such as evidence checking in multi-document inference (Yang et al., 2018), co-reference resolution (Dasigi et al., 2019), dialog understanding (Reddy et al., 2019), symbolic reasoning (Dua et al., 2019), and so on.

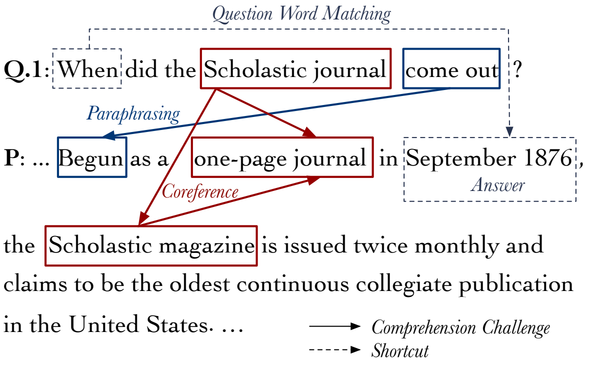

Figure 1: An illustration of *shortcuts* in Machine Reading Comprehension. **P** is an excerpt of the original passage.

However, recent analysis indicates that many MRC models unintentionally learn *shortcuts* to trick on specific benchmarks, while having inferior performance in real comprehension challenges (Sugawara et al., 2018). For example, when answering **Q.1** in Figure 1, we expect an MRC model to understand the semantic relation between *come out* and *begun*, and output the answer, *September 1876*, by bridging the co-reference among *Scholastic journal*, *Scholastic magazine* and *one-page journal.* In fact, a model can easily find the answer without following the mentioned reasoning process, since it can just recognize *September 1876* as the only time expression in the passage to answer a *when* question. We consider such kind of tricks that use *partial* evidence to produce, perhaps unreliable, answers as ***shortcuts*** to the expected comprehension challenges, e.g., *co-reference resolution* in this

example. The questions with *shortcut* solutions are referred to as ***shortcut questions***. For clarity, a model is considered to have ***learned shortcuts*** when it relies on those tricks to obtain correct answers for most *shortcut* questions while performing worse on questions where challenging skills are necessary.

Previous works have found that, relying on *shortcut* tricks, models may not need to pay attention to the critical components of questions and documents (Mudrakarta et al., 2018) in order to get the correct answers. Thus, many current MRC models can be either vulnerable to disturbance (Jia and Liang, 2017), or lack of flexibility to question/passage changes (Sugawara et al., 2020). These efforts disclose the impact of *shortcut* phenomenon on MRC studies. However, concerns have been raised on **why MRC models learn these *shortcuts* while ignoring the designed comprehension challenges.**

To properly investigate this problem, our first obstacle is that there are no existing MRC datasets that are labeled whether a question has *shortcut* solutions. This deficiency makes it hard to formally analysis how the performance of a model is affected by the *shortcuts questions*, and almost impossible to examine whether the model correctly answers a question via *shortcuts*. Secondly, previous methods disclose the *shortcut* phenomenon by analyzing the model outputs through a series of carefully designed experiments, but fail to explain how the MRC models learn the *shortcuts* tricks. We need new methods to help us quantitatively investigate the learning mechanisms that make the difference when MRC models learn to answer the *shortcuts* questions and questions that require challenging reasoning skills.

In this work, we carefully design two synthetic MRC datasets to support our controlled experimental analysis. Specifically, in these datasets, each (passage, question) instance has a *shortcut* version paired with a challenging one where complex comprehension skills are required to answer the question. Our construction method ensures that the two versions of questions are as close as possible, in terms of style, size, and topics, which enable us to conduct controlled experiments regarding the necessary skills to obtain answers. We design a series of experiments to quantitatively explain how *shortcut* questions affect MRC model performance and how the models learn these tricks and challenging skills during the training process. We also propose two evaluation methods to quantify the learning difficulty of specific question sets. We find that *shortcut* questions are usually easier to learn, and the dominant gradient-based optimizers drive MRC models to learn the *shortcut* questions earlier in the learning process. The priority of fitting *shortcut* questions hinders models from exploring sophisticated reasoning skills in later stage of training. Our code and datasets can be found in `https://github.com/luciusssss/why-learn-shortcut`

To summarize, our main contributions are the following: 1) We design two synthetic datasets to study two commonly seen *shortcuts* in MRC benchmarks, *question word matching* and *simple matching*, against a challenging reasoning pattern *paraphrasing*. 2) We propose two simple methods as a probe to help investigate the inherent learning mechanism behind the different performance on *shortcut* questions and challenging ones. 3) We conduct thorough experiments to quantitatively explain the behaviors of MRC models under different settings, and show that the proportions of *shortcut* questions greatly affect model performance, which may hinder MRC models from learning sophisticated reasoning skills.

2 Synthetic Dataset Construction

To study the impact of *shortcut* questions in model training, we require the datasets to be annotated with whether each question has *shortcut* solutions, or can only be answered via complex reasoning. However, none of existing MRC datasets have such annotations. We thus design two synthetic datasets where it is known whether *shortcut* solutions exist for a question.

More importantly, we need to conduct controlled experiments and ensure, for each question, the existence of *shortcuts* solutions is the only independent variable. The extraneous variables, such as sizes of datasets, topics, answer types, and even the vocabulary, should be controlled relatively steady. Thus, in our designed datasets, each entry has a *shortcut* version instance and a challenging version. The question of the *shortcut* version can be correctly solved by a certain *shortcut* trick, while an expected comprehension skill is required to deal with the challenging version. Note that we expect the two versions of questions are as close as possible so that we can switch between the two versions freely while maintaining other factors relatively steady.

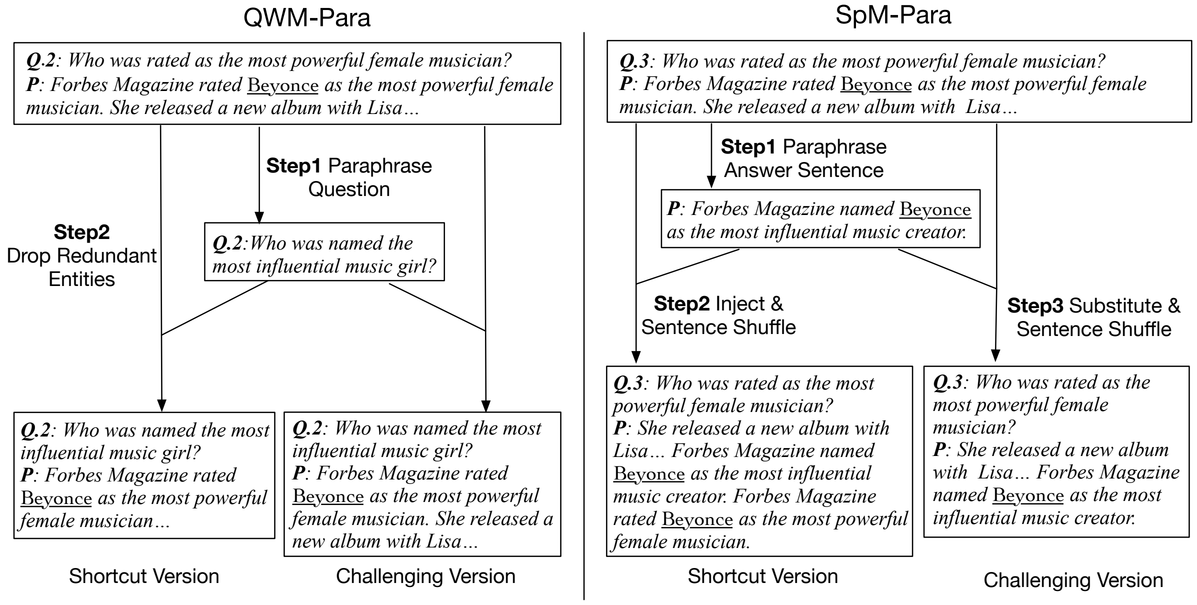

Figure 2: An illustration of how the instances in the synthetic datasets are constructed from original SQuAD data. Each instance has a *shortcut* version paired with a challenging version where comprehension skills are necessary.

In this work, we focus on *paraphrasing* (***Para***) as the complex reasoning challenge, since it widely exists in many recent MRC datasets (Trischler et al., 2017; Reddy et al., 2019; Clark et al., 2019). The paraphrasing challenge requires MRC models to identify the same meaning represented in different words. Regarding the *shortcut* tricks, we study two typical kinds: *question word matching* (***QWM***) and *simple matching* (***SpM***) (Sugawara et al., 2018). For *QWM*, MRC models can simply obtain an answer phrase by recognizing the expected entity type confined by the *wh*-question words of question Q. For *SpM*, a model can find the answers by identifying the word overlap between answer sentences and the questions.

QWM-Para **Dataset:** As elaborated in Algorithm 1, given an original instance (Q, P) from SQuAD (Rajpurkar et al., 2016), we paraphrase the question Q in Q_p to embed the *paraphrasing* challenge, and derive the corresponding *shortcut* version by dropping the sentences containing other entities with the matched type according to the question words from the given passage.

An example is shown in the left of Figure 2. In the challenging version of **Q.2**, both *Beyonce* and *Lisa* are person names which match the question word *who*. Thus, one should at least recognize the paraphrasing relationship between *named the most influential music girl* and *rated as the most powerful female musician* to distinguish between the two names to infer the correct answer. For the *shortcut* version, removing the sentence containing *Lisa* from the passage, which is also of the expected answer type *person* indicated by the question word *who*, would help a model easily get the correct answer, *Beyonce*.

Algorithm 1 Construction of *QWM-Para*

```
Input: SQuAD
Output: QWM-Para
QWM-Para ← ∅
for each instance $(Q, P)$ in SQuAD do
    if $Q$ does not start with who, when, where then
        Discard this instance.
    end if
    if the answer sentence contains other entities matching the question word then
        Discard this instance.
    end if
    Use back translation to paraphrase $Q$, obtain $Q_p$
    if the non-stop-word overlap rate between $Q_p$ and the answer sentence $> 25\%$ then
        Discard the instance.
    end if
    Delete sentences in passage $P$ that does not contain the golden answer but containing other entities matching the question word, note the modified passage as $P_s$.
    $I_s \leftarrow$ the shortcut instance version $(Q_p, P_s)$
    $I_c \leftarrow$ the challenging instance version $(Q_p, P)$
    Append the pair of questions, $(I_s, I_c)$, to QWM-Para.
end for
```

SpM-Para **Dataset:** As shown in Algorithm 2, for instances from SQuAD, we paraphrase the answer sentences in the passage to embed the *paraphrasing* challenge and obtain its challenging version. We insert the paraphrased answer sentence in front of the original one in the passage to con-

Algorithm 2 Construction of *SpM-Para*

```
Input: SQuAD
Output: SpM-Para
SpM-Para ← $\emptyset$
for each instance $(Q, P)$ in SQuAD do
    if the non-stop-word overlap rate between $Q$ and the answer sentence $S < 75\%$ then
        Discard the instance.
    end if
    Use back translation to paraphrase the answer sentence $S$ in $P$, obtain $S_p$.
    if the answer span no longer exists in $S_p$ then
        Discard this instance.
    end if
    if the non-stop-word overlap rate between $Q$ and $S_p$ $> 25\%$ then
        Discard the instance.
    end if
    Replace $S$ in $P$ with $S_p$ and shuffle sentences, noted the modified passage as $P_c$.
    Append $S_p$ to $P$ and shuffle sentences, noted the modified passage as $P_s$.
    $I_s \leftarrow$ the shortcut instance version $(Q, P_s)$
    $I_c \leftarrow$ the challenging instance version $(Q, P_c)$
    Appen d the pair of questions, $(I_s, I_c)$, to SpM-Para.
end for
```

struct the corresponding *shortcut* version, where a model can obtain the answers by either identifying the paraphrase in the passage or using the *simple matching* trick via the original answer sentences. We randomly shuffle all sentences in the passage to prevent models from learning the pattern of sentence orders in the *shortcut* version, i.e., there are two adjacent answer sentences in the passage. Here, we assume the sentence-level shuffling operation will not affect the answers and solutions for most questions, since the supporting evidence is often concentrated in a single sentence. This can also be supported by Sugawara et al. (2020)'s findings that the performance of BERT-large (Devlin et al., 2019) on SQuAD only drops by around 1.2% after sentence order shuffling.

For example, in the *shortcut* version of **Q.3** shown in the right of Figure 2, MRC models can find the answer, *Beyonce*, either from the matching context, *rated as the most powerful female musician*, or via the paraphrased one, *named as the most influential music girl*. For the challenging version, only the paraphrased answer sentence is provided, thus, the paraphrasing skill is necessary.

Dataset Details Our synthetic training and test sets are derived from the accessible training and development sets of SQuAD, respectively. We adopt back translation to obtain paraphrases of texts (Dong et al., 2017). A sentence is translated from English to German, then to Chinese, and finally back to English to obtain its paraphrased version.[1]

The *QWM-Para* dataset contains 7072 entries, each containing two versions of (question, passage) tuples, 6306/766 for training and testing, respectively. And for *SpM-Para*, there are 8514 entries, 7562/952 for training and testing, respectively.

Quality Analysis We randomly sample 20 entries from each training set of the synthetic datasets, manually analyzing their answerability. We find that 76/80 questions could be correctly answered. The unanswerable questions result from the wrong paraphrasing. Furthermore, among the answerable questions, the paraphrasing skill is necessary in 30 out of 36 questions in the challenging version, and 36 out of 40 questions of the *shortcut* version can be correctly answered via the corresponding *shortcut* trick.

3 How the *Shortcut* Questions Affect Model Performance?

Previous efforts show that *shortcut* questions widely exist in current datasets (Sugawara et al., 2020). However, there are few quantitative analysis to discuss how these *shortcut* questions affect the model performance. A reasonable guess is that, when trained with too many *shortcut* questions, the models tend to fit the *shortcut* tricks, which are possible solutions to a large amount of questions in training. We thus argue that ***the high proportions of shortcut questions in training data make models rely on the shortcut tricks.***

One straightforward way to elaborate on this point is to observe the model performance on challenging test questions when the model is trained with different proportions of *shortcut* questions. For example, if a model trained on a dataset, in which 90% of questions are *shortcut* ones, cannot perform as well as its 10% variant on challenging test questions, that will probably indicate that higher proportions of *shortcut* questions in the training data may hinder the model from learning other challenging skills.

Setup We evaluate two popular MRC models, BiDAF (Minjoon et al., 2017) and BERT-base (Devlin et al., 2019), which are widely adopted in the research for *shortcut* phenomena (Sugawara et al., 2018; Min et al., 2019; Si et al., 2019; Sugawara et al., 2020). For each combination of model and

---

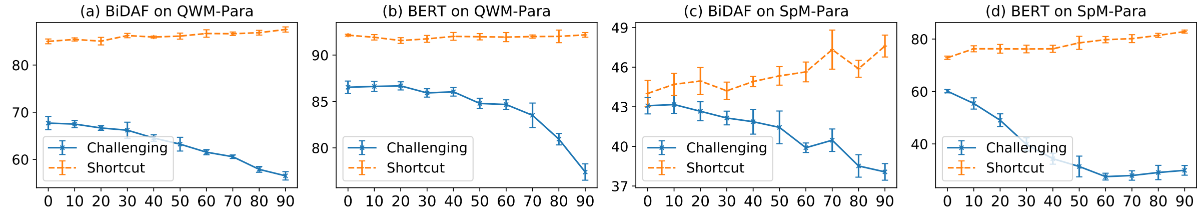

Figure 3: F1 scores on challenging and *shortcut* questions with different proportions of *shortcut* questions in training. The error bars represent the standard deviations of five runs.

dataset, we train 10 versions of the model, adjusting the proportion of *shortcut* questions in the training set from 0% to 90%, and report performance on pure challenging and pure *shortcut* test sets. We report the mean and standard deviation in five runs to alleviate the impact of randomness. Detailed settings are elaborated in Appendix A.

Results and Analysis Figure 3 shows the performance of BiDAF and BERT on *QWM-Para* and *SpM-Para* when trained with various proportions of *shortcut* questions. For both models, the F1 scores on challenging versions of both test sets drop substantially with the increase in *shortcut* questions for training (Figure 3 (a) $\sim$ (d)). This result indicates that higher proportions of *shortcut* questions in training limit the model's ability to solve challenging questions.

Take BiDAF on *QWM-Para* as an example (Figure 3 (a)). The F1 score on the test set of challenging questions is 69% after training BiDAF with a dataset entirely composed of challenging questions, showing that even a simple model is able to learn the paraphrasing skill from *shortcut*-free training data. As the proportion of *shortcut* training questions increases, the model tends to learn *shortcut* tricks and performs worse on the challenging testing data. The F1 score on challenging questions drops to 55% when 90% of the training data are *shortcut* questions. This drop shows that training data with a high proportion of *shortcuts* actually hinders the model from capturing paraphrasing skills to solve challenging questions. In contrast, the performance on *shortcut* questions are relative steady to the changes of *shortcut* proportions during training. When trained with sufficient challenging questions, models not only perform well on comprehension challenges, but also correctly answer the *shortcut* questions where only partial evidence is required.

In Figure 3, we can observe similar trends in model performance on *SpM-Para*. The performance on challenging questions also drops with higher proportions of *shortcut* training questions. Compared with BiDAF, although the overall scores of BERT are better, BERT also performs poorly on questions that require to perform paraphrasing when trained with more *shortcut* questions, as shown in Figure 3 (b) & (d).

Case Study When answering the example question **Q.4** from *QWM-Para*, BiDAF trained with pure challenging questions tends to detect the correlation between *graduate* and *received his master's degree*, and locates the correct answer *1506* when there are two spans matching the question word *when*. However, when there are more than 70% *shortcut questions* in training, BiDAF only captures the type constraint from the question word *when*, and fails to identify the paraphrasing phenomenon to answer the challenging version.

Q.4: When did Luther graduate?
P-challenging: In 1501, at the age of 19, he entered the University of Erfurt. ... He received his master's degree in *[1506]*$_{Ans}$
P-shortcut: He received his master's degree in *[1506]*$_{Ans}$

4 Whether *Question Word Matching* is Easier to Learn than *Paraphrasing*?

It is still confusing that, with the coexistence of both *shortcut* and challenging questions for training, even in a 50%-50% distribution, both BERT and BiDAF still learn *shortcut* tricks better, thus, achieve much higher performance on *shortcut questions* comparing to the challenging ones. We think one possible reason is that ***MRC models may learn the shortcut tricks, like QWM, with less computational resources than the comprehension challenges, like identifying paraphrasing***. In this case, MRC models could better learn the *shortcut* tricks with equal or even lower proportions of *shortcut* questions during training.

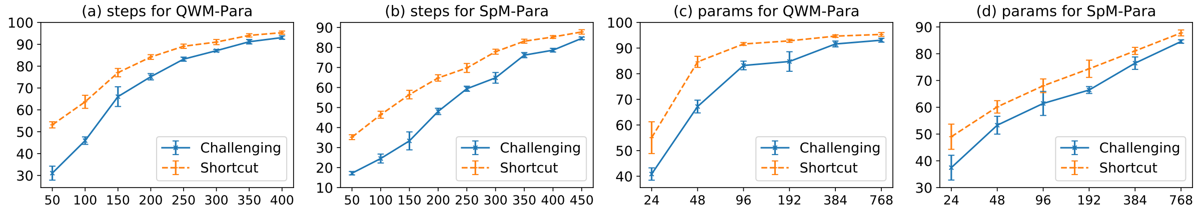

Figure 4: F1 scores on training sets when BERT learns challenging and *shortcut* questions with different optimizing steps ((a) & (b)) and parameter size (represented by the unmasked hidden size in the last hidden layer of BERT, (c) & (d)). The error bars represent the standard deviations of five runs.

To validate this hypothesis, we propose two simple but effective methods to measure the difference in required computational resources. Specifically, we can train models with either pure *shortcut* questions or challenging ones, and compare the learning speed and required parameter sizes when achieving certain performance levels on the training sets.

For learning speed, we train MRC models with different steps and observe how the performance changes. Intuitively, models should converge faster on easier training data.

For parameter sizes, our intuition is that the models should learn the easier questions with fewer parameters. However, the high computational consumption prevents us from pre-training the models like BERT with different parameter sizes. To simulate BERT with fewer parameters, we mask some hidden units in the last hidden layer of BERT and use the number of unmasked units to reflect the parameter size. The information in these masked units could not be conveyed to the span boundary prediction module. Thus, only partial parameters could be used to make the final predictions.

Setup We use BERT as the basic learner and train on the training sets of *QWM-Para* and *SpM-Para*. We report model performance on the training data with various learning settings. We use all the parameters when adjusting learning steps. When tuning parameter size, we fix the learning steps to 400 and 450 for *QWM-Para* and *SpM-Para*, respectively. All other settings including batch size, optimizer, and learning rate are fixed. We report the mean and standard deviation in five runs to alleviate the impact of randomness. The implementation details are similar to §3, elaborated in Appendix A.

Results and Analysis Figure 4 compares the performance of BERT trained on the *shortcut* questions and challenging questions separately under different settings. On both *QWM-Para* and *SpM-Para*, BERT converges faster in learning *shortcut* questions than learning challenging ones (Figure 4 (a) & (b)). When fixing the training steps, BERT could learn to answer the *shortcut* questions with fewer parameters (Figure 4 (c) & (d)). These results show that *shortcut* questions may be easier for models to learn than the ones requiring complex reasoning skills.

Take *QWM-Para* as an example. As can be seen from Figure 4 (a), BERT trained on the *shortcut* questions achieves a 90% F1-score on the training set after 250 steps. When trained on the challenging version, this score will not reach 90% until 350 steps. This result indicates that models could learn to answer the *shortcut* questions with the *QWM* trick faster than the paraphrasing skill.

When we train BERT on *QWM-Para* with different numbers of output units masked (Figure 4 (c)), BERT could reach the F1-score of 91% on *shortcut* data with no fewer than 96 unmasked hidden units. However, when trained on the challenging questions, BERT has to use 384 hidden units to reach the 91% F1 score, which indicates that the questions with the *paraphrasing* challenge may require more parameters to learn.

We observe similar trends on *SpM-Para* (Figure 4 (b) & (d)). BERT requires more parameters and training steps to learn the challenging version questions in *SpM-Para* than the *shortcut* version. To some extent, these results confirm our hypothesis that learning to answer questions with *shortcut* tricks like *SpM* or *QWM* requires smaller amounts of computational resources than the questions requiring challenging skills like paraphrasing.

Case Study For the example question **Q.5**, BERT trained on *shortcut* questions could correctly answer its *shortcut* version and find the only location name, *Palácio da Alvorada*, with only 48 unmasked hidden units. However, when trained with the challenging data only, the model predicts the other location name, *the Monumental Axis* as the answer with such parameter size. BERT could not recognize the paraphrasing relationship between *the place the president live* and *presidential residence* and choose the correct answer, *Palácio da Alvorada*, from the distracting location name, until using all 748 parameters.

Q.5: Where does the president of Brazil live, in Portuguese?
P-challenging: ... on a triangle of land jutting into the lake, is the Palace of the Dawn (*[Palácio da Alvorada]*$_{Ans}$; the presidential residence). Between the federal and civic buildings on the Monumental Axis is the city 's cathedral...
P-shortcut: ... on a triangle of land jutting into the lake, is the Palace of the Dawn (*[Palácio da Alvorada]*$_{Ans}$; the presidential residence)

---

5 How do Models Learn *Shortcuts*?

In previous section, we show that *shortcut* questions are *easier* to learn compared to the questions that require the complex *paraphrasing* skill. Then, it is interesting that, trained with a mixture of both versions of questions, how such discrepancy affects or even drives the learning procedure, e.g., how the increasing of challenging training questions alleviate the over reliance on *shortcut* tricks.

We guess one of the possible reasons is how most existing MRC models are optimized. We hypothesize that with a larger proportion of *shortcut* questions for training, ***the models have learned the shortcut tricks at the early stage, which may affect the models' further exploration for challenging skills.*** In other words, in the early stage of training, models tend to find the easiest way to fit the training data with gradient descent. Since the *shortcut* tricks require less computational resources to learn, fitting these tricks may be a priority. Afterwards, since the *shortcut* trick can be used to answer most of the training questions correctly, the limited unsolved questions remained may not motivate the models to explore sophisticated solutions that require challenging skills.

To validate this idea, we investigate how the models converge during training with different *shortcut* proportions in the training data. Notice that if a model can only answer the *shortcut* version of a question correctly, it is highly likely that the model only adopts the *shortcut* trick for this question instead of performing sophisticated reasoning skills. Thus, we think the performance gap on two versions of test data may indicate to what extent the model relies on the *shortcut* tricks, e.g., the smaller the performance gap is, the stronger complex reasoning skills the model have learned.

Setups We explore how BERT and BiDAF converge with 10% and 90% *shortcut* training questions on *QWM-Para* and *SpM-Para*. We report the F1 scores on the challenging and *shortcut* test questions, respectively, and together with their performance gaps. We compare the model performance at different learning steps to investigate when and how well the models learn the *shortcut* tricks and the challenging comprehension skills. The implementation details are the same as §3, elaborated in Appendix A.

Results and Analysis Figure 5 illustrates how the MRC models converge during training under different settings. The gap line (green with "$\star$") shows the gap between models' performance on *shortcut* questions and that on challenging ones.

For all settings, in the first few epochs, the model performance on *shortcut* questions increases rapidly, much faster than that on challenging questions, causing a steep rise of the performance gap. This result indicates that models may learn the *shortcut* tricks at the early stage of training, thus quickly and correctly answering more *shortcut* questions. And then, for the following epochs after reaching the peaks, the gap lines slightly go down (Figure 5 (a), (c), (e), and (f)) or maintain almost unchanged (Figure 5 (b), (d), (g), and (h)), which also indicates the models may learn the challenging skills later than *shortcut* tricks. One possible reason is the gradient based optimizer drives the model to optimize the global target greedily via the easiest direction. Thus, trained with a mixture of *shortcut* and challenging questions, models choose to learn the *shortcut* tricks, which require less computational resources to learn, earlier than the sophisticated paraphrasing skills.

Comparing models with different proportions of *shortcut* training questions, we find that, with 90% *shortcut* training questions (Figure 5 (b), (d), (f) and (h)), the performance gap remains at a high level in the later training stage, where the performance on the challenging test questions is relatively lower. These results provide evidence that, for most cases, after fitting on the *shortcut* questions, models seem to fail to explore the sophisticated reasoning skills.

When there are only 10% of *shortcut* training data (Figure 5 (a), (c), (e), and (g)), we can ob-

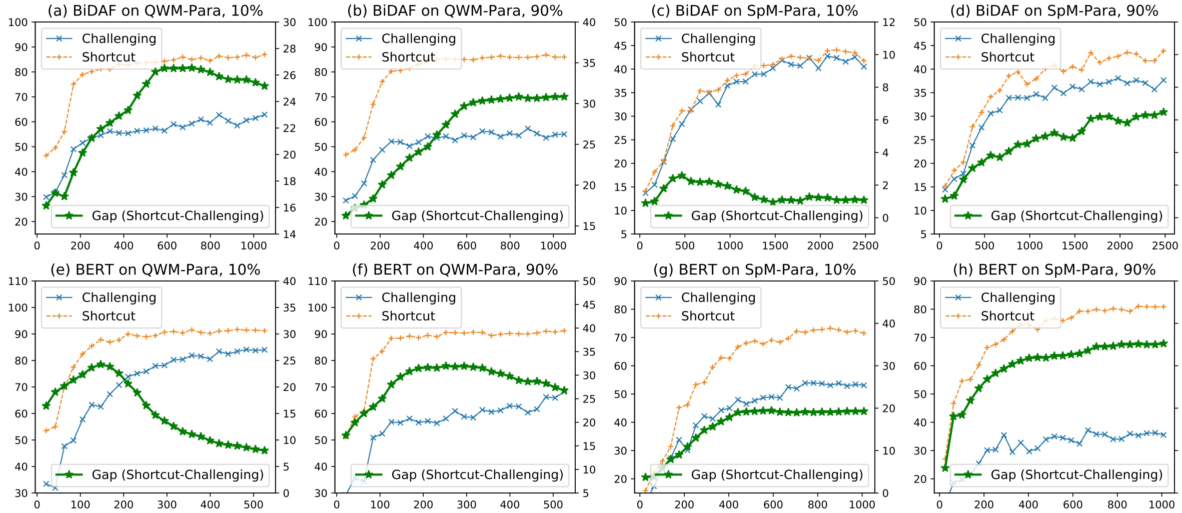

Figure 5: F1 scores on challenging and *shortcut* questions with different training steps under different settings. 10% and 90% are the proportions of *shortcut* questions in the training datasets. *Gaps* (green lines with "⋆" dots) represent the performance gap between *shortcut* questions and challenging ones, which is smoothed by averaging over fixed-size windows to mitigate periodic fluctuations.

serve that after a few hundreds of steps, the gap lines stop increasing and even slightly go down. This phenomenon shows that higher proportions of challenging questions in the training set could encourage the models to explore the sophisticated reasoning skills, but in a later stage of training.

Take BiDAF trained on *QWM-Para* as an example (Figure 5 (a) & (b)). The F1 scores on *shortcut* test questions increase quickly in the first 300 steps, while the performance gap also widens rapidly, indicating a possible fast fitting on the *shortcut* tricks. In Figure 5 (b), with 90% *shortcut* training questions, the model performance on challenging questions are relatively steady during the next 800 steps, while the F1 score on *shortcut* questions maintains a high level of about 85%. This result shows that after fitting on the *shortcut* tricks, the model trained with a higher *shortcut* proportion has almost correctly answered all the *shortcut* questions but fail to answer the challenging ones. Actually, with the gradient based optimizer, it is difficult for the model to learn the challenging questions while keeping the high performance on the *shortcut* ones, which account for 90% of the training set. We guess it is because the few unsolved challenging questions could not motivate the model to explore sophisticated reasoning skills.

On the contrary, when 90% of the training data require challenging skills, the gap line peaks at 0.27, as shown in Figure 5 (a). Afterwards, the gap decreases to 0.24, with the F1 score on challenging questions increasing to more than 60%. Larger proportions of challenging questions for training prevent the models from heavily relying on the *shortcut* tricks. This phenomenon may be because, with fewer *shortcut* questions in training, the fitting of *shortcut* tricks only benefits the training objective in a small favor. The large number of challenging questions that can not be correctly answered during the early training steps now encourage models to explore more complicated reasoning skills.

Case Study When answering the example question **Q.6** from *SpM-Para*, BERT trained with 10% *shortcut* questions tends to learn the *simple matching* trick quickly and correctly answers the *shortcut* version as early as 380 steps. However, the model cannot correctly answer the challenging variant until 630 steps. This difference demonstrates that, training with both type of questions, BERT can learn the *simple matching* trick earlier than identifying the required paraphrasing between *why defections occur* and *errors caused by*.

Q.6: Why do these defections occur?
P-challenging: ... Most of these errors are caused by *[economic or financial factors]*$_{Ans}$ ...
P-shortcut: ... Most of these defections occur because of *[economic or financial factors]*$_{Ans}$. Most of these errors are caused by *[economic or financial factors]*$_{Ans}$. ...

6 Related Works

Reading documents to answer natural language questions has drawn more and more attention in recent years (Xu et al., 2016; Minjoon et al., 2017; Lai et al., 2019; Glass et al., 2020). Most previous works focus on revealing the *shortcut* phenomenon in MRC from different perspectives. They find that manually designed features (Chen et al., 2016) or simple model architectures (Weissenborn et al., 2017) could obtain competitive performance, indicating that complicated inference procedure may be dispensable. Even without reading the entire questions or documents, models can still correctly answer a large portion of the questions (Sugawara et al., 2018; Kaushik and Lipton, 2018; Min et al., 2019). Therefore, current MRC datasets may lack the benchmarking capacity on requisite skills (Sugawara et al., 2020), and models may be vulnerable to adversarial attacks (Jia and Liang, 2017; Wallace et al., 2019; Si et al., 2019). However, they do not formally discuss or analyze why models could learn *shortcuts* from the perspectives of the learning procedure.

On the way of designing better MRC datasets, Jiang and Bansal (2019) construct adversarial questions to guide model learning the multi-hop reasoning skills. Bartolo et al. (2020) propose a model-inloop paradigm to annotate challenging questions. More recent works (Jhamtani and Clark, 2020; Ho et al., 2020) propose new datasets with evidence based metrics to evaluate whether the questions are solved via *shortcuts*. Our work aims at providing empirical evidence and analysis to the community by tracing into the learning procedure and explaining how the MRC models learn *shortcuts*, which is orthogonal to the existing works.

For a more general machine learning perspective, there are also efforts trying to explain how models learn easy and hard instances during training. Kalimeris et al. (2019) prove that models tend to learn easier decision boundaries at the beginning stage of training. Our results empirically confirms this theoretical conclusion in the task of MRC and quantitatively explain that larger proportions of *shortcut* questions in training make MRC models rely on *shortcut* tricks, rather than comprehension skills like recognizing the paraphrase relationship.

7 Conclusions

In this work, we try to answer why many MRC models learn *shortcut* tricks while ignoring the pre-designed comprehension challenges that are purposely embedded in many benchmark datasets. We argue that ***large proportions of shortcut questions in training data push MRC models to rely on shortcut tricks excessively***. To properly investigate, we first design two synthetic datasets where each instance has a *shortcut* version paired with a challenging one which requires *paraphrasing*, a complex reasoning skill, to answer, rather than performing *question word matching* or *simple matching*. With these datasets, we are able to adjust the proportion of *shortcut* questions in both training and testing, while maintaining other factors relatively steady. We propose two methods to examine the model training process regarding the *shortcut* questions, which enable us to take a closer look at the learning mechanisms of BiDAF and BERT under different training settings. We find that learning *shortcut* questions generally requires less computational resources, and MRC models usually learn the *shortcut* questions at their early stage of training. Our findings reveal that, with larger proportions of *shortcut* questions for training, MRC models will learn the *shortcut* tricks quickly while ignoring the designed comprehension challenges, since the remaining truly challenging questions, usually limited in size, may not motivate models to explore sophisticated solutions in the later training stage.

A Implement Details

Synthetic Dataset Construction During the construction of synthetic datasets, we used Stanford CoreNLP (Manning et al., 2014) to identify named entities and stop-words.

We set two empirical thresholds for identifying questions can be solved by *Simple Matching* or requiring paraphrasing skills. We consider a question as solvable via the *simple matching* trick if more than 75% of non-stop words in the question exactly appear in the answer sentence. On the other hand, if the matching rate is below 25%, we think it is unsolvable via *simple matching*, calling for other skills like paraphrasing. Thus, in dataset construction, if the matching rate is above 25% after paraphrasing, we consider that the back translation fails to incorporate paraphrasing skills into the instance.

We construct the synthetic datasets from SQuAD (Rajpurkar et al., 2016). Compared with more recent MRC datasets (Yang et al., 2018; Kwiatkowski et al., 2019), most questions in SQuAD can be solved by a single sentence with *simple matching* so that we can conveniently use back translation to construct questions with paraphrasing challenges.

Paraphrasing in *SpM-para* When constructing the *SpM-Para* dataset, we only select the instances whose questions are very similar to the corresponding answer sentences (overlap $>$ 75%) to ensure that a *simple matching* step can obtain the answers. For the *shortcut*-version of an instance, we insert the paraphrased answer sentence into passage and keep both the original answer sentence and paraphrased answer sentence (see Algorithm 2). This operation aims to control the *shortcut* instances to have both *shortcut* solutions and challenging solutions. For the challenging version, we only keep the paraphrased answer sentences in the passages and discard the original answer sentence, so that such instances can only be solved by identifying the embedded paraphrasing relationship.

Hyper-Parameters for QA models We adopt BERT (BERT-based uncased) (Devlin et al., 2019) and BiDAF (Minjoon et al., 2017) models with the implementation in SogouMRC tools (Wu et al., 2019). The hyper-parameters are shown in Table 1. We used 100-d glove vectors (Pennington et al., 2014) in BiDAF. Notice that these hyper-parameters are adopted in §3, §4, and §5. Our code and datasets can be found in `https://github.com/luciusssss/why-learn-shortcut`

For the *simple matching* setting where multiple answer spans may appear in one passage, we follow (Pang et al., 2019) and aggregate the possibilities of each span before computing the likelihood losses.

Data Sampling in Difficulty Evaluation In §4, we train BERT on the training sets of *QWM-Para* and *SpM-Para* and observe how the model converges with different learning steps and parameter sizes. However, we find BERT achieves outstanding performance on both datasets with only one or two epochs. This is because the strong learning ability of BERT model and, with only one kind of answering pattern, both the pure *shortcut* and challenging training sets are relatively easy to learn.

Under this circumstance, BERT performance on most of the evaluation checkpoints after one epoch will almost reach the final performance, which make the comparison vague. If we compare the checkpoints within one epoch, considering that models have only been trained on partial training data, the evaluation results would reflect the models' generalization ability on unseen questions. This differs from our purpose of evaluation, namely comparing the fitting difficulty of different kinds of questions. Therefore, we randomly sample 1000 pair of instances for training and evaluation. With less training data, BERT will not converge in only one or two epochs, thus we could truly evaluate the learning ability.

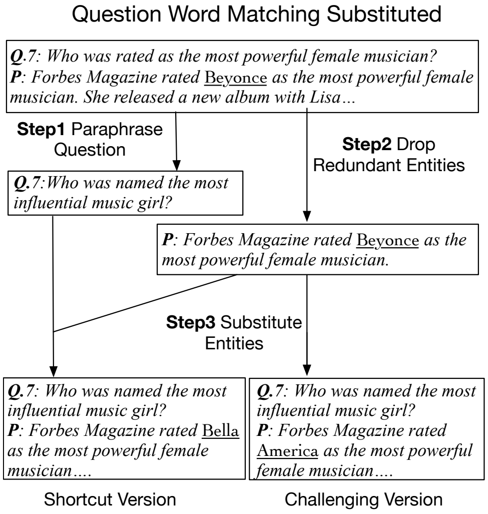
Computation Cost We train the models on an NVIDIA 1080 Ti GPU. The number of parameters is 5M for BiDAF and 110M for BERT. The average training time on synthetic datasets for an epoch is 1 minute for BiDAF and 10 minutes for BERT.

	BERT-base Uncased	BiDAF
# Epoch	3	15
Batch size	6	30
Optimizer	AdamWeightDecay	Adam
Learning rate	3e-5	1e-3

Table 1: Hyper-Parameters for the experiments in §4, §5, and §6.

B A Variant of *QWM-Para* Dataset

When we train models with different proportions of *shortcut* questions on *QWM-Para* (Figure 3 (a) & (b), which is described in §3), we observe that even with pure challenging questions in training, BiDAF



Q.7: Who was rated as the most powerful female musician?
P: Forbes Magazine rated Beyonce as the most powerful female musician. She released a new album with Lisa...

Q.7: Who was named the most influential music girl?

P: Forbes Magazine rated Beyonce as the most powerful female musician.

Q.7: Who was named the most influential music girl?
P: Forbes Magazine rated Bella as the most powerful female musician....

Q.7: Who was named the most influential music girl?
P: Forbes Magazine rated America as the most powerful female musician....

Figure 6: An illustration of how the questions in the new synthetic datasets, *question word matching substituted*, are constructed from original questions.

and BERT still perform much better on *shortcut* questions than on the challenging ones. We think this is possibly because in these settings, models fail to exploit the paraphrasing skill but learn to guess one from the the entities matching the question words as the answer. Using such a guessing trick instead of the paraphrasing skill could improve the performance on the challenging questions to some extent, but it results in more gains on the *shortcut* questions. Therefore, even with 100% challenging questions in training, the gap between the performance on challenging and *shortcut* test questions is still wide.

To avoid these guess solutions, we redesign a variant of the *QWM-Para* dataset, named as ***QWM/subs-Para***.[2] We aim at investigating: 1) Whether this variant could avoid the guessing alternative and decrease the performance gaps between challenge questions and *shortcut* ones when training with relatively lower *shortcut* proportions. 2) Whether the experiments on this variant still confirms our previous findings about how *shortcut* questions in training affect model performance and learning procedure, as described in §3 and §5.

B.1 Dataset Construction

The construction process of *QWM/subs-Para* is shown in Figure 6. The first two steps, question paraphrasing and redundant entities dropping, are the same as those in the construction of *shortcut* questions in *QWM-Para* (see §2). Then, we perform entity substitution to avoid the potential guessing solutions.

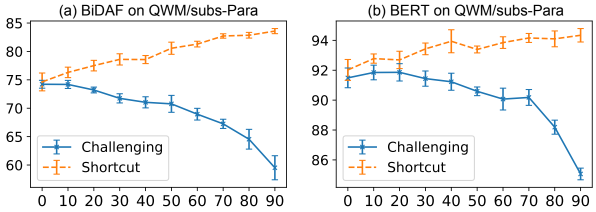


Figure 7: F1 scores on challenging and *shortcut* questions with different proportions of *shortcut* questions in training. This experiment is conducted on *QWM/subs-Para*. The error bars represent the standard deviations of five runs.

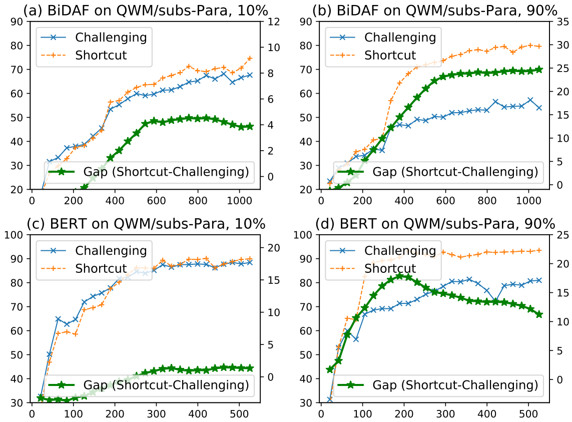

Figure 8: F1 scores on challenging and *shortcut* questions with different training steps under different settings. This experiment is conducted on *QWM/subs-Para*. 10% and 90% are the ratios of *shortcut* questions in the training datasets. *Gaps* (green lines with "⋆" dots) represents the performance gap between *shortcut* questions and challenging ones, which is smoothed by averaging over fixed-size windows to mitigate periodic fluctuations.

Particularly, for each candidate question, we substitute all the entities in the passage with random ones whose type uniformly distributes in Person/Time/Location to construct the challenging questions. With this random substitution, one can hardly guess the correct answer via the question words. As shown in **Q.7**, after substituting the answer entity *Beyonce* to *America*, one can not answer the new question by simply finding a *Person* entity according to the question word *who*. Replacing a person's name with a location may break the original semantic, but it will force the model to comprehend the context to find the answers. For the *shortcut* version, we also conduct the random entity substitution, but within the same entity types,

---

[2] *subs* refers to substituted, elaborated in §B.1.

e.g., from *Beyonce* to *Bella*.

This strategy could avoid the models from learning the trick that identifying replaced words as the answers.

B.2 Results and Analysis

Shown in Figure 7, we can see that, when constructing the challenging questions with entity substitution, both BiDAF and BERT model perform comparably between challenging and *shortcut* test questions with 100% challenging questions in training. These results provide evidence that, after the substitution, models could not use guessing as an alternative solutions to the paraphrasing skill.

We conduct similar experiments in §3, §5 on *QWM/subs-Para*, which is shown in Figure 7 and Figure 8, respectively. The tendency could also support our previous findings. For example, the larger *shortcut* ratio expands the performance gaps between challenging and *shortcut* questions in Figure 7.

Handling Cross- and Out-of-Domain Samples in Thai Word Segmentation

Abstract

While word segmentation is a solved problem in many languages, it is still a challenge in continuous-script or low-resource languages. Like other NLP tasks, word segmentation is domain-dependent, which can be a challenge in low-resource languages like Thai and Urdu since there can be domains with insufficient data. This investigation proposes a new solution to adapt an existing domain-generic model to a target domain, as well as a data augmentation technique to combat the low-resource problems. In addition to domain adaptation, we also propose a framework to handle out-of-domain inputs using an ensemble of domain-specific models called *Multi-Domain Ensemble* (MDE). To assess the effectiveness of the proposed solutions, we conducted extensive experiments on domain adaptation and out-of-domain scenarios. Moreover, we also proposed a multiple task dataset for Thai text processing, including word segmentation. For domain adaptation, we compared our solution to the state-of-the-art Thai word segmentation (TWS) method and obtained improvements from 93.47% to 98.48% at the character level and 84.03% to 96.75% at the word level. For out-of-domain scenarios, our MDE method significantly outperformed the state-of-the-art TWS and multi-criteria methods. Furthermore, to demonstrate our method's generalizability, we also applied our MDE framework to other languages, namely Chinese, Japanese, and Urdu, and obtained improvements similar to Thai's.

1 Introduction

Word segmentation (WS) is a crucial upstream process for most *natural language processing* (NLP) tasks such as *named entity recognition* (NER), *machine translation* (MT), and *part-of-speech tagging* (POS). Nguyen et al. (2017) showed POS performance increased from 87% to 93% when the WS was improved. WS can also enhance the performance of MT, such as the work done by Chang et al. (2008) for Chinese-English MT.

While word segmentation is considered a solved problem in many languages, the task is still a challenge in continuous-script languages. A great number of writing systems have no word boundary, e.g., Thai, Chinese, and Japanese. Deep learning has been effective in performing WS in these languages. However, it requires a large amount of training data to construct a reliable model, which can be a limitation for low-resource languages like Thai and Urdu. Furthermore, like other NLP tasks, word segmentation is domain-dependent (Fu et al., 2020). To handle a variety of data domains, there should be a substantial amount of data for each of them, exacerbating the low-resource problem. To make the matter worse, we may also need to handle input from a completely unseen domain.

In this paper, we propose a framework to address two domain dependency problems: (i) how to effectively construct a WS model to handle input from a given domain in a data-poor setting; (ii) how to effectively handle out-of-domain input. To address the first problem, we propose a new domain adaptation solution based on the concept of stacked ensemble (SE) learning (Limkonchotiwat et al., 2020) and data augmentation. To handle out-of-domain input, we use an ensemble of domain-specific models to produce predictive results.

The crux of our proposed method lies in the following technical contributions:

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1003–1016
August 1–6, 2021.

- We introduce multiple deep learning models following the concept of SE to construct domain-specific models that obtain better performance than the original SE and existing techniques in domain-adaptation problems. We call this technique *Deep Stacked Ensemble* (DSE).
- To make sure that each domain has sufficient data to build an accurate model, we design a data augmentation approach which consists of two techniques to generate hard-to-segment and semi-hard-to-segment samples to help improve the performance based on *Masked Language Model* (MLM).
- We use multiple domain-specific models and a result aggregation module to form an ensemble learning framework addressing the out-of-domain problems. We call this method *Multi-Domain Ensemble (MDE).*
- Furthermore, we propose a multiple task dataset called "*VISTEC-TP-TH-2021*", a social media dataset for Thai text processing, annotated for four text processing tasks: word segmentation, named-entity boundary, and misspelling detection and correction.

To assess the effectiveness of our approach, we compare our method with competitors in domain adaptation and out-of-domain scenarios on Thai, Chinese, Japanese, and Urdu. Experimental results showed that DSE improved the performance of the state-of-the-art Thai word segmentation (TWS) from 93.47% and 84.03% to 96.67% and 91.51% at character and word levels in domain adaptation settings. With the proposed data augmentation approach, our domain-specific model has improved even further at both character and word levels. For out-of-domain scenarios, our MDE framework outperformed the state-of-the-art TWS and multi-criteria baseline at character and word levels. Moreover, we applied our framework to Chinese, Japanese, and Urdu which resulted in improvement showing the applicability of our method to other languages. We make our code available at: `github.com/mrpeerat/OSKut`

2 Related Work

In this section, we discuss literature related to our investigation, namely *ensemble learning*, *domain adaption*, and *data augmentation*.

Ensemble Learning. Recently, considerable research attention has been dedicated to applying ensemble learning to boost the performance obtained from individual models (Sikdar and Gambäck, 2017; Chen et al., 2020a; Kuwabara et al., 2020) and to introduce previously ignored features for ensemble models such as provenance information in slot filtering (Viswanathan et al., 2015).

Several studies have used ensemble methods to boost the accuracy in WS. For example, Liu and Lin (2014) proposed a probabilistic ensemble learning framework using multiple weak word segmenters to form a strong segmenter. Moreover, Min et al. (2015) proposed an ensemble learning model to address the word segmentation and Part-of-Speech tagging problems by combining both discriminative and generative methods.

Domain Adaptation. Several WS studies proposed techniques to adapt the data distribution from one domain to another (Zhang et al., 2013; Ding et al., 2020). Another popular approach is to add new features or change network architectures of the target model (Monroe et al., 2014; Liu et al., 2014; Bao et al., 2017; Huang et al., 2020).

Ding et al. (2020) presented a semi-supervised approach for performing Chinese WS on a new domain by using adversarial training to help learn the difference between the source and target domain. Recently, Limkonchotiwat et al. (2020) proposed a filter-and-refine solution based on the stacked ensemble (SE) to convert a base model to a target domain. The SE consists of a domain-generic base model and a domain-specific model that analyzes the output of the domain-generic model and revises the segmentation. The method achieved similar performance to traditional transfer learning methods while requiring no access to the domain-generic model weights.

Data Augmentation and Self-Supervised learning. Word segmentation for low-resource languages is a challenging task due to the data limitation. Most Thai WS models report below 90% accuracy in domain-adaptation settings (Kittinaradorn et al., 2019; Chormai et al., 2020). Many researchers proposed data augmentation methods for Asian languages to increase the performance of WS models by using existing models' output as input to new models such as synthetic data, entropy parser, and character embedding (Zheng et al., 2018; Wang et al., 2019; Fung et al., 2004).

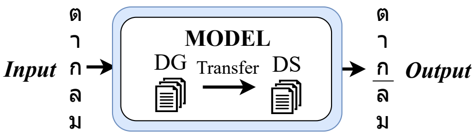
With the advent of large language models (Devlin et al., 2018; Yang et al., 2019; Brown et al., 2020), we have been witnessing an explosion in self-supervised learning techniques. Data augmentation methods such as the *Masked Language Model* (MLM) using BERT (Devlin et al., 2018) allow us to generate new sentences that are similar to real data by randomly selecting words in a sentence to replace them with new words (Chen et al., 2020b; Liao et al., 2020). Yavuz et al. (2020) proposed MaskAugment, a controllable mechanism and augmentation method that used a pre-trained BERT model to replace words in a sentence. The method is used in an unsupervised teacher-student framework to improve domain adaptation for dialog act task. Furthermore, Li et al. (2020) proposed a MLM-based augmentation method that could also preserve the underlying labels of the sentence in the aspect term extraction task.

Out-Of-Domain Scenarios. While domain adaptation presents a useful paradigm to adjust an existing model to a target domain, it is impracticable to anticipate all different input types in advance. Hence, the ability to handle samples from unseen domains (i.e., out-of-domain samples) is critical to the solution's performance. For example, Wagner et al. (2020) proposed utilizing treebank vectors and a method to interpolate a prediction from existing treebank vectors to handle out-of-domain input samples. Ng et al. (2020) proposed a solution utilizing data augmentation to generate training samples to diversify the training set so that the model can handle out-of-domain samples better.

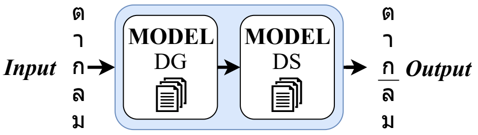
Discussion. For domain adaptation, an ensemble learning method such as SE (Limkonchotiwat et al., 2020) provides a flexible framework for adapting any base model to a target domain. We hypothesize that we can improve the accuracy of SE by introducing a deep learning architecture at the domain-specific part. However, this adjustment would require a larger amount of data for each domain than the original SE method which uses a traditional Conditional Random Field (CRF) model (Lafferty et al., 2001). To tackle this problem, data-augmentation presents an avenue to address the data requirements. Regarding out-of-domain scenarios, we hypothesize that an ensemble of domain-specific models can be used to boost the accuracy of out-of-domain situations. This is the first WS work to address this problem without using any out-of-domain data.

3 Methodology

In this section, we present the overview of domain adaptation in Section 3.1. We present our domain adaptation solution based on the concept of stacked ensemble (SE) learning (Limkonchotiwat et al., 2020) and an MLM-based data augmentation method in Section 3.2. Section 3.3 presents how multiple domain-specific models can work as an ensemble to support out-of-domain scenarios.



(a) Domain-specific model with transfer learning.



(b) Domain-specific model with stacked ensemble.

Figure 1: Comparison between transfer Learning (TL) and SE to build domain-specific (DS) models. For domain-specific with transfer learning, there is one model that is first trained on domain-generic (DG) data then domain-specific data. For SE there are two models. The first is a domain-generic model that feeds initial prediction results to a second domain-specific model.

3.1 Overview of Domain Adaptation

A popular method to construct a *domain-specific* (DS) model is to adapt from a *domain-generic* (DG) base model using transfer learning as shown in Figure 1a. Stacked ensemble learning presents an alternative when making changes to the base model is impossible. Unlike transfer learning, the SE model consists of two parts: a domain-generic model and a domain-specific model as shown in Figure 1b. The domain-specific model takes the output predictions from the domain-generic model to make better predictions on the target domain. Before feeding into the domain-specific model, there is also a filter-and-refine stage where only uncertain predictions are re-visited by the domain-specific model. Only the domain-specific model is trained on the target data, while the base model is left untouched.

The main advantages of SE over TL are as follows: (i) the architecture of the domain-specific model can be selected independently of the existing domain-generic one; (ii) it is able to handle models where we cannot adjust their weights, i.e., black boxes. Consequently, we adopt SE as our approach to tackling the domain adaptation problem.

3.2 Deep Stacked Ensemble (DSE)

As stated earlier, SE allows us to introduce a new architecture to handle domain-specific input. To exploit this advantage, we introduce the *Bidirectional Long Short-Term Memory* (Bi-LSTM) with *Attention mechanism* to the current state-of-the-art TWS architecture (Kittinaradorn et al., 2019). We call our proposed domain adaptation method *Deep Stacked Ensemble* (DSE).

Figure 2 shows the structure of the domain specific part of our solution. There are three main kinds of features. A character n-gram is passed through a CNN following Kittinaradorn et al. (2019) to create an embedding vector (shown in blue). A character type n-gram which indicates whether a character is either a vowel, digit, special character, or an English character, is turned into an embedding vector (shown in red). Lastly, we use probability and entropy values from the domain-generic model, which indicates whether a character is a start or end of a word or not in a dictionary, as the additional features (colored as green). We then concatenate all of the embeddings and feed them to the Bi-LSTM layer (Hochreiter and Schmidhuber, 1997; Ma et al., 2018).

The Attention model is connected to the Bi-LSTM output layer for improved accuracy because the attention mechanism is effective at capturing long-range dependencies (Duan and Zhao, 2020). The attention layer is followed by a fully connected network that ends with a single sigmoid output for Thai and Chinese (boundary or not) and a softmax output for Japanese and Urdu (the beginning, middle, or end of a word, or a word with a single character).

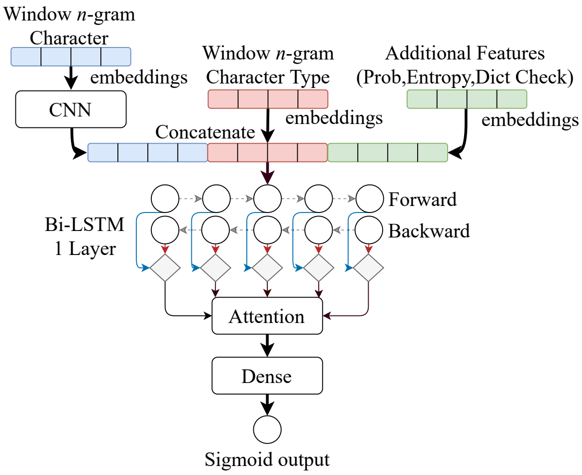


Figure 2: The domain-specific model of DSE.

Ablation studies, results given in Table 11, show that each component in the domain-specific model improves the performance incrementally. Unlike the original SE that relies only on the CRF as the domain-specific model, our deep learning approach to construct the domain-specific model can capture intricate WS patterns in the domain better than the original SE and transfer learning method.

However, unlike deep learning approaches, the classical machine learning approach, i.e., CRF, does not require a large amount of training data. To handle this problem, we propose the data augmentation technique at the character level. This can increase the amount of training data and thus improves the performance significantly.

Data Augmentation The main advantage of using a separate model for each domain is the ability to handle contradicting segmentation conditions from different domains (Fu et al., 2020). However, this approach requires a substantial amount of data in each domain as stated earlier. To mitigate this problem, we also propose two data augmentation methods based on the *Masked Language Model* (MLM) WangchanBERTa (Lowphansirikul et al., 2021) trained on Thai Wikipedia Dump. As shown in Figure 3, we mask words based on the output of the domain-generic model. The output posteriors from the model are used to compute the character-level entropy values. Then, the values are summed together to represent the score for each word. We select the words with the highest scores to mask in order to perform data augmentation. This is done to favor long words, since long words are harder to segment. We select the the top-k words to mask and replace them (substitution) using MLM. This a pretrained process to ensure the generation of hard-to-segment sentences. We also introduce semi-hard-to-segment samples by preferring word insertion after the word (rather than substitution). The same MLM is used to perform next word prediction instead of masked prediction. The ratio between hard-to-segment and semi-hard-to-segment is 80:20. This is found via grid search (see Table 13).

The insertion method gives the best performance compared with other semi-hard-to-segment generation methods (see the results in Table 13). The entropy selection method, compared with competitive selection methods in Table 12, shows that our method has the best performance for all Top-k selection and average scores.

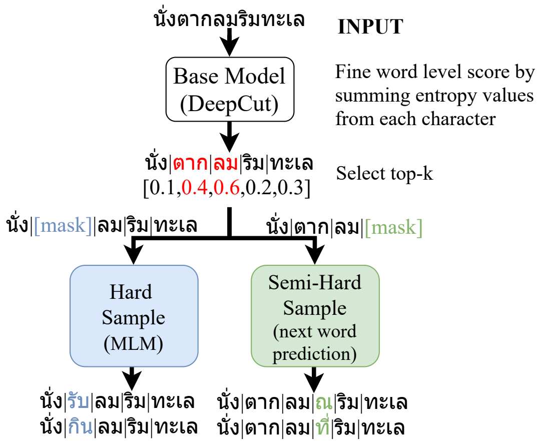

Figure 3: Overview of our data augmentation pipeline.

3.3 Muti-Domain Ensemble (MDE)

It is unrealistic to expect that the training and test distributions always match. Getting new training data for the out-of-domain scenarios can be expensive and time consuming (Ng et al., 2020; Liu et al., 2019). In such cases, transfer learning or the previously described DSE method are not sufficient.

We propose a framework, which utilizes an ensemble of domain-specific models to handle out-of-domain samples, called *Muti-Domain Ensemble (MDE)*. Figure 4 presents the structure of MDE.

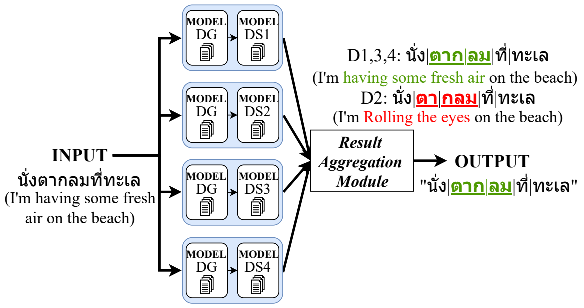

Figure 4: *Multi-Domain Ensemble (MDE).*

The framework consists of multiple word segmentation models, where each model is adapted to a specific target domain (except for the out-of-domain data) using the method described in Section 3.2. Results from multiple word segmentation models are combined using a result aggregator to form the final prediction. In this investigation, we formulate two result aggregation strategies as follows. (i) We compute a simple average of the posterior output from each model. Then, we predict the class that has the highest probability: this is a basic method for ensemble modeling (*Avg*); (ii) We calculate the entropy from each model based on their posterior distribution output. We then choose the prediction of the model with the lowest entropy and we call it *Min Entropy (ME)*.

The results of the MDE framework and aggregation module given in Tables 5 and 10 show that the entropy method performs better than the basic method and improves the performance significantly over other models in out-of-domain scenarios.

4 Performance Evaluations on Thai Word Segmentation

In this section, we report results from experimental studies on four *Thai word segmentation* (TWS) benchmark datasets. The studies are organized as follows. (i) we compare our method with competitive methods on domain adaptation; (ii) we show the effect of the data augmentation technique on domain adaptation; (iii) we report the results on out-of-domain setups; (iv) we show the effect of WS in downstream tasks.

Note that experimental studies on Chinese, Urdu, and Japanese are presented in Section 5.

4.1 Experimental Setup

Competitive Methods. We evaluate our proposed solution against two state-of-the-art methods namely DeepCut (DC) (Kittinaradorn et al., 2019) and AttaCut (AC) (Chormai et al., 2020). These methods are based on the *Convolutional Neural Network* (CNN) and trained on a generic corpus (BEST2009 (Boriboon et al., 2009)). For domain adaptation experiments, we also applied the concept of *Transfer Learning* (TL) to adapt DC and AC to the target corpora, and we call these adaptations TL-DC and TL-AC, respectively. Similarly, for the Stacked Ensemble Filter-and-Refine (SEFR) method (Limkonchotiwat et al., 2020), we created two variants, SE-DC and SE-AC, using DC and AC as the base model, respectively. For the evaluation of our method, *Deep Stack Ensemble* (DSE), we followed the same principle and created two variants DSE-DC and DSE-AC based on DC and AC, respectively.

Evaluation Metrics. We use F1 score as the evaluation metric for the TWS task at character and word levels to avoid the overestimation of TWS (Chormai et al., 2020; Limkonchotiwat et al., 2020).

Parameter Settings. In these experiments, we used grid search on 4 parameters including Bi-LSTM nodes, attention nodes, optimizer, and top-k inside the domain-specific model. We started the learning rate at 0.01 on an optimizer. For every 10 steps where the loss did not decrease, the learning rate was multiplied by a factor of 0.1. We set the number of training epochs to 300 with an option of early stopping. For the CNN layer and character embedding settings, we followed Kittinaradorn et al. (2019). We tuned the top-k value of the filtering system in a domain-specific model to be the same as the original SE. For the top-k value in the out-of-domain scenarios, we used the same k for all domain-specific models in the domain adaptation settings. Lastly, we tuned all of the parameters by using 10% of training data of the target domain. The hyper-parameters and their values are given in Table 1.

Hyper-parameters	Values for grid search
Optimizer	[Adam,RMSprop]
Learning Rate	0.01
Bi-LSTM nodes	[128, 160, 192, 224, 256]
Attention nodes	[32, 64, 96, 128, 160]
Top-k	[1-100]

Table 1: Hyper-parameters list.

4.2 Datasets

Benchmark Datasets. Our benchmark corpora can be seen in Table 2. They vary in domain and size from very small (Wisesight (Suriyawongkul et al., 2019) social media domain), moderate (TNHC (Sawatphol, 2019) classical literature), and large (LST20 (Boonkwan et al., 2020) generic).

Lang	Corpora	# Sentences	# Words
TH	Wisesight	1K [0.16K]	22K [3.9K]
TH	TNHC	13K [7K]	374K [239K]
TH	LST20	63.3K [5.2K]	2.7M [207K]
TH	VISTEC	39.8K [9.9K]	2.7M [690K]

Table 2: TWS corpora (# Training [# Testing]).

New Dataset. Due to social media data being underrepresented and difficult (Medina Serrano et al., 2020; Benton et al., 2017), it is challenging to improve the performance of models with only 997 training sentences. Most TWS models (Kittinaradorn et al., 2019; Chormai et al., 2020) performed under 82% in out-of-domain social media scenarios (Wisesight). To address this problem, we introduce a new dataset called "*VISTEC-TP-TH-2021*[1]" (VISTEC), which consists of 49,997 text samples from Twitter (2017-2019). VISTEC corpus contains 49,997 sentences with 3.39M words where the collection was manually annotated by linguists on four tasks, namely word segmentation, misspelling detection and correction, and named entity recognition. In the data collection process, we focused on the longest sentences to create a more challenging dataset due to the fact that long sentences made the model's performance decrease significantly compared with short sentences in the same domain (Section 4.3). The Out-of-Vocabulary rate on the test set is 13.65%.

We followed Boriboon et al. (2009) for the word and named entity tasks annotation guideline. We also included new guidelines about word editing criteria for misspelt words such as words used on the internet (Netspeak), transliterated loanwords, abbreviations, and shortened words, by using the Royal Institute Thai dictionary. We compared our dataset to the biggest Thai social media dictionary (Horsuwan et al., 2020) and found 79K words that did not appear in the dictionary.

4.3 Domain Adaptation

Without Data Augmentation. We evaluate the performance of our domain-specific model against competitive methods in four TWS benchmark corpora, WS160, TNHC, LST20, and VISTEC. The experimental results are given in Table 3. The competitive methods are defined in Section 4.1.

The DSE-DC (DeepCut) outperformed the strongest base model, DC, by 3.2% and 7.2% on WS160, 6.23% and 13.74% on TNHC, 4.41% and 10.18% on LST20, and 4.59% and 11.13% on VISTEC at character and word levels, respectively. Our domain-specific model also outperformed the original SE by 2.16% and 6.46% on SE-DC and 1.87% and 4.88% on SE-AC (AttaCut) at character and word levels on all setups. More importantly, our domain-specific model outperformed TL (transfer learning) methods showing the strength of our DSE model.

As expected, the newly constructed TWS social media dataset (VISTEC) shows that even TL-DC performed below 91% at word level, a large drop from the 96% achieved in the generic domain LST20 corpus. Also, the VISTEC dataset creates a new challenge for the social media domain. Comparing the WS160 and VISTEC datasets, the AC's performance decreased from 93.5% to 91.47% and 84.04% to 79.30% at the word level and the character level, respectively.

With Data Augmentation. In this experiment, we show the effect of the data augmentation in domain adaptation settings for different amounts of

Method	WS160		TNHC		LST20		VISTEC	
	Char	Word	Char	Word	Char	Word	Char	Word
DC	93.47	84.03	89.48	75.40	94.60	87.15	92.77	81.78
AC	93.50	84.04	88.82	73.71	95.24	87.21	91.47	79.31
TL-DC	96.30	90.60	95.43	88.60	98.63	96.30	96.78	90.99
TL-AC	94.10	85.00	90.57	77.54	98.04	94.77	95.47	89.27
SE-DC	95.20	86.90	95.20	84.10	94.96	87.72	94.76	86.33
SE-AC	94.50	85.60	93.70	83.90	96.30	89.87	93.86	84.43
DSE-DC	**96.67**	**91.51**	**95.71**	**89.14**	**99.01**	**97.33**	**97.36**	**92.91**
DSE-AC	94.57	86.24	95.51	88.52	98.46	95.79	97.31	92.78

Table 3: Performance comparison on TWS in domain adaptation settings. TL, SE, and DSE models used target domain data besides BEST2009. DC = DeepCut, AC = AttaCut, TL = transfer learning, SE= stacked ensemble, and DSE = deep stacked ensemble.

adaptation data. We report the findings of the data augmentation process on 2 corpora, i.e., Wisesight (social media domain) which is the smallest corpus and LST20 which is the largest generic domain corpus LST20 (see Table 2). We fixed the top-k value in the data augmentation step at 60% and 10% of the segmentation predictions of the Wisesight and LST20 corpora, respectively. This value is found via grid search (see Table 12). We then use these augmented data with TL, SE, and DSE.

As shown in Table 4, the data augmentation process can improve the performance in the small corpus, i.e., Wisesight (WS160). DSE-DC (DeepCut) outperformed the base model by 5.01% and 12.72% at character and word levels. Also, DSE-DC outperformed TL-DC by 1.39% and 3.36% at the character and word levels respectively.

Method	WS160 (F1)		LST20 (F1)	
	Char	Word	Char	Word
DC	93.47	84.03	94.60	87.15
AC	93.50	84.04	95.24	87.21
TL-DC	97.69	93.96	98.11	94.00
TL-AC	97.59	94.57	97.45	93.25
SE-DC	95.08	86.37	96.47	90.40
SE-AC	94.66	86.36	96.28	89.77
DSE-DC	98.48	96.75	**98.67**	**97.03**
DSE-AC	**98.60**	**96.99**	98.61	96.18

Table 4: Performance on augmented WS160 and LST20.

However, since LST20 is sufficiently large, the augmentation did not produce performance improvement with respect to the model constructed using the original data only.

4.4 The Effect of Data Augmentation in Insufficient Data Scenarios

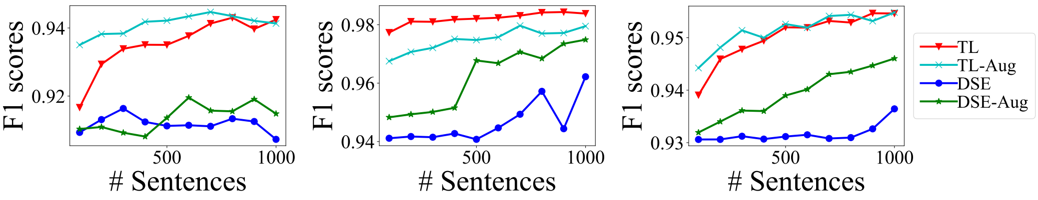
In this experiment, we evaluated the transfer learning (TL) and our method (DSE) trained on a varying numbers of sentences ranging from 100 to 1000 on the large datasets TNHC, LST20, and VISTEC to show the effectiveness of data augmentation in the insufficient data scenarios. As can be seen from Figure 5, the data augmentation improved the performance by 0.77% on average for TNHC, 1.55% for LST20, and 0.19% for VISTEC using DSE on the proposed data augmentation technique. Also, the transfer learning F1 performance is improved by 0.14% on average for TNHC and 0.57% for VISTEC. However, the performance of transfer learning on the LST20 data augmentation technique did not improve on this method as the baseline model (DeepCut) was trained on the same domain as the LST20 corpus. The performance of transfer learning in this setting is similar to the LST20 transfer learning model in Table 3.

The results of our method in insufficient data scenarios show that we improved the performance using the proposed data augmentation method when the original data is insufficient. Also, the best number of sentences for the augmentation technique in transfer learning is between 100 to 500 sentences and for our method is 500 to 1,000 sentences.

4.5 Experiments on Out-of-Domain Scenarios

In this experiment, we evaluated our *Multi-Domain Ensemble* (MDE) framework against two methods namely, DC trained on BEST2009 and *Multi-Criteria* (MC). MC is a multi-task model which learns multiple segmentation criteria from different domains jointly use shared layers (Chen et al., 2017). For MC and MDE, the target domains were left out from the training and the models are trained on the remaining domain.

As shown in Table 5, the performance improvements on Wisesight and TNHC were statistically significant ($P<0.001$ using McNemar's test) compared with MDE-ME and DC. Moreover, in comparison to DC, the performance improvement provided by MDE-Avg was also statistically significant on TNHC. As a result of MDE framework, we improved the performance from the base model (DC) at character and word level by 1.17% and 3.53% on WS160, 2.97% and 6.77% on TNHC, 0.26% and 0.42% on LST20, and 0.68% and 1.17% on VISTEC. Moreover, our MDE framework also outperformed the MC model in this experiment with significant results. In addition, the ME (Min Entropy) can improve the performance better than



(a) TNHC (b) LST20 (c) VISTEC

Figure 5: The effectiveness of Data Augmentation with limitation of training data with DSE and TL at Chracter-level F1.

the Avg except on TNHC.

Method	WS160		TNHC		LST20		VISTEC	
	Char	Word	Char	Word	Char	Word	Char	Word
DC	93.47	84.03	89.48	75.40	94.60	87.15	92.77	81.78
MC-Avg	88.59	72.30	84.96	72.36	87.55	66.52	89.67	70.38
MC-ME	91.59	84.80	85.13	72.63	91.10	80.70	90.81	77.13
MDE-Avg	93.85	84.64	**92.45**	**82.17**	94.81	87.54	93.17	82.71
MDE-ME	**94.64**	**87.56**	90.29	76.98	**94.86**	**87.57**	**93.45**	**83.53**

Table 5: Out-of-domain experimental results when the base model of MDE is DC (DeepCut), ME = Min Entropy.

As mentioned earlier, word segmentation is a domain-dependent task and we cannot expect the input to always be in domain. A model that can robustly handle the out-of-domain scenarios is desirable. Even with the improvement gained by our proposed solution, the gap between out-of-domain and domain adaptation is still large, showing potential for further investigation. In the next experiment, we show the effect of the data augmentation on downstream tasks.

4.6 The Effect of Word Segmentation and Data Augmentation on Downstream Tasks

Previously, we showed the proposed data augmentation improved the performance of TWS in the domain adaptation settings. In this experiment, we applied TWS to downstream tasks such as named entity recognition (NER), text classification, and sentiment analysis compared with the TWS base model (DC and AC), TL, DSE, and DSE with augmented data. For the text classification experiments, we use Wongnai corpus and Wisesight corpus for sentiment analysis. The exact model setting and evaluation metric follow Thai classification benchmark [2]. For the NER experiment, we used NCRF++ (Yang and Zhang, 2018) trained with data from Nutcha (2016)'s work. We trained our DSE and competitive methods (except the baseline model) on the Wisesight corpus to show the performance of the proposed augmentation technique.

The results are given in Table 6. When the downstream tasks are not dependent on WS performance, the results one similar i.e., text and sentiment classification tasks. On the other hand, when the downstream task is dependent on WS performance, i.e., NER, we can significantly improve the downstream task. For example, we improved the performance of DSE-DC from 93.47% to 96.67% at the character level, and when combined with data augmentation, increased the accuracy to 98.48%. As a result, the F1 score in the NER task increased from 63.46% to 72.27%.

Method	TC	SA	NER
DC	57.10	71.55	63.46
AC	57.20	71.66	72.98
TL-DC	57.26	72.38	61.70
TL-AC	56.72	71.61	64.28
DSE-DC	57.04	**72.63**	71.47
+ Augment	**58.01**	72.27	72.27
DSE-AC	57.01	72.35	66.60
+ Augment	56.99	72.41	**73.47**

Table 6: The effect of TWS data augmentation on downstream tasks. All models were trained on Wisesight.

5 Chinese, Urdu, and Japanese Word Segmentation

In this section, we demonstrate the generalizability of our method on Chinese word segmentation (CWS), Urdu word segmentation (UWS), and Japanese word segmentation (JWS). For Chinese and Urdu, we performed in-domain experiments showing the effectiveness of DSE over SE and other competitive baselines. For Japanese and Chinese, we show the effectiveness of DSE and MDE over baselines in domain adaptation and out-of-domain settings. The corpora used in these experiments are shown in Table 7. The exact setup and evaluation metrics follow those of Limkonchotiwat et al. (2020).

---

Lang	Corpora	# Sentences	# Words
C	AS (Emerson, 2005)	636K [13K]	4.8M [110K]
C	CITYU (CI)	46K [1.1K]	1.2M [28K]
C	MSR (MS)	56K [3.5K]	1.4M [91K]
C	PKU (PK)	7.7K [1.1K]	371K [48K]
J	GSD (GS) (Asahara et al., 2018)	7K [0.5K]	159K [12K]
J	Modern (MO)	0.6K [0.16K]	11K [2.6K]
J	PUD (PU)	0.7K [0.19K]	19K [5K]
U	UCRF (UC) (Bin Zia et al., 2018)	3.5K [825]	90K [21K]

Table 7: WS corpora (# Training [# testing]) for Chinese (C), Japanese (J), and Urdu (U).

In-Domain Experiments on Chinese and Urdu. For Chinese, we used PyWordSeg (Chuang, 2019) trained on each of the four Chinese corpora as our baseline models (*BL*). We then trained SE and DSE models on top of each baseline model for each domain. For Urdu, we used the model and dataset provided by Bin Zia et al. (2018). The results are summarized in Table 8.

Method	Chinese				Urdu
	AS	CI	MS	PK	UC
BL	97.09	94.30	87.29	85.76	93.73
SE	97.51	96.13	93.82	93.55	93.90
DSE	**97.85**	**96.67**	**96.89**	**95.85**	**95.14**

Table 8: F1-scores on in-domain CWS and UWS tasks for each corpus. BL refers to the baseline chosen for each language.

Both stacked ensemble methods improve over the baseline models in all settings showing the potential of stacked ensemble in improving WS performance. Moreover, the proposed DSE outperforms the original SE (Limkonchotiwat et al., 2020) significantly for MSR, PKU, and UCRF ($P<0.001$). The largest performance improvement is over 10% on the PKU corpus.

Domain Adaptation on Japanese. As in the TWS experiments, DSE can also be used for domain adaptation by training the domain-specific portion on the target domain. For this JWS task, we used Nagisa (Ikeda, 2018) trained on *Balanced Corpus of Contemporary Written Japanese* (BCCWJ) (Maekawa et al.) corpora as the base model. The domain-specific part of the SE was trained on the target corpus to create an adapted model. Note that the Nagisa model released does not lend itself for transfer learning because the authors did not provide the model weights. From Table 9 SE and DSE improves significantly over the baseline showing the effectiveness of SE in situations when one cannot perform typical transfer learning.

Method	Japanese		
	GS	MO	PU
BL	87.10	78.80	87.10
SE	90.11	90.27	91.76
DSE	**92.36**	**90.65**	**91.89**

Table 9: F1-scores on domain adaptation JWS tasks for each corpus.

Out-of-Domain Experiments on Chinese and Japanese. Multiple models can form an MDE to provide robustness in out-of-domain scenarios. For Chinese, we used PyWordSeg trained on the AS corpus as the base model. The MDE included two domains (non-target) and was tested on the left-out target domain.

Method	Chinese			Japanese		
	CI	MS	PK	GS	MO	PU
BL	92.51	83.92	82.21	87.10	78.80	87.10
MDE-Avg	88.90	89.15	89.77	87.11	79.36	87.42
MDE-ME	**93.98**	**93.01**	**93.56**	**87.12**	**79.39**	**87.44**

Table 10: F1-scores on out-of-domain CWS and JWS experiments.

Table 10 summarizes the results of the out-of-domain experiments. The MDE provides a minimal improvement over the baseline on JWS. We hypothesize that this is because two out of the three corpora are too small to train a reliable model. However, on Chinese the MDE provides large gains over the baseline with the min entropy method performing better than the simple averaging method.

6 Concluding Remarks

This investigation presents a set of solutions to address two domain dependency problems: handling cross-domain and out-of-domain samples. Our key findings are as follows. First, we applied deep learning to the original stacked ensemble method and obtained a significant improvement. Second, we show that data augmentation is an effective method to combat the low-resource limitation in domain adaptation. Third, we can use an ensemble of domain-specific models to obtain a performance improvement over each domain-specific model acting alone. Finally, in addition to Thai, we can apply the same principle to Chinese, Japanese, and Urdu and obtain similar improvements. As future work, we plan to experiment with novel techniques, i.e., Transformer and contrastive learning.

A Appendices

A.1 Ablation Studies

In this experiment, we show the effect of Bi-LSTM with attention mechanism on the performance of the TWS domain adaption problem with the help of an ablation study. This study was performed on the Wisesight corpus (test set) and used DC (DeepCut) as the base model. As can been seen from Table 11, each component significantly improved the performance from the base model.

System	F1 Char	F1 Word
Baseline	93.47	84.03
+ Additional Feature	94.27	85.39
+ Bi-LSTM	96.31	90.35
+ Attention	**96.67**	**91.51**

Table 11: TWS domain adaptation ablation studies.

A.2 How to Select a Word to Mask? Entropy vs Random vs Maximum Length Selections.

The Section 3.2 presented the way we select a word to augment and compared it against the traditional method i.e., random selection. In this study, we show the validation score of random, entropy, and maximum length selections in our data augmentation technique on the Wisesight corpus with DC base model by varying the k value from top-10% to 100% on the substitution method and fixed top-20% value for the insertion method.

The validation score results are given in Table 12, the best range top-k value for the data augmentation is 50% to 60%. The performance of entropy selection is better than competitive methods with reasonable results. Due to the fact that long words are harder to segment than short ones, the entropy selection method favors long words with a high uncertainty. Maximum length selection, gives a similar score with entropy selection due to the fact that high uncertainty score mostly comes from long words. Also, the best F1 score is obtained using top 60% not 100% as words in top-60% might have the most incorrect answers and bias from frequency word.

A.3 Ablation Studies For Different Semi-Hard-Sample Procedures

Section 3.2 mentioned a competitive method to produce semi-hard-to-segment samples. We use the semi-hard-to-segment method with substitution by fixing the k value at top-60% for substitution method and we vary k in the range of 10% to 100% on the semi-hard-to-segment methods to show the performance of each method. We show the validation score on Wisesight (training data) with character and word levels, respectively. The results are presented in Table 13. As can be seen, the insertion method reports the best performance on every top-k entropy selection. The deletion method is inappropriate due to the fact that we might delete some information in the training data.

Top-k Entropy	ES		RS		MLS	
Select	char	word	char	word	char	word
10	99.74	99.29	99.50	98.67	99.71	99.13

AVG	**99.86**	**99.66**	98.79	96.80

Table 13: Performance comparison on insertion VS deletion to produce semi-hard-to-segment samples with WS160 (F1 validation score).

A.4 Error Analysis

We performed an error analysis on Wisesight (WS160) corpora for DC, SE-DC, and DSE-DC to investigate the improvement from the baselines as well as the benefits of our method in domain adaptation setups. We used the same setting as mentioned in Section 4.3. The samples presented here were randomly selected from the Wisesight validation set.

As shown in Figure 6, DSE-DC did better especially on compound words. However, all models still cannot properly handle the special character (+), since the character is rare in the WS160 corpus.

Sensei: Self-Supervised Sensor Name Segmentation

Jiaman Wu, Dezhi Hong, Rajesh K. Gupta, Jingbo Shang

Halıcıoğlu Data Science Institute, University of California San Diego, CA, USA
{j4wu, dehong, gupta, jshang}@eng.ucsd.edu

Abstract

Sensor names as alphanumeric strings typically encode their key contextual information such as their function or physical location. We focus here on sensors used in smart building applications. In these applications, sensor names are curated in a building vendor-specific manner using different structures and esoteric vocabularies. Tremendous manual effort is needed to annotate sensor nodes for each building or even to just segment these sensor names into meaningful chunks for intelligent operation of buildings. We propose here a *fully automated* self-supervised framework, Sensei, that can learn to segment sensor names without any human annotation. We employ a neural language model to capture the underlying structure in sensor names and then induce self-supervision based on information from the language model to build the segmentation model. Extensive experiments on five real-world buildings comprising thousands of sensors demonstrate the superiority of Sensei over baseline methods.

1 Introduction

Sensor name segmentation seeks to partition a sensor name string into semantic segments. It is an essential task to enable smart building applications (Weng and Agarwal, 2012) that critically depend upon understanding the context of sensory data. For example, to increase the flow of air to improve air quality, such an application will need to identify and locate the airflow controller for the specific area. Such a controller is identified as a control point associated with a specific actuator such as a variable air valve. This is typically done manually by searching appropriate strings in the name that refer to specific sensor or actuator type and/or its location. This information is encoded as a concatenation of *segments*. Correct segmentation of sensor names is a key first step. Note, we use sensor to refer to both sensors and actuators in a building application.

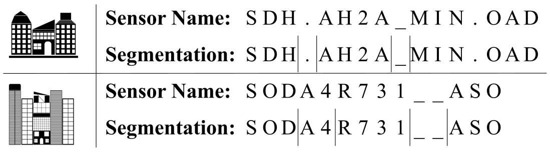

Figure 1: Sensor names adopt distinctive structures and vocabularies in different buildings, thus requiring manual effort to interpret.

Figure 1 shows examples of sensor names consisting of multiple segments, each encoding key context about the sensor (building name, location, sensor type, etc). Thus, the sensor name `SODA4R731__ASO` should be segmented as `SOD` (building name), `A4` (equipment id), `R731` (room id), and `ASO` (measurement type – area temperature setpoint). Note that the meanings of the same punctuation may vary; for example, '_' can be a delimiter or part of a segment.

Currently, sensor name segmentation requires domain knowledge and tedious manual effort due to its building-specific nature. Sensor names are created by building vendors, and as we see from Figure 1, in different buildings they usually adopt distinctive structures and vendor-specific esoteric vocabularies. Thus, constructing a sensor name segmentation model involves a building systems technician to comprehend these sensor names and then design rules to segment and annotate these names. There are no universal pre-defined parsing rules such as regular expressions for sensor names. This obscurity of sensor data remains a major obstacle to the wide adoption of smart building applications from both cost and efficiency perspectives (Bhattacharya et al., 2015a).

We need an automated solution for sensor name segmentation. Despite the recent progress in apply-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1017–1027

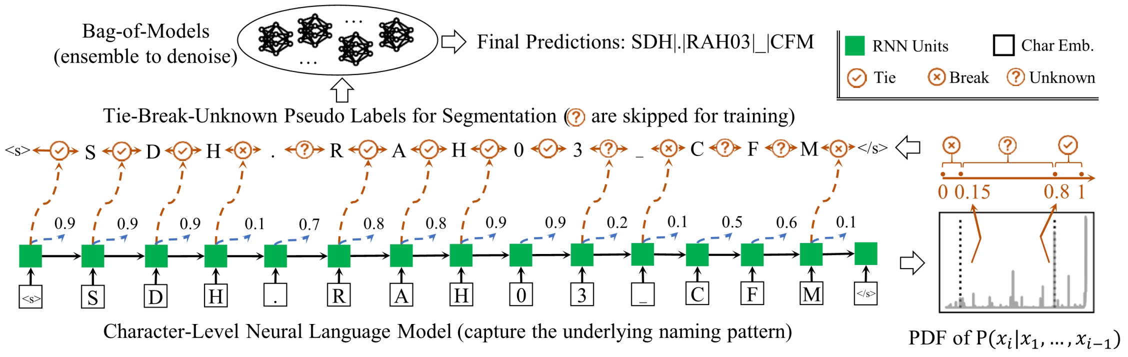

Figure 2: Overview of Sensei: We induce pseudo labels for segmentation using the transition probabilities from a character-level neural language model. Segmentation model training uses the hidden states from this model.

ing active learning (Schumann et al., 2014; Hong et al., 2015b; Balaji et al., 2015; Koh et al., 2018; Shi et al., 2019) and transfer learning (Hong et al., 2015a; Jiao et al., 2020) to sensor name interpretation, all these methods still require human annotation effort and thus they are not *fully* automated.

We propose here a novel self-supervised segmentation framework, Sensei, to segment sensor names into meaningful chunks *without any human effort*. This would enable understanding of important contextual information at scale and enable new regime of building applications. Figure 2 presents an overview.

Sensei builds upon the observation that sensor names are not randomly generated. Instead, installers of building management system would generally follow *some* underlying pattern for naming. For instance, in some buildings, the sensor name often starts with the building name, followed by the room id and type of measurement. Further, technicians would generally use similar phrases to express the same concept (e.g., "temperature" would be encoded as "T", "temp", or "ART"), at least within the same building. Based on this observation, we first employ a character-level neural language model (Karpathy et al., 2015) to capture the latent generative pattern in sensor names. This language model learns the probability of observing a character in the sensor name given all the preceding characters. Intuitively, the segment boundaries in a sensor name should highly correlate with this probability. Frequent transitions would have a higher probability than the infrequent ones, which might well imply the start of another segment. Therefore, we induce pseudo segmentation labels by setting a pair of thresholds on these transition probabilities, and then build a binary classifier to segment sensor names upon their contextualized representations produced by the language model. Since these pseudo labels may contain noise, we create an ensemble of independent classifiers, each trained on a uniformly random subset of the pseudo labels, in order to further improve the efficacy.

To the best of our knowledge, Sensei is the first framework for sensor name segmentation without human annotation. This paper makes the following contributions:

- We study an important problem of *fully automated* sensor name segmentation.
- We propose a novel self-supervised framework Sensei, which leverages a neural language model to capture the underlying naming patterns in sensor names and produces pseudo segmentation labels for training binary classifiers.
- We conduct extensive experiments on five real-world buildings comprising thousands of sensor names. Sensei on average achieves about 82% in F_1, roughly a 20-point improvement over the best compared unsupervised method.

Reproducibility. Our code and datasets are readily available on Github[1].

2 The Sensei Framework

Sensei consists of three steps:

- Train a neural language model (NLM) at the character level to capture the underlying naming patterns in sensor names;
- Generate `Tie-Break-Unknown` pseudo la-

---

[1] `https://github.com/work4cs/sensei`

bels using two thresholds, t_0 and t_1, decided by inspecting the distribution of transition probabilities (i.e., likelihood of observing the current character given the previous ones);

- Train a set of segmentation models based on the pseudo labels to mitigate the effect of noise in these labels.

We next elaborate on each step.

2.1 Language Model for Underlying Patterns

As sensor names are created by humans (e.g., a technician with knowledge about building particulars), they often follow a certain naming convention (e.g., start with the building name, then room id, and then type). The names also have an internal consistency, that is, within a building, segments of sensor names corresponding to the same kind of information (e.g., location or function) would use similar phrases; e.g., the concept of "room" would be encoded as "`RM`", "`R`", or similar variants. This prompts us to model the generative patterns in these names such that given the characters seen so far we can predict the next one. This coincides with the language modeling task in NLP.

Since the sensor name segmentation task works on characters, we adopt a popular character-level neural language model to capture the underlying sensor naming pattern, the classical Char-RNN (Karpathy et al., 2015) architecture, and use LSTM (Hochreiter and Schmidhuber, 1997) as the RNN model. Note that, our method is compatible with any character-level neural language models.

Given a character sequence of length N, $X = \langle x_1, x_2, \ldots, x_N \rangle$, the Char-RNN learns the probability of observing a character given all the previous characters, namely, $p(x_{i+1}|x_1, x_2, \ldots, x_i)$. During this process, we will obtain an embedding vector $\mathbf{x}_i$ for each character x_i, and a hidden state vector $\mathbf{h}_i$ after observing the characters from x_1 to x_i. A softmax layer is then applied to $\mathbf{h}_i$ to predict a distribution $\hat{\mathbf{p}}_\mathbf{i}$ over the entire vocabulary:

$$\hat{\mathbf{p}}_\mathbf{i}(c) = p(c|x_1, x_2, \ldots, x_i) = \frac{\exp\left(\mathbf{w}_c^\top \mathbf{h}_i\right)}{\sum_{c'} \exp\left(\mathbf{w}_{c'}^\top \mathbf{h}_i\right)},$$

where $\mathbf{w}_c$ is the linear transformation for character c. The cross-entropy between $\hat{\mathbf{p}}_\mathbf{i}$ and the one-hot encoding of x_{i+1} is used as the loss function for this character.

Given a building, we train the Char-RNN on all its sensor names. As each sensor name is independent of each other, we can have the same initial hidden state for each sensor name to ensure sensor names do not interfere with each other. Once the model converges, we apply it to all the sensor names to obtain the character transition probabilities, i.e., $\hat{\mathbf{p}}_\mathbf{i}(x_{i+1})$. The perplexity of the trained Char-RNN in our experiments is typically small (i.e., < 0.3 per batch with batch size 32). Therefore, we believe it captures the underlying naming pattern within the input building well.

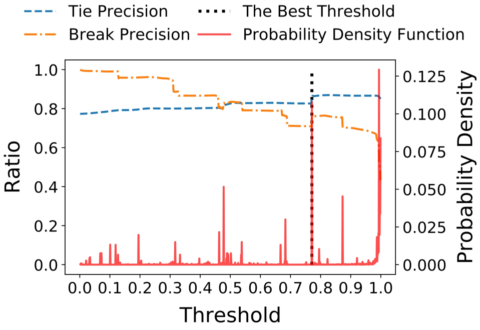

Figure 3: Plots of $\hat{\mathbf{p}}_\mathbf{i}(x_{i+1})$ histogram (grey bars) and Tie/Break precision curves for an example building. The "sweet spot", achieving a great balance between the tie- and break-precision scores, is highly aligned with the peak in the histogram.

2.2 Pseudo Labels from Transition Probabilities

Inspired by (Shang et al., 2018b), we use `Tie` and `Break` to decide the segmentation results. The transition between two adjacent characters (x_i, x_{i+1}) is labeled as (1) `Break` when we should segment after character x_i, or (2) `Tie` otherwise, denoting that the two successive characters belong to the same segment.

For a given character sequence $x_1, x_2, \ldots, x_N$, we hypothesize that the transition probability $\hat{\mathbf{p}}_\mathbf{i}(x_{i+1})$ obtained from Char-RNN is closely related to the `Tie/Break` relation between x_i and x_{x+1}. Intuitively, the Char-RNN model should produce a high likelihood for common transitions in sensor names, e.g., substrings for building name, room, and common sensor types. Therefore, when Char-RNN suggests a low transition probability, the transition is very likely to be a `Break`; otherwise, the possibility of a `Tie` becomes higher.

We empirically verify our hypothesis via data analysis of an example building as shown in Figure 3. We present the probability density from histogram of $\hat{\mathbf{p}}_\mathbf{i}(x_{i+1})$. In addition, based on the ground-truth segmentation results, we plot the Tie and Break precision curves w.r.t. different thresholds. The *Tie Precision* refers to the ratio of Tie transitions among all the transitions above a certain threshold, while the *Break Precision* refers to the ratio of Break transitions among all the transitions below a certain threshold. One can observe that the"turning" points on the break precision curve are highly correlated to the peaks in the histogram. An uptick on the break precision curve indicates that there might be abundant same patterns in the bin of probabilities, which typically are more likely to be `Ties`. Therefore, the thresholds should be below the probability bins with high frequency to classify the steep upslope regions as `Tie`.

If one wants to set up a single threshold on $\hat{\mathbf{p}}_{\mathbf{i}}(x_{i+1})$ to classify all transitions into {`Tie`, `Break`} in an unsupervised manner, the highest peak in the "confidence" interval $[0.550, 0.950]$ on the distribution (e.g., 0.771 in Figure 3) would be a good choice to achieve a high F_1 score. We generalize this threshold selection criterion to the other buildings, and as we shall demonstrate in our experiments, such a selection strategy gives results close to grid search that uses ground-truth labels.

In addition to `Tie` and `Break`, we mark those uncertain transitions as `Unknown`. We need to decide on two thresholds, t_0 and t_1, and categorize the transitions according to three transition probability intervals, $[0, t_0]$, (t_0, t_1), and $[t_1, 1]$, denoting `Break`, `Unknown`, and `Tie`, respectively, as the *pseudo labels*. We wish these pseudo labels would be of high accuracy while having a sufficient amount of labels. Based on our observations, the above single threshold criterion satisfies t_1. Considering that `Breaks` are considerably fewer than `Ties`, we should decide on a `Break` more carefully. The highest peak in a narrowed high precision interval $[0.050, 0.150]$ would be appropriate (e.g., 0.101 in Figure 3).

2.3 Ensemble to De-noise Pseudo Labels

There could exist errors in these automatically induced pseudo labels, so we leverage the idea of ensemble learning to mitigate the impact of such errors on the final predictions (Breiman, 1996). Specifically, we independently sample a subset of pseudo labels to train K binary classifiers and then average their predictions. In the pseudo labels, the number of `Tie` transitions is usually much higher than that of `Break`. To balance the training data, we sample $\epsilon \cdot M$ `Tie` and `Break` labels, respectively, from all the pseudo labels, where M is the number of `Break` transitions and ϵ is a small coefficient between 0 to 1 for sampling a subset (e.g., $\epsilon = 0.1$). Such a sampling strategy makes the label errors less likely to affect every binary classifier, so the final prediction becomes more accurate.

All types of binary classifiers could be used to construct the ensemble. We adopt a Multi-Layer Perceptron (MLP) as the binary classifier. For the i-th transition, we retrieve the hidden state vector $\mathbf{h}_i$ yielded by the Char-RNN and feed it as input to the MLP. The final prediction is the average of predictions from the K classifiers. As the training data is sampled in a balanced way, we simply use 0.5 as the threshold to decide on `Tie` or `Break`.

3 Experiments

We empirically evaluate Sensei on datasets from real-world buildings and discuss our results as well as findings of particular interest.

3.1 Datasets and Pre-processing

We collected the sensor names from five office buildings contracted with four different building vendors at three different sites located in different geographic regions. We also collected the character-level ground-truth labels of these names from their building vendors. We adopted the `BIO` tagging scheme in generating labels, marking the beginning (`B`), inside (`I`), and outside (`O`) of each segment (e.g., for location or function). Table 1 summarizes details of each building.

Digits. The digits in sensor names indicate detailed and specific information such as room or equipment identifiers, so preserving the variety in numbers does not help our segmentation task. Conversely, it disturbs the transition probability distribution and thus confuses the model in predicting the next characters – the model would only need to learn and recognize the transitions from digit to digit, as opposed to the specific values (e.g., "`1`" to "`2`" or "`4`" to "`3`"). Therefore, we replace all numerical digits with the same digit "0".

Punctuation and Whitespace. There are symbols such as underscores and whitespace in sensor names that are inserted by technicians at the time of metadata construction. We leave them *as-is* for our model to learn their meanings because the meanings of these characters vary from case to case. This is, in fact, one of the major challenges in this

Table 1: Statistics of five buildings in our experiments. These builds are from three different campuses: Buildings **SDH** and **IBM** are from the first campus, **APM** and **EBU** from the second, and **SOD** from the third. Example sensor names are also listed for reference.

Building	#Sensors	#Segments	#Characters	Example Sensor Name
SDH	$2,551$	$2 \sim 5$	$7 \sim 31$	`SDH.AH1_RHC-4:CTL STPT`
IBM	$1,366$	$2 \sim 3$	$6 \sim 28$	`1F_FCU10_11_13_23_COLLAB`
APM	$1,079$	$1 \sim 7$	$4 \sim 34$	`AP&M-CRAC-2-MIG-009.COOLING ON-OFF`
EBU	$1,074$	$2 \sim 3$	$7 \sim 35$	`EBU3B.3RD FLR AVG CLG-PID1`
SOD	$1,335$	$2 \sim 4$	14	`SODC3P09DP_STA`

sensor name segmentation problem. For example, the sensor name "`SODH1______L_L`" should be segmented as "`SOD|H1|______|L_L`", with the three segments corresponding to its building name, equipment id, and measurement type, respectively. The underscores between "`H1`" and "`L_L`" are padded to make the sensor name fixed-length, while the underscore inside "`L_L`" connects two initial letters (i.e., for a Lead-Lag sensor, commonly existing in water pumps).

3.2 Evaluation Metrics

We evaluate the performance of all the considered methods by the F_1, precision, and recall scores. A segment is represented as a span with the starting and the ending character indices. A predicted segment is correct if and only if there exists an exactly same segment in the ground truth. Therefore, we define the precision and recall as follows:

$$\text{prec} = \frac{|\mathcal{S}_{GT}| \cap |\mathcal{S}_{Pred}|}{|\mathcal{S}_{Pred}|}, \text{rec} = \frac{|\mathcal{S}_{GT}| \cap |\mathcal{S}_{Pred}|}{|\mathcal{S}_{GT}|},$$

where $\mathcal{S}_{GT}$ is the set of ground-truth spans and $\mathcal{S}_{Pred}$ is the predicted set. The F_1 score is the harmonic mean of precision and recall. We report the averaged F_1 score of all sensor names, which is relatively unbiased (Opitz and Burst, 2019).

As we mentioned before, there will be some extra delimiters between segments. Therefore, during the evaluation, we ignore segments containing only delimiter(s) in both ground truth and predicted segments. When calculating the start and end indices for predicted segments, we also skip their prefix and suffix delimiters. The same process here applies to the evaluation of all methods.

3.3 Compared Methods

We compare Sensei with the following methods:

- **Delimiter**. There are punctuation (such as "-" and "_") and whitespace characters in sensor names, and they could indicate the boundaries between segments. Therefore, this method segments a sensor name by delimiters (i.e., non-alphanumeric characters). This method mainly serves as a sanity check.
- **NLTK TweetTokenizer**. NLTK (Bird et al., 2009) provides a tweet tokenizer to segment a string into tokens according to predefined regular expressions (regexes). We directly apply it to segment our sensor names.
- **CoreNLP**. We adopt the pre-trained tokenizer in the CoreNLP package[2] (Manning et al., 2014), which adopts the Universal Dependencies[3] version 2 (UD v2) standard for segmentation .
- **Stanza**. We also adopt Stanza[4] and use its built-in neural tokenizer (Qi et al., 2020) following UD v2. This method combines convolutional filters and bidirectional LSTM to realize tokenization and sentence segmentation as a tagging task (Qi et al., 2018).
- **N-gram-LM**. Character-level N-gram language model (N-gram-LM) can also provide character transition probabilities. To obtain an "upper bound" of the N-gram-LM's performance, we apply a grid search technique of Sensei-GS detailed in the following to find the optimal threshold on the test set. As most segments in the ground truth contain fewer than 5 characters, we tried N from 1 to 5 and reported on the best performance. However, this model does not offer any representations that we can use to train the ensemble classifiers for the "break/tie" decisions.
- **BayesSeg**. Topic segmentation divides a document into topic-coherent segments. An unsupervised Bayesian model, BayesSeg[5] (Eisenstein and Barzilay, 2008), is used to segment char-

---

[3] Universal Dependencies is a framework of annotation guidelines by open community effort. `https://universaldependencies.org/`

[4] `https://stanfordnlp.github.io/stanza/`

[5] `https://github.com/jacobeisenstein/bayes-seg`

acters of sensor names as a topic segmentation task that decides the boundary between sentences. However, this method requires to manually specify the number of segments, which is a parameter we do not know without human input.

- **ToPMine**. ToPMine (El-Kishky et al., 2014) provides a method that groups frequent words into phrases in an unsupervised manner and incorporates these phrases into topic modeling. We adapt the model to work at the character level. That is, we regard each character of sensor names as a word in document and group characters into segments as group words into phrases.
- **SeNsER**. Besides the above unsupervised methods, we compare with a transfer learning model, SeNsER (Jiao et al., 2020), a supervised method that uses both source and target buildings' raw sensor names and source building's annotations to learn a sensor name tagger for use in the target building.

Note that, we do not use custom **regexes** to segment sensor names because they require tremendous manual effort to create in order to exhaustively cover all the possible substring patterns, which deviates from our self-supervised problem setting. Moreover, since different buildings follow different sensor naming conventions, manual effort is required from domain experts to create regexes on a per-building basis, which is a costly process.

We also compare with two ablations of our method:

- **Sensei-Forward (Sensei-FW)**. It leaves out the self-supervised ensemble learning. Specifically, we keep the Char-RNN to obtain the distribution of observing next characters, and then find the *single* threshold as stated in Section 2.2.
- **Sensei-Backward (Sensei-BW)**. This is similar to the forward counterpart. The only difference is that the Char-RNN takes as input the *reversed* sensor names. As we shall see in the results, this method does not add much value to our task due to the intrinsic irregularity of sensor names when examined backward.

We further examine a method using grid search based on ground truth for threshold tuning to verify the effectiveness of our threshold decision:

- **Sensei-GridSearch (Sensei-GS)**. Compared to Sensei-FW, this method finds the best threshold for deciding `Tie` using ground-truth labels, i.e., it searches through all the possible threshold values on the transition probability distribution and picks the one producing the best segmentation results. This method is only used to demonstrate that a single threshold chosen based on the transition distribution (as detailed in Section 2.2) gives results reasonably close to the best we can achieve for Sensei-FW using the ground truth.

3.4 Experimental Setup

We modify the Char-RNN library[6] and use Keras (Chollet et al., 2015) to implement our method. As our method is unsupervised, we do not employ the commonly used early-stopping scheme when training the Char-RNN. Instead, we train our models for 100 epochs and empirically find this to be sufficient. All the thresholds have three decimal places. We assign `Ties` as positives and `Breaks` as negatives. For binary classifier, any supervised learning algorithm (e.g., logistic regression, SVM, etc) would accommodate our need in this work. We choose a vanilla Multilayer Perceptron with 2 fully-connected layers, each with 64 cells. We set the number of binary classifiers in our ensemble, K, at 100. The subsampling rate for the ensemble, ϵ, is 10% and for each subsampling, we use pandas with the iteration index as seed. Training a Sensei model on a Colab GPU with 12GB RAM takes less than 40 minutes for each building. For the other compared methods, we tune at our best based on the recommended settings in their papers or repositories and report the best performance.

3.5 Main Results and Analysis

Experimental results for all the unsupervised methods are summarized in Table 2. Overall, Sensei significantly outperforms all the compared methods, attributed to its strategy of complementing the language model with a self-supervised ensemble classifier. Besides the variants of Sensei, the N-gram-LM baseline achieves the second-best performance among all the other unsupervised methods, with an average 62.13% in F_1 across all the buildings. This also illustrates the usefulness of a language model. By contrast, our Sensei achieves over 80% in F_1, which demonstrates a 20-point improvement over N-gram-LM.

When looking at the F_1 scores of baselines including Delimiter, ToPMine, BayesSeg, and the off-the-shelf tokenizers in NLTK, Stanza, and CoreNLP, they are not competitive; this highlights the need for a solution to our challenging problem.

SOD	48.44	39.15	43.30	74.56	61.10	67.16	5.85	2.89	3.87	16.76	8.79	11.53	99.75	99.77	99.76

The performance of Delimiter confirms the fact that the semantics of these delimiters are mixed. If one recalls the examples in Table 1, vendors usually use delimiters in sensor names. Sometimes, these delimiters well indicate the segment boundaries. However, as we illustrated in the example sensor name “`SOD|H1|______|L_L`”, punctuation could be also used within the segment, and therefore simply segmenting at delimiters results in a considerable amount of false positives.

From Sensei-FW to Sensei, there is a significant boost, roughly 27 points in F_1 on average. Since the major difference between Sensei and Sensei-FW is our self-supervised ensemble learning module, we empirically verified its power.

Comparing Sensei-FW and Sensei-BW, we observe that the forward version performs dramatically better. Sensei-FW also performs better than Delimiter, ToPMine, and all the pre-trained tokenizers in all cases. By contrast, Sensei-BW takes the reversed sensor names as input but performs much worse than Sensei-FW. We notice that this is because there are not sufficient variations in the sensor string patterns when being looked at backward, compared to the forward case. For example, there are names like “`SODA4R731__ASO`” and “`SODA1R516__VAV`”, and the Sensei-FW model can see various substrings (e.g., “`ASO`” and “`VAV`”) following the common pattern “`SODA0R000__`”. Variations as such provide enough information for the model to learn where to segment. However, when reversed, the above example becomes “`OSA__000R0ADOS`” and the *prefix* “`OSA`” sees no variations following, which makes it nearly impossible for Sensei-BW to figure out the right segmentation. Consequently, Sensei-FW better captures generative patterns while Sensei-BW achieves poor segmentation results.

Comparing Sensei-FW and Sensei-GS, one can observe that, in most cases (4 datasets out of 5), Sensei-FW finds the best single threshold found by Sensei-GS. Note that Sensei-GS utilizes the ground truth to exhaustively search among all the possible thresholds, while Sensei-FW decides the threshold based on the transition distribution without requiring any labels. This small difference in performance indicates that our data-driven threshold finding solution based on the distribution is reasonable and reliable.

From Table 3 we see that the performance of transfer learning varies drastically across buildings. This is because, as the method takes a transfer learning approach, its performance highly hinges on how similar the sensor names in the source building are to those in the target building. For example, **APM** and **EBU** are from the same vendor, and thus

Table 4: Performance of Sensei using different amounts of sensor names for training.

	SDH		**IBM**		**APM**		**EBU**		**SOD**	
Percentage (%)	#Sensors	F_1	#Sensors	F_1	#Sensors	F_1	#Sensors	F_1	#Sensors	F_1
25	637	72.67	341	75.95	269	39.99	268	33.50	333	57.86
50	1,275	92.28	683	71.84	539	48.99	537	47.77	667	85.62
75	1,913	86.38	1,024	85.04	809	57.61	805	70.45	1,001	85.31
100	2,551	84.95	1,366	86.84	1,079	73.21	1,074	80.39	1,335	86.43

SeNsER is relatively more effective on these two buildings. Moreover, since **APM** has more diverse patterns than **EBU** as shown in Table 4, it is reasonable that the transfer from **APM** to **EBU** results in a higher score than the opposite. Additionally, **SOD** are so different from all the other buildings that transfers to **SOD** produce poor results. The noticeable high diagonal scores, whose source and target buildings are the same (i.e., learning within a building), provide an upper-bound reference. We shall also note that, referring to the last row in Table 2, Sensei outperforms SeNsER on four buildings except for **APM**, as Sensei is focused on more effectively capturing patterns inside a building.

3.6 Effect of Number of Sensors

As Sensei framework is fully automated in a self-supervised manner, its performance is solely affected by the amount and variety of sensor names available for learning the segmentation classifier. As shown in Table 4, Sensei generally gets better performance with more sensor names available with an exception of Building **SDH**. We hypothesize that the performance relates more closely to the variety of sensor name patterns in the dataset rather than the number of sensor names.

3.7 Case Studies and Discussions

We next showcase some examples that Sensei correctly segments, in order to illustrate its capability.

"Flukes" for False Positives. In Building **IBM**, some of the `Breaks` are recognized as `Ties` by Sensei-FW and Sensei-GS. For example,

`0F|_|SRVC|_|D0D0D0D00`,
`GF|_|SRVC|_|QR000_000`,

are mistakenly segmented as

`0F_SRVC|_|D0D0D0D00`,
`GF_SRVC|_|QR000_000`.

By contrast, Sensei avoids the mistakes by learning the pattern from many other sensor names. The following case is a great example.

`GF|_|LGHT|_|COFFEEDOCK`.
`GF|_|FRONTAISLE|_|LHS`,
`0F|_|FCU_KWH`.

There are only 89 occurrences of "`_|LGHT|`" compared to 177 of "`_|SRVC|`". Thus, with a lower transition probability, it can be recognized as a `Break` before "`_|LGHT|`". Many similar cases can teach Sensei that `Break` is more likely in this pattern, facilitating its performance.

"Flukes" for False Negatives. Building **SOD** contains many cases as follows:

`SOD|A0|R000|__|ASO`,
`SOD|A0|R000|__|AGN`.

Sensei-FW, and even Sensei-GS which employs the ground truth, are not able to segment these names correctly; they instead segment them as

`SOD|A0|R000|__|A|SO`,
`SOD|A0|R000|__|A|GN`,

because of the same prefix "`SODA0R000__A`".

By contrast, Sensei is able to correctly segment them owing to the self-supervised ensemble learning, which is more robust to noise in pseudo labels.

Discussion. We notice that even though Sensei on average achieves about 80% in F_1, it still has limitations. Sensei is sensitive to the variation of patterns in datasets—the patterns cannot be too varied or too monotonous.

4 Related Work

There are three lines of prior and related work, namely, sensor metadata mapping, language model, and phrase mining.

Sensor Metadata Tagging. Sensor Metadata Tagging refers to the process of parsing and annotating the sensor metadata (or sensor name) for understanding a sensor's key context, including the measurement type (Balaji et al., 2015; Hong et al., 2015b), location (Bhattacharya et al., 2015b), relationships with others (Koh et al., 2018), and many more (Schumann et al., 2014). The majority body of work exploits an active learning-based procedure (Settles, 2009), where it iteratively selects an "informative" and "representative" metadata example for a domain expert to label, in order to learn a model to annotate the metadata. Complementary to the use of textual metadata, there are also efforts exploring the use of time-series data for inferring the sensor context (Koc et al., 2014; Pritoni et al., 2015; Hong et al., 2015a). While they can significantly reduce the required manual labeling, they still rely on the availability of at least one human annotator to segment, parse, and provide labels.

By contrast, the method proposed in this work is fully automated, i.e., completely removing humans from the process, and we demonstrate its use in an essential first step—segmenting a sensor name string into meaningful substrings.

Language Model and Tokenization. Language models originate from the areas of natural language processing and information retrieval (Schütze et al., 2008). They aim at modeling the likelihood of observing one token given all the tokens before it, capturing the underlying language patterns. Recent advances in deep learning have pushed the language modeling from traditional n-gram models to neural language models (Kiros et al., 2014; Karpathy et al., 2015; Kim et al., 2016; Peters et al., 2018; Devlin et al., 2018), achieving significantly better performance using recurrent neural networks.

Analogizing sensor names to human languages, we employ neural language models to capture the underlying naming pattern. As we seek to segment a sensor name string into substrings, we choose the classic Char-RNN model (Karpathy et al., 2015). In general, any character-level language models are applicable in our method.

One can also view our problem as tokenization of sensor names. We thus compare with multiple existing tokenizers provided in NLTK Twitter, Standford CoreNLP (Manning et al., 2014), and Stanza (Qi et al., 2020). As we demonstrate in the evaluation, our method significantly outperforms these methods in segmenting sensor names.

Phrase Mining. Treating characters as words, our problem can be viewed as an unsupervised phrase mining problem with phrasal segmentation as output. Existing methods mainly leverage statistical signals based on term frequency in the corpus (Deane, 2005; Parameswaran et al., 2010; Danilevsky et al., 2014; El-Kishky et al., 2014). Among all these methods, ToPMine (El-Kishky et al., 2014) is arguably the most effective one. Our method Sensei significantly outperforms ToPMine in our empirical evaluation. There exist weakly/distantly supervised phrase mining methods (Liu et al., 2015; Shang et al., 2018a); however, such supervision signals (e.g., Wikipedia) are difficult to obtain for building sensors.

5 Conclusions and Future Work

Smart buildings critically rely upon contextual information associated with its sensors and actuators to appropriately sense and operate building subsystems. Such contextual information appears in the form of sensor metadata that is part of the installation of building management system. In this paper, we have presented Sensei, a system for automated segmentation of metadata information. Sensei is a fully automated method without requiring human labels that employs a character-level neural language model to capture the underlying generative patterns in building sensor names. Based on the probability distribution of character transitions (i.e., likelihood of observing the current character give the previous ones), it decides on two thresholds for sifting out examples for which it is confident to be `Tie` or `Break`. Considering these pseudo-labeled examples as supervision, Sensei constructs an ensemble of binary classifiers to segment sensor names with the information provided by the language model. We conducted experiments on the sensor names from five real-world buildings, and Sensei on average achieves $F_1 > 80\%$ in segmenting sensor names, a roughly 20-point improvement over the best compared unsupervised method. Our ongoing work addresses pre-training methods for the language model to improve Sensei's performance and its use in standard NLP tasks.

Abstract

We propose a simple and effective few-shot model for slot tagging. Recent work shows that it is promising to extend standard few-shot classification methods to sequence labeling with CRF-specific augmentations. Such methods show strengths in encoding slot name semantics and slot dependencies. However, we find these strengths can be obtained by a much simpler method, which casts slot tagging into machine reading comprehension (MRC). We fine-tune a standard BERT-based MRC model with a mixture of source domain and (few-shot) target domain data. Such simple method outperforms state-of-the-art methods by a large margin on the SNIPS dataset.

1 Introduction

This paper considers the task of few-shot slot tagging. Slot tagging (Zhang and Wang, 2016; Haihong et al., 2019) is a core component for task-oriented dialog systems (Papineni et al., 2001), where the goal is to provide a fine-grained, structured description of user request for a given intent. Example (1) shows the input-output of a slot tagging module for the `book restaurant` intent, where the module yields the semantic analysis for the input query in terms of slot label-value pairs such as `restaurant type` is 'brasserie' and `time range` is '15 minutes', etc.

(1) **Query**: I want to book a far brasserie that serves minestrone in PA for a party of 9 in 15 minutes.
Tagged Slots: {`restaurant type`: 'brasserie', `time range`: '15 minutes', `state`: 'PA', `party size number`: '9', `served dish`: 'minestrone'}

In real world systems, slot taggers are required to rapidly cover new domains to address increasing user needs. A key challenge here is that labeled data are often scarce in new domains and the high cost of manually annotating large-scale data becomes a major obstacle for domain adaptation. An attractive alternative is few-shot learning, which aims at achieving reasonable good results using only a few labeled instances in the new domain.

Although there are many successful few-shot *classification* methods, especially meta learning ones (Bapna et al., 2017; Luo et al., 2018; Fritzler et al., 2019), directly adapting them to slot tagging often yields unsatisfactory results (Hou et al., 2020). This is due to the *sentence-level, extractive nature* of slot tagging, where token dependencies within sentences are important but ignored by token-level classification models. Recent work (Hou et al., 2020) tackles this problem by extending meta learning methods to sequence transduction within the BERT-CRF framework, using several CRF-specific augmentations. Such augmentations show strengths in both encoding *slot name semantics* and modeling *slot dependencies*, which are key elements for effective few-shot slot tagging.

This paper shows that we can enjoy similar strengths with a *frustratingly simple* method. Our approach is based on the idea of transforming few-slot tagging into supervised machine reading comprehension (MRC), the detailed formulation of which is described in Section 3, with an example shown in Table 1. The implementation of our method is incredibly simple: we fine-tune an off-the-shelf BERT-based (Devlin et al., 2019) MRC model with data being merged from the source domain and (few shot) target domain data, without any meta learning or extra engineered components.

Our simple method works for good reasons. As the MRC-based approach extracts the full span of each slot value based on the complete sentence, such a model is aligned with the extractive nature of the task and implicitly considers slot dependencies. Moreover, the model can naturally encode label se-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1028–1033
August 1–6, 2021.

mantics by mentioning the label names in the constructed questions. For our MRC model, the slot labels and the sentences being tagged from both source and target domains all reside in the same semantic space, where the training upon mixed data forces the model to generalize to a semantic space that is compatible with both domains. Through experiments, we also find that our model can better leverage linguistic and world knowledge in pre-trained language models, than previous BERT-based few-shot slot taggers.

The contributions of this paper are twofold: (1) We propose a simple and effective approach to few-shot slot tagging, which is based on training a supervised MRC model. (2) We empirically show the effectiveness of the proposed method, which outperforms previous state-of-the-art by 4+ points on the SNIPS benchmark.

2 Related Work

Slot Tagging Intent detection and slot tagging are two key modules in spoken language understanding. Slot tagging is often cast to sequence labeling problem (Zhang and Wang, 2016; Liu and Lane, 2016; Haihong et al., 2019; Qin et al., 2019). This paper adopts MRC formulation and focuses on the few shot learning setup.

Few Shot Learning In NLP, few shot learning methods mostly focus on classification tasks (Sun et al., 2019; Geng et al., 2019), while efforts on sequence labeling like slot tagging are rarely (Luo et al., 2018; Fritzler et al., 2019). Hou et al. (2020) explored few shot slot tagging by considering both label dependency transfer and label name semantics. Our model enjoys similar strengths but is much simpler and more effective.

QA Format for NLP Tasks Question answering, in particular machine reading comprehension (MRC) models (Seo et al., 2017; Xiong et al., 2018), is typically trained to answer questions by extracting a text span from the given context. Recently, there is a trend to cast non-QA NLP tasks, such as information extraction (Levy et al., 2017; Li et al., 2019, 2020), coreference resolution (Hou, 2020; Wu et al., 2020) and more (McCann et al., 2018) into MRC, which can achieve comparable or improved results. Our work is inspired by these works, but tackles a new task of slot tagging with a focus on few-shot learning.

3 Method

3.1 Slot Tagging as MRC

MRC formulation Given a *question* $Q = q_1, q_2, ..., q_L$, and a *context* passage $C = c_1, c_2, ..., c_M$, where $|Q| = L$ and $|C| = M$ are their token numbers respectively, while question Q is used to extract required spans from context C. The task is to find the span between the start token C_{start} and end token C_{end} in the context, for the given question w.r.t. each slot type. Some example questions and their context are shown in Table 1. For all questions associated with the same sentence, we provide one *context* C, which consists of the original sentence, being concatenated by special tokens “NO ANSWER” , which should be extracted, when no answer (*span*) is available in the given sentence for that question (*slot type*).

Following the MRC setup as in BERT (Devlin et al., 2019), we resort to the standard question-answer usage of BERT to find span C_{start}-C_{end}, i.e. feeding the token sequence in the form of `[CLS]`, $q_1, q_2, .., q_L$, `[SEP]`, $c_1, c_2, ..., c_M$ as the input to the BERT model, where the special tokens `[CLS]` and `[SEP]` are inserted between Q and C to distinguish them. Then, the hidden states from the last layer of BERT are extracted as the representations of input tokens. Probabilities $P_{start}(i)$ and $P_{end}(i)$ of each token position being the start and end position of the answer span are computed through the following formulas (1), where $i = 1, 2, ..., M$. For both start and end index predictions, tokens between the highest $P_{start}(i)$ and $P_{end}(j)$ will be predicted as the slot content for the slot type being asked in the question Q.

$$\begin{aligned} H^Q; H^C &= \text{BERT}([Q; C]) \\ H^C &= [v_1; v_2; ...; v_M] \\ P_{start}(i) &= softmax(W_s v_i) \\ P_{end}(i) &= softmax(W_e v_i) \end{aligned} \tag{1}$$

To train the MRC model, we first convert the original dataset, pairs of split sentence tokens and slot types into a set of <*question*, *answer*, *context*> triples, similar to the *format* of SQuAD 1.1 dataset (Rajpurkar et al., 2016). Triples of different samples are shuffled into batches to feed into the MRC model to get predictions of start and end position indices. Every slot type in the corresponding domain will be asked sequentially to find corresponding spans, or ‘NO ANSWER’ will be extracted if that slot type doesn’t appear. We use cross entropy loss between predictions and ground truths.

Question Generation For each slot type $y \in Y$ to be predicted, we use a unified template to generate a *question* Q by joining domain name with slot type, which are both split by upper case letters and underlines, since they have the necessary information and short enough to keep model focusing on context C. As shown in example (1), question about slot type `restaurant_type` in domain `book restaurant` is constructed as *Book Restaurant, restaurant type ?*.

Context: *I want to book a far brasserie that serves minestrone in PA for a party of 9 in 15 minutes NO ANSWER*

Question	**Answer Set**
Book Restaurant restaurant type ?	{brasserie}
Book Restaurant party size description ?	{NO ANSWER}

Table 1: Samples of Context, questions and answers in the MRC formulation for Example (1).

3.2 Few Shot Learning

For a few-shot learning task, we have a *target domain* $D_1 = (x_i, y_i)$ with few labeled data, and n resource-rich source domains $D_2 ... D_n$. The task is to discover the optimal hypothesis h from x to y in domain D_1. To fit our MRC model into N-way k-shot settings, we follow the data construction procedures in Hou et al. (2020), where the support set $S = (x_i, y_i)$ is constructed by ensuring every slot in target domain appears approximately k times and each entity only appears once in a sentence.

We randomly generate 100 above support sets. For each set, we pair it with a query set having 20 excluded samples to form an episode. Together with D domains, our test set is made up of $D \times 100$ episodes. Note that our model is trained in one-go with the data being mixed up from the source domain and the support set of the target domain in each episode, unlike two-phase training in typical few shot learning methods. Despite the difference, the amount/split of the data for training and evaluation is exactly the same as in previous work.For zero-shot learning, we directly evaluate the source domain trained model on the full target domain.

4 Experiment

4.1 Setup

Dataset Our experiment is based on the SNIPS data set (Coucke et al., 2018) which is a benchmark dataset for slot tagging. It has data samples from 7 different domains, namely, Weather (We), Playlist (Pl), Book (Bo), Music (Mu), Restaurant (Re), Screening Event (Se) and Creative Work(Cr). Following few-shot setup in previous work, we split SNIPS data by domain. Each time, we leave one for testing, one for development and the others for training. Such procedure is repeated 7 times for cross validation.

Baselines **Bi-LSTM** (Schuster and Paliwal, 1997) is trained on the support set and tested on the query set using word embeddings of GloVe (Pennington et al., 2014). **Matching Network (MN) with BERT**(Vinyals et al., 2016) builds on top of BERT and labels the sequence in a token-level classification way. For each word, the most similar token in the support set is chosen and its label is assigned accordingly. **WarmProtoZero (WPZ)** (Fritzler et al., 2019) adopts similar strategy as MN, except replacing matching network with the prototypical network (Snell et al., 2017). **SimBERT** also classifies each token with the most similar word in the support set and assigns the corresponding label, where BERT embeddings are used without fine-tuning. **TransferBERT** is a domain transfer model based on vanilla BERT. It is pre-trained on source domain data, followed by fine-tuning on the support set of the target domain. **L-TapNet+CDT** (Hou et al., 2020) is a sequence labeling model based on BERT+CRF, where the Collapsed Dependency Transfer is used for transferring label-to-label dependencies and TapNet is used for transferring label semantics.

Implementation Details The pre-trained BERT-base uncased model is used for our method, where the batch size is set to 16, with max sequence length of 512. We use Adam optimizer (Kingma and Ba, 2014) with initial learning rate of 1×10^{-5} during training. We train the model with 30 epochs for each episode of evaluation, and get results according to develop domain.

4.2 Experimental Results

Main Results for 5-Shot Learning Table 2 shows the results for 5-shot learning. Each column indicates the per-domain results, where that domain

Table 2: F1 scores results on 5-shot slot tagging. `+CDT` denotes `collapsed dependency transfer`. Scores below mid-line are from our methods, which achieve the best performance. AVG shows the averaged scores. Best results in bold.

is used as the target domain while others are used as source domains. In most domains, our model achieves improved results than all baseline, being based on BERT or not. In particular, our method outperforms the previous SOTA, L-TapNet+CDT, by 4.16% on average F1 score.

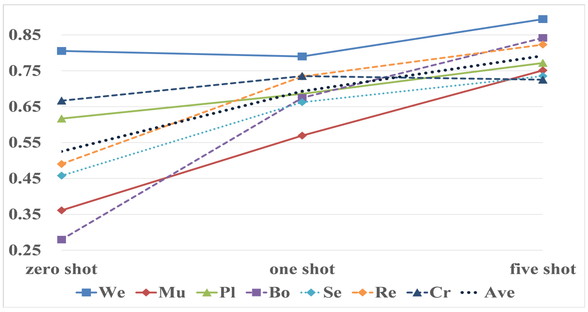

Figure 1: Avg F1 score for each domain for 1-shot and zero-shot learning, which have the same setup for training.

Analysis Figure 1 compares the performance of our model in zero/one/five-shot setup. Since the training of our method is just fine-tuning upon the mixture of source and target domain data, one-shot setup means using 0.01% extra (target domain) data over zero-shot setup. Yet, the boost is dramatic for most domains. We speculate that these tiny bit of target domain has a *catalyst effect*, which changes the optimization trajectory of model. It might be the case that such training forces our MRC model to generalize to a semantic space that is compatible with both source and target domains.

Note that our zero-shot model achieves an average F1-score of 52.5%, outperforming previous zero-shot SOTA, such as 40.6% of Shah et al. (2019) and 37.39% of Liu et al. (2020). As for one-shot setting, the average F1-score of our model is 69.3%, on par with 70.4% of the 1-shot SOTA (Hou, 2020).

Few shot learners typically rely on source domain data to arrive at a good hypothesis. Figure 2 shows the sensitivity of our model w.r.t. the scale of available *source domain* data. In each episode of evaluation, we select a subset (100, 1000, 2000) of sentences from source domains according to the rank of text similarity between them and the support set. While *the more the better* holds in general, we see that 1000 source domain sentences suffice for competitive results.

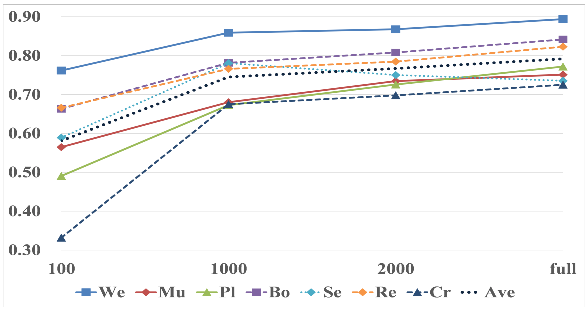

Figure 2: Avg F1 for each domain with different numbers of sentences from source domain. Where the `full` means all sentences from source domains and the number is near 12,000

5 Conclusion

In this paper, we propose a BERT-based MRC approach to few-shot slot tagging. By casting slot tagging into MRC problem, the learning consists of fine-tuning the MRC model with labeled sentences from a mixture of source domain and few-shot target domain data. Such an MRC-based method can naturally encode the label semantics in the form of questions, while the training forces the model to generalize to a semantic space that is compatible with both domains. Experiment results show the effectiveness of our simple method, as it outperforms previous SOTA on the SNIPS benchmark by a large margin. For future work, we plan to extend our approach to similar tasks, such as semantic role labeling and named entity recognition.

Abstract

Medical code assignment from clinical text is a fundamental task in clinical information system management. As medical notes are typically lengthy and the medical coding system's code space is large, this task is a long-standing challenge. Recent work applies deep neural network models to encode the medical notes and assign medical codes to clinical documents. However, these methods are still ineffective as they do not fully encode and capture the lengthy and rich semantic information of medical notes nor explicitly exploit the interactions between the notes and codes. We propose a novel method, gated convolutional neural networks, and a note-code interaction (GatedCNN-NCI), for automatic medical code assignment to overcome these challenges. Our methods capture the rich semantic information of the lengthy clinical text for better representation by utilizing embedding injection and gated information propagation in the medical note encoding module. With a novel note-code interaction design and a graph message passing mechanism, we explicitly capture the underlying dependency between notes and codes, enabling effective code prediction. A weight sharing scheme is further designed to decrease the number of trainable parameters. Empirical experiments on real-world clinical datasets show that our proposed model outperforms state-of-the-art models in most cases, and our model size is on par with light-weighted baselines.

1 Introduction

Automatic medical code assignment is a routine healthcare task for medical information management and clinical decision support. The International Classification of Diseases (ICD) coding system, maintained by the World Health Organization (WHO), is widely used among various coding systems. Thus, the medical code assignment task is also called ICD coding. It uses all types of clinical notes to predict medical codes in a supervised manner with human-annotated codes (Perotte et al., 2014), which is formulated as a multi-class multi-label text classification problem in the medical domain.

While there are increasing works in the community in automatic medical code assignment (Prakash et al., 2017; Shi et al., 2017; Mullenbach et al., 2018; Ji et al., 2020), this task remains challenging from the perspectives of note representation and code prediction. First, medical note representation, a critical step in understanding medical notes, is formidably challenging due to the lengthy and complex semantic information in the discharge documents. There are typically thousands of tokens in a medical note due to the various diagnoses and procedures experienced by a patient. Furthermore, clinical notes also contain a vocabulary with many professional words and phrases, making it hard for a neural network model to encode and understand critical information. Second, the medical coding system has a very high and sparse dimensional label space, which renders the code prediction task incredibly difficult. For example, ICD9 and ICD10 coding systems have many labels, i.e., more than 14,000 and 68,000 codes. However, a patient typically is diagnosed with only a couple of codes over the whole coding space.

Early works for medical code assignment typically follow statistical approaches. They either employ rule-based methods (Farkas and Szarvas, 2008) or apply classification methods such as SVM and Bayesian ridge regression (Lita et al., 2008) to assign the codes. These methods are shallow and do not exploit the complex semantic information in medical notes, leading to unsatisfactory performance. Recently, Natural language processing (NLP) techniques based on deep learning have been developed (Mullenbach et al., 2018; Li et al.,

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1034–1043
August 1–6, 2021.

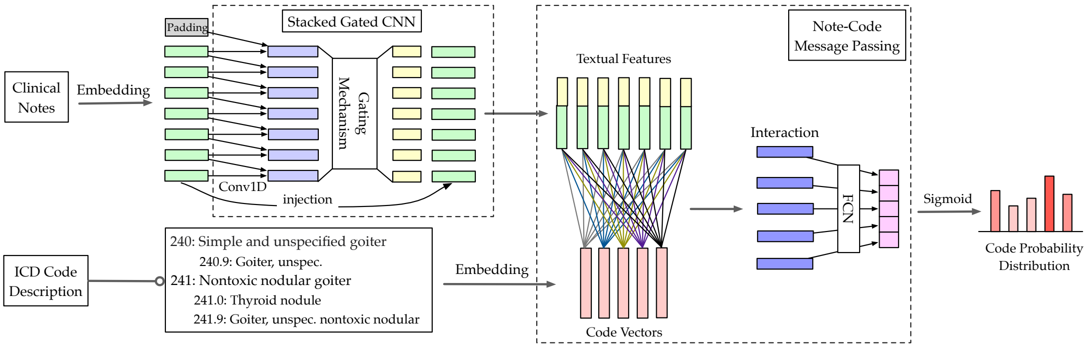

Figure 1: Illustration of the GatedCNN-NCI model architecture. The gating mechanism controls the information propagation. Textual features interact with each code vector in the note-code interaction module. FCN is a fully connected layer.

2018; Cao et al., 2020; Ji et al., 2020), which learn the note representation via convolutional neural networks. Specifically, CAML (Mullenbach et al., 2018), MultiResCNN (Li et al., 2018) and DCAN (Ji et al., 2020) treat ICD coding as a general text classification problem and develop complex neural encoders to learn the note representation. HyperCore (Cao et al., 2020) proposes the hyperbolic embedding to capture code hierarchy and co-occurrence. However, these approaches are still ineffective, as they do not explicitly capture the fine-grained interactions between textual elements and medical codes. These interactions naturally represent the interdependencies between the complex medical words and associated codes, and thus should be well exploited.

This paper puts forward a novel neural architecture, Gated Convolutional Neural Network with Note-Code Interaction (GatedCNN-NCI), for effective medical code assignment. Our goal is to learn rich representation from clinical notes and exploit the interactions between medical texts and clinical codes. To capture the long sequential history of clinical documents, we design a novel dilation information propagation component with a forgetting mechanism to selectively utilize the useful information for note representation learning. To tackle the large labeling space, we formulate textual notes and medical codes as a complete bipartite graph and develop a graph message passing approach to capture the explicit interaction between notes and codes. The ICD code descriptions are used as an external medical knowledge source to learn more accurate code representations that preserve the semantic relations of the codes. Considering the practical application in real-world medical institutes, especially those with limited computing resources, our architecture also prioritizes computational efficiency when designing the sub-modules. Our contributions are itemized as follows.

- We propose a CNN-based neural architecture with dilation and gating mechanism for clinical text encoding. We enhance the feature representation learning with 1) embedding injection, enhancing the deeper features of lengthy clinical notes; 2) and the gating mechanism to control the information propagation.
- We view the note-code interaction as a complete bipartite graph and propose a graph message passing mechanism to capture the interactions between textual features and ICD codes explicitly.
- To reduce the trainable parameters and make our model computationally efficient, we develop a weight-sharing mechanism across the length of the sequence and the depth of the network.
- Experiments in real-world clinical datasets empirically validate our model's effectiveness by comparison with the state of the art.

2 Related Work

Classical medical coding systems used rule-based methods (Farkas and Szarvas, 2008), studied feature selection (Medori and Fairon, 2010), and applied classification models such as SVM and Bayesian ridge regression (Lita et al., 2008). Perotte et al. (2014) utilized the hierarchical structure of the ICD code systems and provided a flat and hierarchical SVM for diagnosis code classification, while Kavuluru et al. (2015) studied explicit co-occurrence relations between codes. Scheurwegs et al. (2016) investigated heterogeneous data of both structured records and textual data. Recent deep learning-based models use word embedding techniques and develop complex neural network architectures to learn rich text features for automatic medical code assignment. Popular models use recurrent architectures such as the LSTM network with an attention mechanism (Shi et al., 2017) and GRU network with hierarchical attention (Baumel et al., 2018). Prakash et al. (2017) used Wikipedia as a knowledge source and proposed condensed memory networks (C-MemNNs) with iterative condensation of memory representation. Although CNNs are traditionally applied in computer vision, many ICD coding methods utilize convolutional architectures. CAML (Mullenbach et al., 2018) used CNN with multiple filters and label attention. Li et al. (2018) adopted the doc2vec embedding and CNN architecture, and Bai and Vucetic (2019) incorporated online knowledge sources. The recent MultiResCNN model (Li and Yu, 2020) extensively concatenated and stacked CNNs with multi-filter convolution and residual learning. HyperCore (Cao et al., 2020) utilized hyperbolic embedding and cograph representation to capture the code hierarchy.

3 Method

3.1 High-level Model Architecture

3.2 Problem Definition

The input clinical note with n words is denoted as $\mathbf{x}_{1:n} = x_1, \ldots, x_n$, where each x_i is a word (or token). The medical coding system is the set of all possible diagnosis and procedure codes denoted as $\mathcal{C}$. The medical code assignment learns a function $\mathcal{F} : \mathcal{X}^n \rightarrow \mathcal{Y}^m$ such that

$$y = \mathcal{F}\left(x_1, \ldots, x_n; \mathcal{D}\right), \qquad (1)$$

where $y \in \mathbb{R}^m$ is the medical code at discharge, m is the number of medical codes, and $\mathcal{D}$ is an optional external knowledge source. This paper uses the ICD coding system and naturally utilizes the official textual ICD code description as an external knowledge source.

The high-level model architecture of GatedCNN-NCI is illustrated in Fig. 1. Our model consists of two main components, i.e., stacked gated CNN layers for clinical note encoding and note-code interaction to fuse the external ICD code description. The stacked gated CNNs include three sub-modules, i.e., dilated convolution, embedding injection, and gating mechanism.

We use word2vec (Mikolov et al., 2013) to train word embeddings from raw tokens. Word embedding matrix of a clinical note is denoted as $[\mathbf{w}_1, \ldots, \mathbf{w}_n]^{\mathrm{T}} \in \mathbb{R}^{n \times d_e}$, where d_e is the dimension of word vectors. Then we input the word embeddings into stacked gated CNN layers for long-range information propagation. The stacked module uses dilated convolution as its backbone (Oord et al., 2016). To further enhance the feature learning, we inject the original embedding into each stacked layer. The gating mechanism is originated from the long short-term memory network (LSTM) (Hochreiter and Schmidhuber, 1997). We adopt the LSTM-like gate (Dauphin et al., 2017) to control the information flow.

To avoid blurry memory in higher layers, we inject the original word embeddings (Bai et al., 2019). Label interaction has been studied by Wang and Jiang (2016) and Du et al. (2019). We utilize descriptive knowledge from the ICD code descriptions and develop the note-code interaction to capture the relational match between clinical note features and ICD codes. To reduce the training cost and stabilize the training process, we also introduce a weight sharing mechanism across the stacked CNNs (Bai et al., 2019).

3.3 Dilated Convolutional Layers

We use the one-dimensional convolution with dilation as the backbone of our encoder, which takes the word embedding $\mathbf{X} \in \mathbb{R}^{n \times d_e}$ as input. Dilated CNN has exhibited a significant capacity for long sequence modeling and computationally efficient for parallelism (Bai et al., 2018). Specifically, we use a 1D convolution operator $\mathrm{Conv1D}(x; f)$, with a filter $f : \{0, \ldots, k-1\} \rightarrow \mathbb{R}$, to each dimension of the word vectors. Given a sequence of one-dimensional elements $\mathbf{x} \in \mathbb{R}^n$, the one-dimensional dilated convolution $\mathcal{F}_d$ is denoted as

$$\mathcal{F}_d(s) = \left(\mathbf{x} *_d f\right)(s) = \sum_{i=0}^{k-1} f(i) \cdot \mathbf{x}_{s-d \cdot i}, \qquad (2)$$

where d is the dilation size (i.e., the space between kernel elements), s is the index of the element of the input sequence, k is the convolving kernel (aka, the filter) size, and $s - d \cdot i$ refers to past time steps. The dilation size of d and kernel size k control the receptive field. The 1D dilated convolution has d_h output channels, i.e., for each of the d_e input channels d_h convolutional features are learned through the dilated $\mathrm{Conv1D}$. Stacking CNN layers can be adopted to learn in-depth features.

3.4 Embedding Injection

Our hypothesis for encoding a very long clinical sequence is that the deep neural encoding architecture tends to forget important information, mainly because the clinical note contains fruitful professional expression about the patient's diagnosis. Thus, in-depth features become blurry with the increase of neural layers. We propose to inject original word embedding into each intermediate layer of the proposed architecture, attempting to remind the network to reactivate the original diagnostic notes and mitigate the failure of extracting meaningful, in-depth features. We denote the hidden representation at the l-th layer as $\mathbf{H}^l \in \mathbb{R}^{n \times d_h}$, where the dimension d_h is the hidden dimension. Word embedding is concatenated into lth-layer hidden representation as

$$\mathbf{J}^l = \text{concat}[\mathbf{X}, \mathbf{H}^l], \tag{3}$$

where $\mathbf{J}^l \in \mathbb{R}^{n \times (d_e + d_h)}$ are the deep features enhanced with the original clues, used as the new input of the next convolutional encoding layer. We randomly initialize the $\mathbf{H}^0$ matrix for the first convolutional layer.

3.5 Gating Mechanism

Embedding injection of original word vectors brings low-level features to higher-level, which may lead to difficulty in feature learning in higher layers. Thus, we develop an LSTM-style gating mechanism to control the information flow and capture a long history in the sequence. Unlike the recurrent gate such as the LSTM that controls the information flow along the time coordinate, this gating mechanism controls the flow through stacked layers' depth. The gating mechanism is depicted in Fig. 2, where σ and $\tanh$ are sigmoid and hyperbolic tangent activation functions respectively. After the embedding injection, the dilated CNN upsamples the injected signal $\mathbf{J}^l$ into $\mathbf{U}^l \in \mathbb{R}^{n \times d_u}$ at the l-th layer. We divide $\mathbf{U}^l$ into four matrices with the same dimension, i.e., $\mathbf{I}$, $\mathbf{O}$, $\mathbf{G}$ and $\mathbf{F} \in \mathbb{R}^{n \times d_g}$, such that:

$$\mathbf{U}^l = \text{concat}[\mathbf{I}, \mathbf{O}, \mathbf{G}, \mathbf{F}]. \tag{4}$$

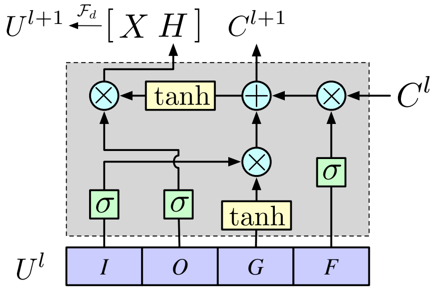

Figure 2: Gating mechanism that controls the flow's convolutional features through stacked layers' depth.

Here, we have $d_u = 4 \times d_g$. Then, these four matrices are fed into the LSTM-like gating module that controls what information should be propagated to deeper layers. The input gate $\sigma(\mathbf{I})$ decides the information to be infused and stored into the cell state $\mathbf{C}$. The forget gate $\sigma(\mathbf{F})$ chooses the information to be remembered. The output gate $\sigma(\mathbf{O})$, working with the cell state, focuses on what signals propagate into the next layer. This process is formalized as

$$\begin{aligned} \mathbf{C}^{l+1} &= \sigma(\mathbf{F}) * \sigma(\mathbf{C}^l) + \sigma(\mathbf{I}) * tanh(\mathbf{G}) \\ \mathbf{H} &= \sigma(\mathbf{O}) * tanh(\mathbf{F}), \end{aligned}$$

where $\mathbf{C}^l$ is the cell state at the l-th layer and $\mathbf{H}$ is the hidden state produced by the gated unit. The embedding injection trick concatenates the original word embedding $\mathbf{X}$ and the hidden representation $\mathbf{H}$, and the dilated convolutional layer upsamples the concatenation to get the new feature $\mathbf{U}^{l+1}$ at the $(l+1)$-th layer, denoted as:

$$\mathbf{U}^{l+1} \xleftarrow{\mathcal{F}_d} [\mathbf{X}, \mathbf{H}]. \tag{5}$$

Gated CNNs can be stacked into a deep architecture, as shown in the general framework of Fig. 1. As a result, our model can represent a large-sized context and extract hierarchical features at each layer. Moreover, the gating mechanism can also extract important features to remember and focus, while less critical features are forgotten and ignored at each layer.

3.6 Note-Code Interaction as Message Passing

To capture the explicit note-code interaction (NCI) between the medical codes and textual mentions, we build a complete bipartite graph $G = \{U, V, E\}$, where $U = \{w_i\}^n$ and $V = \{c_j\}^m$ represent the words and ICD codes respectively, and E is the fully connected edge set. For simplicity, we omit the superscript of the last convolutional features $\mathbf{U}^{l+1}$ extracted by the stacked gated CNNs and denote the textual node features $\mathbf{U}$ as the vertex set U in the note-code bipartite graph. We incorporate the ICD code descriptions of WHO to represent the medical knowledge about ICD codes. For example, the ICD code 240 in Fig. 1 is about simple and unspecified goiter. Instead of merely using the ICD code index to represent the prediction target, we include the code description, which contains rich domain knowledge. Word embeddings of description are averaged to obtain code vectors $\mathbf{V} \in \mathbb{R}^{m \times d_v}$, where m is the number of codes, and d_v is the embedding dimension. We take the code vectors as the node features of the vertex set V.

Our novel formulation of the bipartite graph preserves the source-target matching between textual features and ICD code vectors. We utilize the graph message passing mechanism (Gilmer et al., 2017; Wu et al., 2020) to infer fine-grained clues about dependencies between textual features and code semantics. The composition function $\mathrm{NCI} : \mathbb{R}^{n \times d_u} \times \mathbb{R}^{m \times d_v} \to \mathbb{R}^m$ is denoted as:

$$\mathrm{NCI}(U, V) = f_\theta\left(\sum_{i,j} g_\xi(w_i, c_j)\right), \tag{6}$$

where g_ξ with parameter ξ is a neural message function and f_θ with parameter θ is an output function. It takes the textual features of all tokens in a note and embeddings of code vectors as inputs and produces an interaction score between the note and each code. To improve the computational efficiency, we take the dot product as the message function g_ξ. The explicit interaction score between token w_i and code c_j is calculated as

$$\mathbf{I}_{ij} = \mathbf{V}_{i,:} \mathbf{U}_{j,:}^{\mathrm{T}}, \tag{7}$$

where $\mathbf{V}_{i,:}$ is the row vector of textual features representing the i-th word, $\mathbf{U}_{j,:}$ is the row vector of ICD code matrix representing the j-th code in ICD code set. We set $d_u = d_v$ and get the interaction matrix $\mathbf{I} \in \mathbb{R}^{m \times n}$ with dot product. We use a fully connected network f_θ to calculate the scores of the note-code interactions as output. Similar to the matrix factorization formulation of language models (Yang et al., 2017; Li et al., 2020), this dot-product interaction between notes and codes approximates the point-wise mutual information of note-code co-occurrence.

3.7 Parameter-efficient Weight Sharing

The embedding injection and convolutional feature concatenation make the hidden feature high-dimensional. Moreover, as a result of stacking deep layers, the overall model will become cumbersome. Thus, we utilize a weight sharing mechanism (Bai et al., 2019) to decrease the number of parameters. Specifically, we share the weights of gated CNN layers across time steps and depth through neural layers. This mechanism has two benefits. First, it can decrease the number of trainable parameters because weights across the network are tied. Second, it provides a form of regularization to stabilize the training process.

3.8 Objective and Training

We formulate the ICD code assignment as a multi-label multi-class classification problem. We adopt the binary cross entropy loss denoted as:

$$\mathcal{L} = \sum_{i=1}^{m} \left[-y_i \log(\hat{y}_i) - (1 - y_i) \log(1 - \hat{y}_i)\right], \tag{8}$$

where $y_i \in \{0, 1\}$ is the ground-truth label, $\hat{y}_i$ is the sigmoid score for prediction, and m is the number of ICD codes. We use Adam optimizer (Kingma and Ba, 2014) to train the model with backpropagation.

4 Experiments

In the experimental analysis on real-world datasets, we compare our proposed model with several recent strong baselines. Our code is available[1].

4.1 Datasets

This paper focuses on textual discharge summaries from a hospital stay. Specifically, we use raw notes, ICD diagnoses, and procedures for patients from two public clinical datasets, i.e., MIMIC-II and MIMIC-III[2], for experiments. Discharge summaries labeled with a set of ICD-9 diagnosis and procedure codes include descriptions of procedures performed by the physician, diagnosis notes, patient's medical history, and discharge instructions.

MIMIC-II. The first dataset of clinical notes is from the Multiparameter Intelligent Monitoring in Intensive Care II (MIMIC-II) database (Saeed et al., 2011). We follow the standard train-test split performed by Perotte et al. (Perotte et al., 2014), where 90% and 10% of 22,815 non-empty discharge summaries are used for training and testing, respectively.

MIMIC-III. The second dataset is an updated database from Medical Information Mart for In-

---

[1] `https://agit.ai/jsx/GatedCNN-NCI`

[2] `https://mimic.physionet.org`

tensive Care III (MIMIC-III) repository (Johnson et al., 2016), containing patient admitted to Intensive Care Unit (ICU) at a US medical center during 2001 to 2012. We use the "noteevents" table in the latest version 1.4, with 58,576 hospital admissions. Free-text discharge summaries in the MIMIC-III database are extracted to form the dataset with clinical text. The experimental evaluation considers two settings. The first one uses the full set of ICD codes. Following Shi et al. (Shi et al., 2017) and Mullenbach et al. (Mullenbach et al., 2018), an additional experiment on the subset of MIMIC-III with the top 50 frequent labels is conducted. This MIMIC-III top-50 subset has a train/dev/test split with 8,066, 1,573, and 1,729 samples.

4.2 Settings

Preprocessing We preprocess the textual documents following the preprocessing procedures developed by Mullenbach et al. (2018) and Li and Yu (2020). The NLTK package[3] is utilized for tokenization, and all tokens are converted into lowercase. All words appearing in less than three training documents were replaced with "unk". We truncate all documents at the length of 2500 tokens. The word embeddings are initialized with embedding vectors pre-trained on all discharge notes with the continuous-bag-of-words (CBOW) method of word2vec (Mikolov et al., 2013).

Hyper-parameters Some standard settings follow the prior works. For example, the word embedding dimension is 100, and the dropout rate is 0.2. Adam optimizer (Kingma and Ba, 2014) is used to optimize our model parameters. For the rest hyper-parameters, the random search is utilized to search the optimal settings. The searching range or choices of specific hyper-parameters are listed in Table 1. The searching interval of learning rate is $[1e^{-6}, 1e^{-2}]$. Besides, we optimize for kernel size, levels of residual connections, and hidden representation dimension.

Table 1: Range and choices of hyper-parameter search

Hyper-parameters	Range/choices
Learning rate	$[1e^{-6}, 1e^{-2}]$
Kernel size	2, 3, 5, 9
CNN levels	1, 2, 3, 4, 5
Hidden dimension	100, 200, 300, 400, 500, 600

Evaluation Metrics We use area under the receiver operating characteristic curve (AUC-ROC), F1-score, and precision at k (P@k) for evaluation. We set $k = 5$ for MIMIC-III subset with top-50 frequent codes and $k = 8$ for full sets of MIMIC-II and MIMIC-III. In the multi-label classification setting, we use two averaging strategies, i.e., micro and macro. The macro scores are obtained by averaging the respective label-wise scores across all labels. Micro scores give more weight to frequent labels by considering all labels jointly. We run the experiments for 5 times and report the mean ± standard deviation.

4.3 Baselines

We consider the following baseline models. MultiResCNN (Li and Yu, 2020) and HyperCore (Cao et al., 2020) are two recent strong models with the state-of-the-art performance. **Bi-GRU (Mullenbach et al., 2018)** uses a simplified gated recurrent unit with bi-direction, where last hidden representations are used for classification. **C-MemNN (Prakash et al., 2017)** introduces an iterative condensation of memory representations and utilizes external knowledge source from Wikipedia to enhance memory networks by preserving the hierarchical structure in the memory. **AttentiveLSTM (Shi et al., 2017)** encodes clinical descriptions and ICD long titles jointly with character- and word-level LSTM networks and uses attention mechanism for matching important diagnosis snippets. **CAML (Mullenbach et al., 2018)** integrates CNNs and a label-wise attention mechanism to learn rich representations. It has a variant called DR-CAML that uses ICD code descriptions to regularized the loss function. **LEAM (Wang et al., 2018)** encodes two channels of inputs and leverages the compatibility between word and label embeddings to calculate attention scores. **MultiResCNN (Li and Yu, 2020)** combines residual learning (He et al., 2016) and multiple channels concatenation with different convolutional filters, achieving good performance in most settings. **HyperCore (Cao et al., 2020)** utilizes hyperbolic embedding and co-graph representation with code hierarchy. It gains slightly better performance than the MultiResCNN.

4.4 Results

Our model performs consistently the best for frequent labels. First, it beats all models in the MIMIC-III subset with top-50 codes (columns 2-6 in Table 2). For the micro scores that give more

weight to frequent labels, our model also has the best predictive metrics (columns 8&10 in Table 2 and columns 3&5 in Table 3). Moreover, our model is competitive also with the rest of the metrics: it consistently has the best P@k scores and at worst, the second best macro scores in all datasets.

MIMIC-III (Top-50 Codes) The first experiment uses the MIMIC-III subset with top-50 codes, showing models' performance on predicting the frequent diagnosis. The results in Table 2 show that our model outperforms all the baselines in all the evaluation metrics. Significantly, our model gains a higher macro F1-score by 2% and micro F1-score by 1.6% than the state of the art.

MIMIC-III (Full Codes) We then run our model on the MIMIC-III dataset with full codes. Our model outperforms most baselines, gaining the best scores in macro AUC-ROC, macro F1, micro F1, and precision@8. For the macro AUC-ROC, our model is ranked at the second place.

MIMIC-II (Full Codes) In the third dataset of MIMIC-II, we also predict the full set of ICD-9 codes. Our model achieves predictive performance on par with two recent strong baselines of MultiResCNN and HyperCore. We gain the best scores in micro AUC-ROC, micro F1-score, and P@8. Macro AUC-ROC and F1 scores of our model are the second best of the models compared.

Table 3: Results on MIMIC-II full codes. **Bold** text denotes the best and *italic* text denotes the second best.

Model	AUC-ROC		F1		P@8

4.5 Comparison with BERT

Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2019) has revolutionized the NLP community recently. The pre-trained language model has been applied to different downstream NLP tasks. We compare our model's performance with the BERT model and a domain-specific variant, i.e., ClinicalBERT (Alsentzer et al., 2019) pre-trained on the clinical text of MIMIC-III. For the BERT model, we use the uncased BERT-base with a hidden dimension of 768. Because these two BERT models require the configuration of the maximum sequence length of 512, we truncate the text sequence for our model to ensure a fair comparison. BERT models have two special tokens, i.e., `[CLS]` and `[SEP]`. Thus, we truncate clinical notes with a length of 510. We use Huggingface's transformer framework[4] when implementing these two models. The results in Table 4 show that pretraining the language model with domain data improves the performance, and our model has better performance in most evaluation metrics.

Table 4: Comparison with BERT and ClinicalBERT using the MIMIC-III top-50 code dataset with sequence length truncated at 510.

Model	AUC-ROC		F1		P@5
	Macro	Micro	Macro	Micro	
BERT-base	80.6	85.2	43.3	53.2	53.3
ClinicalBERT	81.0	85.6	**43.9**	54.3	54.5
GatedCNN-NCI	**83.7**	**87.7**	42.9	**54.4**	**56.6**

4.6 Model Size

We compare the number of trainable parameters (Table 5) of our model with two models with quali-

fied performance, i.e., CAML (Mullenbach et al., 2018) and MultiResCNN (Li and Yu, 2020). HyperCore (Cao et al., 2020) didn't publish the code or provide the values of all hyperparameters. Thus, we omit it in this comparison. Our proposed model is more efficient than the MultiResCNN in terms of the number of trainable parameters. The CAML model has the fewest parameters but performs poorly in prediction. Our model has a much better predictive performance than the CAML model, with only a slight increase in model size.

Table 5: Number of trainable parameters

Model	num. params.
CAML (Mullenbach et al., 2018)	6.2M
MultiResCNN (Li and Yu, 2020)	11.9M
ClinicalBERT (Alsentzer et al., 2019)	113.8M
GatedCNN-NCI (Ours)	7.6M

4.7 Ablation Study

We further conduct an ablation study the investigate the effectiveness of different components of our proposed model. We evaluate two variants by removing two critical components of the proposed model. The first variant without NCI replaces the note-code interaction with max-pooling and linear projection. The second variant removes the gating mechanism that controls the information progation over the CNN layers. Table 6 compares the experimental results on the MIMIC-III subset with top-50 codes. The performance drops to some extent after removing these two modules, which shows the effectiveness of our proposed architectures. Moreover, the note-code interaction module has slightly more contribution than the gating mechanism. Possible explanations are that the explicit interaction perseveres the semantics of medical codes well and captures the relation between codes and notes in the embedding space.

Table 6: Ablation study

Model	AUC-ROC		F1		
	Macro	Micro	Macro	Micro	P@5
GatedCNN-NCI	91.5	93.8	62.9	68.6	65.3
without NCI	90.1	92.7	61.4	67.2	63.9
without gating	90.0	92.0	60.2	66.9	63.7

4.8 Case Study

We conduct a case study to interpret an example prediction. Table 7 shows the predictions for a clinical note of a patient with cardiovascular diseases and diabetes. The patient also had 'dyspnea on exertion' as a symptom caused by either pneumonia or cardiac diseases. Our model and MultiResCNN predict the correct diagnosis codes: coronary atherosclerosis (ICD code: 414.01), hypertension (401.9), and diabetes (250.00). When predicting procedure codes, MultiResCNN is confused by dyspnea on exertion and incorrectly predicts pneumonia-related treatments: endotracheal intubation (96.04) and invasive mechanical ventilation (96.71). Our model correctly predicts a cardiac catheterization procedure and diagnostic interventions of heart surgery (39.61) and coronary artery bypass (36.15). Hence, our model is not misled by the ambiguous interpretation for dyspnea on exertion but learns the correct cardiac-related context, consistent with the rest of the note.

Table 7: Case study on a clinical note with cardiac-related diseases (**bold**, in green). Dyspnea on exertion (*italic*, in red) can be caused by cardiac- or pneumonia-related diseases.

Clinical note	old male with multiple **cardiac risk factors** and *dyspnea on exertion* . . . , he then underwent further workup which included **a cardiac catheterization** that revealed significant **coronary artery disease**. he was then transferred for surgical evaluation".

5 Conclusion

Medical code assignment from clinical notes is a fundamental task for healthcare information systems and diagnosis decision support. This paper proposes a novel framework with gated convolutional neural networks and note-code message passing mechanism for automated medical code assignment. Our solution can learn meaningful features from lengthy clinical documents and effectively control the deep propagation of information flow. Moreover, the message passing mechanism can enhance the ICD code space's semantics and model the note-code interaction to improve medical code prediction. Experiments show the effectiveness of our proposed method.

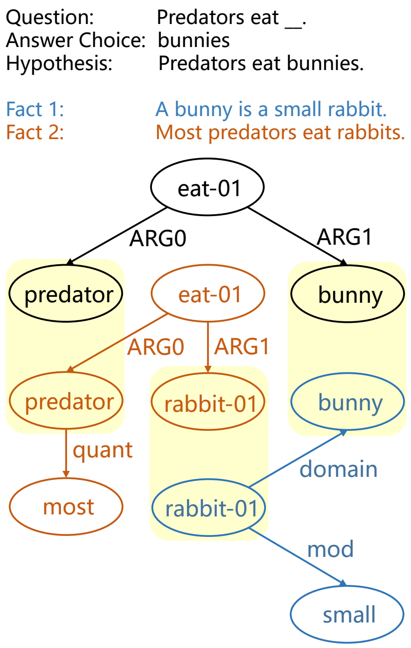
Abstract

Knowledge retrieval and reasoning are two key stages in multi-hop question answering (QA) at web scale. Existing approaches suffer from low confidence when retrieving evidence facts to fill the knowledge gap and lack transparent reasoning process. In this paper, we propose a new framework to exploit more valid facts while obtaining explainability for multi-hop QA by dynamically constructing a semantic graph and reasoning over it. We employ Abstract Meaning Representation (AMR) as semantic graph representation. Our framework contains three new ideas: (a) `AMR-SG`, an AMR-based Semantic Graph, constructed by candidate fact AMRs to uncover any hop relations among question, answer and multiple facts. (b) A novel path-based fact analytics approach exploiting `AMR-SG` to extract active facts from a large fact pool to answer questions. (c) A fact-level relation modeling leveraging graph convolution network (GCN) to guide the reasoning process. Results on two scientific multi-hop QA datasets show that we can surpass recent approaches including those using additional knowledge graphs while maintaining high explainability on OpenBookQA and achieve a new state-of-the-art result on ARC-Challenge in a computationally practicable setting.

1 Introduction

Multi-hop QA is one of the most challenging tasks that benefits from explainability as it mimics the human question answering setting, where multi-hop QA requires both the collection of information from large external knowledge resources and the aggregation of retrieved facts to answer complex natural language questions (Yang et al., 2018).



Question: Predators eat __.
Answer Choice: bunnies
Hypothesis: Predators eat bunnies.

Fact 1: A bunny is a small rabbit.
Fact 2: Most predators eat rabbits.

Figure 1: The AMR of the hypothesis (black), Fact 1 and Fact 2. A hypothesis is a statement derived from a question and a choice. The hypothesis AMR can be inferred by relevant fact AMRs.

Currently, external knowledge is mostly stored in two forms – textual and graph structure (e.g. Knowledge Graph (KG)). Textual corpora contain rich and diverse evidence facts, which are ideal knowledge resources for multi-hop QA. Especially with the success of pretrained models (Devlin et al., 2019; Liu et al., 2019; Lan et al., 2019), we can get powerful representations for such textual facts. However, retrieving relevant and useful facts to fill the knowledge gap for inferring the answer is still a challenging problem. In addition, the reasoning process over the facts is hidden by the unexplainable neural network, which hinders the deployment of real-life applications. On the other hand, KG is able to provide structural clues about relevant entities for explainable predictions (Feng et al.,

---

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1044–1056
August 1–6, 2021. ©2021 Association for Computational Linguistics

2020; Saxena et al., 2020; Xu et al., 2020). But it is known to suffer from sparsity, where complex question clues are unlikely to be covered by the closed-form relations in KG (Zhao et al., 2020; Zhang et al., 2020b). Another issue is that KG requires large human labor and is easy to become outdated if not maintained timely.

To take advantages of both rich textual corpora and explicit graph structure and make it compatible to all textual knowledge, we explore the usefulness of Abstract Meaning Representation (AMR) as a graph annotation to a textual fact. AMR (Banarescu et al., 2013) is a semantic formalism that represents the meaning of a sentence into a rooted, directed graph. Figure 1 shows some examples of AMR graphs, where nodes represent concepts and edges represent the relations. Unlike other semantic role labeling that only considers the relations between predicates and their arguments (Song et al., 2019), the aim of AMR is to capture every meaningful content in high-level abstraction while removing away inflections and function words in a sentence. As a result, AMR allows us to explore textual facts and simultaneously attributes them with explicit graph structure for explainable fact quality assessment and reasoning.

In this paper, we propose a novel framework that incorporates AMR to make explainable knowledge retrieval and reasoning for multi-hop QA. Our framework works on textual knowledge, which is easy to obtain and allows us to get informative facts. The introduced AMR serves as a bridge that enables an explicit reasoning process over a graph structure among questions, answers and relevant facts. As exemplified in Figure 1, a hypothesis is first derived from a question and an answer choice. We then parse the hypothesis and a large number of facts to corresponding AMRs. After that, we dynamically construct `AMR-SG` for each question-choice pair by merging the AMRs of its hypothesis and relevant facts. Unlike previous works on multi-hop QA that rely on existing KGs to find relations among entities (Wang et al., 2020; Feng et al., 2020), our proposed `AMR-SG` is dynamically constructed, which reveals intrinsic relations of facts and can naturally form any-hop connections. After construction, we analyze all connected paths starting from the question to the answer on `AMR-SG`. We focus the consideration of facts on those paths because they together connect the question with the answer, indicating their active roles in filling the knowledge gap. The connections of facts on `AMR-SG` can be further used as the supervision for downstream reasoning. Therefore, we adopt GCN (Kipf and Welling, 2017) to model the fact-level information passing.

Experimental results demonstrate that our approach outperforms previous approaches that use additional KGs. It obtains 81.6 accuracy on OpenBookQA (Mihaylov et al., 2018), and pushes the state-of-the-art result on ARC-Challenge (Clark et al., 2018) to 68.94 in a computationally practicable setting.

2 Related Work

Multi-hop QA with External Resource. Despite the success of pretrained model in most Natural Language Processing (NLP) tasks, it performs poorly in multi-hop QA, where some information is missing to answer questions (Zhu et al., 2021b).

Textual corpora contain rich and diverse knowledge, which is likely to cover the clues to answer complex questions. Banerjee et al. (2019) demonstrate some carefully designed queries can effectively retrieve relevant facts. Yadav et al. (2019); Deng et al. (2020) extract groups of evidence facts considering the relevance, overlap and coverage, but such method requires exponential computation in the retrieval step. Feldman and El-Yaniv (2019); Yadav et al. (2020) construct a fact chain by iteratively reformulating the query to focus on the missing information. However, the fact chain often grows obliquely as a result of the failure of first fact retrieval, making the QA model brittle. As some recent QA datasets (Yang et al., 2018; Mihaylov et al., 2018; Khot et al., 2020) annotate a gold evidence fact for each question, it enables training supervised classifier to identify the correct fact driven by a query (Nie et al., 2019; Qiu et al., 2019; Tu et al., 2020; Banerjee and Baral, 2020). Min et al. (2018) take a further step to jointly predict the answer span and select evidence facts in a unified model. Though these supervised retrievers have achieved impressive improvement, they heavily rely on the annotated gold facts, which are not always available in real-world applications.

In addition, previous works also explore the effectiveness of structured knowledge by either encoding the nodes (Yang and Mitchell, 2017; Wang et al., 2019), triples (Mihaylov and Frank, 2018; Wang et al., 2020), paths (Lin et al., 2019; Lei et al., 2020) or tabular (Zhu et al., 2021a) to capture the

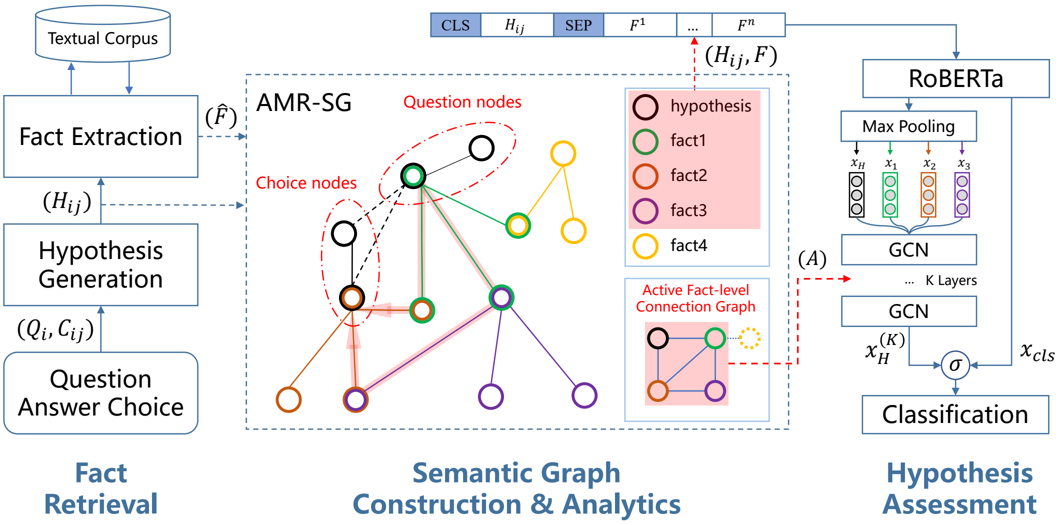

Figure 2: Overall architecture of our proposed model. The black dash lines in `AMR-SG` indicate that we cut the connection between question nodes and choice nodes. The pink arrows indicate two paths that can be spotted in `AMR-SG`. Facts with red background are active facts detected. The dashed node *Active Fact-level Connection Graph* indicates fact4 is not considered as a valid node as it is not an active fact.

missing information. Other works avoid the sparsity of KGs by constructing KGs directly from textual knowledge. OpenIE (Saha and Mausam, 2018) is widely used in knowledge base question answering to extract entity-relation triples (Bosselut et al., 2019; Zhao et al., 2020; Deng et al., 2019). However, OpenIE favors precision over recall, which is not necessarily effective to form connections among diverse evidence facts for multi-hop QA. Wikipedia contains internal hyperlinks, which are effective to build graph connections from unstructured articles (Asai et al., 2020; Liu et al., 2020). However, such hyperlinks are not available in most textual corpora.

AMR. Recent success in AMR research makes it possible to benefit downstream tasks, such as summarization (Takase et al., 2016; Dohare et al., 2017; Liao et al., 2018), event detection (Li et al., 2015) and machine translation (Song et al., 2019). In the domain of QA, AMR has been used to form logic queries and conduct symbolic reasoning (Mitra and Baral, 2016; Kapanipathi et al., 2020). Comparing to name entity (Zhong et al., 2020) or other cross-sentence annotations (Lei et al., 2018; Zhang et al., 2020a), we use AMR to build our semantic graph because it is align-free and can be easily adapted to powerful pretrained models.

3 Framework Description

In this paper, we consider the multi-hop QA in the form of multi-choice, where a question Q_i is provided with J answer choices $C_{ij}, j \in \{1, 2, ..., J\}$. As shown in Figure 2, our framework consists of three components: (1) a Fact Retrieval component to retrieve evidence facts $\hat{F} = \{\hat{F}^1, ..., \hat{F}^m\}$[1] for each question-choice pair from a large textual corpus; (2) a Semantic Graph Construction & Analytics component that dynamically constructs a semantic graph, named `AMR-SG`, to select active facts $F = \{F^1, ..., F^n\}$ from $\hat{F}$ and capture their relations A; and (3) a Hypothesis Assessment component that classifies whether the question-choice is correct, given the active facts and their relations in (2).

3.1 Fact Retrieval

Hypothesis Generation. As shown in Figure 2, we first generate a hypothesis H_{ij} for the i^{th} question and the j^{th} choice. A hypothesis is a completed statement derived from each question-choice pair. Comparing to simply concatenating the question and the choice, a hypothesis contains less meaningless words and maintain a good grammatical structure, which can avoid retrieving noisy facts and allow AMR parser to generate high-quality AMR graphs. We generate hypotheses by the rule-based model of Demszky et al. (2018). For some unsolvable cases, we directly concatenate the question and the choice. We apply this process for all training, develop and test sets.

---

[1] We omit the subscript ij for simplicity.

Fact Extraction. We retrieve a pool of evidence facts $\hat{F}$ for each hypothesis separately using *Elasticsearch* (Gormley and Tong, 2015). We set a large size m of the fact pool to cover as many valid facts as possible.

3.2 Semantic Graph Construction & Analytics

Active facts F are facts that really fill the knowledge gap between question and choice. The activeness of a fact cannot be simply determined by comparing it with the hypothesis, as multi-hop QA requires multiple facts to complete the reasoning chain. Therefore, we need to filter out facts that are just partially related and focus on the consideration of active facts and their roles in the reasoning chain. In this component, we first construct `AMR-SG`. Then, we propose a path-based analytics approach to extract active facts and construct an *Active Fact-level Connection Graph* to capture their relations with the question and the answer choice.

3.2.1 AMR-SG Construction

As the nodes of AMR are high-level abstraction of concepts conveyed in the corresponding textual fact, two AMRs sharing the same node indicate that they concern about the same concept, which shows their correlation. This motivates us to construct `AMR-SG`, shown in Figure 2, to represent the relations of the corresponding hypothesis and evidence facts for each question-choice pair.

We leverage the state-of-the-art AMR parser (Cai and Lam, 2020) to generate AMR $G = \{G^H, G^1, ..., G^m\}$ for a hypothesis and all facts in the corresponding fact pool, where G^H, G^i are the AMR of the hypothesis and the i^{th} fact respectively. AMR is also a directed and edge-labeled graph, which implies information specified in the edge is propagated in one predefined direction. However, such inner-AMR (edge labels and directions) information does not contribute to inter-AMR relations. Therefore, we only care about if there exists an edge between two nodes but ignore the edge labels and directions.

During construction, we regard G^H as the start point of `AMR-SG`. Then, we incrementally find one fact AMR in the fact pool sharing some nodes with it and add this fact AMR onto it by merging the shared nodes. The merging operation stops when no AMR can be added onto `AMR-SG` or the fact pool is empty. In fact, as shown in Figure 2, we do not change the architecture of each individual AMR, but reuse some shared nodes as the nodes in `AMR-SG`. Note that, some nodes are over-general, which are not appropriate to connect two AMRs (e.g. `(p/planet :name(n/name :op1"Earth"))`, the node `n/name` is an over-general concept). Fortunately, such over-general nodes always have non-node attributes (e.g. `Earth` of `n/name`) that shows the specific referent. Therefore, we replace the nodes with their non-node attributes if any to address this issue.

3.2.2 Path-based Analytics

Current multi-hop QA models are hindered by the quality of retrieved facts (Banerjee et al., 2019). We address this issue by a path-based analytics approach to guarantee the selected facts having a positive effect to answer the question.

As shown in Figure 2, `AMR-SG` reveals any-hop relations of the hypothesis and all facts. Completed paths can be spotted out of G^H to connect the question nodes with the choice nodes by passing through multiple facts. These facts, which together provide the missing knowledge to maintain complete reasoning chains, are active facts that we want to extract.

Specifically, we split the nodes of G^H into *question nodes* Q^H and *choice nodes* C^H. Question nodes represent the concepts extracted in the question text. As one question is provided with J choices, where we can generate J hypothesis AMRs. We take the shared nodes of these AMRs as Q^H, while the remaining as C^H:

$$Q_{ij}^H = \cap_{j=1}^J \{v | v \in G_{ij}^H\} \quad (1)$$

$$C_{ij}^H = \{v | v \in G_{ij}^H, v \notin Q_{ij}^H\}, j = 1, ..., J \quad (2)$$

We cut the edges between Q^H and C^H to guarantee the paths are spotted outside G^H. Then we apply depth-first search on `AMR-SG` to find all paths that connect at least one question node and one choice node, including the path that does not have a minimum length (e.g. the path passing through fact3 in Figure 2). All facts that the paths pass through (one node in and another node out) are considered as active facts. This is because we try to cover more facts as long as they do not deviate from the correct reasoning direction to provide enough information for QA model.

In addition, the any-hop relations of the hypothesis and active facts in `AMR-SG` can be used for a hypothesis to precisely aggregate knowledge from relevant facts to reduce ambiguity during the reasoning process. Therefore, we construct an *Active Fact-level Connection Graph* from `AMR-SG` to capture such relations among the hypothesis and all active facts. As shown in Figure 2, each node in *Active Fact-level Connection Graph* is either the hypothesis or an active fact. We draw an edge between two facts (include hypothesis) if they share one concept node in `AMR-SG`.

3.3 Hypothesis Assessment with Fact-level Reasoning

As shown in Figure 2, we concatenate the hypothesis with all active facts, where `[SEP]` token is inserted between the two texts and `[CLS]` is put at the beginning of the sequence. We feed the whole sequence into a pretrained model based on RoBERTa (Liu et al., 2019) architecture to get the hidden representation of each token.

Then, *Active Fact-level Connection Graph* is used as an additional supervision in fact-level modeling to guide the reasoning process. Formally, let $s^H_{1:l_H} \in \mathbb{R}^{l_H \times d}$, $s^i_{1:l_i} \in \mathbb{R}^{l_i \times d}$ be the hidden representations of the hypothesis and the i^{th} active fact respectively, where l_H, l_i denote the length and d is the dimension of the representation. A max pooling layer is applied over these hidden representations to get the node representations respectively:

$$\begin{aligned} x_H &= \textbf{MaxPool}(s^H_{1:l_H}) \in \mathbb{R}^{1\times d} \\ x_i &= \textbf{MaxPool}(s^i_{1:l_i}) \in \mathbb{R}^{1\times d}, i = 1, ..., n \end{aligned} \tag{3}$$

The connections of hypothesis (0^{th}) and active facts in *Active Fact-level Connection Graph* can be viewed as an adjacency matrix $A \in \mathbb{R}^{(n+1)\times(n+1)}$, where

$$A_{ij} = \begin{cases} 1 & \text{if } F^i \text{ is connected with } F^j \\ 0 & \text{otherwise} \end{cases} \tag{4}$$

As there is no edge information in the graph, a simple GCN is enough to model the knowledge fusion among the hypothesis and multiple active facts in the reasoning process. We also introduce multi-head mechanism (Vaswani et al., 2017) to stabilize the learning of different knowledge:

$$X^{(k)} = [head^{(k)}_1 : ... : head^{(k)}_h] \tag{5}$$

where $[:]$ denotes concatenation operation, $X^{(k)}$ is the node states at the k^{th} layer, $X^{(0)} = [x_H; x_1; ...; x_n]$, $[;]$ denotes the sequential concatenation operation, $head_i$ is the i^{th} head. Specifically, we compute the nodes states by aggregating knowledge from their neighboring nodes in each layer:

	Train	Dev	Test
OpenBookQA	4957	500	500
ARC-Challenge	8992	299	1172

Table 1: Number of instances in each dataset.

$$head^{(k)}_i = \text{ReLU}(\Lambda X^{(k-1)} W^{(k)}_i) \tag{6}$$

where $W^{(k)}_i \in \mathbb{R}^{d\times(d/h)}$ is the projection matrix of $head_i$ at the k^{th} layer, h is the head number. Λ is the normalization constant to avoid scale changing:

$$\begin{aligned} \Lambda &= D^{-1/2} A D^{-1/2} \\ D_{ii} &= \textstyle\sum_j A_{ij} \end{aligned} \tag{7}$$

After that, a σ gate is applied to calculate how much knowledge can be propagated to score the question-choice pair:

$$\lambda = \sigma(W^\lambda[x_{cls} : x^{(K)}_H] + b^\lambda) \tag{8}$$

$$s(q, a) = W^o(\lambda x^{(K)}_H + (1 - \lambda)x_{cls}) + b^o \tag{9}$$

where $W^\lambda \in \mathbb{R}^{1\times 2d}$, $W^o \in \mathbb{R}^{d\times d}$, b^λ, b^o are the parameters. We get the final probability by normalize all question-choice pairs with softmax.

4 Experiments

4.1 Datasets

We evaluate our approach on two multi-choice multi-hop QA datasets: ARC-Challenge (Clark et al., 2018) and OpenBookQA (Mihaylov et al., 2018). The textual corpus we use for both datsets is ARC Corpus (Clark et al., 2018), which contains about 14M science facts. OpenBookQA and ARC-Challenge have their leaderboards with train, develop and test sets publicly available. we follow AllenAI (2019) to combine the training set of OpenBookQA (4957), ARC-Easy (2251), ARC-Challenge (1119) and RegLivEnv (665) as the final training set of ARC-Challenge task. The data splits is shown in Table 1.

For ARC-Challenge, we retrieve 100 facts to form the fact pool. Based on this, we select up to 20 active facts using our approach as the context for each question-choice pair.[2] OpenBookQA provides an accompanying open-book of 1326 science

---

[2] We can only reproduce the results similar to AllenAI (2019) using 20 facts as the context.

facts, which are highly related to the questions in this dataset. Therefore, for OpenBookQA, we retrieve 10 facts from the open-book and another 90 facts from ARC Corpus, forming the 100 facts in the fact pool. We then select up to 15 active facts using our approach as the context.

4.2 Implementation

We implement our approach on two pretrained models: RoBERTa (Liu et al., 2019) and AristoRoBERTa (AllenAI, 2019). AristoRoBERTa employs the RoBERTa architecture but uses RACE (Lai et al., 2017) to first fine-tune the RoBERTa model. We prepare active facts as the context to further fine-tune the model with the target dataset. For OpenBookQA, we continue to fine-tune the QA model following the same procedure as AllenAI (2019), where the initial learning rate is 2e-5, the batch size is 12 and the max sequence length is 256. For ARC-Challenge, the initial learning rate, the batch size and the max sequence length are 1e-5, 6, and 416 respectively. We use grid search to find optimal hyper-parameters, where the learning rate is chosen from {5e-6, 1e-5, 2e-5}, the batch size is chosen from {4, 6, 8, 12, 16}. The number of GCN layer K is chosen from {1,**2**,3,4}, while the head number h is the RoBERTa-Large default value.[3]

We introduce 6M parameters of the fact-level reasoning module in addition to 355M of RoBERTa-Large. We run all experiments on one TITAN RTX card, which takes about 1 hour and 3 hours to complete the training of OpenBookQA and ARC-Challenge respectively.

4.3 Comparison Methods

We compare with recent existing methods that make use of similar power of pretrained models in order to conduct a fair comparison. These include the baseline AristoRoBERTaV7 (AllenAI, 2019) finetuned on top of AristoRoBERTa, KF-SIR (Banerjee and Baral, 2020) that exploits the knowledge fusion among facts, FreeLB (Zhu et al., 2020) that tackles the robustness issue and another three methods leveraging an additional knowledge graph (Speer et al., 2017) in addition to the textual knowledge: PG (Wang et al., 2020), MHGRN (Feng et al., 2020), AlBERT + KB. PG(albert + gpt2, roberta + gpt2) are two implementations with different pretrained model architectures (Liu et al., 2019; Lan et al., 2019; Radford et al., 2019), where the latter is more fair to compare with us.

Methods	Model Architecture	Additional KG	Test Acc.
PG	albert + gpt2	✓	81.8
PG	roberta + gpt2	✓	80.2
AlBERT + KB	albert	✓	81.0
MHGRN	roberta	✓	80.6
KF-SIR	roberta	×	80.0
AristoRoBERTaV7	roberta	×	77.8
+ AMR-SG-Full	roberta	×	**81.6**

Table 2: Test accuracy on OpenBookQA. Methods using additional KG are ticked.

5 Results

5.1 Main Results

OpenBookQA. The test set accuracy is shown in Table 2. AMR-SG-Full is our full model based on AristoRoBERTa. Results show that AMR-SG-Full can surpass models leveraging additional KG. It demonstrates that the fundamental improvement of AMR-SG-Full comes from the knowledge mining of the textual corpus. However, such knowledge resource has not been fully investigated by existing methods and contains richer and more diverse evidence facts than KGs. We do not compare with UnifiedQA (Khashabi et al., 2020) and T5 3B (Raffel et al., 2020) as they rely on extremely large pretrained models (at least 3B parameters), which are not fair for comparison.

ARC-Challenge. We also implement AMR-SG-Full on another difficult multi-hop QA dataset: ARC-Challenge. It consists of the questions only answered incorrectly by both a retrieval-based algorithm and a word co-occurrence algorithm (Clark et al., 2018), which theoretically is not friendly to our approach. As shown in Table 3, we can still obtain 2.47 accuracy improvement comparing to AristoRoBERTaV7 and achieve a new state-of-the-art performance in a computationally practicable setting.

5.2 Ablation Study

We conduct ablation study by incrementally adding each component of AMR-SG-Full to investigate its effectiveness on two pretrained models in Table 4. We include the analysis on RoBERTa because it is a more general and widely used pretrained model.

Table 4: Ablation study of model components on OpenBookQA (adding one component incrementally). ♠ is our reimplementation of (AllenAI, 2019).

We start from the vanilla pretrained models, where no textual facts are provided (denoted as *No Fact*). We retrieve 15 facts as the context to create the first variant (denoted as + *Fact Context*). The purpose is to test the contribution of the facts retrieved by the simple information retrieval (IR) system (*Elasticsearch*). We continue to add the path-based fact analytics component (denoted as + *Fact Analytics*). In fact, this variant merely use the facts selected from `AMR-SG` to fine-tune the pretrained models. On top of both two pretrained models, we observe a great performance improvement, where the improvement brought by + *Fact Analytics* is higher than + *Fact Context* on top of RoBERTa, which demonstrates this component can effectively select useful facts to fill the knowledge gap that have not been covered by the IR system. We finally equip our model with the fact-level reasoning component (denoted as + *Fact-level Reasoning*). From the results, we can observe that this component performs well on top of RoBERTa, but has very little effect on top of AristoRoBERTa. This is because this component tries to infuse some fact-level connections to ease the reasoning process of the model. Such information can be learned automatically by the model itself if exposed to enough in-domain data (AristoRoBERTa). Nevertheless, the fact-level reasoning is a more general method when such data is unavailable.

6 Explainability Analysis

6.1 Analysis of AMR-SG

Impact of Evidence Facts. As discussed above, the major improvement of our approach comes from more useful facts selected for each question-choice pair. In this section, we take a deep look at the quality and the composition of those facts on OpenBookQA. We derive five variants by varying the composition of core (facts retrieved from open-book) or common (facts from ARC Corpus) facts. For core facts, as open-book annotates one gold core fact for each question, the retrieval accuracy of the gold fact is a natural way to evaluate the quality. For common facts, we conduct human analysis to evaluate the quality from three aspects: (1) Relatedness: Does the retrieved fact related to the question or the answer? (2) Informativeness: Does the retrieved fact provided useful information to answer the question? (3) Completeness: Do all retrieved facts together fill the knowledge gap to completely answer the question? We randomly sample 50 questions and evaluate the evidence facts corresponding to the correct answer choice, where one fact would contribute 1 score if it meets the requirement of Relatedness or Informativeness respectively and all 15 facts contribute 1 score if they together meet the requirement of Completeness. Evaluation results are presented in Table 5.

When varying the fact composition of IR variants, we find the gold core fact retrieval accuracy has a positive impact on the final accuracy on top of RoBERTa. At this stage, some questions can be inferred sufficiently with the gold core facts. Higher retrieval accuracy accounts for more questions of this kind to be correctly answered. However, this advantage is not as obvious for AristoRoBERTa. Our human evaluation reveals that such facts are unlikely to form a complete reasoning chain, making it hard for real multi-hop reasoning.

On the other hand, our approach directly models the intrinsic fact relations, where the path-based analytics ensures that the facts selected are in the reasoning chain from the question to the answer. Results show that our approach makes an overall improvement with regard to Relatedness, Informativeness and Completeness and is

Facts Composition	Core Fact	Human Evaluation			Test set Accuracy	
(total 15 facts)	Retrieval Accuracy	Rel.	Info.	Comp.	RoBERTa	AristoRoBERTa
IR (5/10)	56.4	5.86	2.50	0.46	68.8	78.4
IR (10/5)	63.6	5.20	2.24	0.42	70.4	77.4
IR (15/0)	68.4	3.36	1.62	0.26	72.2	77.4
`AMR-SG` (10/30)	61.0	5.85	2.58	0.48	72.4	80.4
`AMR-SG` (10/100)	61.0	6.22	2.98	0.56	**74.2**	**81.6**

Table 5: Automatic and Human Evaluation of the evidence facts on OpenBookQA. IR (x/y) indicates we use simple IR system to retrieve x core facts and y common facts. `AMR-SG` (x/y) indicates we construct `AMR-SG` with x core facts and y common facts, based on which we then select 15 active facts and extract their relations.

less harmful to core fact retrieval. We also find that `AMR-SG` (10/100) can make a further improvement compared to `AMR-SG` (10/30) by including more facts to construct `AMR-SG`. It demonstrates that `AMR-SG` has the capability of detecting useful facts from a large and noisy fact pool, thus making up for the deficiency of the IR system.

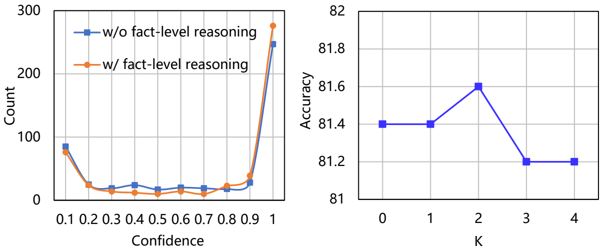
Impact of AMR Consistency. We investigate the quality consistency of AMR graphs to see how it affects the construction of `AMR-SG` and thus affects the QA model. We prepare AMR in three consistency levels, where *Fully-Automatic* is generated by automatic AMR parser; *Mixed* is that we manually annotate the error-free AMRs for the core facts in open-book (1326 in total) and use the error-free core fact AMRs and other automatically generated AMRs to construct `AMR-SG`; *Error-Free-Adapted* is that we use the error-free AMRs annotated to fine-tune the AMR parser and use the tuned parser to generate AMR for all the remaining facts (including hypotheses and common facts, about 900k in total). The test set accuracy are 81.6, 80.2, 80.4 for *Fully-Automatic*, *Mixed* and *Error-Free-Adapted* respectively. It is interesting to note that using *Fully-Automatic* AMRs results in higher QA accuracy than *Mixed* and *Error-Free-Adapted*, where the latter two contain a mix of AMRs with different levels of quality. This phenomenon has also been observed in other AMR applications (Liu et al., 2015; Hardy and Vlachos, 2018), where automatic parses perform well than manual parses. We conjecture that this can be attributed to the discrepancy between the error-free AMRs and the automatically parsed AMRs in the choices of AMR concepts with similar meaning. This small difference in concept choices may omit potential connections, results in some important facts failing to be detected. In contrast, automatically parsed AMRs contain errors, but they are consistent in their concept choices, which is more likely for AMRs to form connections. The 0.2 accuracy improvement between *Mixed* and *Error-Free-Adapted* also demonstrates our assumption, since the parser is finetuned on the error-free AMRs, where its parsed AMRs should be more consistent with the error-free AMRs.

Question: *A seismograph can accurately describe* (A) how rough the footing will be (B) how bad the weather will be **(C) how stable the ground will be** (D) how shaky the horse will be
Useful facts retrieved by IR: N.A.
Additional facts from path-based analytics: A seismograph is a kind of tool for measuring the size of an earthquake. An earthquake is a shockwave travelling through the ground.
Relevant path in `AMR-SG`: `seismograph→tool→measure-01→size-01→earthquake→ground`

Table 6: A case study showing how our framework selects useful facts to completely fill the knowledge gap.

6.2 Case Study

Table 6 shows one case study of evidence facts selected by our framework. Since the important term *earthquake* is missing from the search query, the IR system assigns low retrieval scores for the two facts, causing a low ranking. However, the two facts can form a complete reasoning chain with the question and the answer via several concept nodes, where our approach can successfully extract the two facts despite the low retrieval scores. More cases can be found in Appendix A.1.



(a) (b)

Figure 3: Analysis of fact-level reasoning on OpenBookQA. (a) presents the distribution of prediction confidence with or without fact-level reasoning module. (b) shows the QA performance with different GCN layer K. Size 0 denotes the original pretrained model.

6.3 Analysis of Fact-level Reasoning

Why Fact-level reasoning. Figure 3(a) shows that fact-level reasoning improves the performance by making a more confident prediction for the correct answer. This is because the fact-level connections of `AMR-SG` inform the model how these active facts are intrinsically related, which allows the model to precisely receive knowledge from related facts.

Impact of Number of Hops (K). We vary the hyper-parameter K to consider the impact of K-hop neighbors on OpenBookQA. As show in Figure 3(b), the performance reaches the top at $K = 2$. It indicates that most of the questions can be well answered using two evidence facts, which is consistent with the construction of this dataset. However, the performance drops when $K > 2$. It might be attributed to exponential noise found in longer reasoning chains.

7 Conclusion

We propose to dynamically construct `AMR-SG` that can reflect the intrinsic relations of relevant facts leveraging AMR, a graph annotation. `AMR-SG` combines the advantages of rich textual corpus and graph structure, where we can select useful facts that completely form the reasoning chain and make fact-level modeling. Experimental results show that `AMR-SG` can maintain high explainability, and successfully couple with strong pretrained models to achieve significant improvement on OpenBookQA and ARC-Challenge over approaches leveraging additional KGs.

Abstract

A good open-domain chatbot should avoid presenting contradictory responses about facts or opinions in a conversational session, known as its consistency capacity. However, evaluating the consistency capacity of a chatbot is still challenging. Employing human judges to interact with chatbots on purpose to check their capacities is costly and low-efficient, and difficult to get rid of subjective bias. In this paper, we propose the **A**ddressing **I**nquiries about **H**istory (**AIH**), an efficient and practical framework for the consistency evaluation. At the conversation stage, **AIH** attempts to address appropriate inquiries about the dialogue history to induce the chatbot to redeclare the historical facts or opinions. We carry out the conversation between chatbots, which is more efficient than the human-bot interaction and can also alleviate the subjective bias. In this way, we manage to rapidly obtain a dialog session that contains responses with high contradiction possibilities. At the contradiction recognition stage, we can either employ human judges or a natural language inference (NLI) model to recognize whether the answers to the inquiries are contradictory with history. Finally, we are able to rank chatbots according to the contradiction statistics. Experiments on open-domain chatbots show that our approach can efficiently and reliably assess the consistency capacity of chatbots and achieve a high ranking correlation with the human evaluation. We release the framework and hope to help improve the consistency capacity of chatbots.[1]

	DialoGPT 762M
Human:	*What movies do you like most?*
DialoGPT:	*The Unforgiven from Metallica.*
Human:	*What do you think of the Unforgiven?*
DialoGPT:	*I never heard of it.*
	Blender 2.7B
Human:	*What do you like to cook?*
Blender:	*I only cook Indian cuisine. How about you?*
Human:	*I enjoy cooking Chinese food, especially the dumplings.*
Blender:	*Chinese food is delicious. I also like cooking the Chinese food.*
	Plato 1.6B
Human:	*Do you like dogs?*
Plato:	*Yes, dogs are cool, I prefer cats though.*
Human:	*Do you have a dog?*
Plato:	*I do not, but I'd love a dog. I think dogs are so cute.*
Human:	*I love dogs very much. I have three dogs.*
Plato:	*I have three dogs too. One puppy and two Huskies.*

Table 1: Several human-bot conversations demonstrate that popular chatbots (DialoGPT, Blender, and Plato) generate inconsistent responses when talking to a human under some specific conditions.

1 Introduction

In recent years, open-domain intelligent chatbots (Adiwardana et al., 2020b; Bao et al., 2020; Smith et al., 2020) have approached great progress due to the development of the large-scale pre-training approaches (Devlin et al., 2019; Radford et al., 2019; Brown et al., 2020) and the large amount of high-quality conversational datasets (Dinan et al., 2019; Baumgartner et al., 2020; Smith et al., 2020). Though the success is indisputable and exciting, there is still a long way to build a truly human-like open-domain chatbot.

Current open-domain chatbots hold a superiority in generating fluent, engaging, and informative responses, but show the soft spot on consistency (Nie et al., 2020). As shown in Table 1, we present some interactive dialogue samples between human and several popular open-domain chatbots (e.g. DialoGPT (Zhang et al., 2020), Blender (Smith et al., 2020), and Plato (Bao et al., 2020)). All open-

domain chatbots occasionally generate responses that are contradictory with history when interacting with humans, which is really annoying and severely disrupts the communication once happening. Therefore, it is imperative to improve the consistency of the open-domain chatbots. However, one crucial reason that restricts consistency development is the lack of an effective and practical evaluation method.

To estimate the consistency of chatbots, the most straightforward approach is to ask human annotators to distinguish whether the conversations generated from the chatbots are consistent or not. However, the instructions followed by annotators are often chosen ad-hoc, and there is no explicit definition, which leads to the relatively low inter-agreement in the human chatbot consistency evaluation (Mehri and Eskénazi, 2020). As a result, several works have been proposed to develop automatic evaluation methods (Welleck et al., 2019; Song et al., 2020; Nie et al., 2020). While these methods can detect contradictions efficiently in the dialogue, they depend on the human-bot conversations, which is still cost-inefficient and tend to suffer from low quality (Deriu et al., 2020; Dinan et al., 2020). Besides, the occurrence rate of contradiction is low under this condition. All these problems slow down the development of consistency evaluation of dialogue systems severely.

Towards that end, based on the observations: (i) chatbots are likely to generate contradictions when chatting about facts and opinions; (ii) answering the questions about the conversational history correctly can reveal the ability to understand the conversation and keep consistency, we present the *Addressing Inquiries about History* (AIH) framework, an effective and practical framework for open-domain chatbot consistency evaluation. The framework can be used to rank different chatbots with regard to the ability to be consistent with themselves in the conversation. Specifically, AIH consists of two stages: (i) during the inquiry stage, questions about the facts and opinions mentioned in the conversation history are inserted into the conversation between chatbots; (ii) during the contradiction recognition stage, the responses of the inserted questions are collected, and automatic models or human judges can be adopted to decide whether the responses are consistent with the dialogue history.

In brief, our AIH has the following key advantages: *Firstly*, it is based on bot-bot conversation, which avoids the human intervention and brings down the cost and time effort significantly. *Secondly*, by inserting specific questions, contradictions occur more frequently, and it is easier for human annotators or automatic consistency detection model to distinguish the contradiction compared with natural conversations. Extensive experiments demonstrate that the proposed framework can produce effective, efficient, and reliable consistency evaluation. Furthermore, we also make an in-depth discussion about the influence of question generation, contradiction detection, and evaluation agreement in our framework.

Our contributions are summarized as follows:

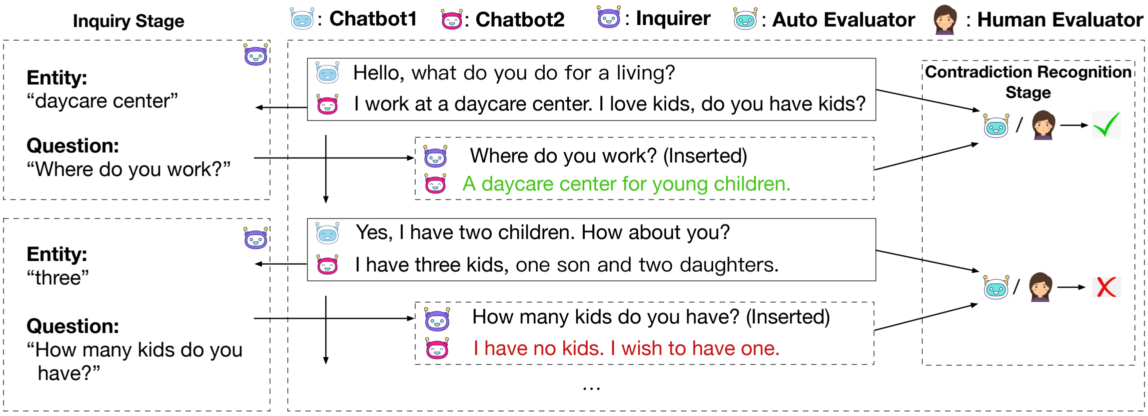
- We propose the *Addressing Inquiries about History*(AIH), an effective and practical framework for open-domain chatbot consistency evaluation.
- Experiments show that AIH can produce effective, efficient, and reliable consistency evaluation. We release the framework as a ready-to-use tool for evaluating the consistency of chatbots. We hope AIH can facilitate and provide standard evaluation for future work on developing self-consistent open-domain chatbots.

2 Related Work

There are various methods to evaluate the consistency of chatbots, containing automatic and human-based methods. The methods mainly fall into two dimensions: the static and interactive evaluation.

2.1 Static Evaluation

Static evaluation denotes evaluating if the responses generated based on the static context are contradictory with the pre-defined persona or profile and the dialogue history by neural models or human annotators. Welleck et al. (2019) and Song et al. (2020) focus on the persona-related consistency and profile-related consistency, and characterize the chatbot consistency evaluation as the natural language inference problem. Nie et al. (2020) build a new human-craft dataset called DECODE and propose a structured utterance-based approach to detect the contradictions in the dialogue history. While being cost-efficient, static evaluation can not accurately reflect the conversation capacity of the chatbot in the real world.



Hello, what do you do for a living?

I work at a daycare center. I love kids, do you have kids?

Where do you work? (Inserted)

A daycare center for young children.

Yes, I have two children. How about you?

I have three kids, one son and two daughters.

How many kids do you have? (Inserted)

I have no kids. I wish to have one.

Figure 1: Overview of the Addressing Inquiries about History framework. There are five “agents”: **Chatbot1**, **Chatbot2**, **Inquirer**, **Auto Evaluator**, and **Human Evaluator** and two stages: **Inquiry Stage** and **Contradiction Recognition Stage** in the framework. Chatbot1 and Chatbot2 are the participants in the bot-bot conversation, in which Chatbot2 is the one to be evaluated. In the Inquiry stage, Inquirer extracts opinion- or fact-related entities and generate inquiries based on them. In the Contradiction Recognition stage, the Auto Evaluator is generally a contradiction detection model to automatically evaluate if the responses from Chatbot2 are consistent and the Human Evaluator can also be employed for more accurate evaluation. Note that the inserted inquiries do not affect the natural conversation. Better view in color.

2.2 Interactive Evaluation

Human-bot Conversations. In order to pursue more authentic evaluation, the standard method is to let humans converse with a chatbot and evaluate it by aforementioned models or humans afterward (Mehri and Eskénazi, 2020). However, apart from the high cost of collecting human-bot conversations, there is also a high cognitive strain on humans, which leads to unstable results (Dinan et al., 2020).

Bot-bot Conversations. Recently, bot-bot conversations, which significantly reduce the cost and human bias, are focused. Deriu et al. (2020); Li et al. (2019) propose to let humans evaluate bot-bot or self-talk conversations to give a relative ranking of the overall quality of chatbots. Different from these methods, we focus on the chatbot consistency and insert inquiries to redeclare historical facts. And we introduce both automatic and human approaches to evaluate the chatbot consistency.

3 Approach

In this section, we first provide an overview of the *Addressing Inquiries about History* (AIH) framework. We then describe the Inquiry stage, the Contradiction Recognition stage, and the chatbot ranking process.

3.1 Overview

To estimate the consistency capacity, questions about the opinions and facts in the dialogue history are inserted into the current bot-bot conversation. Then, the corresponding responses are collected and judged by automatic tools or human evaluation. The workflow of our proposed AIH framework is shown in Figure 1.

To be specific, there are five “agents” in the framework: Chatbot1, Chatbot2, Inquirer, Auto Evaluator, and Human Evaluator. The Chatbot1 and Chatbot2 are the participants in the bot-bot conversation. The Inquirer extracts opinion- or fact-related entities and generates inquiries based on the entities. The Auto Evaluator is generally a contradiction detection model to automatically evaluate if the responses from Chatbot2 are consistent. The Human Evaluator is used for more accurate evaluation.

Formally, assume a pool of N chatbots $\{B_1, ..., B_N\}$ which are ready to be evaluated in terms of consistency capacity. For each pair of chatbots (referred as Chatbot1 and Chatbot2), we let Chatbot1 talk with Chatbot2 for K turns. Note that Chatbot2 is the one to be evaluated. (i) During the inquiry stage, within the conversation between Chatbot1 and Chatbot2, for each utterance u_{2k} generated by Chatbot2, Inquirer extracts the entities about opinions and facts, then asks Chatbot2 a question q_k about these entities, where k is the turn number. Chatbot2 answers the question q_k and generates the corresponding response r_k. Note that we ignore the questions generation operation when there is no entity that can be extracted. (ii) During the contradiction recognition stage, we use neural models (e.g. Natural Language Inference Model) or employ human judges to decide if the utterance pair $\{u_{2k}, r_k\}$ exists non-consistent problem. We collect at least M dialogues from each chatbot pair, then calculate the ranking order on the consistency. In this way, we can discriminate the consistency capability of chatbots effectively and efficiently. In the following, we will introduce the inquiry stage and the contradiction recognition stage, respectively.

3.2 Inquiry Stage

Based on our observation and prior work (Nie et al., 2020), in natural human-bot or bot-bot conversation, contradiction is more likely to occur when chatting about repeated facts and opinions, especially after similar questions. Therefore, to mimic such a contradiction occurrence process, we make chatbots to produce responses by asking chatbots related questions about previous facts and opinions. In this condition, generating appropriate questions is pretty important. Hence, we first extract entities about facts and opinions from the historical utterances, then employ a neural model to generate questions about the extracted entities.

Entity Extraction

Considering that chatbots usually generate contradictions when chatting about facts and opinions, we apply Named Entity Recognition tools in Stanza (Qi et al., 2020), a popular natural language analysis package, to extract named entities from utterance u_{2k} containing person, organization, location, etc. [2] For example, for the utterance *"I would love to visit New York next year."*, we can extract out two entities: *"New York"* and *"next year"*.

Question Generation Model

For question generation, we employ UniLM (Dong et al., 2019) model that is fine-tuned on the SQuAD dataset (Rajpurkar et al., 2016) with question generation task (Wangperawong, 2020). We utilize a public implementation and checkpoint.[3] In our framework, given the entities extracted before and utterance, UniLM generates a suitable question for each entity. For example, given *"New York"* and *"I would love to visit New York next year."*, the model generates *"Where would you like to visit next year?"*. We then randomly select one question and insert it into the bot-bot conversation.

3.3 Contradiction Recognition Stage

In our framework, since the question q_k is based on the previous Chatbot2's utterance u_{2k}, the response from Chatbot2 should be consistent with the utterance u_{2k}. Therefore, the Auto Evaluator and Human Evaluator can just consider the answer r_k and utterance u_{2k}.

Auto Evaluator

For automatic evaluation, the Auto Evaluator is generally a contradiction detection model. The Auto Evaluator take the response r_k answered by Chatbot2 and the previous utterance u_{2k} as input, and output the contradiction score y_k. It can be formulated as:

$$y_k = f_\theta(r_k, u_{2k}), \tag{1}$$

where f_θ is the detection function and θ is the parameters. Compared to other contradiction detection methods that consider the whole dialogue, the Auto Evaluator can refrain from the noise contained in the whole dialogue. In practice, we select the Roberta-large model (Liu et al., 2019) fine-tuned on the Multi-Genre Natural Language Inference dataset (Williams et al., 2018) as the implementation of Auto Evaluator.[4]

Human Evaluator

In traditional dialogue consistency evaluation methods, human judges are asked to read the whole dialogue and give an overall consistency score, usually 0 or 1. In our opinion, these methods suffer from high cost and low inter-agreement because there is no specific instruction, and it is too hard for human judges to give an overall score on the whole dialogue (Mehri and Eskénazi, 2020).

In our framework, human evaluators are only asked to decide if the response r_k answered by Chatbot2 is consistent with the previous utterance u_{2k} or not, which is more specific and easier than the traditional methods. As a result , the cost decreases, and the evaluation quality increases. Besides, the human annotation in our framework is much more fine-grained than the traditional methods, which can provide more information for the development cycle of dialogue systems.

---

[2] There are 18 named entity types. Please refer to (Weischedel et al., 2013) for more details.

[4] `https://huggingface.co/roberta-large-mnli`

3.4 Consistency Metrics and Bot Ranking

Based on the previous results, we can obtain a ranking list about different chatbots on consistency capacity. Formally, for each chatbot pair $\{B_i, B_j\}$, we collect M dialogues. For each inquiry pair, the detection of contradiction is made by comparing y_k with a threshold τ:

$$c_k = \mathbb{I}(f_\theta(r_k, u_{2k}) > \tau). \tag{2}$$

The contradiction rate of the chatbot B_j within chatbot pair B_{ij} can be computed as:

$$C_{ij} = \frac{1}{M} \sum^{m} c_k, \tag{3}$$

where m is the number of inquiries in each dialog and M is the total number of inquiry pairs. For the overall contradiction rate of the chatbot B_j is calculated as:

$$C_j = \frac{1}{N} \sum_{i=1}^{N} C_{ij}. \tag{4}$$

Finally, we can rank the chatbots using the overall contradiction rate.

4 Experiment Setup

In this section, we first list the dialogue systems used in our experiments, then describe the experimental settings in detail.

4.1 Chatbots

We select several popular open-domain chatbots in our experiments.

Blender (BL) (Adiwardana et al., 2020a) is firstly pre-trained on Reddit dataset (Baumgartner et al., 2020) and then fine-tuned with high-quality human annotated dialogue datasets (BST), which containing four datasets: Blended Skill Talk (Smith et al., 2020), Wizard of Wikipedia (Dinan et al., 2019), ConvAI2 (Dinan et al., 2020), and Empathetic Dialogues (Rashkin et al., 2019). By fine-tuning, Blender can learn blend conversational skills of engagement, knowledge, empathy and personality. Blender has three model sizes: 90M, 2.7B, and 9.4B. Since 2.7B parameter model achieves the best performance in (Adiwardana et al., 2020a), we use the 2.7B version in our experiments.

Plato (PL) (Bao et al., 2020) is an open-domain chatbot, pre-trained on Reddit dataset and fine-tuned with BST dataset, which is claimed to be superior to Blender. According to the evaluation in (Bao et al., 2020), we select the 1.6B parameter version in our experiments.

DialoGPT (DG) (Zhang et al., 2020) is trained on the basis GPT-2 (Radford et al., 2019) using Reddit comments. There are three model sizes: 117M, 345M, and 762M. We fine-tuned the 762M version on the BST datasets.

DialoFlow (DF) (Li et al., 2021a,b) is a top method in DSTC9 Interactive Dialogue Evaluation track (Gunasekara et al., 2021). We reproduced the DialoFlow model based on GPT2-large (Radford et al., 2019) and fine-tuned it with BST dataset.

4.2 Experimental Settings

We adopt four experimental paradigms to evaluate the effectiveness of the AIH.

Bot-Bot Interaction. For bot-bot interaction, the maximum interaction turn is set to 15. All chatbots exploit Nucleus Sampling (Holtzman et al., 2020) with p=0.9 when generating responses. For each chatbot pair, we collect at least 200 dialogues.

Human Annotation. To verify the effectiveness of our framework, we conduct the human evaluation. For the bot-bot conversation under our framework, we employ three professional human annotators from a commercial data annotating company to separately annotate three fields: whether inquiry chatbot generates appropriate questions, whether Chatbot2 answers the questions relevantly, and whether the responses from chatbot2 are contradictory with the dialogue history. We pay the company reasonable salary. For each chatbot pair, we randomly sample 50 dialogues to be annotated. We compute the final decision via voting.

In Human-bot Natural Interaction and Expert Evaluation, we deployed the four chatbots on the remote server and designed a web interface. Human could chat with a random chatbot each time through the web interface and give the consistency score, being unaware of which chatbot they are chatting with.

Human-Bot Natural Interaction. For each chatbot, we filtered out the dialogues with <5 turns and the dialogues with abusive words. For each chatbot, there are at least 40 eligible dialogues. Then we employ the three professional human annotators to individually annotate whether each utterance from the chatbot is consistent or not.

Expert Evaluation. To obtain the human ranking

Expert Consistency Score ↑				
	BL	**PL**	**DG**	**DF**
Expert.1	0.55	0.80	0.72	0.69
Expert.2	0.37	0.87	0.60	0.56
Expert.3	0.31	0.89	0.60	0.55
Avg.	0.41	**0.85**	0.64	0.60

Table 2: The expert consistency score of each chatbot. Higher is better.

Contradiction Rate (Auto $\tau = 0.15$) ↓					
	BL	**PL**	**DG**	**DF**	**Avg.**

Table 3: The contradiction rate of each chatbot pair. The column name and the row name represent Chatbot1 and Chatbot2 respectively.

for the consistency of the chatbots, we invite three expert volunteers from our lab, who have 2-3 years experience of dialogue system development, to chat with each bot at least 10 times and about 15 turns each time. In the chatting, experts are asked to intentionally induce the chatbots to re-answer the questions about the dialogue history and give the consistency score from 0 to 1. Note that we ask the experts to chat with the chatbots for >20 times before the formal evaluation. We average the scores from three experts as the overall consistency score.

Note that Expert Evaluation and Human Annotation were done before the automatic evaluation. Human-bot Natural Interaction was done after the automatic evaluation. All human evaluations were independent from the automatic evaluation.

5 Experimental Results

In this section, we conduct experiments to illustrate the effectiveness, efficiency, and stability of the proposed AIH framework.

5.1 Evaluation Effectiveness

We report the expert ranking results in expert evaluation, automatic evaluation, and human evaluation under the AIH framework, respectively.

Expert Ranking. Table 2 shows the expert consistency scores for different chatbots. We can find that Plato achieves the best expert consistency score, up to 0.85. And the ranking of consistency for these four chatbots is: Plato > DialoGPT > DialoFlow > Blender, which can serve as the gold reference.

Auto Evaluation Results. Table 3 shows the contradiction rate of each chatbot pair in auto evaluation. The lower contradiction rate means the better consistency. The column name and the row name represent Chatbot1 and Chatbot2, respectively. The "Avg." in column name represents the overall contradiction rate of each chatbot. The "Avg." in row name can be regarded as the ability to induce other chatbots to redeclare about the facts or opinions that are likely to be contradictory. In the automatic evaluation, the ranking of consistency for the chatbots is Plato > DialoGPT > DialoFlow > Blender, which is the same with expert evaluation. The Blender reaches the highest contradiction rate.

Human Evaluation Results. We list the evaluation results in the bottom of Table 3. As we expected, BL obtains the highest contradiction rate. Meantime, human evaluation also provides the same consistency ranking: Plato > DialoGPT > DialoFlow > Blender as before.

Summary. Both automatic evaluation and human evaluation in our framework can give the same performance ranking with the expert, which demonstrates that our framework is general and can effectively evaluate the consistency of chatbots.

5.2 Time Efficiency

Prior consistency evaluation methods with human-bot interaction are costly and take up a long time, which seriously slows down the development cycle of dialogue systems. In this section, we try to illustrate that our proposed *Addressing Inquiries about History* framework is time and cost efficient and can help the evolution process of dialogue systems compared to the other methods.

As shown in Table 4, we compare the time cost on two aspects: (i) the time to create inquires, and (ii) the time to detect contradictions in conversation. *Addressing Inquiries about History* framework is based on the bot-bot conversation so that the time to create conversation can be ignored, while the

Method	Time (Sec)	Contradiction
AIH (Auto)	- + -	1.56
AIH (Human)	- + 24	1.69
Human-bot	246 + 59	0.50

Table 4: The time efficiency of our proposed *Addressing Inquiries about History* framework and traditional evaluation method with human-bot interaction. "Time" represents the time to create a conversation and the time to annotate the contradictions in a conversation. "Contradiction" denotes the average number of contradictions per conversation (average 15 turns). Dash line denotes the time can be ignored.

human-bot conversation takes around 4 minutes per conversation. For the contradiction detection time, prior methods take around 1 minute considering the whole dialogue, while in our proposed framework, it is only about 24 seconds for human annotation or ignored for automatic evaluation. Besides, we also compare the number of contradictions per conversation. As shown in Table 4, in our framework, the chatbots generate much more contradictions than those in prior methods. The detected contradictions are helpful for the chatbot developer to further improve the consistency of the chatbot.

Summary. Our proposed framework can detect more contradictions with much less time than previous methods. Correspondingly, *Addressing Inquiries* framework will accelerate the evolution process of consistency of chatbots.

5.3 Ranking Stability

One key requirement for an evaluation framework is that repeated executions of the procedure result in the same outcomes. We measure how many conversations between each chatbot pair are required to guarantee a stable ranking. We randomly sample $\hat{S}$ conversations for each chatbot pair and compute the consistency ranking using automatic evaluation, where $\hat{S} \in \{1, \cdots, 200\}$. We repeat this sub-sampling procedure 1000 times and compute the accuracy of achieving the same ranking with the expert ranking. As shown in Figure 2, when $\hat{S}>100$, the ranking results of the four chatbots are the same with the expert in 95% cases and guarantee a stable ranking. We also do more in-depth analysis. The ranking stability depends on the significance of ranking. Table 2 shows the consistency scores of DialoGPT and DialoFlow are close. We applied a leave-one-out stability analysis, in which we drop one chatbot. Figure 2 shows that when leaving one between DialoGPT or DialoFlow out, the stability is achieved with $\hat{S} = 50$ dialogues.

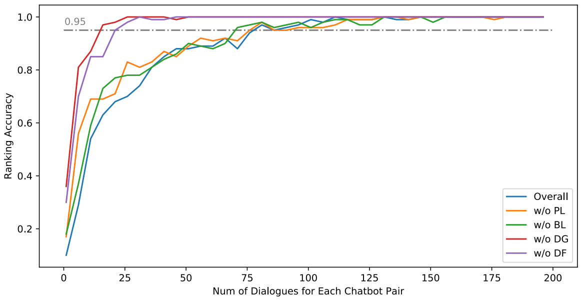

Figure 2: Ranking stability experiments. The x-axis denotes the number of conversations for each chatbot pair. The y-axis denotes the rate achieving the same ranking with the experts.

Summary. The number of conversations needed for a stable evaluation in AIH framework is dependent on the chatbots to be tested, and more conversations usually lead to more stable evaluation. In general cases, 75 conversations are enough to get a valid contradiction detection.

6 Further Investigation

In this section, we will further discuss the effectiveness of three parts in our framework containing question generation, contradiction detection, and human annotation evaluation.

6.1 Question Generation

Since a suitable question is necessary for the inquiry stage under our AIH framework, we make an in-depth analysis about the characters of question generation during inquiry stage.

Number of Questions and Contradictions
We randomly sample 200 dialogues for each chatbot pair and make statistics on the average number of the inquiry pairs and contradictions per conversation. As shown in Table 5, there are 4.57 inquiry pairs per conversation on average. There are 6.37 and 5.10 inquiry pairs per conversation when the Blender acts as Chatbot2 and serves as Chatbot1, respectively, which are both highest among all chatbots. The number of inquiry pairs reveals that the Blender can chat more about persona and facts, and the DialoGPT mentions these things less. Table 5 also shows the number of contradictions per conversation. Similarly, the Blender makes the most contradictions and is the most likely to induce the chatbot interacting with it to redeclare facts or opin-

Number of Questions					
	BL	**PL**	**DG**	**DF**	**Avg.**
BL	6.54	6.13	2.62	5.12	**5.10**

PL	2.82	1.40	0.58	1.56	1.53
DG	2.66	1.12	0.57	1.31	1.38
DF	2.63	1.53	0.77	1.56	1.61
Avg.	**2.73**	1.38	0.69	1.57	1.56

Table 5: Statistic of average number of inquiry pairs and the contradictions per conversation for each chatbot pair. The column name and the row name represent Chatbot1 and Chatbot2 respectively.

Question Appropriateness					
	BL	**PL**	**DG**	**DF**	**Avg.**
BL	0.932	0.960	0.922	0.936	0.938
PL	0.942	0.976	0.940	0.948	0.951
DG	0.784	0.870	0.928	0.882	0.866
DF	0.867	0.934	0.922	0.939	0.915
Avg.	0.881	0.935	0.947	0.942	0.927

Table 6: The appropriateness of the generated questions (Human evaluation).

ions that are likely to be contradictory.

Question Appropriateness

We analyze the appropriateness of the generated questions. We randomly sample 50 dialogues from each chatbot pair and ask human annotators to decide if the generated questions are appropriate based on the provided context (0/1). As shown in Table 6, the overall appropriateness score is about 0.93, which reveals that our question generation strategy is simple yet highly effective. We further study the wrong questions and find that most of them can be attributed to that the general question generation model can not work well in the dialogue context. We leave the better question generation task in open-domain dialogue for future work.

	CR	**F1**	r
$\tau = 0.1$	**0.401**	0.650	0.430
$\tau = 0.15$	0.364	**0.655**	**0.436**
$\tau = 0.3$	0.287	0.606	0.423
$\tau = 0.5$	0.235	0.572	0.421

Table 7: The analysis of threshold τ. CR means contradiction rate. r denotes the Pearson correlation. Pearson correlation and F1 score are measured with human annotations.

Inter-Annotator Agreement					
	BL	**PL**	**DG**	**DF**	**Avg.**
AIH	0.818	0.817	0.812	0.807	0.814

Table 8: We analyse the inter-annotator agreement of the human evaluation in our proposed AIH framework. The correlation is measured by correlating each annotation with overall decision.

6.2 Effect of Contradiction Threshold τ

We evaluate the effect of hyper-parameter τ in Equ.2, and the results are reported in Table 7. We compute the F1 score and Pearson correlation between the automatic evaluation results and the human annotations under different τ. We can make the following observations: (i) When $\tau = 0.15$, the Pearson correlation and F1 score reaches the highest. Thus we choose $\tau = 0.15$ in our main experiments. (ii) The highest F1 score is 0.655, and the highest Pearson correlation is 0.436, which is a moderate correlation. The observations reveal that there is a big gap between automatic evaluation and human evaluation, though the contradiction rate is similar. We consider that it is because the NLI model we employ is trained on the general domain rather than the dialogue domain, so there are lots of reference problems that can not deal with well.

6.3 Inter-Annotator Agreement

To investigate the quality of human annotation, we compute the inter-annotator agreements, i.e., the correlation between each annotation and the overall decision is measured. The Pearson correlation for each chatbot is shown in Table 8. The inter-annotator agreement is high for all chatbots, suggesting that the evaluation instructions are well-understood by the annotators.

7 Conclusion and Future Work

In this work, we introduced the *Addressing Inquiries about History* (AIH), an effective and practical framework for open-domain chatbot consistency evaluation. AIH works by inserting questions about the mentioned facts and opinions in the history into the bot-bot conversation and employing human annotators or neural models to evaluate whether the responses are consistent or not. Based on this, we can rank different chatbots accurately and efficiently. We show that our framework can effectively evaluate the consistency of chatbots and the evaluation results well correlate with experts. Also, our framework is cost and time-efficient and can not only give an overall consistency score but also provide exactly the contractions, which can accelerate the evolution process of chatbots.

As in this work, we only focus on the contradictions about entities, and future work can improve the inquirer module and explore more kinds of contradictions. Besides, future work should also develop a more effective contradiction recognition module in the dialogue domain, while in this work we just exploit the general Natural Language Inference model to detect contradictions. The non-consistency problem is serious in current open-domain chatbots. We hope our work could facilitate and provide guidelines for future work on developing self-consistent open-domain chatbots.

Ethic Statement

For the human evaluation and human interaction included in our paper, we state the ethical impact here. In Expert Evaluation, we recruited three expert volunteers from our lab, who had 2-3 years experience of the dialogue system development. They were asked to chat with the chatbots for $>$20 times before the formal evaluation. In Human-bot Natural Interaction, we collected human-bot conversations by inviting student volunteers from our university through the web interface. The participants were instructed to chat with the chatbots naturally. They were asked to sign the agreement before the dialogue: (i) They were at least 18 years old and could type into the web interface to chat with the chatbots. (ii) They were told that their interaction would generate anonymous text data which would only be used for the research on dialogue systems. In Human Annotation, we employed three well-educated professional annotators from a commercial data annotating company to annotate the contradictions for bot-bot conversations and human-bot natural conversations. We paid the company reasonable salary. The company provided comfortable working conditions and fair salaries for the annotators.

Investigating the Reordering Capability in CTC-based Non-Autoregressive End-to-End Speech Translation

Shun-Po Chuang* **Yung-Sung Chuang*** **Chih-Chiang Chang*** **Hung-yi Lee**

Abstract

We study the possibilities of building a non-autoregressive speech-to-text translation model using connectionist temporal classification (CTC), and use CTC-based automatic speech recognition as an auxiliary task to improve the performance. CTC's success on translation is counter-intuitive due to its monotonicity assumption, so we analyze its reordering capability. Kendall's tau distance is introduced as the quantitative metric, and gradient-based visualization provides an intuitive way to take a closer look into the model. Our analysis shows that transformer encoders have the ability to change the word order and points out the future research direction that worth being explored more on non-autoregressive speech translation.[1]

1 Introduction

Recently, there are more and more research works focusing on end-to-end speech translation (ST) (Bérard et al., 2016; Weiss et al., 2017; Bérard et al., 2018; Vila et al., 2018; Di Gangi et al., 2019; Ran et al., 2019; Chuang et al., 2020). Instead of cascading machine translation (MT) models to an automatic speech recognition (ASR) system, end-to-end models can skip the error bottleneck caused by ASR and be more computationally efficient. However, in the inference time, an autoregressive (AR) decoder is needed to decode the output sequence, causing the latency issue.

In MT, non-autoregressive (NAR) models have been heavily explored recently (Gu et al., 2018; Lee et al., 2018; Ghazvininejad et al., 2019; Stern et al., 2019; Gu et al., 2019; Saharia et al., 2020) by leveraging the parallel nature of transformer (Vaswani et al., 2017). In contrast, such kind of models is rarely explored in the field of speech translation, except for a concurrent work (Inaguma et al., 2020). In this work, we use connectionist temporal classification (CTC) (Graves et al., 2006) to train NAR models for ST, without an explicit decoder module. Our entire model is merely a transformer encoder. Multitask learning (Anastasopoulos and Chiang, 2018; Kano et al., 2021) on ASR, which is often used in speech translation, can also be applied in our transformer encoder architecture to further push the performance. We achieve initial results on NAR speech translation by using a single speech encoder.

CTC's success on the translation task is counter-intuitive because of its monotonicity assumption. Previous works directly adopt the CTC loss on NAR translation without further verification on the reordering capability of CTC (Libovický and Helcl, 2018; Saharia et al., 2020; Inaguma et al., 2020). To further understand the reason that the CTC-based model can achieve ST task, we analyze the ordering capabilities of ST models by leveraging Kendall's tau distance (Birch and Osborne, 2011; Kendall, 1938), and a gradient-based visualization is introduced to provide additional evidence. To the best of our knowledge, this is the first time to examine the ordering capabilities on the ST task.

We found that after applying multitask training, our model can have more tendency to re-arrange the positions of the target words to better positions that are not aligned with audio inputs. We highlight that our contribution is to 1) take the first step on translating pure speech signal to target language text in a NAR end-to-end manner and 2) take a closer look at the reason that NAR model with CTC loss can achieve non-monotonic mapping.

2 Approaches

2.1 CTC-based NAR-ST Model

We adopt transformer architecture for non-autoregressive speech-to-text translation (NAR-ST). The NAR-ST model consists of convolutional

August 1–6, 2021. ©2021 Association for Computational Linguistics

layers and self-attention layers. The audio sequence X is downsampled by convolutional layers, and self-attention layers will generate the final translation token sequence Y based on the downsampled acoustic features. We use CTC loss as the objective function to optimize the NAR-ST model. The CTC decoding algorithm allows the model to generate translation in a single step.

CTC predicts an alignment between the input audio sequence X and the output target sequence Y by considering the probability distribution marginalized over all possible alignments.

The CTC loss function is defined as:

$$\mathcal{L}_{\text{CTC}} = -\sum_{(x,y)\in D} \log p_\theta(y|x), \tag{1}$$

where x is audio frame sequence, y is target sequence, and D is the training set. CTC uses dynamic programming to marginalize out the latent alignments to compute the log-likelihood:

$$\log p_\theta(y|x) = \log \sum_{a\in\beta(y)} \prod_t p(a_t|x;\theta) \tag{2}$$

where $a = \{a_t\}_{t=0}^{|x|}$ is an alignment between x and y and is allowed to include a special "blank" token that should be removed when converting a to the target sequence y. $\beta^{-1}(a)$ is a collapsing function such that $\beta^{-1}(a) = y$ if $a \in \beta(y)$.

CTC has a strong conditional independence and monotonicity assumption. It means that the tokens in Y can be generated independently, and there exists a monotonic alignment between X and Y. The monotonicity property is suitable for tasks such as ASR. However, in translation tasks, there is no guarantee that the output sequence should follow the assumption, as word orders differ in different languages. In this work, we want to examine whether the powerful self-attention based transformer model can overcome this problem to some degree or not.

2.2 CTC-based Multitask NAR-ST Model

Multitask learning improves data efficiency and performance across various tasks (Zhang and Yang, 2017). In AR end-to-end ST, multitask learning technique is often applied using ASR as an auxiliary task (Anastasopoulos and Chiang, 2018; Sperber and Paulik, 2020). It requires an ASR decoder in addition to the ST decoder to learn to predict transcriptions while sharing the encoder.

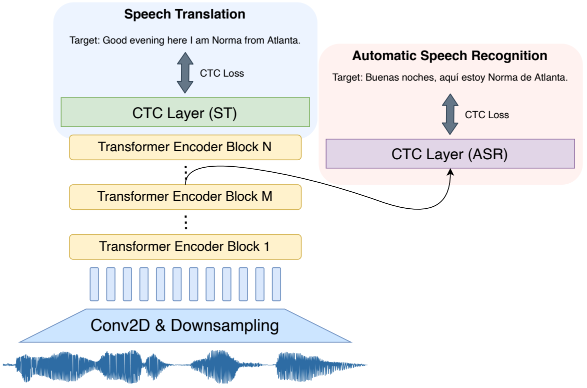

Figure 1: Multitask CTC model for ST and ASR.

To perform multitask learning on NAR-ST model, we propose to apply CTC-based ASR on a single M-th layer in the model, as illustrated in Figure 1. It helps the NAR-ST model capture more information with a single CTC layer in an end-to-end manner. And the ASR output will not be involved in the translation decoding process.

2.3 Reordering Evaluation – Kendall's Tau Distance

We measure reordering degree by Kendall's tau distance (Kendall, 1938). LRscore (Birch and Osborne, 2011) also introduced the distance with consideration of lexical correctness. Different from LRscore, we purely analyze the reordering capability rather than lexical correctness in this work.

Given a sentence triplet (T, H, Y), where $T = \langle t_1, ..., t_{|T|}\rangle$ is the audio transcription. $H = \langle h_1, ..., h_{|H|}\rangle$ and $Y = \langle y_1, ..., y_{|Y|}\rangle$ are hypothesis and reference translation, respectively. An external aligner provides two alignments: $\boldsymbol{\pi} = \langle \pi(1), ..., \pi(|T|)\rangle$ and $\boldsymbol{\sigma} = \langle \sigma(1), ..., \sigma(|T|)\rangle$. $\boldsymbol{\pi}$ maps each source token t_k to a reference token $y_{\pi(k)}$, and $\boldsymbol{\sigma}$ maps t_k to a hypothesis token $h_{\sigma(k)}$. We follow the simplifications proposed in LRscore to reduce the alignments to a bijective relationship. The proportion of disagreements between $\boldsymbol{\pi}$ and $\boldsymbol{\sigma}$ is:

$$\mathrm{R}(\boldsymbol{\pi}, \boldsymbol{\sigma}) = \frac{\sum_{i=1}^{|T|} \sum_{j=1}^{|T|} z_{ij}}{|T|(|T|-1)/2}$$

$$\text{where } z_{ij} = \begin{cases} 1 & \text{if } \pi(i) < \pi(j) \text{ and } \sigma(i) > \sigma(j) \\ 0 & \text{otherwise} \end{cases}$$

Then, we define the term **reordering correctness** R_{acc} by introducing the brevity penalty (BP):

$$\mathrm{R}_{acc} = (1 - \sqrt{\mathrm{R}(\boldsymbol{\pi}, \boldsymbol{\sigma})}) * BP$$

$$\text{where } BP = e^{1-|Y|/|H|} \text{ if } |H| \leq |Y| \text{ else } 1$$

Method	fisher_dev	fisher_dev2	fisher_test	CH_devtest	CH_evltest	Speed-Up

Table 1: BLEU on Fisher Spanish dataset and CALLHOME (CH) dataset, including autoregressive and non-autoregressive models. The abbreviation *b* stands for the beam size for beam search decoding. Multitask learning (MTL) represents using ASR as the auxiliary task trained with ST. In *Autoregressive Models*, the auxiliary loss always applied on the final encoder output in MTL, and we applied it on different layers in NAR models.

The higher the value, the more similar between two given alignments. Ideally, a well-trained model could handle the reordering problem by making $\boldsymbol{\sigma}$ close to $\boldsymbol{\pi}$ and result in $R_{acc} = 1$.

3 Experiments

3.1 Experimental Setup

We use the ESPnet toolkit (Watanabe et al., 2018) for experiments. We perform Spanish speech to English text translation with Fisher Spanish corpus. The test sets of CALLHOME corpus are also included for evaluation. The dataset details and download links are listed in Appendix B.

The NAR-ST model consists of two convolutional layers followed by twelve transformer encoder layers. Knowledge distillation (Kim and Rush, 2016) is also applied. More training details and parameter settings can be found in Appendix C.

3.2 Translation Quality and Speed

We use BLEU (Papineni et al., 2002) to evaluate the translation quality, as shown in Table 1. Beam-search decoding with beam-size *b* is considered for the AR models in this experiments. Greedy decoding is always used for the NAR models.

In the results of AR models (part (A)), multitask learning (MTL) can get better performance compared to the model without jointly training with an auxiliary task (row (b) v.s (a)). Further improvement can be brought by using a pre-trained ASR encoder as the initialization weight (row (c) v.s (b)). It shows that using ASR data for MTL and initialization are the essential steps to achieve exceptional performance. The performance drops when beam-size decreases, which shows a trade-off between the decoding speed and the performance (row (c) v.s (d)(e)).

To better optimize the decoding speed, NAR-ST provide a great solution to reach a shorter decoding time (part (B)). NAR-ST models is ×28.9 faster than the AR model with beam-size 10 (part (B) v.s rows (a)-(c)) and ×3.4 faster than the AR model with greedy decoding (part (B) v.s row (e)). We initialize the NAR-ST models with the weight pre-trained on ASR task and applied the proposed MTL approach on different intermediate layers (rows (g)-(j)). As the results showed in part (B), applying MTL on the higher layers improves the performance (rows (i)(j) v.s (f)). It shows that speech signal needs more layers to model the complexity, and sheds light on selecting the intermediate layer to apply MTL is essential. We also evaluate the ASR results of the MTL models in Appendix D.

Some text-based refinement approaches can further improve the translation quality (Libovickỳ and Helcl, 2018; Lee et al., 2018; Ghazvininejad et al., 2019; Gu et al., 2019; Chan et al., 2020). We leave it as the future work and focus on analyzing the reordering capability of the CTC-based model.

3.3 Word Order Analysis

In this section, we discuss the word ordering problem in the translation task. We use R_{acc} defined in section 2.3 to systematically evaluate the reordering correctness across the corpora. Besides, we examine the gradient norm in models to visualize the reordering process.

Quantitative Analysis We use SimAlign (Sabet et al., 2020) to align the transcriptions and translations with details in Appendix E. Table 2 shows

		R_{acc}		
	Method	**dev**	**dev2**	**test**
(a)	random permutaion	41.37	41.84	42.42
	Autoregress Models			
(b)	Tr. (b=10)	77.79	79.16	79.09
(c)	Tr. + MTL (b=10)	79.32	80.18	80.30
	Non-Autoregress Models (Ours)			
(d)	CTC	71.69	74.00	74.57
(e)	CTC+MTL@8	71.91	74.35	74.96

Table 2: The reordering correctness evaluated on Fisher Spanish dataset. The values are selected as the best among 4 references. Tr. stands for Transformer. All models are initialized with pretrained ASR.

R_{acc} evaluated on ST models. We included the correctness of random permutation as a baseline.

The AR models obtain high R_{acc} scores (rows (b)(c)), it shows that the AR model can handle a complex word order. The NAR models also have the ability to rearrange words (rows (d)(e) v.s. (a)) but are weaker than AR models due to the independent assumption brought by CTC. An interesting observation is that applying MTL tends to improve R_{acc} (rows (c)(e) v.s. (b)(d)). We conclude that the monotonic natural in ASR improves the stability in training ST (Sperber et al., 2019).

To investigate the relation between model performance and the reordering difficulty, we measure the reordering difficulty by $\mathrm{R}_{\boldsymbol{\pi}} = \mathrm{R}(\boldsymbol{\pi}, \boldsymbol{m})$, where $\boldsymbol{m} = \langle 1, ..., |T| \rangle$ is a dummy monotonic alignment. We split all the testing data (dev/dev2/test) into smaller equal-size groups by different reference $\mathrm{R}_{\boldsymbol{\pi}}$. The BLEU scores for these groups were plotted in Figure 2. Obviously, AR models are more robust to higher reordering difficulty. Nonetheless, we observed that when MTL is applied at layer 8, CTC model is more robust to reordering difficulty, in some cases ($\mathrm{R}_{\boldsymbol{\pi}}$<0.07) even come close to the AR model without ASR pretraining.

Gradient-based Visualization We consider the gradient norm as an approximated indicator of reordering in our model. For each output token h_i, we concatenate the relative influence on it across all layers, which yields a matrix $\mathbf{O}^i \in \mathbb{R}^{|X| \times L}$, where each row is a frame and each column is a layer. We refer to this as the reordering matrix for token h_i. We leave the computational details in Appendix H.

Figure 3 shows a reordering matrix for token `_thing`. We can observe that the single-task CTC model (Figure 3, right) tends to keep focusing on the same position of the output token `_thing` at the lower layers. In contrast, the model with MTL (Figure 3, left) does not focus on the same position at the lower layers. It can focus more on the other position where the corresponding speech segment appears, and aggregate the information to the output position at the higher layers. Additional examples can be found in Appendix I.

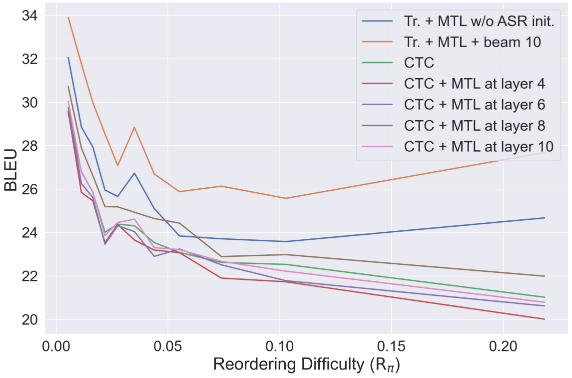

Figure 2: The BLEU score curve under different reordering difficulties (R_π). Details are in Appendix G.

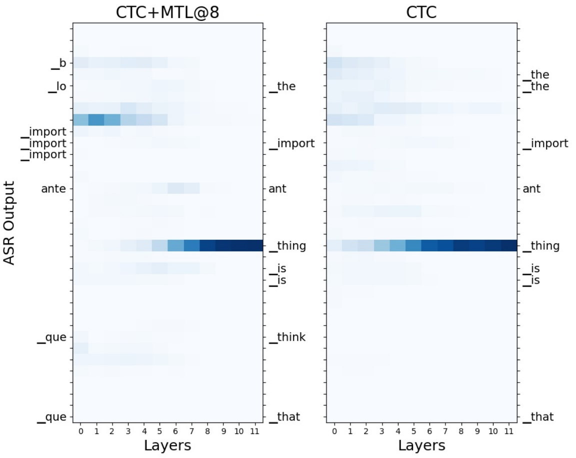

Figure 3: The re-ordering matrix of the token "thing". The ASR output from MTL model is included as a proxy for word positioning in source speech.

4 Concluding Remarks

We propose a CTC-based NAR-ST model with an auxiliary CTC-based ASR task and are the first to study the reordering capability in CTC-based NAR-ST model. R_{acc} is adopted to analyze reordering in the ST task, and gradient-based visualizations reveal the internal manipulation of the models. Besides trying to improve BLEU scores, we encourage future research on NAR models to also evaluate whether the NAR models have inferior reordering capabilities in order to close the gap between AR and NAR models.

Broader Impact and Ethical Considerations

We believe that our work can help researchers in the NLP community understand more about the non-autoregressive speech translation models, and we envision that the model proposed in this paper will equip the researchers with a new technique to perform better and faster speech translation. We do not see ourselves violating the code of ethics of ACL-IJCNLP 2021.

A Source Code

Please download our code at https://github.com/voidism/NAR-ST and follow the instructions written in `README.md` to reproduce the results.

B Dataset Details

We use the Fisher and CALLHOME Spanish dataset (a Spanish-to-English speech-to-text translation dataset), which can be downloaded in the following links: 1) Fisher Spanish Speech https://catalog.ldc.upenn.edu/LDC2010S01
2) CALLHOME Spanish Speech https://catalog.ldc.upenn.edu/LDC96S35
3) Fisher and CALLHOME Spanish–English Speech Translation https://catalog.ldc.upenn.edu/LDC2014T23.

B.1 Statistics

The data statistics are listed in Table 3.

Data Split	# of Utterance	Duration (hours)
Training sets		
fisher_train	138792	171.61
Validation sets		
fisher_dev	3973	4.59
fisher_dev2	3957	4.70
callhome_devtest	3956	3.82
Testing sets		
fisher_test	3638	4.48
callhome_evltest	1825	1.83

Table 3: The data statistics of the Fisher and CALLHOME Spanish dataset.

B.2 Preprocessing

We use ESPnet to preprocess our data. For text, we use Byte Pair Encoding (BPE) (Sennrich et al., 2016) with vocabulary size 8,000. We convert all text to lowercase with punctuation removal. For audio, we convert all audio files into wav file with a sample frequency of 16,000. We extract 80-dim fbank without delta. We use SpecAugment (Park et al., 2019) to augment our data. More details can be found in our source code in Appendix A.

C Training Details

C.1 Computing Infrastructure and Runtime

We use a single NVIDIA TITAN RTX (24G) for each experiment. The average runtime of experiments in Table 1 is 2-3 days for both autoregressive and non-autoregressive models.

C.2 Hyperparameters

Our training hyperparameters are listed in Table 4. We do not conduct hyperparameter search, but follow the autoregressive ST best setting in ESPnet toolkit (Watanabe et al., 2018), and use the same hyperparameter for our non-autoregressive models. Due to the limited budget, we run each experiment for once. For inference stage of CTC-based models, we simply use greedy decode to produce the output sequences.

Hyperparameter	Value
encoder layers	12
hidden units	2048
attention dimension	256
attention heads	4
label smoothing weight	0.1
batch size	64
optimizer	noam
learning rate	2.5
warmup steps	25000
attention dropout rate	0.0
gradient accumulate step	2
gradient clipping	5.0
epoch	30
dropout rate	0.1

Table 4: The main hyperparameters in the experiment.

C.3 Knowledge Distillation

To perform sequence-level knowledge distillation (Seq-KD) (Kim and Rush, 2016) to improve the performance of NAR models, we firstly trained an autoregressive transformer-based MT model on the transcriptions and translations in same training set with ESPnet. Then we used the trained model to produce the hypotheses with beam search size of 1 for the whole training set. We swapped the ground truth sequences with the hypotheses for all NAR ST model training. We also show the ablation results on knowledge distillation in Table 5.

We also try the possibility of using the autoregressive ST model to produce the hypotheses for Seq-KD, but the results are not as good as using a MT model. The results are shown in the second row in Table 5. The download links to MT/ST decode results for conducting Seq-KD are also provided in the `README.md` file in our source code (See Appendix A).

Method	Fisher			CALLHOME	
	dev	dev2	test	devtest	evltest
NAR w/ MT Seq-KD	**44.45**	**45.23**	**44.92**	**14.20**	**14.19**
NAR w/ ST Seq-KD	41.08	41.28	40.85	13.63	13.27
NAR w/o Seq-KD	41.59	43.13	42.25	13.05	12.81

Table 5: Ablation test on sequence-level knowledge distillation (Seq-KD) on Fisher Spanish dataset and CALLHOME (CH) dataset. The NAR model we used is CTC+MTL at 8-th layer.

C.4 Model Selection

When evaluating the models, we average the model checkpoints of the final 10 epochs to obtain our final model for NAR experiments. For AR experiments, we follow the original setting in ESPnet to average the 5 best-validated model checkpoints to obtain the final model.

C.5 Model Size

The number of parameters of our CTC model is 18.2M. The number of parameters of the autoregressive model is 27.9M.

D Automatic Speech Recognition Evaluation

Method	Fisher		
	dev	dev2	test
CTC+MTL@4	47.84	46.79	45.97
CTC+MTL@6	40.21	39.02	38.08
CTC+MTL@8	32.87	31.99	30.88
CTC+MTL@10	**29.31**	**28.36**	**27.10**

Table 6: The Word Error Rate (WER) on Fisher Spanish dataset of CTC results of the intermediate layers in multitask CTC models.

We compute the Word Error Rate (WER) for ASR output obtained from the intermediate ASR branch of our proposed models. The results are shown in Table 6. We can observe that when applying multitask learning in the higher layers, the WER becomes lower. It indicates that ASR need more layers to perform better. However, the best ST scores are achieved by CTC+MTL@8 instead of CTC+MTL@10. It may be caused by the fact that there are only two transformer encoder layers for CTC+MTL@10 to perform ST. It may be too difficult for the model to convert the information from source language to target language in two encoder layers, even though the lower WER indicates useful information is provided to perform ST.

E SimAlign setup

We use the released code[2] by the authors of SimAlign as the external aligner to obtain word alignments used for calculating reordering metrics. SimAlign uses contextualized embeddings from pretrained language models, and there are several proposed algorithms to do word alignments. We use XLM-R (Conneau et al., 2019) as the underlying contextualized word embeddings with the itermax matching algorithm.

F Reordering Difficulty

We provide reordering difficulty measured on all en-xx language pairs in CoVoST2 dataset in Table 7.

en-xx	R_π	en-xx	R_π
de	5.92	tr	15.80
zh-CN	10.63	fa	13.93
ja	20.86	sv-SE	2.94
ar	6.04	mn	16.28
et	5.98	cy	5.78
ca	4.39	id	3.41
sl	5.13	ta	15.57
lv	5.34		

Table 7: The training set reordering difficulty evaluated on each pairs of languages in the CoVoST2 dataset.

G Details on Figure 2

In Figure 2, the primary goal is to view the relation between reordering difficulty and the model's performance. We describe the method used in (Birch and Osborne, 2011) to represent the reordering difficulty as follows: For each example in the fisher dev and test set, calculate Kendall's tau distance between 1) its reference alignment (alignment between source transcription and reference translation) and 2) a dummy monotonic alignment, which is just the sequence 1...m. Intuitively this shows how much the reference alignment disagrees with monotonic alignment, and hence the reordering difficulty. Next, we divide all examples into 10 bins, where each bin contains examples with similar reordering difficulty, and all bins have an equal number of examples. Finally, we calculate the BLEU score of the hypotheses in each bin. The result is plotted in Figure 2.

---

[2] `https://github.com/cisnlp/simalign`

H Gradient-based Visualization

We first obtain a saliency matrix $\mathbf{J}^M \in \mathbb{R}^{|X| \times |X|}$ for the M-th transformer layer by computing the gradient norm of output logits w.r.t. the latent representations of each timestep in that layer. An example is shown in Figure 4. Then, we normalize $\mathbf{J}^M$ across the dimension corresponding to the source audio sequence. Intuitively, the i-th column of $\mathbf{J}^M$ can be interpreted as the relative influence of the representations at each position on the i-th output token.

Consequently, we proceed to re-arrange $\mathbf{J}^M$ in the following way: for each output token h_i, we concatenate the relative influence on it across all layers, which yields the reordering matrix for token h_i, denoted as $\mathbf{O}^i \in \mathbb{R}^{|X| \times L}$.

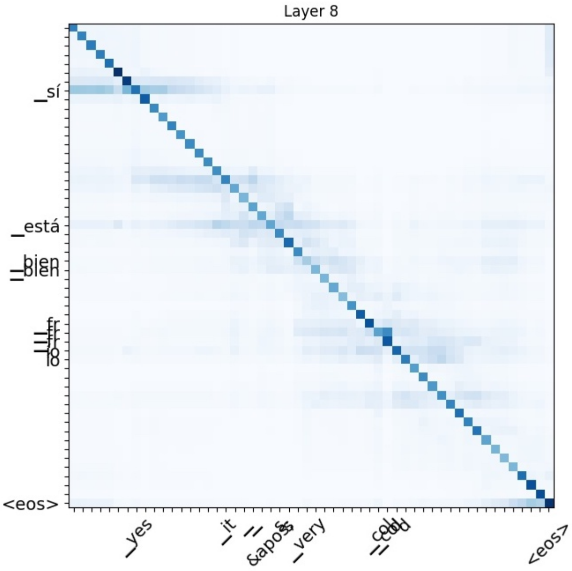

Figure 4: The saliency matrix of layer 8 input.

I Reordering Matrix

We provide some additional examples of visible reordering in our CTC-based models. In Figure 5, "_`we`" is heavily influenced by the position of audio signal "amos", even though the ASR output is incorrectly predicted as "as". In Figure 6, "_`you`" also influenced by audio signal "usted". It is interesting to observe that in some cases the pure CTC-based model appears more capable of reordering, while in others it does not.

J Higher Reordering Difficulty

We address instances of higher difficulty by analyzing Figure 7. In the figure, the horizontal axis corresponds to the reordering difficulty, and the vertical axis corresponds to the reordering correctness. In this figure, there is a very consistent decrease in reordering correctness when reordering difficulty increases, and the rate of decrease is very similar between NAR and AR models. This observation reveals that when evaluated on distant language pairs, that the reordering difficulty is large, the gap between NAR and AR will probably remain roughly the same. We will conduct experiments on different language pairs to verify the above claim in future work.

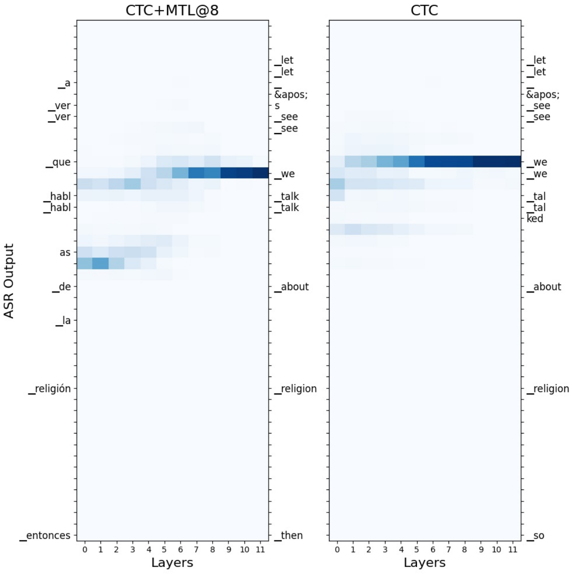

Figure 5: The re-ordering matrix of the token "_`we`".

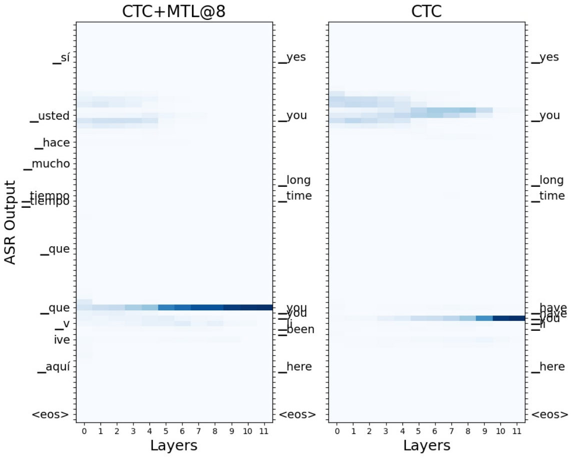

Figure 6: The re-ordering matrix of the token "_`you`".

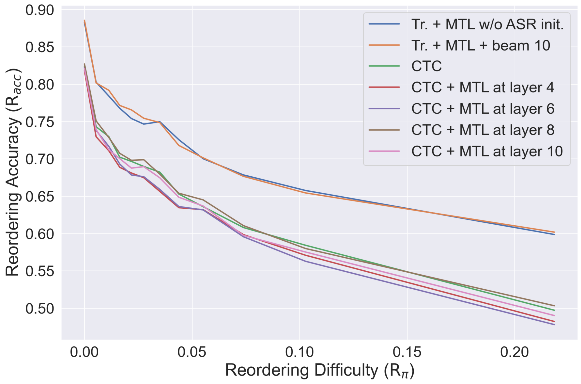

Figure 7: The reordering accuracy (R_{acc}) curve under different reordering difficulties (R_π).

Code Summarization with Structure-induced Transformer

Abstract

Code summarization (CS) is becoming a promising area in recent language understanding, which aims to generate sensible human language automatically for programming language in the format of source code, serving in the most convenience of programmer developing. It is well known that programming languages are highly structured. Thus previous works attempt to apply structure-based traversal (SBT) or non-sequential models like Tree-LSTM and graph neural network (GNN) to learn structural program semantics. However, it is surprising that incorporating SBT into advanced encoder like Transformer instead of LSTM has been shown no performance gain, which lets GNN become the only rest means modeling such necessary structural clue in source code. To release such inconvenience, we propose structure-induced Transformer, which encodes sequential code inputs with multi-view structural clues in terms of a newly-proposed structure-induced self-attention mechanism. Extensive experiments show that our proposed structure-induced Transformer helps achieve new state-of-the-art results on benchmarks.

1 Introduction

By 2020, software development and maintenance become an indispensable part of human work and life. Various assistant technical measures have been taken to facilitate more enjoyable software development, among which it is especially welcomed by programmers when there is a code summarization task generating sensible human language annotations automatically.

Code (Java)

```
private void attachPlot (SVGPlot newplot) {
    this.plot = newplot;
    if (newplot == null) {
        super.setSVGDocument(null);
        return;
    }
    newplot.synchronizeWith(synchronizer);
    super.setSVGDocument(
        newplot.getDocument());
    super.setDisableInteractions(
        newplot.getDisableInteractions());
}
```

Summ. Attach to a new plot and display.

Code (Python)

```
def get_change_lines_in_file_for_tag(tag,
                                     change_dict):
    cleaned_lines = []
    data_list = change_dict.get('data', [])
    for data_dict in data_list:
        block = data_dict.get('block', '')
        lines = block.split('\\n')
            for line in lines:
                index = line.find(tag)
                if (index >(-1)):
                    line = line[index:]
                    cleaned_lines.append(line)
    return cleaned_lines
```

Summ. The received change_dict is the jsonified version of the changes to a file in a changeset being pushed to the Tool Shed from the command line. This method cleans and returns appropriate lines for inspection.

Table 1: Task samples of code summarization, where summ. refers to the output summary.

In early days, code summarization was a derivative problem of information retrieval (Haiduc et al., 2010; Eddy et al., 2013; Wong et al., 2013, 2015) by matching the most similar code snippets which are labeled with summaries. Such method lacks generalization and performs unsatisfactorily. Thus in recent years, researchers treated code summarization as a task of language generation (Iyer et al., 2016; Liang and Zhu, 2018), which usually depends on RNN-based Seq2Seq models (Cho et al., 2014; Bahdanau et al., 2015).

It is already known that RNN-based models may encounter bottleneck when modeling long

Transformer + SBT	✓	✓	
SiT	✓	✓	✓

Table 2: Comparison of the previous models with proposed SiT model. The last column refers to whether input features match with the corresponding model.

sequences due to its poor long-term dependency. For instance, a normal snippet of Java as shown in Table 1 usually has hundreds of tokens. More recently, Ahmad et al. (2020) used an enhanced Transformer-based model to capture long-term and non-sequential information of source code, which outperformed previous RNN-based models by a large margin.

On the other hand, in the light of the structural nature of programming languages, structure clues are supposed to greatly enhance programming language processing task like code summarization (Fernandes et al., 2019). Indeed, substantial empirical studies showed that Abstract Syntax Tree may help models better comprehend code snippets and achieve more sensible generation results. Previous approaches could be divided into two categories. The first is to employ non-sequential encoders (e.g., TBCNN (Mou et al., 2016), Tree-LSTM (Shido et al., 2019), Tree-Transformer (Harer et al., 2019), Graph Neural Network (Allamanis et al., 2018; Liu et al., 2020; Alex et al., 2020; Wang et al., 2021)) to directly model structural inputs. The other is to pre-process structural inputs to apply sequential models on them. Uri et al. (2019) used LSTM to encode code structure by sampling possible paths of AST. Another similar work is structure-based traversal (SBT) (Hu et al., 2018a), which manages to flatten ASTs into linear sequences.

Though existing studies achieve success on the concerned code summarization task more or less, there is still room in improving both of the above modeling approaches. It is well known RNN encoders like LSTM only have limited capabilities in capturing long-range dependencies in sequence, and GNN-like models may be too sensitive to local information, which casts a natural solution, what if incorporating SBT into the Transformer? However, it is surprising that SBT only works effectively with LSTM but not the Transformer according to Ahmad et al. (2020). We attribute this to the linear and nonlinear inconsistence between SBT and encoder forms. SBT enables sequential encoders to learn non-sequential relationship (such as syntax) still in a certain elaborate linear forms. RNN may be effectively enhanced by SBT right because of its sequential architecture through attention mechanism. Transformer learns features through self-attention network (SAN), nevertheless which acts more like a non-sequential process. Consequently, such sequential features are unsuitable for a non-sequential architecture to extract implicit structural information. We boldly call it Feature-Model Match problem in Table 2. In this paper, we thus design an improved Transformer variants, structure-induced Transformer (SiT) to alleviate such difficulty in terms of a structure-induced self-attention mechanism, so that the resulted model may enjoy both merits, capturing long-range dependencies and more global information. The proposed model design has been applied to benchmark datasets and helps achieve new state-of-the-art performance.

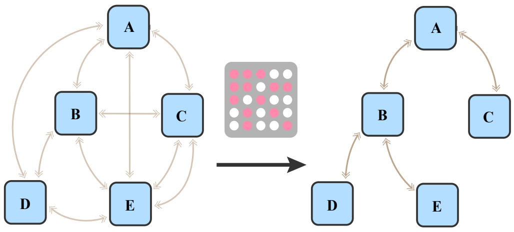

Figure 1: Use of adjacency matrix to transform original self-attention, left-hand complete graph, into structure-induced self-attention, right-hand graph which looks clear-cut. Note that we omit self-circles for concision.

2 Structure-based Code Summarization

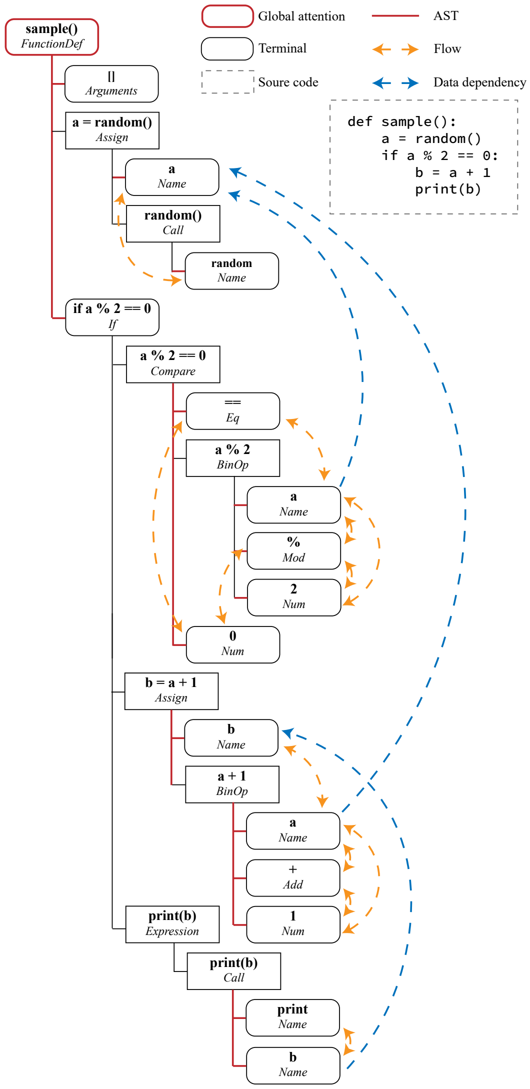
The following sections present our code summarization method with two parts, in which the first is about structure representation of code, and the second is our proposed structure-induced Transformer.

2.1 Structure Representation of Code

Note that programming language like source code is subtle that certain different formats may result in different compilations. Thus pre-processing could be an great impact in code summarization.

We adopt Abstract Syntax Tree (AST) for representing the language grammar of source code as usual. Figure 2 depicts a typical AST, which is composed of terminal nodes and non-terminal nodes. A non-terminal node represents certain construction like *If* and *BinaryOp*, while terminal nodes represent its semantic components, such as identifiers and numbers.

In model implementation, we adopt adjacency matrix A to represent the AST instead of structure based traversal method as in Hu et al. (2018a), which represents tree structure in a sequential format. Such choice is well compatible with Transformer, which calculates attention weights by performing a dot-product of key-query pairs and results in an attention matrix of $l \times l$. We let l equal to number of AST nodes, then code summarization with Transformer becomes possible through applying a position-wise multiplication of A and original attention matrix.



```
def sample():
    a = random()
    if a % 2 == 0:
        b = a + 1
        print(b)
```

Figure 2: A Python code sample of multi-view graph used in Si-SAN. The code snippet is referred from Liu et al. (2020), which is original in Java.

Inspired by Code Property Graph (CPG) (Yamaguchi et al., 2014; Liu et al., 2020), we further expand AST into a multi-view network (MVN or multi-view graph) (Sindhwani et al., 2005; Zhou and Burges, 2007; Kumar et al., 2011). An MVN is composed of multiple views, each view corresponding to a type of structural relationships while all views sharing the same set of vertexes (Shi et al., 2018). In this paper, we construct a three-view graph based on different code semantics, which are abstract syntax, control flow and data dependency. We show an example in Figure 2, where we use colorful strokes to describe different compositions in the graph. Note that we only utilize terminal nodes which are marked as rounded rectangles.

Specifically, we first generate an AST, on the basis of which we add additional edges to further represent the flow of control and data. For control flow, since Transformer is order-sensitive with position encoding, we only need to focus on each statement node. For instance, nodes b, $=$, a, $+$, 1 make a complete statement $b{=}a{+}1$. We connect each of them since they are in the same execution order. For data dependencies, we connect relevant data across the whole program, as the variable b in expression *print(b)* and assignment $b{=}a{+}1$ respectively, where the former is defined and loaded from the latter.

Now we may obtain three adjacency matrices of syntax, flow and dependency respectively, which are colored in red, yellow and blue in Figure 2. We combine them together and finally obtain a multi-view graph. Additionally, we add global attention on the root, which is allowed to attend to all tokens in the code, and all tokens in the code can attend to it. With aggregated structure, our structure-based code summarization is expected to capture various semantics of programs.

Note that our multi-view graph is different from CPG. which is original for C/C++ only and we do not find an appropriate analysis platform for other languages.

2.2 Structure-induced Transformer

Followed by appropriate structure representation and graph construction, we now propose our structure-induced Transformer (SiT) for code summarization, which is a structure-sensitive transformer (Zhang et al., 2020b; Narayan et al., 2020; Xu et al., 2020) model and is able to comprehend code snippets both semantically and syntac-

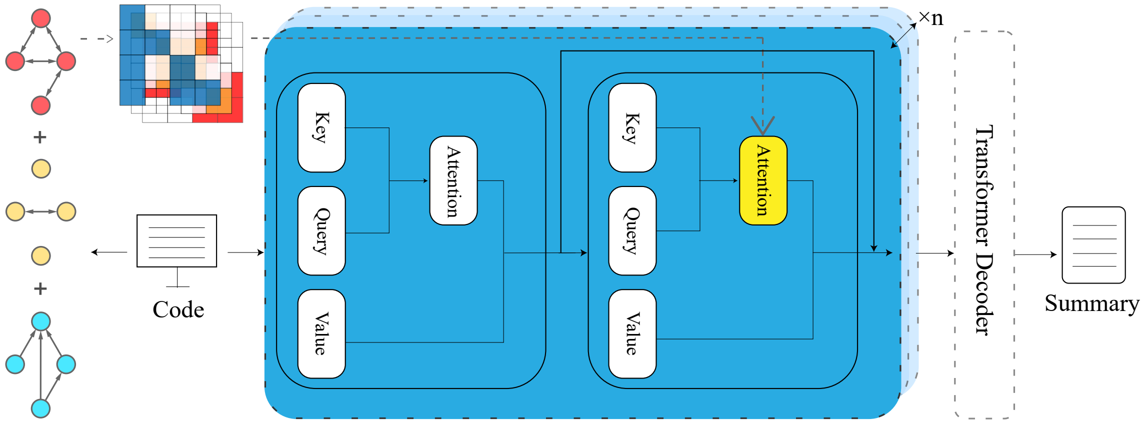


Figure 3: Overall architecture of Structure-induced Transformer (SiT).

tically. Meanwhile, we do not introduce extra parameters in SiT so that guarantee the training efficiency. In this section, we first review the self-attention network (SAN) of Transformer in terms of attention graph. Then we correspondingly propose structure-induced self-attention to build the structure-induced Transformer.

Vanilla Self-Attention Transformer is composed of stacks of identical layers for both encoder and decoder (Vaswani et al., 2017). Each layer emphasizes on self-attention mechanism, which is denoted as:

$$SAN(X) = Softmax\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (1)$$

where $X = (x_1, \ldots, x_l)$ denotes the input sequence of sub-words, l denotes the sequence length and d_k denotes the hidden size per head. Now we view each sub-word as a vertex n and inner product of each key-value pair as a directed edge e, the SAN can be described as a directed cyclic graph. Equation 1 can be rewritten as follow:

$$SAN(X) = E \cdot N \quad (2)$$

The attention scores $E = \{e_{ij}\}$ refers to a weight matrix of edges where e_{ij} represents how significant node n_i attend to node n_j, while value matrix $N = \{n_i\}$ refers to each node representation. Figure 1 depicts the process of calculating attention scores.

Note that SAN actually generates a fully connected cyclic graph without consideration of the very needed structure-aware representation for our concerned task.

Structure-induced Self-Attention To represent the needed structure information, we propose structure-induced self-attention network (Si-SAN).

Specifically, we introduce multi-view network into Equation 1, that is, multiply the adjacency matrix by key-query pairs:

$$SiSAN(X) = Softmax\left(\frac{A_{mv} \cdot QK^T}{\sqrt{d_k}}\right)V \quad (3)$$

where A_{mv} refers to the multi-view representation of code.

Note that Si-SAN does not change the input code but appropriately incorporate code structure into SAN by changing its attention pattern. As shown in Figure 1, when $a_{ij} = 0$ in A_{mv}, the attention between n_i and n_j will be dropped out (Wu et al., 2021). We consequently obtain a more explicit attention graph. Different from calculating global information onto the whole sentence in original SAN, Si-SAN is expected to calculate structural information more accurately.

Structure-induced Module To enhance robustness and avoid over-pruning, we introduce structure-induced module, which is a stack of two layers, SAN and Si-SAN. In each module, SAN is followed by Si-SAN and the output is the combination of both layers. Specifically, given input sequence $X = (x_1, \ldots, x_l)$, where l denotes sequence length, we first pass it through an SAN layer to obtain hidden representation denoted as $H = (h_1, \ldots, h_l)$:

$$H = Concat(SAN_1(X), \ldots, SAN_h(X)) \quad (4)$$

where h refers to number of heads of multi-head attention while SAN_i refers to self-attention of

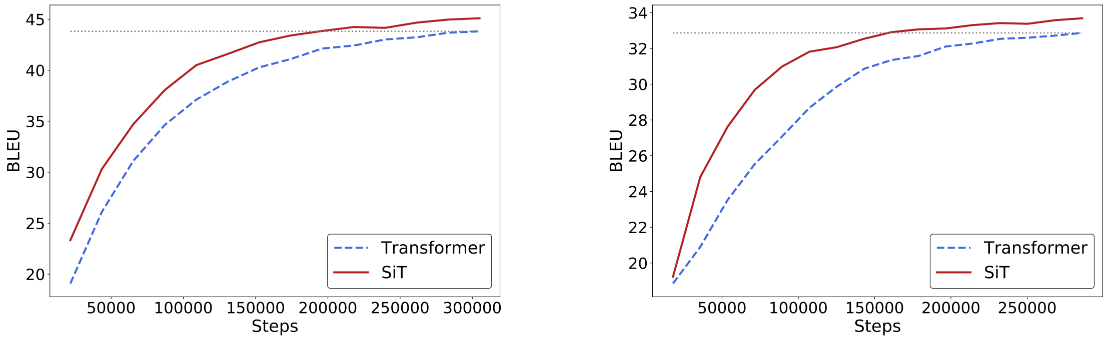
The results of upper part are directly reported from Ahmad et al. (2020). Note that we only rerun Transformer and CodeBERT since they are much stronger than the other baselines. However, our results are even stronger. We show the ranges compared to the Transformer in Ahmad et al. (2020).



(a) BLEU score with training steps on Java

(b) BLEU score with training steps on Python

Figure 4: Convergence between Transformer and SiT.

head i. Subsequently, we pass H through a Si-SAN layer to obtain $H' = (h'_1, \ldots, h'_l)$:

$$H' = Concat(SiSAN_1(H), \ldots, SiSAN_h(H)) \tag{5}$$

Finally, we use an aggregation to fuse H and H' to obtain final representation $\bar{H} = (\bar{h}_1, \ldots, \bar{h}_l)$:

$$\bar{H} = Aggr(H, H') \tag{6}$$

where the aggregation we use is simple position-wise sum. We explore that the structure-induced module is more robust and leads to a better performance. In each stack, model begins to learn global information with SAN, where all connections are available. Subsequently, through Si-SAN, model is told which of the connections are useful and which should be shut down and thus avoiding over-pruning. Note that SiT with 3 stacks of structure-induced modules still consists of 6 encoder layers and 6 decoder layers, but only changes the architecture between modules of Transformer, not introducing any extra parameters.

Figure 3 depicts the overall architecture of SiT. Compared to original Transformer, our SiT with Si-SAN encodes a more accurate relative representation of code through pruning redundant connections.

2.3 SiT-based Code Summarization

Based on our structure-induced Transformer (SiT), now we specify our code summarization process.

We first transform the input code into adjacency matrices of multiple views and combine them through a weighted sum:

$$A_{mv} = \alpha A_{ast} + \beta A_{fl} + \gamma A_{dp} \tag{7}$$

where α, β, γ refer to the corresponding weight for each view. Then we pass code sequences and corresponding adjacency matrices into SiT encoder, which contains 3 Si-SAN layers. For decoder, we apply original Transformer decoder with cross attention. Finally, the summarization of the input code is generated through autoregressive decoding.

3 Experiments

3.1 Datasets and Pre-processing

Datasets Our experiments are conducted on two benchmarks of Java (Hu et al., 2018a) and Python (Wan et al., 2018), and for both we follow their training, test and development divisions.

Graph Construction For Java code, we refer to the method provided in (Hu et al., 2018a). They use *javalang* module of Python to compile Java and fetch AST in a dictionary form. For Python code, we generate trees by ourselves based on *ast* and *asttokens* modules. Finally, we write a script to resolve ASTs into multi-view adjacency matrices[1], where we let $\alpha = \beta = \gamma = 1$ for all experiments[2].

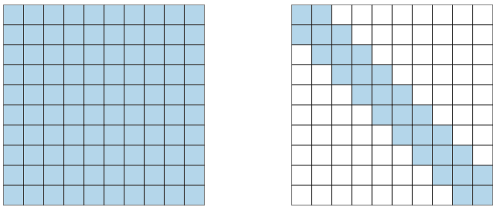
Out-Of-Vocabulary Code corpus in programming language may have a much bigger vocabulary than natural language, including vast operators and identifiers. We have to introduce vast out-of-vocabulary (OOV) tokens (usually replaced by $\langle$UNK$\rangle$) (Hu et al., 2018a) to keep it in a regular size. To avoid OVV problem, we apply *CamelCase* and *snake_case* tokenizers (Ahmad et al., 2020) to reduce code vocabulary and remove all extra nodes which do not correspond to specific tokens.

3.2 Baselines

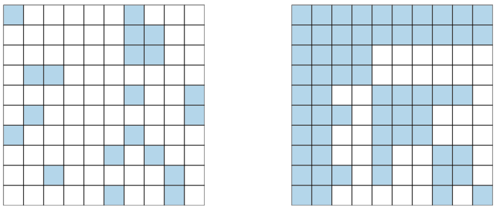
We take all three categories of state-of-the-art models as our baselines for comparison.

Transformer We refer to the enhanced Transformer in (Ahmad et al., 2020) which equipped with copy attention (See et al., 2017) and relative position encoding (RPE) (Shaw et al., 2018). For fair enough comparison, we run their model on our machine under the same environment with SiT. Note that we also utilize RPE in SiT because of its better capability in capturing long sequences, while we do not utilize copy attention.

LSTM This group includes all relevant LSTM models with sequential and non-sequential inputs (Iyer et al., 2016; Eriguchi et al., 2016; Wan et al., 2018; Hu et al., 2018a,b; Wei et al., 2019).



(a) Full (b) Window



(c) Random (d) Structure-induced

Figure 5: Comparison of different types of self-attention pattern. (b) Window attention with $w = 2$. (c) Random attention with $r = 2$.

Pre-trained Language Model We also compare our model with CodeBERT (Feng et al., 2020), a pre-trained language model on both natural and programming languages. It is pre-trained over six programming languages with MLM (Devlin et al., 2019) and RTD (Clark et al., 2020).

3.3 Training Details

We train our model on a single nVidia Titan RTX with batch size in $\{32, 64\}$. The learning rate is in $\{$3e-5, 5e-5$\}$ with warm-up rate of 0.06 and L2 weight decay of 0.01. The maximum number of epochs is set to 150 for Transformer and 30 for CodeBERT. For validation, we simply use greedy search, while for evaluation, we use beam search with beam size in $\{4, 5, 8\}$ and choose the best result[3].

3.4 Main Results

Scores Table 3 shows the overall results on Java and Python benchmarks. The Transformer baseline is strong enough as it outperforms all the previous works by a significant margin. However, our model is more powerful, further boosting Transformer with more than 1 BLEU points on Java and Python respectively and achieves new state-of-the-art results. Specifically, SiT achieves higher scores

---

[1] https://github.com/gingasan/astruc

[2] We try to adjust the weights of three views, showing little performance variant, which suggests that self-attention network itself may balance the relative significance between the three.

[3] https://github.com/gingasan/sit3

on Python, increasing by 1.59, 1.62 and 1.34 points on BLEU, ROUGE-L and METEOR respectively. According to dataset statistics, Python contains 5 times more unique code tokens than Java, which makes it much more challenging. Thus the superiority of SiT on Python tends to be notable. Even so, SiT still boosts Transformer by 1.18, 0.82 and 1.15 points on BLEU, ROUGE-L and METEOR respectively on Java.

Convergence Moreover, Figure 4 shows the trend of BLEU scores on development set over training steps. SiT achieves a much faster convergence rate than Transformer. For instance on Python dataset, SiT arrives the best performance of Transformer in about 100 epochs, while the latter one still needs 50 more to finally achieve the optimal. Note that the running time of each epoch for both models is the same. Such high convergence rate helps showcase the necessity of Si-SAN.

Pre-training On the other hand, we can see that CodeBERT also achieves competitive results on both Java and Python. However, SiT is still more powerful on most metrics, which outperforms CoderBERT by 2.15, 0.95 and 1.15 points on BLEU, ROUGE-L and METEOR respectively on Java. However, CodeBERT performs much better on Python, which outperforms SiT by 1.00 and 0.58 points on ROUGE-L and METEOR. Note that CodeBERT is much bigger in size than Transformer and SiT (see Appendix A).

For further verification, we follow CodeBERT and conduct a RoBERTa-based (Liu et al., 2019) SiT to further fine-tune on both Java and Python. As shown in Table 3, pre-trained SiT obtains attractive results, further improving CodeBERT on all the metrics, which implies that our elaborate encoder design is still effective even under powerful pre-training assistance.

4 Ablation Study and Analysis

This section reports our ablation studies to valid our model on the dataset of Python-V2[4] (Barone and Sennrich, 2017), in which we conduct standard and unified pre-processing for strict fair comparison.

4.1 Si-SAN vs. SAN

To valid the effectiveness of Si-SAN, we gradually replace SAN layers in original Transformer with Si-SAN. Take Transformer model with Si-SAN proportion of 50% as an instance, we replace the second, fourth and last three encoder layers with Si-SAN and do not apply structure-induced module.

Model	Prop.	BLEU	ROUGE-L	METEOR
Transformer	0	47.42	57.28	29.62
Transformer	50%	49.64	59.39	31.16
Transformer	100%	49.80	59.38	31.30
SiT	50%	**50.04**	**59.56**	**31.46**

Table 4: BLEU, ROUGE-L and METEOR for variant models with incremental proportions of Si-SAN.

Model	Attn.	BLEU	ROUGE-L	METEOR
Transformer	Full	47.42	57.28	29.62
Transformer	Window	49.28	58.80	30.90
Transformer	Random	38.06	57.28	22.76
Transformer	Struc.	**49.80**	**59.38**	**31.30**

Table 5: BLEU, ROUGE-L and METEOR for variant models with different attention patterns.

The results of variant models with incremental proportions of Si-SAN layers are shown in Table 4. Intuitively, all of the Transformers obtain improvements when equipped with Si-SAN layers. We can also see that SiT outperforms Transformer with similar proportion of Si-SAN, which proves the effectiveness of structure-induced module. However, it is surprising that Transformer with all 6 layers of Si-SAN still outperforms original Transformer even if it may be over-pruned.

4.2 Si-SAN vs. Sparse SAN

To further valid our structure-based approach, we compare the performance of structure-induced attention with other sparse attention patterns, window attention in Longformer, ETC (Beltagy et al., 2020; Ainslie et al., 2020) and random attention in BigBird (Zaheer et al., 2020). We depict different attention patterns in Figure 5. The default sequence length in SiT is 400, and then we set both w and r to 64 in window and random attention respectively.

As shown in Table 5, Transformer with arbitrary sparse attention can not bring improvement as Si-

Model	BLEU	RE.-L	MTR.	SPEED
Transformer	44.87	54.95	26.58	1.0x
Transformer + SBT	43.34	53.97	25.02	1.5x
SiT-AST only	45.43	55.30	27.21	1.0x
SiT	**45.76**	**55.58**	**27.58**	**1.0x**

Table 6: Comparison of Si-SAN and SBT methods. Both methods only leverage AST information.

SiT-8	139M	50.04	59.56	31.46
Transformer-12	244M	50.11	59.47	31.44
SiT-12	242M	50.53	60.08	31.96
Transformer-16	370M	50.43	59.80	31.75
SiT-16	367M	**50.97**	**60.51**	**32.35**
Transformer-ALBERT enc.	124M	44.83	55.34	27.73
SiT-ALBERT enc.	124M	**49.31**	**58.46**	**30.83**

Table 7: BLEU, ROUGE-L and METEOR for variant models with different sizes, where RE.L and MTR. refer to ROUGE-L and METEOR respectively. Models like SiT-12 refers to SiT with 12 heads.

SAN, which refutes that SiT learns better through denoising. Specifically, random attention seriously deteriorates Transformer. It is surprising that window attention achieves a better result than Vanilla Transformer. Intuitively, tree structures like AST are highly localized. That is why window attention may show good performance. Nevertheless, Transformer with Si-SAN still outperforms window attention by 0.52 BLEU point.

4.3 Si-SAN vs. SBT

We reproduce SBT method on Java (Hu et al., 2018a) and apply it on our Transformer. For fair enough comparison, we let $\beta = \gamma = 0$ and conduct single-view SiT which only leverages AST information. As depicted in Figure 6, flattening ASTs into linear sequences does not result in improvement, which is consistent with Ahmad et al. (2020). However, we achieve substantial improvement while incorporating AST into Transformer using Si-SAN, which indicates our improved model design is indeed effective.

In addition, the average length of the input code will be much longer with SBT, which may introduce additional training cost. As shown in Figure 6, SiT is 1.5 times faster than Transformer with SBT.

4.4 Large Model

It is known that for nearly all deep models, increasing model size may cover quite much of model structure design improvement. Thus, it is possible that the improvement on base-size model may not work on large-size one. To valid this, we compare SiTs with Transformers under larger scale. As we can see pictorially in Table 7, with increasing parameter scale, SiTs with 12 heads and 16 heads both outperform the corresponding Transformers by 0.42 and 0.54 BLEU point respectively.

4.5 Parameter Sharing

Recently, parameter sharing on BERT (Devlin et al., 2019) has achieved promising results (Lan et al., 2020). Similar as ALBERT, we introduce cross-layer parameter sharing in both Transformer and SiT, sharing all parameters in all encoder layers. Note that we train our models from scratch and keep the decoder fixed.

As shown in Table 7, SiT performs much better on parameter sharing than Transformer does. We believe that code summarization task highly depends on structural information, and this is why SiT can still achieve good results with simply one group of encoder parameters while Transformer encounters a serious decline. On the other hand, it makes possible for lite model, which may balance high efficiency and performance.

5 Related Work

RNN-based Approaches While numbers of works (Haiduc et al., 2010; Eddy et al., 2013; Wong et al., 2013, 2015; Zhang et al., 2020a) on code summarization usually depended on information retrieval, most of the recent works tend to treat it as a machine translation problem. Meanwhile attention mechanism is broadly used for better performance on capturing long-range features. Allamanis et al. (2016) proposed a Convolution Neural Network (CNN) with copy attention, and more commonly, Iyer et al. (2016); Liang and Zhu (2018) proposed to use Recurrent Neural Network (RNN) with attention mechanism to summarize code snippets into natural language. Hu et al. (2018b) introduced API knowledge from related tasks while Cai et al. (2020) introduced type information to assist training, which also gained promising results. Additionally, reinforce learning (Wan et al., 2018) and dual learning (Wei et al., 2019; Ye et al., 2020) are also shown effective to boost model performance.

Transformer-based Approaches It is known that RNN-based models may encounter bottleneck when modeling long code sequences. Ahmad et al. (2020) proposed an enhanced Transformer with copy attention and relative position encoding while Gupta (2020); Dowdell and Zhang (2020) proposed to use Transformer (Vaswani et al., 2017) and Transformer-XL (Dai et al., 2019), all of which outperformed previous RNN-based models by a large margin.

Structure-based Approaches Recent works on code summarization pay more and more attention on structural information, which usually treats the source code in form of its Abstract Syntax Tree (AST). Hu et al. (2018a); LeClair et al. (2019); Uri et al. (2019) leveraged flattened ASTs as inputs and trained with LSTMs. Mou et al. (2016); Bui et al. (2021a); Shido et al. (2019); Harer et al. (2019) proposed TBCNN, TreeCaps, Tree-LSTM and Tree-Transformer to directly encode tree-style inputs. Differ from modeling code with sequential models, Allamanis et al. (2018); Liu et al. (2020); Alex et al. (2020) treated AST as graph and applied graph neural network, while Wang et al. (2021) applied heterogeneous graph neural network to model different types of nodes.

Pre-training Approaches Apart from training from scratch, CodeBERT (Feng et al., 2020) is pre-trained on vast bimodal corpora with masked language model (Devlin et al., 2019) and replaced token detection (Clark et al., 2020), and achieves powerful performances on downstream tasks. Nie et al. (2020) intensified contextualized code representation through masked code fragment predictions while Bui et al. (2021b) incorporated structural information using TBCNN. However, all of them do not include generation-related objectives. It is worth further exploration and practice on pre-training approaches for out concerned tasks.

6 Conclusion

This paper presents a novel structured-induced Transformer model on code summarization task. By well-designed architecture, the proposed model may effectively incorporate multi-view structure into attention mechanism without tricky implementation. We further adopt a new module architecture to aggregate both global self-attention and structure-induced self-attention representations. Experiments on two challenging benchmarks including Java and Python show that the proposed model yields new state-of-the-art results.

A Model Parameters

Model	d_h	d_{ff}	h	l
Transformer	64	2048	8	12
SiT	64	2048	8	12
Transformer-Window	64	2048	8	12
Transformer-Random	64	2048	8	12
Transformer-Struc.	64	2048	8	12
CodeBERT	64	3072	12	12
SiT on CodeBERT	64	3072	12	12
Transformer-ALBERT enc.	64	2048	8	12
SiT-ALBERT enc.	64	2048	8	12

Table 8: Model parameters in our experiments.

B Qualitative Samples

For qualitative analysis, we give some samples of code summarization with different models. We can see that SiT performs most precisely, while CodeBERT performs better than Transformer does.

Code

```java
private float computeOverscrollPercent () {
    if ( mOverScrollOffset >= _NUM ) {return mOverScrollOffset / mMaxOverScroll;}
    else {return mOverScrollOffset / mMaxUnderScroll;}
}
```

Summary	Gold: determine the current amount of overscroll . if the value is 0 , there is no overscroll . if the value is < 0 , tabs are overscrolling towards the top or or left . if the value is > 0 , tabs are overscrolling towards the bottom or right . SiT: determine the current amount of overscroll . if the value is 0 , there is no overscroll . if the value is < 0 , tabs are overscrolling towards the top or or left . if the value is > 0 , tabs are overscrolling towards the bottom or right . Transformer: determine the current amount of overscroll . if the value is 0 , there is no overscroll . if the value is < 0 , tabs are overscrolling towards the top or or left . if the value is > 0 , tabs are overscrolling towards the top or right . CodeBERT: determine the current amount of overscroll . if the value is 0 , there is no overscroll . if the value is < 0 , tabs are overscrolling towards the top or or left . if the value is > 0 , tabs are overscrolling towards the bottom or right .

Code

```java
public String peek () {
    String result = null;
    if (isEmpty()) {return null;}
    else {
        int cachedCurrentIndex = currentIndex;
        if (isEatingBlocksOfDelimiters) {trimStartingDelimiters();}
        int nearestDelimeter = -_NUM ;
        for (int i = _NUM; i <delimiters.length(); i++) {
            int delimiter = source.indexOf(delimiters.charAt(i), currentIndex);
            if (nearestDelimeter == -_NUM || delimiter != -_NUM && delimiter <nearestDelimeter) {
                nearestDelimeter = delimiter;
            }
        }
        if (nearestDelimeter == -_NUM) {result = source.substring(currentIndex);}
        else {result = source.substring(currentIndex, nearestDelimeter);}
        currentIndex = cachedCurrentIndex;
    }
    return result;
}
```

Summary	Gold: returns null if there is nothing left . SiT: returns null if there is nothing left . Transformer: finds the next unique identifier . CodeBERT: returns the index of the first delimited string removing from the current position .

Table 9: Qualitative samples of Java code summarization.

Code

```python
def _asFilesystemBytes(path, encoding=None):
    if (type(path) == bytes): return path
    else:
        if (encoding is None):
            encoding = sys.getfilesystemencoding()
            return path.encode(encoding)
```

Summ.	Gold: return cpath as a string of lbytes suitable for use on this systems filesystem . SiT: return cpath as a string of lunicode suitable for use on this systems filesystem . Transformer: convert a filesystem path of a byte string . CodeBERT: return a byte string suitable for use in cpath as a byte string .

Code

```python
def absent(name, DomainName, region=None, key=None, keyid=None, profile=None):
    ret = {’name’: DomainName, ’result’: True, ’comment’: ”, ’changes’: {}}
    r = __salt__[’boto_elasticsearch_domain.exists’](DomainName, region=region, key=key, keyid=keyid, profile=profile)
    if (’error’ in r):
        ret[’result’] = False
        ret[’comment’] = ’Failed to delete domain: {0}.’.format(r[’error’][’message’])
        return ret
    if (r and (not r[’exists’])):
        ret[’comment’] = ’Domain {0} does not exist.’.format(DomainName)
        return ret
    if __opts__[’test’]:
        ret[’comment’] = ’Domain {0} is set to be removed.’.format(DomainName)
        ret[’result’] = None
        return ret
    r = __salt__[’boto_elasticsearch_domain.delete’](DomainName, region=region, key=key, keyid=keyid, profile=profile)
    if (not r[’deleted’]):
        ret[’result’] = False
        ret[’comment’] = ’Failed to delete domain: {0}.’.format(r[’error’][’message’])
        return ret
    ret[’changes’][’old’] = {’domain’: DomainName}
    ret[’changes’][’new’] = {’domain’: None}
    ret[’comment’] = ’Domain {0} deleted.’.format(DomainName)
    return ret
```

Summ.	Gold: ensure domain with passed properties is absent . SiT: ensure domain with passed properties is absent . Transformer: ensure the iam role exists . CodeBERT: ensure the named domain is absent .

Scheduled Dialog Policy Learning: An Automatic Curriculum Learning Framework for Task-oriented Dialog System

Sihong Liu[1]*, **Jinchao Zhang**[2], **Keqing He**[1], **Weiran Xu**[1]†, **Jie Zhou**[2]

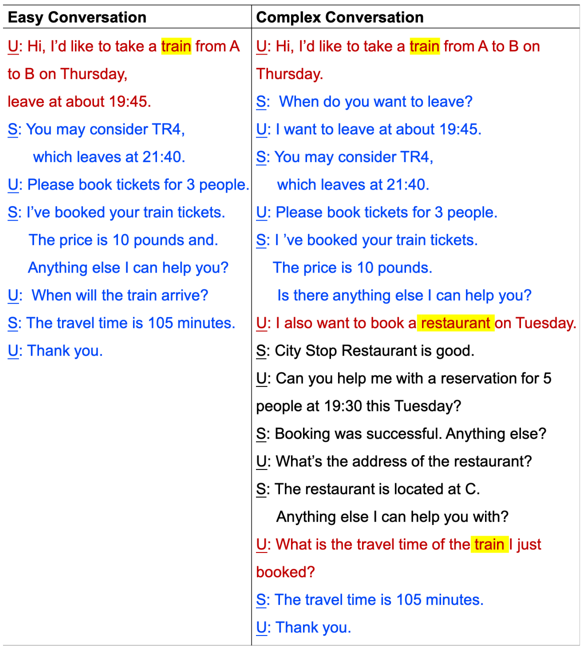
Abstract

In reinforcement learning (RL) based task-oriented dialogue systems, users act as the environment and the agent learns the policy by interacting with users. However, due to the subjectivity of different users, the complexity of user-generated training conversations varies greatly, which leads to different difficulties for the agent to learn. Therefore, it is necessary for modeling dialogue complexity and make a reasonable learning schedule for efficiently training the agent. Towards that, we propose Scheduled Dialog Policy Learning, an automatic curriculum learning framework for jointing curriculum learning and policy optimization in the task-oriented dialog system. To our best knowledge, it is the first RL framework that improves dialogue policy learning by scheduling its learning process. Specifically, we introduce an automatic measurement to evaluate the dialogue complexity, and based on this automatic measurement, we train the dialog agent from easy dialogues to complex ones. Experiments demonstrate that our approach can be applied to the task-oriented dialogue policy learning and outperforms the previous state-of-the-art model, which increases 9.6% and 10.0% in the accuracy on the dialog success rate, respectively on the MultiWoz and Movie-Ticket Booking datasets.

1 Introduction

Dialog policy learning is an important component of the task-oriented dialogue system, and it determines the agent dialog action responding to the user. This learning process is often formulated as a reinforcement learning problem (Young et al., 2013; Levin et al., 1997; Dhingra et al., 2017; Li et al., 2017; Liu and Lane, 2017; Peng et al., 2018b; Su et al., 2018; Gao et al., 2019; Takanobu et al., 2020), where users act as the environment and the agent learns the policy by interacting with users. Thus, the learning performance of the dialogue policy depends much on users' behaviors.



Easy Conversation

U: Hi, I'd like to take a train from A to B on Thursday,
leave at about 19:45.
S: You may consider TR4,
which leaves at 21:40.
U: Please book tickets for 3 people.
S: I've booked your train tickets.
The price is 10 pounds and.
Anything else I can help you?
U: When will the train arrive?
S: The travel time is 105 minutes.
U: Thank you.

Complex Conversation

U: Hi, I'd like to take a train from A to B on Thursday.
S: When do you want to leave?
U: I want to leave at about 19:45.
S: You may consider TR4,
which leaves at 21:40.
U: Please book tickets for 3 people.
S: I 've booked your train tickets.
The price is 10 pounds.
Is there anything else I can help you?
U: I also want to book a restaurant on Tuesday.
S: City Stop Restaurant is good.
U: Can you help me with a reservation for 5 people at 19:30 this Tuesday?
S: Booking was successful. Anything else?
U: What's the address of the restaurant?
S: The restaurant is located at C.
Anything else I can help you with?
U: What is the travel time of the train I just booked?
S: The travel time is 105 minutes.
U: Thank you.

Figure 1: The comparison of the easy conversation (left) and the complex conversation (right) which are task-oriented dialogs between the user (U) and the system (S) sampling from MultiWoz. Comparing to the left conversation, the right one has more turns, intents, slots, and also switches between two domains: *train* (marked as blue) and *restaurant* (marked as dark). The right instance is apparently more complex.

However, due to the subjectivity and open-ended nature of human conversations, the complexity of training dialogues with different users varies greatly (Lison and Bibauw, 2017). Figure 1 shows dialogues with different complexities from MultiWoz (Budzianowski et al., 2018) dataset. Comparing to the left instance, the conversation in the right column has more turns, intents, slots, and also has the switch between two domains: *train*

(marked as blue) and *restaurant* (marked as dark). The right instance is apparently more complex. As different complexity conversations lead to different difficulties for the agent to learn, in this paper, we introduce an automatic curriculum learning framework to improve dialog policy learning by scheduling its learning process where the agent first learns from easy conversations and then gradually manages more complicated ones. There is some related work that examines the curriculum learning in natural language processing (Kocmi and Bojar, 2017; Platanios et al., 2019; Sachan and Xing, 2016; Guo et al., 2019; Cai et al., 2020). Evaluation of training samples complexity is a challenging obstacle when organizing a curriculum. Previous work evaluates training samples mainly applying empirical and heuristic attributes, such as Platanios et al. (2019) defines the difficulty for training sentences concerning the sentence length and word rarity in the neural machine translation. Cai et al. (2020) evaluates the dialogue difficulty by five heuristic conversational attributes.

As the subjectivity and diversity of the conversation task, modeling its complexity by empirical and heuristic attributes is insufficient and relies on prior knowledge on the specific domain or dataset. Inspired by curiosity rewards (Schmidhuber, 1991; Stadie et al., 2015; Sorg et al., 2010; Pathak et al., 2017a), which applied state prediction error to predict uncertainty (Houthooft et al., 2016; Still and Precup, 2012; Wesselmann et al., 2019; Tegho et al., 2018) and improvement (Lopes et al., 2012) in RL tasks, in this paper, we further introduce an automatic measurement to evaluate dialogue complexity by estimating the dialog state differential space without applying any prior knowledge on the domain or dataset. Then we schedule the policy learning curriculum for the dialog agent based on the evaluation. To evaluate the effectiveness of our model for dialogue policy learning, we conduct our experiments on two public task-oriented dialog datasets: MultiWoz (Budzianowski et al., 2018) and Movie-Ticket Booking (Li et al., 2018). Experimental results show that our model reaches 83.3% and 57.0% in the accuracy for dialog successful rate on these two datasets, outperforming the previous state-of-the-art dialog model by 9.6% and 10.0% , respectively. Our main contributions in this work are three-fold:

- We design an automatic measurement to evaluate training dialogues complexity without any prior knowledge on the domain or dataset, which gets rid of empirical and heuristic attributes to model the dialogue complexity.
- Based on the automatic complexity measurement, we propose an automatic curriculum learning framework SDPL to improve the performance and learning efficiency of task-oriented dialogue policy learning.
- We conduct experiments on two task-oriented dialog corpus and results show the superiority of our model to the state-of-the-art baselines. Especially, it increases 9.6% and 10.0% in accuracy on dialog successful rate, respectively.

2 Related work

2.1 RL-based Task-oriented Dialog Policy Learning

Learning policies for the task-completion dialogue is often formulated as a reinforcement learning (RL) problem (Levin et al., 1997; Young et al., 2013; Li et al., 2017; Peng et al., 2018a,b; Su et al., 2018; Gao et al., 2019; Li et al., 2017; Peng et al., 2018b; Su et al., 2018; Takanobu et al., 2020; Li et al., 2020) and this learning process can be regard as a Markov Decision Process (MDP), where the agent interacts with a user through a sequence of actions to accomplish a pre-defined user goal.

Since reinforcement learning requires much interaction for training, a user simulator is often applied to interact with the agent providing the simulated user response in each dialogue turn based on a user goal (Li et al., 2017; Liu and Lane, 2017; Peng et al., 2018a; Su et al., 2018). Specifically, given a user goal G, at each time step t, the agent observes the current dialogue state s_t, and chooses an action a to execute, using the policy $\pi(a|s_t)$. Then the user responds the user action a_u which is sampled from the user goal G. Next, the agent receives reward r_t, observes the response a_u and updates to next state s_{t+1}. And the agent learns and updates the policy aiming to maximize its total discounted rewards. As the entire dialogue is around a user goal and a user goal corresponds to several user-generated dialogues, thus in this paper, we make the complexity evaluation of user goals for curriculum learning feeding different complexity dialogues generated by different complexity user goals to schedule the dialog agent training [1].

---

[1] Refer to the appendix for details on the user simulator

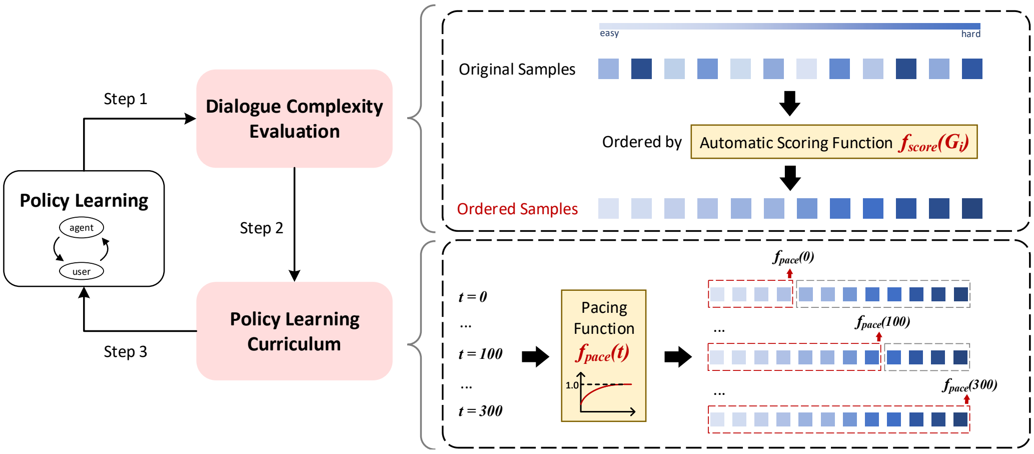

Figure 2: Illustration of proposed curriculum learning framework SDPL. It is defined by two stages. At **dialogue complexity evaluation stage**, an automatic scoring function $f_{score}(G_i)$ defines the instances G_i complexity (darker/lighter blue indicate easy/hard complexity) from easy to hard. Then at the **policy learning curriculum stage**, a pacing function $f_{pace}(t)$ schedules the percentage of training instances available for feeding to the policy learning according to the training step t. The dialog agent interacts with the user to learn the dialog policy on the scheduled instances and updates its learning capacity to execute a new dialog complexity evaluation.

2.2 Curriculum Learning

Curriculum learning (Bengio et al., 2009) is a learning strategy in machine learning, which learns from easy instances and then gradually handles harder ones. Curriculum learning has been used to natural language generation (Cai et al., 2020; Liu et al., 2018) and question answering task (Sachan and Xing, 2016). Cai et al. (2020) utilizes heuristic dialogue attributes to represent the dialogue complexity and propose several curricula, which achieve high performance. And Sachan and Xing (2016) proposes several heuristic strategies to model different complexity QA pairs. As the conversation task is more complex and analytic, in this paper, we propose an automatic curriculum framework to measure dialogue complexity automatically which can get rid of empirical and heuristic attributes and schedule different complexity training dialogues to improve the policy learning.

2.3 Curiosity Rewards

For many RL applications, state error prediction is used for curiosity rewards (Schmidhuber, 1991; Stadie et al., 2015; Sorg et al., 2010; Pathak et al., 2017a) [8, 9, 10, 5] to predict uncertainty (Houthooft et al., 2016; Still and Precup, 2012; Wesselmann et al., 2019; Tegho et al., 2018) and improvement (Lopes et al., 2012), improving the state exploration efficiency. And curiosity rewards are applied to tackle reward sparseness problem and state exploration in many tasks. Especially, Wesselmann et al. (2019) applied the curiosity rewards to the dialog policy to replace random exploration and stabilize training. While in this paper, we applied the curiosity reward as the measurement to evaluate the dialogue complexity.

3 Scheduled Dialog Policy Learning

We propose Scheduled Dialog Policy Learning (SDPL), a flexible and practical framework on joint curriculum learning and policy optimization for task-oriented dialog systems.

3.1 Overview

The overview of the full model is depicted in Figure 2, it schedules and designs the curriculum for dialogue policy learning in mainly two stages:

1) **Dialog Complexity Evaluation.** For the input training instances, we firstly measure original dialog instances complexity by an automatic scoring function, and arrange to sort these instances by their complexity scores, obtaining the ordered training instances. 2) **Policy Learning Curriculum.** After obtaining the ordered training instances, we apply a pacing function to schedule the percentage of instances available for training at each training step. Then these scheduled percentage of instances are fed to the dialogue agent to learn the dialog policy from easy to complex. As the training progressing, the agent updates its learning capacity and executes a new dialog complexity evaluation.

---

and the user goal.

In the subsequent subsection, we systematically describe how to utilize the SDPL for dialogue policy learning. In Section 3.2, we propose an automatic dialogue complexity evaluation approach. Then, we show in Section 3.3 how the automatic curriculum learning framework can contribute to the dialogue policy learning by automatically modeling dialogue complexity and making a reasonable learning schedule for training the dialog agent.

3.2 Dialogue Complexity Evaluation

The complexity of different training dialogues varies greatly which leads to different difficulties for the agent to learn. Therefore, it is necessary for modeling dialogue complexity and scheduling different complexity dialogues for efficiently training. In this paper, we propose a novel measurement to evaluate the dialogue complexity automatically. Inspired by Pathak et al. (2017b), for the agent instant learning capacity, we estimate the dialog state differential space that the agent can explore for current training samples as their training complexity. Less differential space means less error between the real state and predicted state which indicates current agent masters these samples where they are easy to learn for the current learning capacity.

Specifically, during the RL-based dialog policy learning process, in each step t, the agent observes current dialogue state s_t, then it executes the dialog action a_t estimating from current policy learning network. The agent then receives reward r_t [2] and updates to the next state s_{t+1}. Finally, the agent aims to maximize the expected sum of rewards which can be formulated as:

$$\underset{\theta_Q}{max} E_{\pi(s_t,a_t;\theta_Q)}[\sum_t r_t], \tag{1}$$

where $\pi(s_t, a_t; \theta_Q)$ is the policy learning network parameterized by θ_Q. To estimate the state differential space between the real state and predicted state, we first encode the current state and real next state into state feature vectors. Next, we apply a feature predicting neural network to obtain the predicted next state feature encoding which is formulated as:

$$\hat{\phi}(s_{t+1}) = g\Big(\phi(s_t), a_t; \theta_m\Big), \tag{2}$$

where $\phi(\cdot)$ is a state encoding network which transforms the one-hot state variables into a feature space suitable for learning. And $\hat{\phi}(s_{t+1})$ is the predicted next state feature of the real next state feature $\phi(s_{t+1})$. We optimize parameters θ_m by minimizing the mean square error between them:

$$m\Big(\phi(s_{t+1}), \hat{\phi}(s_{t+1})\Big) = \eta\|\hat{\phi}(s_{t+1}) - \phi(s_{t+1})\|^2, \tag{3}$$

where $\eta > 0$ is a scaling factor. The function $m(t)$ calculates feature encoding differentials of states between the real next state feature and estimated next state feature in the latent feature space, which represents the state differential space that agent needs explore. Less state differential space means less error between the real and predicted state feature which indicates that current agent masters these states are easy to learn for the current agent learning capacity. Therefore, we apply the $m(t)$ as the complexity evaluation for the current agent towards current training samples.

We jointly optimize the reinforcement learning process and complexity evaluation as:

$$\underset{\theta_Q}{max} E_{\pi(s_t,a_t;\theta_Q,\theta_m)}[\sum_t r_t + \sum_t m(t)]. \tag{4}$$

We further formulate the complexity evaluation into the task-oriented dialogue system to measure the dialogue complexity (lines 3-8 in Algorithm 1). In the dialogue system, the user and system interact with each other in a dialog session to fulfill the user goal G_i, where $G_i \in \mathcal{D}_{total}$ and $\mathcal{D}_{total}$ is a user goal set, i is the user goal index. Each user goal G_i corresponds to its K generated dialog sessions $\{\tau_1, ..., \tau_k\}$. And during the reinforcement learning process, each dialog session τ_k can be seen as a trajectory of state-action tuples $\{(s_t, a_t, r_t, s_{t+1}), ...\}$, $t \in \{0, 1, ..., N-1\}$, where N stands for the number of turns in each dialogue session. Therefore, based on the Eq. 3, for each dialog τ_k, we obtain its complexity score by an automatic scoring function which can be formulated as:

$$f_{score}(m_{\tau_k}) = \sum_{t=1}^{N} m_{\tau_k}(t). \tag{5}$$

During the RL-based dialog policy learning, as training dialogues are user-generated based on the user goal, we also evaluate the complexity of user goals for later policy curriculum learning. For a given user goal G_i, we obtain its complexity score

---

[2] In the RL based dialogue system, reward measures the degree of whether the dialogue is successful. In our experiment, the agent obtains a reward of 80 when it success, and obtained a reward of -40 when failed, and the agent receives the reward of -1 at each turn to encourage shorter dialogues.

Algorithm 1 Scheduled Dialogue Policy Learning

```
Require: Dialog user goal set $\mathcal{D}_{total}$ with each user goal $\{G_i\}$, $N$
Ensure: Dialog policy $\pi(s, a; \theta_Q, \theta_m)$
initialize $\pi(s, a; \theta_Q, \theta_m)$
for $n$=1:$N$ do
    # Dialogue Complexity Evaluation starts
    user starts dialogues $\tau_1 ... \tau_k$ based on $G_i$
    update the dialogue process by $\pi(s, a; \theta_Q, \theta_m)$
    store training tuples $\{(s_t, a_t, r_t, s_{t+1}), ...\}$ for each dialog $\tau_k$
    compute complexity score for $\tau_k$ and $G_i$ by $f_{score}$ in Sec. 3.2
    sort $\mathcal{D}_{total}$ with the complexity score to obtain $\mathcal{D}_{order}$
    # Policy Learning Curriculum starts
    sample batches from $\mathcal{D}_{order}$ by $f_{pace}$ in Eq. 7.
    user starts dialogues $\tau_1 ... \tau_k$ based on $G_i^{'}$
    agent updates $\pi(s, a; \theta_Q, \theta_m)$ by interacting with the user
end for
```

by calculating its generated dialog sessions average complexity evaluation which is formulated as:

$$f_{score}(G_i) = \frac{1}{K} \sum_{k=1}^{K} f_{score}(m_{\tau_k}). \qquad (6)$$

We sort the user goal set $\mathcal{D}_{total}$ by complexity scores, obtaining the forward complexity ordered user goal set $\mathcal{D}_{order}$. Based on the ordered training set, we further propose the policy learning curriculum to schedule the training of the agent.

3.3 Automatic Curriculum Learning Framework for Dialog Policy Learning

Our proposed automatic curriculum learning framework is shown as Algorithm 1. During the dialogue policy learning process, we first initialize the RL-based dialog policy as $\pi(s, a; \theta_Q, \theta_m)$. For each training step n, we start from the Dialogue Complexity Evaluation process. The user starts dialogues $\tau_1 ... \tau_k$ based on a user goal G_i. Then, we update the dialogue process based on the current policy, and store training tuples $\{(s_t, a_t, r_t, s_{t+1}), ...\}$ for each dialog τ_k. After that, we arrange to sort each user goal in the original training set from easy to complex according to the automatic scoring function f_{score} in Sec. 3.2, obtaining the ordered training set $\mathcal{D}_{order}$.

	Movie-Ticket Booking	MultiWoz
Dialogues	2,890	8,438
Intents	11	13
Slots	29	25
Avg. turns per dialogue	7.5	13.68
Domains	1	7

Table 1: The statistics of two public datasets, Movie-Ticket Booking and MultiWoz.

After obtaining the ordered training set, we start the policy learning curriculum process based on a pacing function $f_{pace}(t)$ aiming to schedule training instances that feeding to the policy learning network. A batch of training instances is sampled from the top $f_{pace}(t)$ percentage of the ordered training set. Following Platanios et al. (2019), we define the pacing function $f_{pace}(t)$ as:

$$f_{pace}(t) \triangleq min(1, \sqrt{t\frac{1 - c_0^2}{N} + c_0^2}) \qquad (7)$$

where $c_0 > 0$ is set to 0.01 and N is the duration of curriculum learning. At the early stage of the training process, the dialogue policy learning model learns from the instances drawing from the front (easy) part of the curriculum. With the advance of the curriculum, the complexity gradually increases, more complex training instances appear.

Based on sampled training instances by Eq. 7, the user starts dialogues from ordered sampling user goal $G_i^{'}$, while the agent interacts with the user to update and learn the dialogue policy $\pi(s, a; \theta_Q, \theta_m)$ from easy to complex, then conducts new dialogue complexity evaluation iteratively. Note that, although we describe the framework in two components for ease of understanding, in fact, the whole framework can be trained in an end-to-end manner. Thus, the proposed automatic curriculum learning framework is capable of not only scheduling the training samples to optimize the dialogue policy learning model, but also can be applied to other RL based training scenarios.

4 Experiments

4.1 Datasets

We conduct the experiments on two public datasets, Movie-Ticket Booking (Li et al., 2018) and MultiWoz (Budzianowski et al., 2018). Movie is a single domain dataset, and its goal is to build a dialogue system to help users find information about movies and book movie tickets. MultiWoz is a multi-domain, multi-intent task-oriented dialog corpus that contains seven domains, including Attraction, Hospital, Police, Hotel, Restaurant, Taxi, Train. A user may change his goal during the session, hence MultiWoz provides more complicated dialogs closer to real-world conversations. We show the full statistics in Table 1 [3].

---

[3] Refer to the appendix for details on datasets.

4.2 Evaluation Metrics

We adopt three metrics to evaluate the quality of policy learning: success rate, average turns, average reward. Success rate is the task completion rate – the fraction of dialogues that ended successfully. The dialog is successfully when all the requested information has been filled in, and the booked entities match all the indicated constraints given by the user goal. Average turns is the average length of the dialogue. Average reward is the average reward that agent received during the conversation.

4.3 Baselines

To verify the effectiveness of our proposed curriculum learning framework, we compare with different RL policy learning agents in task-completion dialogue as baselines:

DQN: A reinforcement learning based task-oriented dialogue model that the agent learned the dialogue policy by standard DQN (Li et al., 2017).

DDQ: The state-of-the-art task-oriented dialogue policy learning approach, Deep Dyna-Q (DDQ) (Peng et al., 2018b). DDQ integrates planning for dialogue policy learning to make the best use of limited real user experiences.

DDQ-CR: A DDQ agent only applied the curiosity reward into the dialogue policy learning but without curriculum learning (Wesselmann et al., 2019).

DDQ-CL-rule: A DDQ agent incorporating the curriculum learning (CL) and the dialogue complexity evaluation is rule-based, where empirically evaluating the dialogue by its slots number.

DDQ-SDPL: A DDQ agent that incorporating our proposed framework.

WDQN: A warm-DQN agent pre-trained by supervised learning (Lee et al., 2019).

WDQN-CR: A warm-DQN agent that only incorporating the curiosity rewards into dialogue policy learning without curriculum learning (Wesselmann et al., 2019).

WDQN-CL-rule: A warm-DQN agent that incorporating the rule-based curriculum learning (CL), similar to **DDQ-CL-rule**.

WDQN-SDPL: A warm-DQN agent that incorporating our proposed framework.

4.4 Settings

The policy learning of the agent is trained by DQN and DDQ algorithm with the same set of hyper-parameters on Movie-Ticket Booking (Li et al., 2018). The batch size is 64, and the learning rate is 0.001. The state encoding network is an MLP layer with 80 node. The optimizer for neural networks is RMSProp. And we employ the WDQN with the same set of hyper-parameters (Lee et al., 2019). The batch size is 16, and the learning rate is 0.001. The state feature encoder is an MLP layer with 300 node. We use Adam as the optimization algorithm. Besides, dialogues are ordered by our complexity evaluation in the training process while during the testing process, dialogues are used as baselines with no order. The training epoch is 100, 200, 300 and each number is averaged over 5 runs, each run tested on 2000 dialogues.

5 Automatic Evaluation

In this section, we first show the experiment results of our proposed method on Movie-Ticket Booking and MultiWoz datasets to verify the effectiveness of our proposed framework. Then we make a comprehensive qualitative analysis to show the merits of automatic evaluation for dialogue complexity.

5.1 Main Results

Table 2 presents the main results at the training epoch on the Movie-Ticket Booking dataset. For each agent, we report its results in terms of success rate, average reward, and average turns. Compared to the original DDQ agent, DDQ-CR, DDQ-CL-rule and DDQ-SDPL respectively achieve 8%, 7% and 10% improvements in terms of success rate, which confirms curriculum learning can facilitate and stable the training process of RL agents.

Further, our proposed automatic evaluation method for dialogue complexity outperforms the empirical method by 3%. The result represents applying the heuristic attribute to model the dialogue complexity is insufficient and it is hard to make effective handcrafted rules, due to subjectivity and diversity of dialogues and the limit of user-generated training. Our proposed method models the dialogue complexity in an automatic method evaluating dialog state differential space of RL agents. For other metrics, average reward and average turns, our method also achieves better performance. Apart from overall performance gain, we observe our method converges fast to similar accuracy 76% at epoch 100, compared to 73% of DDQ agent at epoch 300. It proves a better evaluation method for dialogue complexity can bootstrap training steps of RL agents. Besides,

Agent	Epoch = 100			Epoch = 200			Epoch = 300		
	Success	Reward	Turns	Success	Reward	Turns	Success	Reward	Turns
DQN (Li et al., 2017)	0.42	-3.84	31.93	0.53	10.78	22.72	0.64	27.66	22.21
DDQ (Peng et al., 2018b)	0.60	20.35	26.65	0.71	36.76	19.55	0.73	39.97	18.99
DDQ-CR	0.62	24.82	23.78	0.78	46.52	14.05	0.81	50.16	13.27
DDQ-CL-rule	0.71	32.48	19.01	0.76	45.36	14.56	0.80	48.15	13.59
DDQ-SDPL	**0.76**	**44.75**	**14.90**	**0.80**	**51.15**	**13.29**	**0.83**	**54.63**	**12.73**

Table 2: Results of different task-completion dialogue agents including the DQN,DDQ on Movie-Ticket Booking (Li et al., 2018) and ablation experiments of applying different curriculum learning strategies. The training epoch = {100, 200, 300}. (Success: success rate)

Agent	Epoch = 100			Epoch = 200			Epoch = 300		
	Success	Reward	Turns	Success	Reward	Turns	Success	Reward	Turns
WDQN (Lee et al., 2019)	0.37	-8.93	15.33	0.46	3.26	13.94	0.47	5.33	13.07
WDQN-CR	0.36	-5.16	15.10	0.45	3.21	14.02	0.51	10.68	13.79
WDQN-CL-rule	0.40	-4.79	14.79	0.48	6.41	13.19	0.49	9.35	13.85
WDQN-SDPL	**0.45**	**2.51**	**13.49**	**0.52**	**11.04**	13.36	**0.57**	**12.22**	13.81

Table 3: Results of WDQN agent on MultiWOZ (Budzianowski et al., 2018) and ablation experiments of applying different curriculum learning strategies. The training epoch = {100, 200, 300}. (Success: success rate)

DDQ-CR only applied curiosity-driven exploration with no curriculum learning and it can improve the agent's performance. While based on the curiosity reward's improvement, there is another promotion after applying the curriculum learning. And this ablation study demonstrates the effectiveness of the curriculum learning.

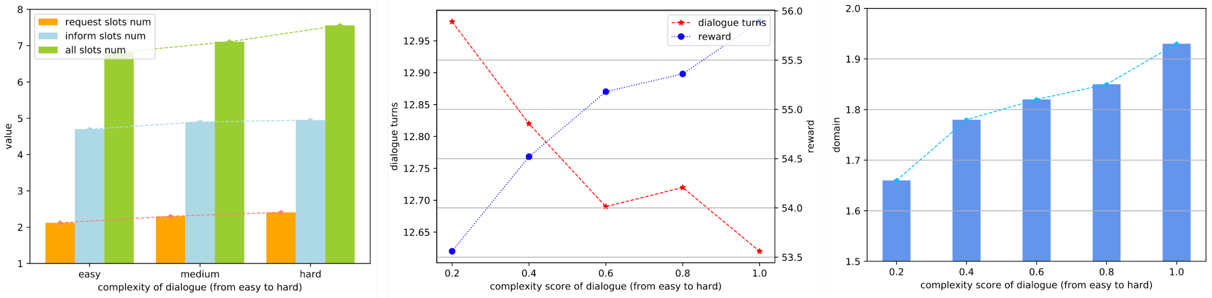
Table 3 shows main results at the training epoch on the MultiWOZ dataset. We aim to verify the effectiveness of our method on the more complicated dataset since MultiWOZ contains multi-domains and more dialog turns. Here we choose another RL agent, WDQN, as the baseline to show our proposed framework can be applied to other RL based models. Results show our method WDQN-SDPL outperforms the empirical rule WDQN-CL-rule by 6%, higher than the improvement of 3% on Movie dataset. The possible reason is that MultiWOZ is significantly complicated than Movie dataset and only the simple attribute of slot numbers evaluates dialog complexity insufficiently. For the Turns metric, our method achieves similar performance with the baselines. We assume the domain switching on MultiWOZ leads to increasing dialog turns to achieve a higher success rate. The comparison exhibits the effectiveness of our automatic evaluation method. Besides, the ablation study in WDQN-CR and WDQN-SDPL also demonstrates the effectiveness of the curriculum learning.

In summary, our proposed curriculum learning framework facilitates the training process of RL agents. Moreover, our automatic evaluation method for dialogue complexity consistently outperforms the rule-based empirical method.

5.2 Analysis

Comparison with Heuristic Complexity We analyze three empirical attributes to show the correlation between heuristics and proposed automatic dialogue complexity evaluation: slot number, dialog length, reward, and domain switching times. We show the correlation statistics results in Fig 3. Fig 3(a) and Fig 3(b) shows the statistics of slots number, dialogue length and reward in complexity ordered instances evaluating by our proposed dialog complexity evaluation on Movie-Ticket Booking dataset. And we perform the qualitative analysis on the correlation between dialogue complexity and the number of domain switching on the MultiWoz dataset in Fig 3(c). Our evaluation method for dialogue complexity reflects positive connections to heuristic methods in these dimensions, which to some extent explains the effectiveness of our method. On the other hand, our method considers multiple empirical dialog attributes which is more flexible than heuristics. We show more comparison analysis details in the Appendix.

Learning Efficiency Fig 4 shows the learning curves comparing different agents, DDQ, DDQ-CL-rule and DDQ-SDPL, to investigate the relative contribution of the automatic complexity evaluation and the curriculum learning strategy. The



(a) *Slot numbers* (b) *dialog length & reward* (c) *domain switching times*

Figure 3: The correlation statistics between heuristics and our proposed automatic dialogue complexity evaluation. We count three heuristic attributes: slot numbers(request slot, inform, all), dialog turns and reward, domain switching times based on ordered training samples evaluating by our proposed automatic complexity evaluation. And we divide obtained dialog complexity scores into different complexity intervals(easy, medium, hard) for statistics.

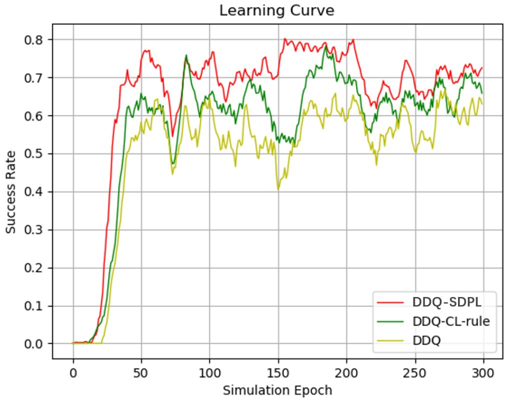


Figure 4: Learning curves of the DDQ, DDQ-CL-rule, DDQ-SDPL. The DDQ-SDPL outperforms baselines and converges fast to achieve higher accuracy.

DDQ-SDPL outperforms the baseline DDQ and DDQ-CL-rule and at each training step and converges fast to higher accuracy.

6 Human Evaluation

For human evaluation, we hire human experts to compare pairwise between DDQ-SDPL and baselines. Given a certain user goal, each expert is asked to read two simulated dialog sessions around this user goal, one from DDQ-SDPL and another from the other baseline. We randomly sample 100 goals for each baseline. For each goal, 3 experts are asked to judge which dialog is better (win, draw or lose) according to different subjective assessments: quality and task success. The quality metric evaluates whether the agent policy provides the user with the required information efficiently.

VS.	Quality			Success		
	W	D	L	W	D	L
DDQ	46	24	30	58	25	17
DDQ-CL-rule	41	28	31	49	26	25

Table 4: Human preference on dialog session pairs that DDQ-SDPL wins (W), draws with (D) or loses to (L) baselines on quality and success by majority voting.

Table 4 shows the results of the human preference by majority voting. DDQ-SDPL outperforms other baselines significantly in all aspects (sign test, p-value < 0.01). Note that the difference between DDQ-CL-rule and DDQ-SDPL is only in the dialog complexity evaluation. This demonstrates again the advantage of the automatic complexity evaluation in DDQ-SDPL over the heuristic method. The human preferences agree well with the results of the automatic evaluation, which also indicates these experimental metrics are reliable to reflect user satisfaction to some extent. Besides, we show some sampled cases in the Appendix to demonstrate the effectiveness of our proposed learning framework.

7 Conclusion

In this paper, we propose a novel curriculum learning framework to improve dialog policy learning by scheduling its learning process from easy to complex. We further propose an automatic dialog complexity evaluation for curriculum scheduling. The effectiveness validation of SDPL is conducted on two dialogue datasets and the state-of-the-art dialog model demonstrates that our proposed learning framework is able to boost the performance of existing dialogue policy learning. Furthermore, we believe that this automatic curriculum learning framework can be applied to improve other types of reinforcement learning based NLP tasks.

	Hotel	**Train**	**Attraction**	**Restaurant**	**Taxi**
Slots	price, type, parking, stay, day, people, area, stars, internet, name	destination, departure, day, arrive by, leave at, people	area, name, type	food, price, area, name, time, day, people	destination, departure, arrive by, leave by

Table 6: The dataset information of MultiWOZ.

B User goal

In the task-completion dialogue setting, the entire conversation is around a user goal $G = (C, R)$ implicitly, where C denotes the constraint and R is the requests. And the agent knows nothing about the user goal explicitly and its objective is to help the user to accomplish this goal. Every time a dialog is launched, the user goal is initialized by the user simulator at the beginning of a dialog session, by randomly sampling the *inform slots* and *requests slots* from the user goal. Generally, the definition of user goal contains two parts: *inform_slots* contain a number of slot-value pairs which serve as constraints from the user. *request_slots* contain a set of slots that user has no information about the values, but wants to get the values by interact with the agent.

A set of 1,000 user goals in MultiWOZ are used for automatic evaluation as shown in Table 8.

C Case study

To further analyze the effectiveness of our automatic complexity measurement qualitatively, we randomly choose three examples of dialogues with different normalized complexity scores. As shown in Table 9, it is clear to see that, the instance with more slots and domains obtains a higher complexity score in our automatic measurement, which is consistent with heuristics. Besides, Table 11 shows two dialog sessions with the same user goal in WDQN and WDQN-SDPL, respectively. The user goal consists of *train* and *restaurant* domains. The system is required to answer all the information in *Request* based on the constraints in *Inform*. When the user asks for some information about the restaurant, WDQN-SDPL manages to provide all the requested information, while original WDQN only answers part of the information(red line). Additionally, WDQN-SDPL answers the postcode of the restaurant (blue line) and the dialog proceeds successfully, however, WDQN fails.

	Movie-Ticket Booking	MultiWoz
Dialogues	2,890	8,438
Intents	11	13
Slots	29	25
Avg. turns per dialogue	7.5	13.68
Domains	1	7

Abstract

While research on explaining predictions of open-domain QA systems (ODQA) is gaining momentum, most works do not evaluate whether these explanations improve user trust. Furthermore, many users interact with ODQA using *voice*-assistants, yet prior works exclusively focus on *visual* displays, risking (as we also show) incorrectly extrapolating the effectiveness of explanations across modalities. To better understand the effectiveness of ODQA explanations strategies in the wild, we conduct user studies that measure whether explanations help users correctly decide when to accept or reject an ODQA system's answer. Unlike prior work, we control for explanation *modality*, *i.e.*, whether they are communicated to users through a spoken or visual interface, and contrast effectiveness across modalities. We show that explanations derived from retrieved evidence can outperform strong baselines across modalities but the best explanation strategy varies with the modality. We show common failure cases of current explanations, emphasize end-to-end evaluation of explanations, and caution against evaluating them in proxy modalities that differ from deployment.

1 Introduction

Despite copious interest in developing explainable AI, there is increasing skepticism as to whether explanations (of system predictions) are useful to end-users in downstream applications. For instance, for assisting users with classifying sentiment or answering LSAT questions, Bansal et al. (2021) observed no improvements from giving explanations over simply presenting model confidence. Similarly, Chu et al. (2020) observed that visual explanations fail to significantly improve user accuracy or trust. Such negative results present a cautionary tale for explainability and emphasize the need to evaluate explanations using careful user studies.

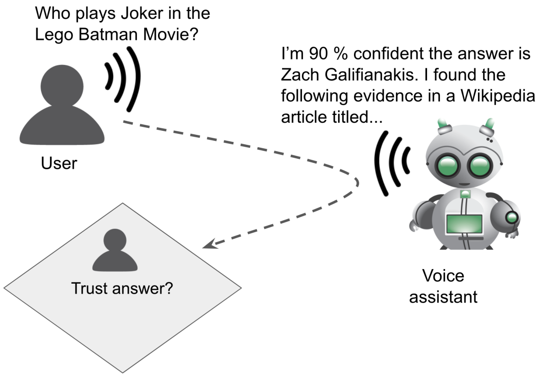

Figure 1: Using end-to-end user studies, we evaluate whether explanation strategies of open-domain QA assistants help users decide when to trust (or reject) predicted answers.

We explore the effectiveness of explanations for ***O**pen-**D**omain **Q**uestion **A**nswering* models, which involves answering users' questions (*e.g.*, *"Who plays the Joker in the Lego Batman movie?"*) using a large corpus (*e.g.*, Wikipedia). Such models are increasingly deployed not only in visual modalities (*e.g.*, Web search) but also in spoken ones (voice assistants).[1] Spoken interfaces for ODQA are also important because they make ODQA systems more accessible for users with visual impairments. Despite improvements in accuracy, deployed ODQA models remain imperfect. This motivates the need to provide users with mechanisms (*e.g.*, estimates of uncertainty or explanations) that can help improve *appropriate reliance* (Lee and See, 2004), *e.g.*, by allowing users to detect erroneous answers. We henceforth refer to a user's ability to distinguish correct and incorrect answers as *error-detectability*, and ask *Does explaining the system's reasoning, help improve error-detectability?* (Figure 1).

Alongside recent negative results (Bansal et al., 2021), Lamm et al. (2020) showed that visually complex "QED" explanations that communicate

---

[1] `https://www.perficient.com/insights/research-hub/voice-usage-trends`

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1103–1116
August 1–6, 2021.

coreference and entailment information along with evidence marginally improve error-detectability. However, the study lacks the recommended baseline (Amershi et al., 2019; PAIR, 2019) of communicating model confidence which has been shown to be effective on other domains (Bansal et al., 2021). Also, the transferability of complex visual explanations to the spoken modality remains unclear. Although Feng and Graber (2019) compare visual explanations with presenting model confidence on a different QA task, i.e., answering timed, multi-clue trivia questions, it was unclear whether explanations led to appropriate reliance (Bansal et al., 2021); thus the effectiveness of explanations for end users of QA systems still remains unclear. In this paper, we set out to evaluate the ability of NL explanations in both visual and spoken modalities, to improve error-detectability for the task of ODQA for non-expert users over strong baselines.

However, explaining ODQA systems in the spoken modality may pose unique challenges, *e.g.*, because the same information content can impose higher cognitive demands when communicated by voice than visually (Sweller, 2011; Leahy and Sweller, 2016); potentially reducing effectiveness of longer, more complex explanations (*e.g.*, QED) in the *spoken* modality. Thus we also ask, *Can the most useful explanation strategy change with the modality?* In summary:

1. We present user studies evaluating how well explanations for ODQA help users detect erroneous answers (error-detectability). Unlike prior work, we evaluate explanations in both visual and spoken interfaces, and compare against calibrated confidence.
2. Our experiments with over 500 MTurk users confirm significant improvements in error-detectability for ODQA over showing confidence. To the best of our knowledge, our work is the first to show statistically significant improvements in appropriate reliance through NL explanations for non-expert users. (Section 4.1)
3. We show that the best explanation approach can change with the modality: while longer explanations (evidence paragraphs) led to the highest error-detectability in the visual modality, shorter explanations (evidence sentence) performed best in the spoken modality. We connect our observations with prior work on cognitive science and identify failure cases for ODQA explanations (Section 4.3).

2 Background

Open-domain QA. ODQA involves answering questions using a large, broad corpus of unstructured documents (*e.g.*, Wikipedia or the Web). More specifically, the questions are factoid and the target answer is present as a span in one of the documents (Voorhees et al., 1999).

Recent models for ODQA use a pipelined approach and contain two components: a document *retriever* that finds a subset of the most relevant documents from the corpus, and a *reader* that selects an answer span from the retrieved documents (Chen et al., 2017; Lee et al., 2019a). We use a state-of-the-art ODQA model and a benchmark dataset that contains questions asked by real lay users (Section 3.3).

An ODQA model's prediction can be explained by providing a justification in natural language, *e.g.*, by extracting snippets of text from the retrieved documents (*rationales*) or more generally by generating new text (*abstractive explanation*). For example, rationales can explain a text classifier using phrases in the input text that are relevant to the prediction (Lei et al., 2016). However, for some tasks, such as NLI (Camburu et al., 2018) and common-sense reasoning (Rajani et al., 2019), the input text alone may not contain enough meaningful justification for the prediction. For other tasks, the evidence can be spread across documents (*e.g.*, HotpotQA; Yang et al. (2018)). In such cases, abstractive explanations become more useful. While we primarily focus on extractive explanations, we also experiment with abstractive explanations (Section 3.1).

Evaluating explanations. One important reason to explain ODQA models is to improve error-detectability (Figure 1).[2] Many prior works evaluate the quality of NL explanations by comparing similarity with human-written explanations for tasks such as NLI, common-sense reasoning and fact verification (DeYoung et al., 2020; Paranjape et al., 2020; Swanson et al., 2020; Camburu et al., 2018; Rajani et al., 2019). Other works conduct user studies but rely on *proxy* tasks, *e.g.*, whether explanations allow users to anticipate the model predictions (Hase and Bansal, 2020; Nguyen, 2018). However, evaluating explanations on such

---

[2] Note that there exists other downstream applications of explanations, such as debugging models (Koh and Liang, 2017).

proxy tasks and metrics, which differ from the actual deployment setting, risks drawing misleading conclusions about the effectiveness of explanations in practice (Buçinca et al., 2020). Thus, we focus on directly evaluating explanations using user studies on error-detectability.

Feng and Graber (2019) found that explanations improve player accuracy when answering Quizbowl questions. Our task differs from Quizbowl in many respects: 1) Unlike Quizbowl where the users are trivia enthusiasts or experts, ODQA users are non-experts, lay people who ask questions to satisfy their information needs. Thus, ODQA users have no or very limited expertise in answering these questions. 2) While Quizbowl questions comprise multiple clues (incrementally revealed) for a single answer, ODQA questions typically contain a single clue. 3) Feng and Graber (2019) observed improvements from the explanations when their QA model was considerably more accurate than their users, outperforming the best trivia players. In contrast, we carefully design our user study so that on our study sample, users cannot achieve high performance by simply trusting the model (Section 3.3).

Visual vs. spoken modalities. We hypothesize that differences in processing of spoken and written information can substantially impact the effectiveness of NL explanations in ODQA. For example, Flowerdew et al. (1994) observed that one of the main differences in processing spoken versus written information is linearity. When listening, information progresses naturally, as opposed to reading, where people are able to jump back and forth in the text (Buck, 1991; Lund, 1991). This results in differences in recall of information across the two modalities (Osada, 2004). Although it is possible to repeat spoken information, Lund (1991) found that for some listeners, listening to information again was not as effective as re-reading. Another difference is the effect on concentration across modalities. Thompson and Rubin (1996) found that the heavier cognitive load imposed by listening to information can make people lose concentration more easily. Our experimental setup is the first to evaluate explanation effectiveness across these two modalities.

3 Experimental Setup

We evaluate explanation effectiveness for ODQA by varying the *type* of explanation and *modality* of communication. We combine variations of each factor to obtain explanation conditions (Section 3.1) for a state-of-the-art ODQA model (Section 3.3). We then deploy these conditions on Amazon Mechanical Turk (MTurk) to validate our hypotheses about the effectiveness of improving error-detectability (Section 3.2). We justify various design choices made to ensure quality in Section 3.4.

3.1 Explanation Types and Conditions

ODQA models can justify their predictions by pointing to *evidence* text containing the predicted answer (Das et al., 2018; Lee et al., 2019a; Karpukhin et al., 2020). We experiment with two types of *extractive* explanations:

- EXT-SENT: Extracts a sentence containing the predicted answer as evidence.
- EXT-LONG: Extracts a longer, multi-sentence paragraph containing the answer as evidence.

While extractive explanations are simpler to generate, we also evaluate a third explanation type that has potential to more succinctly communicate evidence spread across documents (Liu et al., 2019).

- ABS: (Abstractive) Generates a new text snippet to justify the predicted answer.

Explanation conditions. For the *spoken modality*, we test five conditions (two baselines and three explanation types): (1) BASE: present only the top answer, (2) CONF, a stronger baseline that presents the top answer along with the model's certainty, (3) ABS, (4) EXT-LONG, and (5) EXT-SENT. In the *visual modality*, we test two explanation types: EXT-LONG and EXT-SENT. We implemented these two types to contrast their effectiveness effectiveness across modalities (Figure 2, Section 3.4). For all explanation conditions, we show confidence, mention that the answer was obtained from Wikipedia and provide the source article. [3]

3.2 Hypotheses

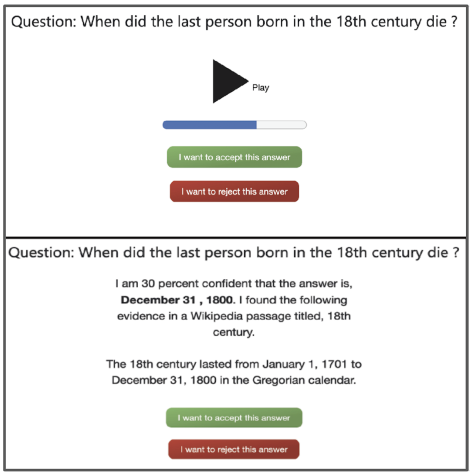
We investigated five (pre-registered) hypotheses about the relative performance of various explanation conditions at improving the accuracy of error-detectability (Section 3.4):

H1 CONF will improve accuracy over BASE.

H2 *Spoken* EXT-SENT will improve accuracy over CONF— the explanation would provide additional context to help validate predicted answers.

---

[3] Appendix A shows more examples.



Question: When did the last person born in the 18th century die ?

Question: When did the last person born in the 18th century die ?

I am 30 percent confident that the answer is, **December 31 , 1800**. I found the following evidence in a Wikipedia passage titled, 18th century.

The 18th century lasted from January 1, 1701 to December 31, 1800 in the Gregorian calendar.

Figure 2: **UI** for spoken (top) and visual modalities (bottom) for the EXT-SENT explanation type. Users either read or hear an explanation and decide whether to trust or discard the QA system's prediction.

- **H3** *Spoken* EXT-SENT will lead to higher accuracy than *Spoken* EXT-LONG. Since the spoken modality may impose higher cognitive limitations on people (Section 2), concise explanations may be more useful despite providing less context.
- **H4** ABS will improve accuracy over *Spoken* EXT-SENT. ABS contains more relevant information than EXT-SENT (same length), which may help users make better accept/reject decisions.
- **H5** *Visual* EXT-LONG will lead to higher accuracy than *Spoken* EXT-LONG.

3.3 Implementation Details for Conditions

Dataset. We used the Natural Questions (NQ) corpus (Kwiatkowski et al., 2019). NQ is composed of anonymized queries posed by real users on the Google search engine. The answers are human-annotated spans in Wikipedia articles. As factoid web search is typically done through both spoken and visual modalities, this data is an ideal choice for our evaluation setup. To simplify the study, we restrict to questions with short target answers (< 6 tokens) (Lee et al., 2019b). This subset contains 80k training examples, 8,757 examples for development, and 3,610 examples for testing.

Model. We train the current (extractive) state-of-the-art model on NQ: Dense Passage Retrieval and Reader (DPR) (Karpukhin et al., 2020). Similar to Karpukhin et al. (2020), we split documents (Wikipedia articles), into shorter passages of equal lengths (100 tokens). To answer an input question, DPR uses two separate *dense* encoders $E_Q(\cdot)$ and $E_P(\cdot)$ to encode the question and all passages in the corpus into vectors. It then retrieves k most similar passages, where *passage similarity* to a question is defined using a dot product: $sim(q,p) = E_Q(q)^{\intercal} E_P(p)$. Given the top k passages, a neural reader (Section 2) assigns a passage selection score to each passage, and a *span score* to every answer span. [4]

Generating explanations. Extractive explanations use the passage associated with DPR's answer— EXT-SENT uses the sentence containing the answer whereas EXT-LONG uses the entire passage. Since DPR does not generate abstractive explanations, we simulate ABS by manually creating a single sentence that captures the main information of EXT-SENT and adds additional relevant information from EXT-LONG, whilst remaining the same length as EXT-SENT. To improve transparency, all explanation conditions also inform the source to the users, by providing them the *title* of the article. Figure 2 shows an example of the final EXT-SENT explanation condition. To convert text to speech, we use a state-of-the-art TTS tool. When spoken, questions in our final ABS and EXT-SENT conditions were on average 15 seconds long, EXT-LONG was between 30-40 seconds.

Confidence calibration. Confidence scores generated by neural networks (*e.g.*, by normalizing softmax scores) often suffer from poor calibration (Guo et al., 2017).To alleviate this issue and to follow best practices (Amershi et al., 2019; Bansal et al., 2021), we calibrate our model's confidence using *temperature scaling* (Guo et al., 2017), which is a *post hoc* calibration algorithm suitable for multi-class problems. We calibrate the top 10 outputs of the model. We defer additional details of calibration to Appendix B.

3.4 User Study & Interface

We conduct our experiments using Amazon Mechanical Turk. For each of the 7 conditions we hire 75 workers, and present each with 40 questions (this amounts to a total of 21,000 data samples) one-by-one, while showing them the model's answer (along with other condition-dependant information, such as confidence or explanation) and ask them to

---

[4] We re-score each answer using the product of the passage and span score and use the highest-scored answer as the prediction— Our initial analysis showed that this re-scoring improved exact match scores of predicted answers.

either *accept* the model's prediction if they think it is correct or *reject* it otherwise. Figure 2 shows an example. Additional details about the platform and participants can be found in Appendix D.

Question selection. We sample a set of questions on which the model's aggregate (exact-match) accuracy is 50%; thus any improvements in error-detectability, beyond random, must be a result of users making optimal assessment about the model's correctness. To improve generalization, we average results over three such mutually exclusive sets of 40 questions. Before sampling the questions, we removed questions that were ambiguous or questions where the model was correct but the explanations failed to justify the answer. Appendix C contains additional details on question selection.

Incentive scheme. In addition to providing a fixed upfront pay of $10 for participating in the task, to encourage workers to engage, we also used a bonus-based strategy (Bansal et al., 2019) — When users accept a correct answer, we provide a 15 cent bonus, but when they accept an incorrect answer they lose the same amount. When they reject an answer, however, they do not receive any bonus.[5] This aims to simulate the real-world cost and utility of users choosing to believe answers of an ODQA model. The maximum cumulative reward is $ 2.70. These values were chosen to ensure workers earned minimum a $15 hourly wage.

Post-task survey. After the main task, we asked participants to (1) rate the length of responses, (2) rate their helpfulness and (3) give us general feedback on what worked and how explanations could be made better. For the *spoken modality*, we also asked participants to rate the clarity of the voice to understand if issues in text-to-speech confused them. Appendix E contains the complete survey.

Metrics for error-detectability. We quantify user performance at error-detectability using the following three metrics:

1. **Accuracy**: Percentage of times a user accepts correct and rejects incorrect answers. A high accuracy indicates high error-detectability.
2. **% Accepts | correct**: Indicates the true positive rate, *i.e.*, percentage of times the user accepts *correct* answers.

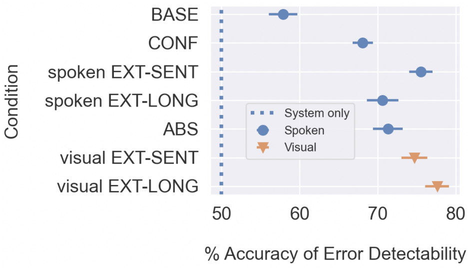


Figure 3: Accuracy of users. In the *spoken modality*, EXT-SENT explanations yield the best results and is significantly better than CONF. In the *visual modality*, EXT-LONG perform best. We observe a statistically significant ($p < 0.01$) difference between EXT-LONG in visual versus spoken, perhaps because of differences in user's cognitive limitations across modalities.

3. **% Accepts | incorrect**: Indicates the false positive rate, *i.e.*, percentage of times the user accepts *incorrect* answers. If a setting yields a high number, this would indicate that this setting misleads users more often.

We do not present true and false negative rates because conclusions are similar. We additionally measure time spent on each question and cummulative reward. These metrics are explained in Appendix F. When computing all metrics, we removed the first 4 questions for each worker to account for workers getting used to the interface. We preregistered this procedure prior to our final studies.

4 Results

To validate our hypothesis (Section 3.2) we compare explanation methods on the quantitative metrics (Section 4.1). To further understand participant behavior we analyze responses to the post-task survey (Section 4.2), and analyze common cases where explanations misled the users (Section 4.3).

4.1 Quantitative Results

Figure 3 displays average accuracy with 75 workers per condition. Similar to Lamm et al. (2020), to validate hypotheses and compute statistical significance, we fit a generalized linear mixed effects model using the `lme4` library in R and the formula `a~ c +(1|w) + (1|q)`, where `a` is accuracy, `c` is the condition, `w` is the worker id and `q` is the question id. We run pairwise comparisons of these effects using Holm-Bonferroni to correct for multiple hypothesis testing. For both the spoken and visual modalities, all conditions lead to significantly higher accuracies than BASE ($p < 0.01$).

---

[5] if bonus is negative, no deductions re made from base pay. Bonus is instead set to zero

Model confidence improved accuracy of error-detectability. In Figure 3, CONF achieves higher accuracy than BASE– 68.1% vs. 57.2%. This difference was statistically significant ($p < 0.01$), **validating H1**. While previous guidelines recommend displaying confidence to users (Amershi et al., 2019; Bansal et al., 2021), our observations provide the first empirical evidence that confidence is a simple yet stronger baseline against which explanations for ODQA should be compared.

Explaining via an evidence sentence further improved performance. The more interesting comparisons are between explanation types and CONF. In both modalities, EXT-SENT performed better than CONF. For example, in the *spoken modality*, EXT-SENT improved accuracy over CONF from 68.1% to 75.6% ($p < 0.01$); thus **validating H2**. Contrary to recent prior works that observed no benefit from explaining predictions, this result confirms a concrete application of explanations where they help users in an end-to-end task.

Longer explanations improved performance over concise explanations in the visual modality, but worsened performance in the spoken modality. Figure 3 shows that for the visual modality, EXT-LONG outperforms EXT-SENT explanations – 77.6% vs. 74.7% ($p < 0.4$). Conversely, for spoken, EXT-SENT is better than EXT-LONG– 75.6% vs. 70.4% ($p < 0.01$); thus **validating H3**. The decrease was severe enough that we no longer observed a statistically significant difference between EXT-LONG and CONF ($p = 0.9$), reemphasizing the importance of comparing against the latter. Although communicating the same content, *visual* EXT-LONG led to significantly better accuracy than their spoken version— 77.6% vs. 70.4% ($p < 0.01$); thus **validating H5**. These results indicate large differences, across modalities, in user ability to process and utilize explanations, and how these differences need to be accounted for while evaluating and developing explanations.

Despite improving conciseness, abstractive explanations did not help improve performance in the spoken modality. Figure 3 shows that ABS performs significantly worse than EXT-SENT in the spoken modality– 71.3% vs. 75.6% ($p < 0.01$) and thus we could **not validate H4**. This result indicates that the length of the explanation (*e.g.*, number of tokens) is not the only factor that affects user performance, instead, the density of information also increases cognitive load on users. This finding is in line with the Time Based Resource Sharing (TBRS) model (Barrouillet et al., 2007), a theory of working memory establishing that time as well as the complexity of what is being communicated, both play a role in cognitive demand. We also observe a similar effect in users' subjective rating of length of explanation (Section 4.2).

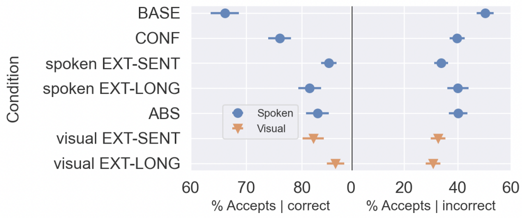

Figure 4: (Left) Explanations significantly increased participant ability to detect *correct* answers compared to CONF. (Right) However, only EXT-SENT in the spoken modality and both explanations in the visual modality decreased the rate at which users are misled.

All explanations significantly increased participants' ability to detect *correct* answers, but only some explanations improved their ability to detect *incorrect* answers. Instead of aggregate accuracy, Figure 4 splits and visualizes how often users accept correct and incorrect answers. For accepting *correct* model predictions, all *visual* and *spoken* explanation conditions significantly helped compared to CONF (at least $p < 0.05$).

For accepting incorrect predictions, in the *spoken modality*, only EXT-SENT is significantly better (*i.e.*, lower) than CONF—34% vs. 40% ($p < 0.05$). Whereas in the *visual modality*, both EXT-LONG and EXT-SENT lead to improvements over CONF—30% ($p < 0.01$) and 32% ($p < 0.05$), respectively. This shows that although explanations decrease the chance of being misled by the system, the least misleading explanations change with modality.

4.2 Qualitative Results

We analyzed user responses to the post-task survey to understand their experience, what helped them and how the system could serve them better. We discuss the main findings here and reserve additional results to the Appendix.

Length preference. We asked participants to rate the length of the explanation as *too short, short, right, long,* or *too-long*. Figure 5 shows the results. For EXT-LONG, over 85% of the workers perceived that in the *visual modality*, responses

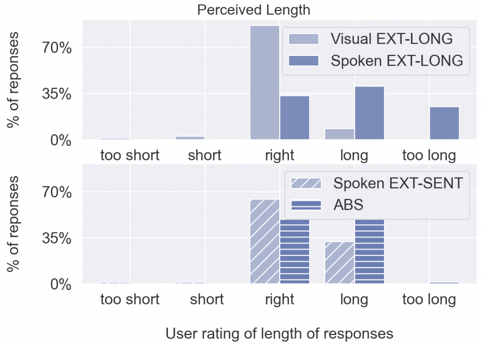

Figure 5: Users rated how they perceived the length of each explanation strategy. **Top:** Spoken explanations were perceived to be longer. **Bottom:** While EXT-SENT and ABS were the same length, the latter was rated as longer more often perhaps because of its complexity.

were the right length. On the other hand, in the *spoken modality*, only 30% of participants agreed the length was right. Thus, user's subjective ratings for the same explanation type were dramatically different across modalities. Indicating, in addition to affecting error-detectability, the modality also changes users' subjective preferences.

While ABS and EXT-SENT were the same duration, users rated ABS as longer than EXT-SENT. As mentioned before, this relates to the TBRS model of working memory (Barrouillet et al., 2007). We hypothesize that *our* ABS explanations, which integrate more information than EXT-SENT in the same amount of time, were more taxing for user's working memory, thereby reducing error-detectability and increasing perception of length.

User feedback. To understand how we can develop better explanations, we asked participants: *Do you have any additional feedback on what the system can improve?* To analyze responses, two annotators (authors) coded 400 responses. After removing responses that were not descriptive (*e.g.*, "can't think of anything to improve"), 175 responses remained for the final analysis. We computed the inter-annotator agreement using Cohen's k (=0.74). Here we describe the most interesting findings, but Appendix F shows additional results and details.

In BASE, where the answer was provided with no additional information, about 50% of **participants mentioned that they would have liked it if the voice changed with system certainty**. In CONF, around 30% of participants give this feedback.

For EXT-SENT in both modalities, EXT-LONG in the visual modality, and ABS, 10-35 % of **participants would like the level of detail to adapt to the model certainty**. Users would like to have more detail *only* when the model is not confident.

For EXT-LONG in the *spoken modality*, the feedback centered around length. 78% of participants mentioned that responses should be shorter, which aligns with the higher perceived length of the explanations in Figure 5. For the *visual modality*, 40 % of participants mention that highlighting some key items would have made it even easier and faster. Introducing highlights would improve the visual interface and would likely increase the differences in modality already observed.

Finally, for all explanation conditions, 20-45% of **participants said they would like to see explanations from multiple sources for an answer**, *e.g.*, from non-Wikipedia sources to help them better decide whether to trust the answer.

4.3 What Misleads Users?

To understand how explanations can mislead users, we analyzed questions where users frequently accepted incorrect predictions (false positives). A single annotator then followed a similar coding procedure to detect categories of such questions. We found that users were frequently misled on the same 30% of our study questions. Below we describe the two main categories:

Plausible explanations. We find 60-65% cases where an explanation does not confirm the predicted answer but makes it seem plausible, misleading users into accepting incorrect responses. This phenomenon is similar to prior work in psychology that has shown that people often fail to evaluate the accuracy of information when they have little prior knowledge and information seems plausible (Hinze et al., 2014).

> **Question:** *Who is the patron saint of adoptive parents?*
> **Response:** I am 37 percent confident that the answer is, **Saint Anthony of Padua**. I found the following evidence in a wikipedia passage titled, Anthony of Padua: Saint Anthony of Padua, born Fernando Martins de Bulhoes, also known as Anthony of Lisbon, was a portuguese catholic priest and friar of the Franciscan order.

In the example above, the model is incorrect (true answer is Saint William of Perth), but users were often misled to accept this answer because the evidence makes the prediction sound plausible.

Lexical overlap. The second most common mistake (from 30 to 35% of errors) that both *the model* and *the users* make is related to the lexical overlap between the question and the evidence. For instance, in the example below, the evidence contains the correct answer (15 teams) but many users are misled by the phrase *"A total of 30 teams play in the National League."*

Question: *How many teams are in the MLB national League?*
Response: I am 60 percent confident that the answer is, **30**. I found the following evidence in a wikipedia passage titled, Major League Baseball: *A total of 30 teams play in the National League(NL)* and American League (AL) , with 15 teams in each league .

5 Discussion

5.1 Why Explanations Worked for ODQA

Unlike previous studies (Bansal et al., 2021; Chu et al., 2020; Hase and Bansal, 2020), we observed significant improvements from explanations over only communicating confidence. One reason for our positive results could be owing to the nature of ODQA i.e. unlike tasks such as sentiment classification, where humans may be able to solve the task without relying on explanations, ODQA requires satisfying a user's information need, which may take considerably longer without explanations; users *require* additional help to navigate through vast amounts of information. Another potential reason is, in ODQA, presenting a single good explanation can allow users to verify whether the prediction is correct. In contrast, in sentiment analysis, even if the explanation points to evidence for a positive sentiment ("the smell was delicious"), there is always a chance that another phrase ("but the taste made me puke") renders the net correct label as negative. It is worth noting that like previous works, not all of our explanation methods provide significant value (Figure 3); thus the success from showing explanations still cannot be taken for granted but should instead be measured using well-designed user studies.

5.2 Implications and Recommendations

Another interesting question is how can our findings inform future research in explainable NLP.

Develop modality-specific explanations. Our results showed that the best explanation varied across modalities, indicating that evaluating explanations on one modality (*e.g.*, visual UI) and deploying them on another (*e.g.*, voice assistant) can lead to sub-optimal deployment decisions. As a result, explanations should be optimized for and evaluated in the task and settings in which they will be deployed in-the-wild.

Further study abstractive explanations. Longer explanations helped improve error-detectability in the visual modality, but they hurt in the spoken case, perhaps because of the increased cognitive load. This may indicate a trade-off between *information content* of explanation and its *cognitive load.* While we hoped abstractive explanations would achieve an optimal balance, results showed that they did not improve end-performance. Perhaps because even though they were more concise, they still had high information density. Though, abstractive explanations showed some promise. For example, compared to longer explanations, they improved speed of error-detectability by 2.2 sec (discussed in Appendix, Table 2) and their length was rated as more satisfactory (Figure 5). Thus future work should explore whether benefits of abstractive increase when explaining multiple sources (*e.g.*, in (Yang et al., 2018)) or candidate answers.

Enable interactive explanations. To manage a balance between information content and cognitive load one may also use interactive explanations (Weld and Bansal, 2018), where the system presents a concise explanation and lets users request more details, *e.g.*additional evidence, sources, or candidate answers (Section 4.2). Another option is *adaptive* explanations, where the model switches explanation strategies based on its confidence (Bansal et al., 2021).

6 Conclusion

We conducted user studies to understand whether explanations from a state-of-the-art open-domain QA system help improve error-detectability for end-users. Our study showed that for ODQA, simple explanations based on evidence snippets can significantly improve error-detectability and beat strong baselines such as communicating model's confidence. We observed this for multiple modalities of interaction: spoken and visual modalities. However, results also indicated that not every explanation type is guaranteed to improve performance over confidence and the best explanation strategy may change with the modality, *e.g.*, due to differences in users' cognitive abilities across modalities. Thus, developers and researchers of explainable ODQA systems should not take the effectiveness of explanations for granted and should evaluate and tune them on the tasks and modalities where these models will be eventually deployed.

7 Ethical Impact Statement

Recent work has shown that explanations may increase blind trust in systems (Bansal et al., 2021). Deploying such explanations in the wild is ethically fraught, hence we should better evaluate explanations using human evaluation before deployment. Our study expands the knowledge in this direction and show that current explanation strategies can work, but they can still considerably mislead users to accept incorrect model predictions. We hope that our findings and recommendations will have a positive impact on how explainable NLP is developed and evaluated in future work; namely, through carefully designed user studies which inform us of the real-world utility of explanations. In terms of data collection, the study was approved by IRB and no sensitive or personally identifiable data was collected, and users were informed that their efforts would end in a research publication.

A Explanation Examples

In Table 1, we show an example of how the responses and explanations looked for each of the conditions. We also indicate in which modalities each explanation is shown in our experiments.

B Temperature Scaling

Temperature scaling (Guo et al., 2017), a multi-class extension of Platt Scaling (Platt et al., 1999), is a post-processing method applied on the logits of a neural network, before the softmax layer. It consists of learning a scalar parameter t, which decreases or increases confidence. t is used to rescale the logit vector z, which is input to softmax σ, so that the predicted probabilities are obtained by $\sigma(z/t)$, instead of $\sigma(z)$.

In our experiments, the model is set to pick from the top 100 solutions, however, in many cases the correct answer occurs within the top 10 items. For our purposes we calibrate the confidence scores of the top 10 outputs. We use the publicly available scripts provided by Guo et al. (2017).[6]

The model confidence before and after calibration can be seen in Figure 6.

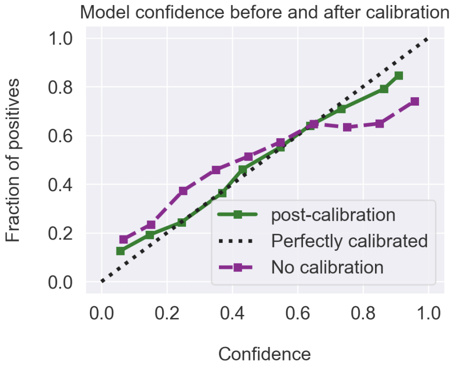

Figure 6: Confidence before and after calibration.

C Additional Preprocessing

Additional preprocessing to ascertain the quality of stimuli in each modality was required. Before sampling questions for the task, to ensure a high-quality and non-ambiguous experience for MTurk workers, we manually filter out several "problematic" questions:

- **Ambiguity in the question**: For various questions in NQ, multiple answers can exist. For example, the question: *when was King Kong released?*, does not specify which of the many King Kong movies or video games it refers to. These cases have been known to appear often in NQ (Min et al., 2020). We remove such questions from our subset.

- **The gold answer was incorrect**: Many examples in NQ are incorrectly annotated. As it is too expensive to re annotate these cases, we remove them.

- **Answer marked incorrect is actually correct** : We present both correct and incorrect questions to users. There are cases where the predicted answer is marked incorrect (not exact match) but is actually correct (a paraphrase). We manually verify that correct answers are paired with contexts which support the answer.

- **Correct answer but incorrect evidence**: The model sometimes, though not as often, chooses the correct answer but in the incorrect context. We discarded examples where the explanation was irrelevant to the question e.g. who plays Oscar in the office? *Oscar Nuñez, is a Cuban-American actor and comedian.*. In order to be able to make more general conclusions about whether explanations help in error-detectability, we restrict our questions to ones containing correct answers in the correct context.

- **Question and prediction do not match type**. We removed cases where the question asked for a certain type e.g. a date, and the prediction type did not match e.g. a location.

In the visual modality, to ensure readability, we fixed capitalizations. For the spoken modality, to ensure fluency and clarity, we manually (1) inserted punctuation to ensure more natural sounding pauses, and (2) changed abbreviations and symbols to a written out form e.g. *\$ 3.5 billion* to *3.5 billion dollars*.

D Task Setup: Additional details

Platform and participant details. We conduct our experiments using Amazon Mechanical Turk[7]. We recruited 525 participants in total, with approval ratings greater than 95 % and had a maximum of 8

---

[6] https://github.com/gpleiss/temperature_scaling

[7] https://www.mturk.com/

EXPLANATION TYPE	RESPONSE+EXPLANATION	MODALITY
BASE	The answer is, **two**.	Spoken
CONF	I am 41 percent confident that the answer is, **two**.	Spoken
ABS	I am 41 percent confident that the answer is, **two**. I summarized evidence from a wikipedia passage titled, Marco Polo (TV series). Netflix cancelled the show after two seasons, as it had resulted in a 200 million dollar loss.	Spoken
EXT-SENT	I am 41 percent confident that the answer is, **two**. I found the following evidence in a wikipedia passage titled, Marco Polo (TV series). On December 12, 2016, Netflix announced they had canceled "Marco Polo" after two seasons.	Spoken/Visual
EXT-LONG	I am 41 percent confident that the answer is, **two**. I found the following evidence in a wikipedia passage titled, Marco Polo (TV series). On December 12, 2016, Netflix announced they had canceled "Marco Polo " after two seasons. Sources told "The Hollywood Reporter" that the series' two seasons resulted in a 200 million dollar loss for Netflix , and the decision to cancel the series was jointly taken by Netflix and the Weinstein Company. Luthi portrays Ling Ling in season 1, Chew in season 2. The series was originally developed at starz, which had picked up the series in January 2012.	Spoken/Visual

Table 1: **Explanation examples:** Example of how system responses looked for each explanation type and baseline, for the question *How many seasons of Marco Polo are there?*

days for approval of responses in order to minimize the amount of spamming.

We use a random sample of 120 questions from our dataset which remains the same across all conditions. In order to keep each session per participant at a reasonable time and ensure the quality of the data wouldn't be affected by workers becoming exhausted, we opted for three fixed batches of 40 questions, all split as 50 % correct and 50 % incorrect. Workers could only participate once (only one batch in one condition). Participants took around from 35-45 minutes to complete the HITs, but were given up to 70 minutes to complete.

We monitored if their screen went out of focus, to ensure that participants did not cheat. We ensured that we had 25 user annotations per question. When analyzing the data, we remove the first 4 questions of each batch, as it may take participants a few tries before getting used to the interface. In the end, we collect about 21,000 test instances.

Task Instructions. Imagine asking Norby a question and Norby responds with an answer. Norby's answer can be correct or wrong. If you believe Norby's answer is correct, you can accept the answer. If you believe it is wrong, you can reject it. If the answer is actually correct and you accept it, you will earn a bonus of \$0.15. But, if the answer is wrong, and you accept it, you will lose \$0.15 from your bonus. If you reject the answer, your bonus is not affected. (Don't worry, the bonus is extra! Even if it shows negative during the experiment, in the end the minimum bonus is 0). In total you will see 40 questions in this HIT (you will only be allowed to participate once) and the task will take about 40 to 45 minutes. You can be compensated a maximum of \$13.50 for about 40-45 minutes of work. Some things to note:

1. You must listen to the audio before the options become available.
2. If you make it to the end there is a submit button there, however, in case of an emergency you can hit the quit early button above and you will get rewarded for the answers you provided.
3. You can play the audio as many times as you need but as soon as you click a choice you will be directed to the next item.
4. **IMPORTANT!!** Please do not look up questions in any search engine. We will monitor when the screen goes out of focus, so please keep the screen on focus or you might risk being rejected.
5. Finally, please do not discuss answers in forums; that will invalidate our results.

E Post-task Survey

1. I found the CLARITY of Norby's voice to be:

   (a) Excellent **(b)** Good **(c)** Fair **(d)** Poor **(e)** Very Poor

2. I found Norby's responses to be HELPFUL when deciding to Accept or Reject:

(a) Strongly Agree **(b)** Agree **(c)** Undecided **(d)** Disagree **(e)** Strongly Disagree

Can you give a few more details about your answer?

3. I found the LENGTH of Norby's responses to be:

   (a) Too Long **(b)** Long **(c)** Just right **(d)** Short **(e)** Too short

4. No AI is perfect and Norby is no exception. We are interested in helping Norby provide responses that can help users to determine whether to trust it or not (to accept or reject, just as you have done in this experiment). From your interaction with Norby, **do you have any additional feedback on what it can improve?**

F Results

Reward. Cummulative reward is the total dollar reward in bonuses earned by a worker based on the payoff described earlier. Note that, unlike accuracy, the payoff matrix is not symmetric wrt. user decision and correctness of predictions. We compute the differences in overall reward for each condition and observe the same trends as we discussed for accuracy. More specifically, all explanation conditions improve the final user reward, with EXT-SENT performing best in the spoken modality and EXT-LONG performing best overall. These differences are shown in Figure 7.

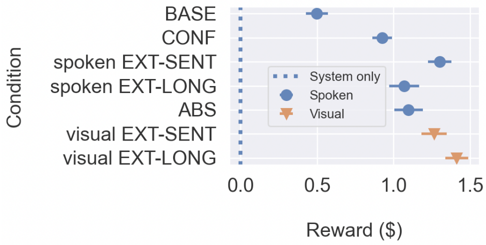

Figure 7: **Reward**: The scores presented here are out of $ 2.70. Although all explanations are better than CONF, the explanations leading to the highest rewards change across modalities.

Time differences. We measured the time (in seconds) that it took participants to complete each question. In Table 2 we present the median times averaged over all workers per condition. We also include an adjusted time, subtracting the length of the audio, in order to measure decision time.

CONDITION	SEC/QUESTION	ADJUSTED
SPOKEN MODALITY		
BASE	10.2 ± 1.6	8.3 ± 1.6
CONF	9.4 ± 1.5	6.0 ± 1.5
ABS	24.4 ± 1.5	7.0 ± 1.4
EXT-LONG	44.9 ± 1.6	9.2 ± 1.6
EXT-SENT	24.3 ± 1.7	7.6 ± 1.7
VISUAL MODALITY		
EXT-LONG	16.1 ± 1.7	-
EXT-SENT	10.4± 1.1	-

Table 2: Time differences across modalities. Time differences in the right column have been adjusted by removing the duration of the audio files. We observe that with additional information, users can make faster decisions than the BASELINE condition.

Voice quality. To verify that the quality of the text-to-speech tool that we employed did not negatively affect our experiments, we asked users to rate the clarity of the assistant's voice as *very poor, poor, fair, good*, or *excellent*. Around 90 % rated the voice as good or excellent. These results are shown in Figure 8.

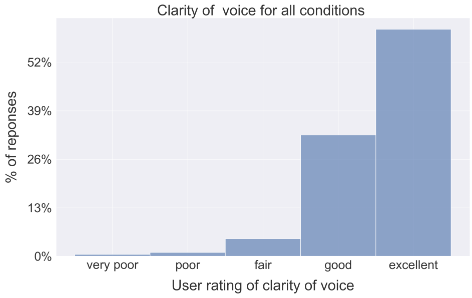

Figure 8: **Voice clarity:** Most participants found the voice of the assistant to be good or excellent.

Helpfulness. Participants were asked whether the responses helped them in their decision making. Their responses showed that CONF and all explanation conditions were perceived as helpful by at least 80% of participants, with no real differences among them except for EXT-LONG in the visual modality (which is perceived helpful by close to 90% of users). Interestingly, 50% of participants indicated BASE to be helpful. In contrast, our results in Figure 3 show that different explanations actually differ in their eventual helpfulness. These results suggest that subjective measures can sometimes correlate with actual performance when the differences are large, but for the most-part and smaller differences, the result from subjective rating can be unreliable. These findings align with prior observa-

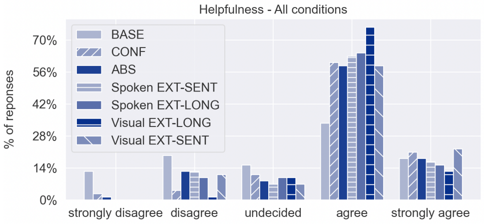

Figure 9: **Helpfulness:** Participants indicated how helpful responses were. These results reflect the large differences we see in performance (BASE vs the rest of the settings), but are not able to capture the more subtle differences among explanation strategies and CONF.

tion made (Buçinca et al., 2020) that showed that evaluating explanations on proxy metrics can lead to incorrect conclusions. These findings are shown in Figure 9.

User feedback. Users provided free-form written feedback on possible ways to improve the system. The prompt they saw was: *do you have any additional feedback on what the system can improve?* After converging on a final set of codes, two annotators coded up about 400 responses across all conditions. The codes and their descriptions can be found in Table 3. The codes are *not* mutually exclusive.

CODE	DESCRIPTION	CATEGORY
len-conciseness len-expand	users wish explanation was shorter users wish explanation was shorter	improvement on length
adapt-detail adapt-voice	users wish details adapted with confidence users wish voice adapted to confidence	adaptability feature
pres-change-confidence pres-highlighting	users wish confidence would be communicated differently e.g. the answer is probably.... users wish important facts would be highlighted	improve presentation
need-more-sources need-confidence need-source need-explanation need-link need-multiple-answers	users wish more source were provided users wish confidence was provided users wished a source was provided users wish an explanation would be provided users wish a link was provided users wish more than 1 answer was provided	need additional info

Table 3: The codes used to uncover areas of improvement from the post-experimental user feedback.

We found that many users across most conditions, would like **adaptability features** added. Additionally, we found that participants would like to be provided with multiple sources which converge on the answer. We also observe that for spoken conditions, **improvements on length** are mentioned more often. The full distribution of codes across conditions is shown in Table 4.

CONDITION	CODE	% PARTICIPANTS
BASE	adapt-voice	50
	need-confidence	36
	need-explanation	25
	need-source	17
CONF	need-explanation	38
	adapt-voice	29
	pres-change-confidence	14

Abstract

Semantic embedding has been widely investigated for aligning knowledge graph (KG) entities. Current methods have explored and utilized the graph structure, the entity names, and attributes, but ignore the ontology (or ontological schema) which contains critical meta information such as classes and their membership relationships with entities. In this paper, we propose an ontology-guided entity alignment method named OntoEA, where both KGs and their ontologies are jointly embedded, and the class hierarchy and the class disjointness are utilized to avoid false mappings. Extensive experiments on seven public and industrial benchmarks have demonstrated the state-of-the-art performance of OntoEA and the effectiveness of the ontologies.

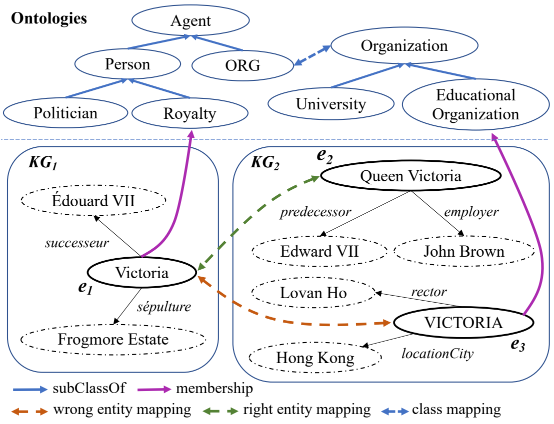

Figure 1: A class conflict example in entity alignment.

1 Introduction

Knowledge graphs (KGs) that are composed of entities and facts in the RDF form (i.e., RDF triples) are of vital importance in various applications, such as search engines and personal assistants (Hogan et al., 2020). Although there have been several large-scale KGs, the content of one individual KG is often incomplete, especially in supporting some domain-specific applications such as clinical AI assistants. As these KGs are developed separately, they are usually heterogeneous and supplementary to each other. Thus it becomes urgently needed to align multiple KGs (i.e., matching the equivalent elements) to fully explore their usability.

Recently, a few embedding-based methods have been proposed for entity alignment (EA) (Sun et al., 2020b; Zhang et al., 2020; Qi et al., 2021), in which entities are embedded into vectors and the equivalent entities are determined via calculating the similarity of their vectors. They extend the embedding of one KG to the embedding of multiple KGs into one vector space by, for instance, a transformation matrix, which is learnt from annotated mappings (a.k.a. seed mappings). They also utilize the entity names and attributes besides the graph structures for better performance. These methods, however, all ignore the ontology (or ontological schema) which is an important part of many KGs such as DBpedia (Auer et al., 2008) and Wikidata (Vrandečić and Krötzsch, 2014) as meta information for higher quality and usability. The ontology typically contains hierarchical classes and properties, and optionally defines some logical constraints such as the class disjointness, the property domain and range (Horrocks, 2008). Meanwhile, the KG usually clarifies the membership relationship between entities and classes.

The entity mappings by the above methods that do not exploit the ontologies may induce some class conflicts. Considering the example in Fig. 1, *Victoria* in KG_1 is often incorrectly aligned to *VICTORIA* in KG_2 by many embedding-based methods, but they belong to two potentially disjointed classes, namely *Person* and *Organization*. We find such class conflicted mappings are quite common in the wrongly predicted mappings. Considering the EN-FR-15K-V1 benchmark by (Sun et al., 2020b), 42.2% and 55.7% of the wrongly pre-

dicted mappings are class conflicted when running BootEA (Sun et al., 2018) and RSN4EA (Guo et al., 2019), respectively. These false positive mappings could be avoided if their ontologies are considered.

In this study, we propose an ontology-guided entity alignment method named OntoEA, which enriches the embedded semantics and avoids wrong mappings by exploring the class conflicts. OntoEA can work well in two contexts: *(i)* one ontology is shared across the to-be-aligned KGs; *(ii)* the ontologies of the to-be-aligned KGs are separated. The first context seems to follow a strict assumption but is actually quite common. For example, DBpedia has multilingual KGs (or versions) that share the same ontology, and in industrial scenarios, it is preferred to create a common ontology and then construct different KGs from different sources. The second context can be transformed into the first context by pre-aligning the ontologies, using existing ontology alignment systems such as PARIS (Suchanek et al., 2011) and LogMap (Jiménez-Ruiz et al., 2012), and/or cost-sensitive human intervention.

There are two challenges to utilize the ontology. First, it is difficult to embed two KGs together with the ontology, and as far as we know, there are currently no such solutions. Second, the class conflicts, indicated by the class disjointness in the ontology, are not all explicitly defined. Most of them should be learned from the KGs and they actually vary from KG to KG. For example, two classes *Human* and *Animal* are often disjointed in artwork KGs, but *Human* may belong to *Animal* in biological KGs. To address these challenges, we develop a joint embedding method that includes five modules for embedding the KGs, the ontology, the class conflicts, the membership relationships, and the seed mappings, respectively. Specifically, we develop a class conflict matrix (CCM) to represent different kinds of class conflicts, including those explicitly defined as disjoint, those indicated by the class hierarchy (e.g., sibling classes likely to be disjointed) and those plausible deduced from the KGs.

To the best of our knowledge, OntoEA is the first to utilize the ontology and the embedding for KG alignment. Extensive experiments on seven benchmarks have verified the effectiveness of the ontology guidance with both one shared ontology or two separated ontologies. OntoEA consistently outperforms the state-of-the-art baselines on all the benchmarks. For example, it on average achieves over 35% higher Hits@1, Hits@5, and MRR than the best baseline on MED-BBK-9K — a new and challenging industrial benchmark. Last but not least, we extend the current benchmarks with ontologies and membership relationships. The source code and benchmarks are publicly accessible at `https://github.com/ZihengZZH/OntoEA`.

2 Methodology

2.1 Problem Statement

A KG is denoted as $G = (E, R, T)$, where E, R, T are the sets of entities, relations and triples, respectively. Each triple $(h, r, t) \in T$, includes a head entity $h \in E$, a relation $r \in R$, and a tail entity $t \in E$. Their embeddings are denoted as $\boldsymbol{h}$, $\boldsymbol{r}$, $\boldsymbol{t}$, respectively. For two to-be-aligned KGs $G_i = (E_i, R_i, T_i)$ and $G_j = (E_j, R_j, T_j)$, an entity mapping, denoted as $m = (e_i, e_j)$ where $e_i \in E_i$, $e_j \in E_j$, indicates that e_i and e_j refer to the same real-world object. The entity alignment (EA) task aims to find all the mappings M between E_i and E_j, where we assume a small set of known entity mappings (or seed mappings) M_s are given.

Each KG is assumed to be associated with an ontology, which contains hierarchical classes and optionally disjoint constraints between classes. For simplicity, we consider the classes as entities in KG and the subsumption relationships between classes, often known as *rdfs:subClassOf*, as relations in KG. The simplified ontology is therefore regarded as a graph. For KGs G_i and G_j, their associated ontologies are represented as $O_i = (C_i, H_i)$ and $O_j = (C_j, H_j)$, respectively. We simply denote both O_i and O_j as $O = (C, H)$ if G_i and G_j share one ontology (i.e., $O_i \equiv O_j$); otherwise we denote the merged ontology after ontology alignment as $O = (C, H)$. Note C_i, C_j and C are the class sets, while H_i, H_j and H are the triple sets with only the *subClassOf* relation. Furthermore, the membership relationships, which link the entities and the corresponding classes, are denoted as B_i and B_j, and e.g., B_i links G_i and C via $b_i = (e_i, c)$ where $e_i \in E_i$ and $c \in C$. The class and membership embeddings are denoted as $\boldsymbol{c}$ and $\boldsymbol{b}$, respectively.

2.2 OntoEA Framework

As shown in Fig. 2, OntoEA includes five modules: *(i) entity embedding* which embeds each KG into a separate embedding space; *(ii) ontology embedding* which embeds the class hierarchical structure with a non-linear transformation; *(iii) confliction loss*

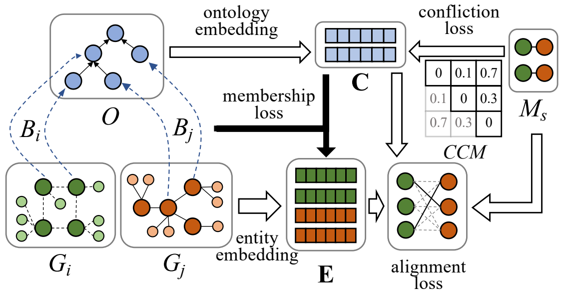

Figure 2: The framework of OntoEA.

which incorporates all potential class conflicts in the embeddings with the CCM; *(iv) membership loss* which incorporates the membership relationships and enables the joint learning of the entity embedding and the ontology embedding; *(v) alignment loss* which bridges the embedding spaces of the to-be-aligned KGs via seed mappings. An iterative co-training strategy is proposed to incorporate these five modules and the entity mappings are predicted with a pre-defined similarity measure between the joint embeddings.

2.3 Entity Embedding

To embed the KGs G_i and G_j, we adopt the translation-based method TransE (Bordes et al., 2013) which interprets a triple (h, r, t) as a translation by the relation r from h to t. The margin-based loss of (h, r, t) is defined as $f_e(h, t) = ||\boldsymbol{h}+\boldsymbol{r}-\boldsymbol{t}||_2$, where $||\cdot||_2$ denotes the L2 norm. Besides, we extend the loss with a limit-based scoring loss (Zhou et al., 2017) to ensure the discrimination between the positive and negative triples and also lower scores for positive triples:

$$\mathcal{L}_E = \sum_{(h,t)\in T} \sum_{(h',t')\in T'} \{[\gamma_e^1 + f_e(h,t) - f_e(h',t')]_+ + \alpha_e[f_e(h,t) - \gamma_e^2]_+\}, \tag{1}$$

where $[\cdot]_+$ denotes the function $f(x) = \max(0, x)$, hyperparameters γ_e^1 and γ_e^2 control the margins, α_e balances the margin-based loss and the limit-based loss, and T' is the set of the negative triples with each triple sampled using the ϵ-truncated uniform negative sampling strategy (Sun et al., 2018) to distinguish two similar triples.

It is worth noting that this study focuses on the EA task and the joint embedding challenge, and TransE is chosen due to its simplicity and efficiency. Our OntoEA framework is open to other advanced KG embedding methods, such as GCN (Wang et al., 2018) and RSN (Guo et al., 2019).

2.4 Ontology Embedding

The shared or merged ontology $O = (C, H)$ is composed of triples with the *subClassOf* relation. For simplicity, a triple (c_h, r, c_t) is written as a class pair (c_h, c_t) in H where $r := subClassOf$. Inspired by Hao et al. (2019) on embedding the hierarchical graph structure, we calculate the scoring loss of (c_h, c_t) with a non-linear transformation, $f_o(c_h, c_t) = ||\tanh(\boldsymbol{W}_o\boldsymbol{c}_h + \boldsymbol{b}_o) - \boldsymbol{c}_t||_2$, where $\boldsymbol{W}_o \in \mathcal{R}^{d_o \times d_o}$ and $\boldsymbol{b}_o \in \mathcal{R}^{d_o}$ are the learnable parameters, and d_o denotes the ontology embedding dimension. This tends to encode each class as a sphere and each subclass as a vector in the same semantic space after the non-linear transformation, and the relative positions are employed to model the relations between class and its subclass.

Similarly, we adopt the margin-based and limit-based loss for training:

$$\mathcal{L}_O = \sum_{(c_h,c_t)\in H} \sum_{(c_h',c_t')\in H'} \{[\gamma_o^1 + f_o(c_h,c_t) - f_o(c_h',c_t')]_+ + \alpha_o[f_o(c_h,c_t) - \gamma_o^2]_+\}, \tag{2}$$

where H' denotes the set of negative class pairs with each pair sampled by replacing c_h or c_t following the uniform negative sampling strategy (Bordes et al., 2013), while γ_o^1, γ_o^2 and α_o are hyperparameters similar to γ_e^1, γ_e^2 and α_e in Eq. 1.

Note that we do not directly utilize TransE in the ontology embedding, because the *subClassOf* relation is transitive (e.g., we can infer (*Royalty*, *subClassOf*, *Agent*) via (*Royalty*, *subClassOf*, *Person*) and (*Person*, *subClassOf*, *Agent*) as shown in Fig. 1), which can lead to one-to-many and many-to-one mappings (or triples) in the ontology, and TransE cannot well address the relation with such transitive property (Lv et al., 2018).

2.5 Confliction Loss

We use a class conflict matrix (CCM) to represent the inter-class conflicts that are either explicitly defined by class disjointness or implicitly discovered from the entities. Within the CCM, the entry on the i^{th} row and j^{th} column, denoted as $m_{i,j}$, represents the conflict degree between class c_i and class c_j. For one ontology, the CCM is a squared and symmetric matrix, and we only maintain the upper triangular for higher efficiency. Given two classes c_i and c_j, $m_{i,j} \in [0, 1]$ is calculated as follows. First, we set $m_{i,j} = 0$ if $c_i \equiv c_j$, which ensures each class does not conflict with itself. Second, c_i and

c_j are regarded as fully conflicted, i.e., $m_{i,j} = 1$, if they are declared as disjointed by the ontology.[1] Third, c_i and c_j are regarded as not conflicted, i.e., $m_{i,j} = 0$, if they have at least one common member (entity) or some of their members are given as seed mapping (i.e., there exists (e_i, e_j) in M_s such that e_i belongs to c_i and e_j belongs to c_j). Note the above three conditions are matched sequentially, and the computation of $m_{i,j}$ is finished if any condition is met. Finally, if none of the three conditions is met, we follow the principle that the farther two classes are separated in the tree-like class hierarchy structure, the lower semantic similarity and higher conflict degree the two classes have (Mumtaz and Giese, 2020). To calculate the distance between c_i and c_j, we use the set of classes passed by routing from c_i and c_j to the root class, denoted as $S(c_i)$ and $S(c_j)$, respectively, and then adopt the ratio of the intersection of $S(c_i)$ and $S(c_j)$. Accordingly, we have $m_{i,j} = 1 - \frac{|S(c_i) \cap S(c_j)|}{|S(c_i) \cup S(c_j)|}$ where $|\cdot|$ denotes the set cardinality.

For the implicitly discovered conflicts, we assume the small conflict degree between two classes if their embeddings are similar (i.e., high cosine similarity). Thus we calculate another cosine similarity-based class conflict degree: $d_{cos}(c_i, c_j) = 1 - \cos(\boldsymbol{c}_i, \boldsymbol{c}_j)$, where $\boldsymbol{c}_i$ and $\boldsymbol{c}_j$ represent the embeddings of c_i and c_j. We propose to minimize the following negative log-likelihood loss to incorporate the class conflicts represented by CCM into the class embeddings,

$$\mathcal{L}_C = -\sum_{c_i \in C} \sum_{c_j \in C} m_{i,j} \log d_{cos}(c_i, c_j). \tag{3}$$

2.6 Membership Loss

We develop the membership embedding module to utilize the membership relationships, B_i and B_j, to associate the KG embedding spaces with the ontology embedding space, which is regarded as enhancing the KG embeddings with the ontology semantics. Given one membership relationship $b = (e, c)$, we utilize a non-linear transformation to map the entity embeddings to the ontology embedding space, and we calculate the scoring loss as $f_m(e, c) = ||\tanh(\boldsymbol{W}_m \boldsymbol{e} + \boldsymbol{b}_m) - \boldsymbol{c}||_2$ where $\boldsymbol{W}_m \in \mathcal{R}^{d_e \times d_o}$ and $\boldsymbol{b}_m \in \mathcal{R}^{d_o}$ are learnable parameters, d_e and d_o denote the dimension of KG embedding and ontology embedding, respectively. Similarly, we minimize the following margin-based and limit-based loss to model all the membership relationships:

$$\mathcal{L}_M = \sum_{(e,c) \in B} \sum_{(e',c') \in B'} \{[\gamma_m^1 + f_m(e, c) - f_m(e', c')]_+ + \alpha_m [f_m(e, c) - \gamma_m^2]_+\}, \tag{4}$$

where B' denotes the set of negative membership relationships with each relationship created by replacing the class c following the uniform negative sampling strategy (Bordes et al., 2013), and γ_m^1, γ_m^2 and α_m are hyperparameters similar to γ_e^1, γ_e^2 and α_e in Eq. 1.

2.7 Alignment Loss

For the alignment embedding module, OntoEA utilizes the seed mappings M_s to bridge the embedding spaces of G_i and G_j such that the equivalent mappings between two cross-KG entities can be calculated via some distance metrics, such as cosine similarity. Given a seed mapping $m = (e_i, e_j)$, its score is calculated as $f_a(e_i, e_j) = ||\boldsymbol{W}_a \boldsymbol{e}_i - \boldsymbol{e}_j||_2$ where $\boldsymbol{W}_a \in \mathcal{R}^{d_e \times d_e}$ is a learnable translation matrix, and the training loss is defined as,

$$\mathcal{L}_A = \sum_{(e_i, e_j) \in M_s} f_a(e_i, e_j). \tag{5}$$

2.8 Iterative Co-Training and Prediction

To incorporate the aforementioned modules and obtain the embeddings of G_i, G_j and O, we can directly minimize the following loss:

$$\mathcal{L} = \mathcal{L}_E + \mathcal{L}_O + \lambda_1 \mathcal{L}_C + \lambda_2 \mathcal{L}_M + \lambda_3 \mathcal{L}_A, \tag{6}$$

where λ_1, λ_2, and λ_3 are hyperparameters that balance the losses of confliction embedding, membership embedding and alignment embedding, respectively. Instead of directly optimizing $\mathcal{L}$, we use an iterative co-training strategy in OntoEA to reduce model complexity and accelerate model convergence. At each iteration, OntoEA first optimizes $\mathcal{L}_E$ and $\mathcal{L}_O$ independently, then sequentially optimizes $\mathcal{L}_C$ and $\mathcal{L}_M$, and finally optimizes $\mathcal{L}_A$. The iteration stops until some stopping criterion on the validation set is met.

With the embeddings of G_i, G_j and O, we calculate the entity mappings with the cosine similarity. Given two entities $e_i \in G_i$ and $e_j \in G_j$, the weighted similarity score is calculated as:

$$sim(e_i, e_j) = \beta \cos(\boldsymbol{e}_i, \boldsymbol{e}_j) + (1 - \beta) \cos(\boldsymbol{c}_i, \boldsymbol{c}_j), \tag{7}$$

---

[1] For ontologies by Web Ontology Language (OWL), the class disjointness is common and is usually defined as a constraint by the built-in relation *owl:disjointWith*.

where hyperparameter $\beta \in [0, 1]$ balances the similarities of entity embeddings and class embeddings. It is possible that one entity has multiple classes declared; for example, *Victoria* in Fig. 1 can be an entity of *Royalty* and another class like *Female Leader*. In this case we calculate the average of the embeddings of all the declared classes as the class embedding ($\boldsymbol{c}_i$ or $\boldsymbol{c}_j$).[2] In the prediction, for each entity in G_i to be aligned, we rank all candidate entities in G_j by their weighted similarity scores.

3 Benchmarks

3.1 Benchmark Details

For comprehensive evaluation, we adopt six popular EA benchmarks including EN-FR-15K-V1/V2, EN-DE-15K-V1/V2 and D-W-15K-V1/V2 from Sun et al. (2020b), and an industrial benchmark MED-BBK-9K from Zhang et al. (2020). Note that for the cross-lingual benchmarks within DBpedia (i.e., EN-FR and EN-DE), the to-be-aligned KGs share one ontology, while for the other benchmarks, the to-be-aligned KGs have different ontologies that need to be aligned beforehand.

The benchmarks themselves do not include ontologies, and we thus extract and append an ontology for each KG, which includes the class structure (i.e., *rdfs:subClassOf* relationships) and membership relationships. Each benchmark therefore contains two KGs, their ontologies, and associated membership relationships. The benchmark statistics are shown in Table 1 where "-15K" and "9K" in the benchmark names are omitted. For the KGs of DBpedia, we use the DBpedia ontology and the membership relationships from the DBpedia SPARQL endpoint[3] by querying the classes of each entity with *rdfs:type*. Note we also utilize the defined class disjointness constraints by *owl:disjointWith* for initializing CCM. For the two Wikidata KGs in D-W-V1/V2, we extract their ontologies and membership relationships from the Wikidata SPARQL endpoint[4] using queries with *rdfs:subClassOf* and *rdfs:type*. For the KGs of the industrial benchmark, we use domain knowledge (with the assistance of medical experts) to construct a shared, small-scale, but high-quality ontology, and the corresponding membership relationships.

Table 1: Statistics of the benchmarks.

Dataset		KG	Ontology[b]		Membership[c]	
			#Cls.	#Trs.	#Links	#Roots
share-O[a]	EN-FR-V1	EN/FR	189	755	15,000	639
	EN-FR-V2	EN/FR	104	755	15,000	533
	EN-DE-V1	EN/DE	175	755	15,000	155
	EN-DE-V2	EN/DE	86	755	15,000	165
	MED-BBK	MED	11	10	9,162	86
		BBK	11	10	9,162	3,362
not-share-O	D-W-V1	DB	172	755	15,000	306
		WK	140	695	15,000	342
	D-W-V2	DB	71	755	15,000	463
		WK	68	695	15,000	418

[a] "*share-O*" means the to-be-aligned KGs share one ontology while "*not-share-O*" means the to-be-aligned KGs have different ontologies.

[b] "#Cls." denotes the number of classes and "#Trs." denotes the number of *rdfs:subClassOf* relation triples.

[c] "#Roots" denotes the number of entities that have no *rdf:type* property and are linked to the root class.

[d] See Table 6 in the Appendix for more benchmark statistics.

3.2 Ontology Alignment

For the benchmarks whose KGs do not share one ontology, we first align the ontologies. We adopt two ontology alignment methods: *manual annotation* and *alignment system*. In the first method, we employ five annotators to annotate class mappings for each ontology pair and the classes annotated by more than three annotators are adopted. It is worth noting that the manual annotation of class mappings is worthwhile and often adopted in KG construction and curation because of the high quality and relatively small scale in comparison with the entity mappings. In the second method, we apply a state-of-the-art ontology alignment system named PARIS[5] and some ad-hoc pre-processing and post-processing for automatic class mapping computation. Please see Appendix C for more details on ontology alignment and merging. For the D-W benchmarks, we considered both methods and compared their performance (see Table 4).

4 Experiments

4.1 Experimental Setup

We compare OntoEA against state-of-the-art EA models including four translation-based models, MTransE (Chen et al., 2017); JAPE (Sun et al., 2017); SEA (Pei et al., 2019); BootEA (Sun et al., 2018), two graph neural network based models, GCNAlign (Wang et al., 2018); AliNet (Sun et al., 2020a), and one recurrent neural network based model, RSN4EA (Guo et al., 2018). We also compare OntoEA against some state-of-the-art models that additionally utilize entity surface information

---

[2] Note that we do not consider the inferred classes, such as *Person* for *Victoria* in Fig. 1.

(SI) (i.e., entity names) including AttrE (Trisedya et al., 2019), MultiKE (Zhang et al., 2019) and RDGCN (Wu et al., 2019). Since using and not using SI are usually regarded as two different evaluation contexts (Guo et al., 2019), we separately evaluate OntoEA without (w/o) and with (w/) SI. Note that OntoEA with SI is implemented by a simple but effective strategy which initializes the embeddings of the translation-based models in Section 2.3 and Section 2.4 (i.e., $\boldsymbol{h}$, $\boldsymbol{r}$, $\boldsymbol{t}$ and $\boldsymbol{c}$) with the pre-trained word embeddings of their names. As in Sun et al. (2020b), we use the unified multilingual word embeddings fastText (Bojanowski et al., 2017) for the cross-lingual benchmarks.[6] All the results of AliNet, and the results of MTransE, JAEP, SEA and GCNAlign on MED-BBK-9K are reproduced locally; while the other baseline results are taken from Sun et al. (2020b) and Zhang et al. (2020). We follow the same train (20%), validation (10%) and test (70%) splits as Sun et al. (2020b) and Zhang et al. (2020).

We implement OntoEA upon the open source library OpenEA[7]. We use the AdaGrad optimizer with a learning rate of 0.01. The batch sizes for entity embedding and ontology embedding are set to 4500 and 64, respectively, and their dimensions are both set to 300. The weight hyperparameters are set as $\lambda_1 = 1$, $\lambda_2 = 1$, $\lambda_3 = 5$ and $\beta = 0.5$, and other hyperparameters are set as $\gamma_x^1 = 0.01$, $\gamma_x^2 = 2.0$ and $\alpha_x = 0.2$ for all the losses where $x \in \{e, o, m\}$. These hyperparamters are tuned w.r.t. the MRR on the validation set. Please see Appendix B for more implementation details.

With the embeddings we use the nearest neighbor search with cross-domain similarity local scaling (Lample et al., 2018) to calculate the entity matching of each to-be-aligned entity. In the evaluation, we rank matching candidates of each to-be-aligned entity and calculate the metrics of Hits@1 (H@1), Hits@5 (H@5) and mean reciprocal rank (MRR). In the following tables, the best (second best resp.) result is **bolded** (underlined resp.).

4.2 Overall Results

Table 2 reports the overall results of OntoEA and the baselines.[8] Overall, in both contexts of using and not using SI, OntoEA performs the best across all the benchmarks on all the metrics, except for H@1 on EN-DE-15K-V2 and D-W-15K-V2.

Without SI. Regarding the benchmarks that share one ontology, OntoEA achieves at least 10% higher performance in all the metrics over the best baseline BootEA on EN-FR-15K-V1 which has sparse KG structures. On EN-FR-15K-V2 with dense KG structures, OntoEA achieves higher H@5 and MRR but competitive H@1 in comparison with the best baseline. For the D-W benchmarks whose KGs have different ontologies, we have a similar finding: the outperformance of OntoEA is more significant on the benchmark with sparse KG structures (i.e., D-W-15K-V1) than on the benchmark with dense KG structures (i.e., D-W-15K-V2). On the one hand, dense KG structures indicate that more information can be utilized with better performance, and relatively the additional positive impact by the ontology becomes more limited. On the other hand, the ontologies of both

---

[6] The word embeddings are publicly available at https://fasttext.cc/docs/en/crawl-vectors.html.

[7] https://github.com/nju-websoft/OpenEA

[8] Results on the two EN-DE benchmarks, which lead to similar findings as the EN-FR benchmarks, are shown in Table 7 in the Appendix.

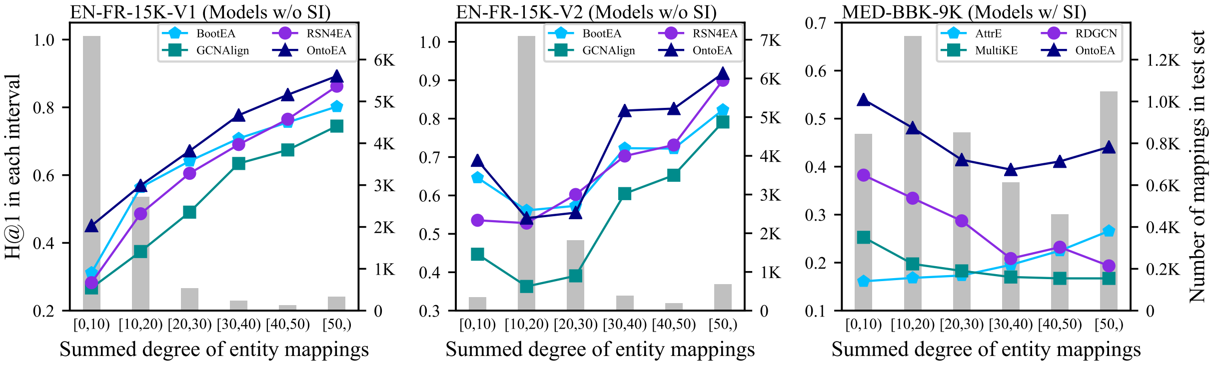

Figure 3: Results of OntoEA and some baselines on test entity mappings with different summed degrees.

EN-FR-15K-V2 and D-W-15K-V2 coincidentally have fewer classes (see Table 1), which would also lead to a lower impact of the ontology guidance. Regarding the industrial MED-BBK-9K, which is quite new and has shown more challenging w.r.t. these baselines (Zhang et al., 2020), OntoEA outperforms the best baseline by more than 10% in all the metrics. Although its ontology has a limited scale, the ontology is of high quality as it is specifically created with the domain knowledge.

With SI. OntoEA shows very promising overall results as OntoEA without SI. It outperforms all the baselines on all the benchmarks, with the improvements over the best baseline ranging from 2% to 68.9%. Regarding the industrial MED-BBK-9K, the performance improvement of OntoEA is especially significant with more than 60% in all the metrics. As aforementioned, this benchmark is challenging to these baselines and it has high-quality ontologies. It is worth mentioning that on the D-W benchmarks, the involvement of SI deteriorates the performance of OntoEA and the best baseline, while the positive impact of the ontologies (i.e., the performance gain of OntoEA over the best baseline) becomes more significant.

4.3 Ablation Studies

Model Component Analysis. To investigate different components in OntoEA, we compare OntoEA variants without the CCM loss (w/o $\mathcal{L}_C$), without the membership relationship loss (w/o $\mathcal{L}_M$), and without the ontology (w/o Onto.). The experimental results of OntoEA w/o SI on EN-FR-15K-V1/V2 are reported in Table 3, which shows that $\mathcal{L}_M$ contributes more to OntoEA than $\mathcal{L}_C$ as removing it leads to a larger performance drop. The results OntoEA w/ SI show similar findings and are thus omitted. As expected, the removal of the ontology deteriorates performance the most. All these results verify the significant role of the ontologies and their associated class conflicts and membership relationships.

Table 3: Results of OntoEA w/o SI and its variants with the removal of different components.

Models	EN-FR-15K-V1			EN-FR-15K-V2		
	H@1	H@5	MRR	H@1	H@5	MRR
OntoEA	**.566**	**.818**	**.678**	**.654**	**.891**	**.757**
w/o $\mathcal{L}_C$	.520	.781	.636	.589	.845	.701
w/o $\mathcal{L}_M$	.481	.750	.601	.549	.810	.665
w/o Onto.	.430	.698	.551	.545	.814	.664

Results on Different Test Entity Mappings. We split the test mappings according to the summed degree, i.e., $\deg(e_i, e_j) := \deg(e_i) + \deg(e_j)$ where (e_i, e_j) are the entity mappings. We select three different experimental settings (benchmarks and usage of SI) and Fig. 3 shows the results of OntoEA and some competitive baselines on different degree intervals. On EN-FR-15K-V1, OntoEA outperforms the baselines on all the intervals and the performance gap reaches the highest on [0,10). On EN-FR-15K-V2 with dense KG structures, OntoEA performs close to or slightly worse than BootEA on intervals [10,20) and [20,30) but outperforms all the baselines on the other intervals. On MED-BBK-9K, OntoEA performs much better than the baselines on all the intervals. All these observations are consistent with our findings from the overall results in Table 2 and also verify the effectiveness of OntoEA on different test entity mappings.

Analysis of Class Conflicts. This part analyses the predicted mappings that have class conflicts, with the results shown in Fig. 4. Note that the class conflict ratio of a method is the rate of its false positive mappings with class conflicts among all its false positive mappings. On EN-FR-15K-V1 and EN-FR-15K-V2, OntoEA significantly decreases the class conflict ratio to 3% and 0.3%, respectively,

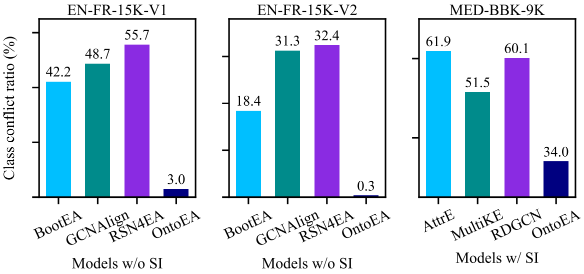

Figure 4: The class conflict ratios.

much lower than those of the baselines. On MED-BBK-9K, OntoEA reduces the class conflict ratio to 34.0% while MultiKE and RDGCN have 51.5% and 60.1%, respectively. The above observations illustrate that OntoEA has effectively implemented our motivation of using the ontologies and class conflicts to avoid false positive mappings.

Analysis of Ontology Alignment Methods. As the case that the to-be-aligned KGs have different ontologies is common, we analyse the impact of different ontology alignment methods proposed in Sec. 3.2, with the results in Table 4. We find that OntoEA with manual annotation achieves better results than OntoEA using the PARIS based alignment system method; the latter, however, still has competitive or better results in comparison with the best baseline (i.e., BootEA or RDGCN). This also provides motivations for the future research and industrial deployment work on iterative ontology alignment to keep a balance between the annotation cost and the alignment quality.

Table 4: Results of OntoEA using different ontology alignment methods where "-M" denotes the manual annotation while "-A" denotes the alignment system.

	Models	D-W-15K-V1			D-W-15K-V2		
		H@1	H@5	MRR	H@1	H@5	MRR
w/o SI	OntoEA-M	**.591**	**.808**	**.688**	.814	**.950**	**.873**
	OntoEA-A	.572	.795	.673	.762	.907	.827
	BootEA	.572	.744	.649	**.821**	.926	.867
w/ SI	OntoEA-M	**.553**	**.787**	**.656**	**.795**	**.943**	**.860**
	OntoEA-A	.510	.758	.621	.737	.893	.808
	RDGCN	.515	.669	.584	.623	.757	.684

5 Related Work

Embedding-based KG Alignment. These methods can be categorised into translation-based, GNN-based and RNN-based. The translation-based methods mainly rely upon some translation-based KG embedding models; for example, MTransE adopts TransE and various mapping losses to align cross-lingual KGs (Chen et al., 2017). To utilize more useful information in the KG, JAPE embeds the to-be-aligned KGs into one unified vector space via leveraging attribute correlations (Sun et al., 2017); AttrE exploits attributes by generating attribute character embeddings (Trisedya et al., 2019); and MultiKE makes full use of entity names, entity attributes and graph structures via multi-view learning (Zhang et al., 2019). The GNN-based methods are typically based on GNN variants for KG embedding, such as Graph Convolutional Networks (GCNs) Wang et al. (2018), dual-primal GCNs Sun et al. (2020a), and GCNs with attentive aggregation Sun et al. (2020a). As an RNN-based method, RSN4EA generates biased random walks on KGs and learns the embeddings by a recurrent skipping network (Guo et al., 2019). Some work has explored a semi-supervised learning setting, and for instance, BootEA (Sun et al., 2018) adopts the bootstrapping strategy to iteratively append new likely mappings during the learning process.

KG Embedding with Ontology. Only a few attempts have been made towards the KG embedding with ontology. The most relevant work is JOIE (Hao et al., 2019) which embeds the KG and the ontology in two embedding spaces and enables them to enhance each other by the cross-view links i.e., membership relationships. Some ontology embedding methods such as OWL2Vec* (Chen et al., 2021a) can be extended to jointly embed KG plus ontology since the KG can be regarded as an assertion part (ABox) of the ontology. However, as far as we know, there are currently no embedding methods that support two KGs along with their ontologies, let alone utilize the ontologies to augment embedding-based KG alignment.

6 Conclusions

This paper presented a novel method OntoEA to augment embedding-based entity alignment with the ontology. OntoEA enriches the semantics of KG embeddings by jointly learning the KGs, the ontology, the membership relationships and the seed mappings, and utilizes the potential class conflicts to avoid false mappings. The evaluation on multiple benchmarks has showed that OntoEA could achieve state-of-the-art performance and reduce the false positive mappings with class conflicts. For future work, we plan to utilize other ontology semantics besides the class hierarchy and class disjointness constraints (Chen et al., 2021b). We also plan to extend the entity embedding module with other advanced KG embedding methods.

Appendix

A More Benchmark Details

Table 6 shows the full statistics of all the benchmarks used in the experiments, including four cross-lingual benchmarks and two cross-KG benchmarks from OpenEA (Sun et al., 2020b), and one recent industrial cross-KG benchmark from Zhang et al. (2020). We report the benchmark statistics from three perspectives: the ontologies, the KGs and the membership relationships. The benchmarks are divided as previous work that 20%, 10% and 70% of all the entity mappings are used as training, validation and test sets, respectively (Sun et al., 2020b; Zhang et al., 2020).

B More Implementation Details

Our experiments are conducted on a workstation with an Intel Xeon E5 2.40 GHz CPU, 128 GB memory, an NVIDIA Tesla M40 GPU, and CentOS 7.2. Search spaces of the hyperparameters used in OntoEA are listed in Table 5. We apply a grid search strategy for the hyperparameter configuration that performs the best on the validation set with respect to mean reciprocal rank (MRR).

Table 5: Search spaces of the hyperparameters.

Hyperparameters	Search spaces
learning rate	{1e-3, 5e-3, 1e-2, 5e-2}
batch size (*entity*)	{4000, 4500, 5000}
batch size (*ontology*)	{32, 64, 128}
γ_x^1 in Eqs. (1) (2) (4) *	{0.01, 0.02, 0.03}
γ_x^2 in Eqs. (1) (2) (4) *	{1.0, 2.0, 3.0}
α_x in Eqs. (1) (2) (4) *	{0.1, 0.2, 0.3}
λ_1 in Eq. (6)	{0, 1, 2, 3, 4, 5}
λ_2 in Eq. (6)	{0, 1, 2, 3, 4, 5}
λ_3 in Eq. (6)	{0, 1, 2, 3, 4, 5}
β in Eq. (7)	{0.3, 0.4, 0.5, 0.6, 0.7}

* where $x \in \{e, o, m\}$.

C Ontology Alignment Methods

In this section, we present the details of the two ontology alignment methods: *manual annotation* and *alignment system*.

C.1 Manual Annotation

We refer to crowdsourcing for manual annotation of the class mappings by the following steps which are presented with the example of the DBpedia ontology and the Wikidata ontology in the D-W benchmarks. First, we recruit five volunteers with at least undergraduate education as the annotators and provide them the two to-be-aligned ontologies. The DBpedia ontology (O_D) contains a total of 755 classes while the Wikidata ontology (O_W) contains 695 classes. Second, for each class in O_D, denoted as c_D, each annotator is required to consider as more classes in O_W as possible and find the equivalent class mapping (c_D, c_W), where c_W denotes a class in O_W. Note that the annotators are allowed to utilize her/his knowledge and accelerate the annotation by searching for class $c_W \in O_W$, using some friendly ontology management and accessing software such as Protégé. After all five annotators finish the work, only the class mappings that are labelled by more than three annotators are accepted as the final class mappings, denoted as M_C.

With the class mappings, we need to further merge the two ontologies as one shared ontology which can then be processed by OntoEA. To this end, our solution is to build new membership relationships between the entities of the Wikidata KG and the classes of the DBpedia ontology. For each original membership relationship within the Wikidata KG and ontology, we replace its class c_W with c_D if $(c_D, c_W) \in M_C$, or with the root class *owl:Thing* otherwise.

C.2 Alignment System

Algorithm 1 Alignment System Method

```
Require: Ontologies $O_D$ and $O_W$, threshold $\lambda$
Build directed graphs $D_D$ and $D_W$ from $O_D$ and $O_W$, respectively, with the relation of rdfs:subClassOf
Obtain equivalent class pairs $P_C$ from pre-defined owl:equivalentClass in $O_D$ and $O_W$
Generate $D'$ via connecting $D_D$ and $D_W$ with $P_C$
Define $\phi(c_1, c_2)$ as the length of directed walk from $c_1$ to $c_2$ where $c_1, c_2 \in D'$
Initialize empty mapping sets $M_C$ and $M'_C$
for each class $c_W$ in $O_W$ do
    Route $D'$ starting from $c_W$ and output routed class set $S = \{c\}$ where $c \in D'$
    if $S = \emptyset$ then
        Append $(c_W, owl:Thing)$ to $M_C$
    else
        Find a class $c$ in $S$ such that for any $c'$ in $S$ $\phi(c, owl:Thing) \geq \phi(c', owl:Thing)$
        Append $(c_W, c)$ to $M_C$
    end if
end for
Perform PARIS on $O_D$ and $O_W$
Append $M'_C$ from PARIS with threshold $\lambda$
for each class mapping $(c_w, c_d)$ in $M_C$ do
    if $(c_w, c'_d) \in M'_C$ and $c'_d \neq c_d$ then
        Remove $(c_w, c_d)$ from $M_C$
        Append $(c_w, c'_d)$ to $M_C$
    end if
end for
return $M_C$
```

The automatic method based on the ontology alignment system PARIS and some ad-hoc pre-processing and post-processing is shown in Algorithm 1. The pre-processing from Line 1 to Line 13 obtains class mappings via finding the most fine-grained mappings (i.e., the farthest class node in the directed graph). Since PARIS generally outputs reliable class mappings, the post-processing from Line 16 to Line 21 updates class mappings with those output from PARIS.

In the implementation we set PARIS hyperparameter λ to 0.4. The *owl:equivalentClass* relationship across the DBpedia ontology and the Wikidata ontology is acquired via DBpedia and Wikidata SPARQL endpoints. After getting M_C, we merge the two ontologies as introduced in the method of manual annotation.

D More Experimental Results

Table 7 reports the overall results on the cross-lingual benchmarks EN-DE-15K-V1 and EN-DE-15K-V2. We have similar findings in these two EN-DE benchmarks as in the EN-FR benchmarks that OntoEA consistently outperform baselines, w/o SI and w/ SI. On EN-DE-15K-V1, OntoEA generally outperforms competitive models by up to 9.9% in H@1 and the performance gap is larger in the models w/o SI than in the models w/ SI. On the dense benchmark (V2), OntoEA shows limited performance gain (about 4%) compared with the models w/o SI but much larger performance gain (more than 9%) compared with the models w/ SI.

Learning Algebraic Recombination for Compositional Generalization

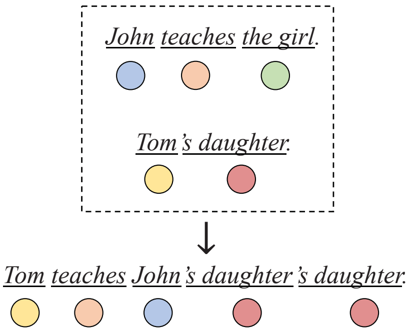
Abstract

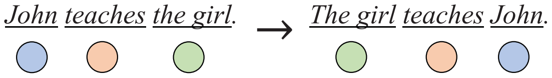
Neural sequence models exhibit limited *compositional generalization* ability in semantic parsing tasks. Compositional generalization requires *algebraic recombination*, i.e., dynamically recombining structured expressions in a recursive manner. However, most previous studies mainly concentrate on recombining lexical units, which is an important but not sufficient part of algebraic recombination. In this paper, we propose LEAR, an end-to-end neural model to learn algebraic recombination for compositional generalization. The key insight is to model the semantic parsing task as a homomorphism between a latent syntactic algebra and a semantic algebra, thus encouraging algebraic recombination. Specifically, we learn two modules jointly: a Composer for producing latent syntax, and an Interpreter for assigning semantic operations. Experiments on two realistic and comprehensive compositional generalization benchmarks demonstrate the effectiveness of our model. The source code is publicly available at https://github.com/microsoft/ContextualSP.

1 Introduction

The principle of compositionality is an essential property of language: the meaning of a complex expression is fully determined by its structure and the meanings of its constituents (Pelletier, 2003; Szabó, 2004). Based on this principle, human intelligence exhibits *compositional generalization* — the algebraic capability to understand and produce a potentially infinite number of novel expressions by dynamically recombining known components (Chomsky, 1957; Fodor and Pylyshyn, 1988; Fodor and Lepore, 2002). For example, people who know the meaning of "*John teaches the girl*" and "*Tom's daughter*" must know the meaning of "*Tom teaches John's daughter's daughter*" (Figure 1a), even though they have never seen such complex sentences before.



(a) Compositional generalization requires **algebraic recombination**, i.e., dynamically recombining structured expressions in a recursive manner.



(b) Most previous studies mainly concentrate on recombining lexical units, which is an important but not sufficient part of algebraic recombination.

Figure 1: Compositional generalization.

In recent years, there has been accumulating evidence that end-to-end deep learning models lack such ability in semantic parsing (i.e., translating natural language expressions to machine interpretable semantic meanings) tasks (Lake and Baroni, 2018; Keysers et al., 2019; Kim and Linzen, 2020; Tsarkov et al., 2020).

Compositional generalization requires **algebraic recombination**, i.e., dynamically recombining structured expressions in a recursive manner. In the example in Figure 1a, understanding "*John's daughter's daughter*" is a prerequisite for understanding "*Tom teaches John's daughter's daughter*", while "*John's daughter's daughter*" is also a novel compound expression, which requires recom-

bining "*John*" and "*Tom's daughter*" recursively.

Most previous studies on compositional generalization mainly concentrate on recombining lexical units (e.g., words and phrases) (Lake, 2019; Li et al., 2019; Andreas, 2019; Gordon et al., 2020; Akyürek et al., 2020; Guo et al., 2020a; Russin et al., 2019), of which an example is shown in Figure 1b. This is a necessary part of algebraic recombination, but it is not sufficient for compositional generalization. There have been some studies on algebraic recombination (Liu et al., 2020; Chen et al., 2020). However, they are highly specific to a relative simple domain SCAN (Lake and Baroni, 2018) and can hardly generalize to more complex domains.

In this paper, our main point to achieve algebraic recombination is to **model semantic parsing as a homomorphism between a latent syntactic algebra and a semantic algebra** (Montague, 1970; Marcus, 2019). Based on this formalism, we focus on learning the high-level mapping between latent syntactic operations and semantic operations, rather than the direct mapping between expression instances and semantic meanings.

Motivated by this idea, we propose LEAR (**Le**arning **A**lgebraic **R**ecombination), an end-to-end neural architecture for compositional generalization. LEAR consists of two modules: a *Composer* and an *Interpreter*. Composer learns to model the latent syntactic algebra, thus it can produce the latent syntactic structure of each expression in a bottom-up manner; Interpreter learns to assign semantic operations to syntactic operations, thus we can transform a syntactic tree to the final composed semantic meaning.

Experiments on two realistic and comprehensive compositional generalization benchmarks (*CFQ* (Keysers et al., 2019) and *COGS* (Kim and Linzen, 2020)) demonstrate the effectiveness of our model: CFQ $67.3\% \rightarrow 90.9\%$, COGS $35.0\% \rightarrow 97.7\%$.

2 Compositionality: An Algebraic View

A semantic parsing task aims to learn a meaning-assignment function $m : L \rightarrow M$, where L is the set of (simple and complex) expressions in the language, and M is the set of available semantic meanings for the expressions in L. Many end-to-end deep learning models are built upon this simple and direct formalism, in which the principle of compositionality is not leveraged, thus exhibiting limited compositional generalization.

To address this problem, in this section we put forward the formal statement that "*compositionality requires the existence of a homomorphism between the expressions of a language and the meanings of those expressions*" (Montague, 1970).

Let us consider a language as a partial algebra $\mathbf{L} = \langle L, (f_\gamma)_{\gamma \in \Gamma} \rangle$, where Γ is the set of underlying syntactic (grammar) rules, and we use $f_\gamma : L^k \rightarrow L$ to denote the syntactic operation with a fixed arity k for each $\gamma \in \Gamma$. Note that f_γ is a partial function, which means that we allow f_γ be undefined for certain expressions. Therefore, $\mathbf{L}$ is a partial algebra, and we call it a **syntactic algebra**. In a semantic parsing task, $\mathbf{L}$ is latent, and we need to model it by learning from data.

Consider now $\mathbf{M} = \langle M, G \rangle$, where G are semantic operations upon M. $\mathbf{M}$ is also a partial algebra, and we call it a **semantic algebra**. In a semantic parsing task, we can easily define this algebra (by enumerating all available semantic primitives and semantic operations), since $\mathbf{M}$ is a machine-interpretable formal system.

The key to compositionality is that the meaning-assignment function m should be a homomorphism from $\mathbf{L}$ to $\mathbf{M}$. That is, for each k-ary syntactic operation f_γ in $\mathbf{L}$, there exists a k-ary semantic operation $g_\gamma \in G$ such that whenever $f_\gamma(e_1, ..., e_k)$ is defined,

$$m(f_\gamma(e_1, ..., e_k)) = g_\gamma(m(e_1), ..., m(e_k)). \quad (1)$$

Based on this formal statement, the task of learning the meaning-assignment function m can be transformed as two sub-tasks: (1) learning latent syntax of expressions (i.e., modeling the syntactic algebra $\mathbf{L}$); (2) learning the operation assignment function $(f_\gamma)_{\gamma \in \Gamma} \rightarrow G$.

Learning latent syntax. We need to learn a syntactic parser that can produce the syntactic structure of each given expression. To ensure compositional generalization, there must be an underlying grammar (i.e., Γ), and we hypothesize that Γ is a context-free grammar.

Learning operation assignment. In the syntax tree, for each nonterminal node with k nonterminal children, we assign a k-ary semantic operation to it. This operation assignment entirely depends on the underlying syntactic operation γ of this node.

In semantic parsing tasks, we do not have respective supervision for these two sub-tasks. Therefore, we need to jointly learning these two sub-tasks only from the end-to-end supervision $\mathcal{D} \subset L \times M$.

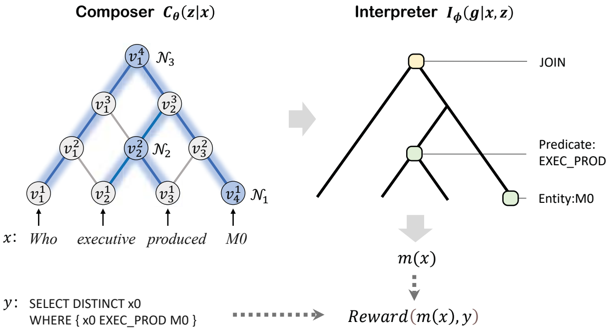

Figure 2: An overview of LEAR: (1) Composer $C_\theta(z|x)$ is a neural network based on latent Tree-LSTM, which produces the latent syntax tree z of input expression x; (2) Interpreter $I_\phi(g|x,z)$ is a neural network that assigns a semantic operation for each nonterminal node in z.

3 Model

We propose a novel end-to-end neural model LEAR (**Le**arning **A**lgebraic **R**ecombination) for compositional generalization in semantic parsing tasks. Figure 2 shows its overall architecture. LEAR consists of two parts: (1) *Composer* $C_\theta(z|x)$, which produces the latent syntax tree z of input expression x; (2) Interpreter $I_\phi(g|x,z)$, which assigns a semantic operation for each nonterminal node in z. θ and ϕ refers to learnable parameters in them respectively. We generate a semantic meaning $m(x)$ according to the predicted z and g in a symbolic manner, then check whether it is semantic equivalent to the ground truth semantic meaning y to produce rewards for optimizing θ and ϕ.

3.1 Composer

We use $x = [x_1, ..., x_T]$ to denote an input expression of length T. Composer $C_\theta(z|x)$ will produce a latent binary tree z given x.

3.1.1 Latent Tree-LSTM

We build up the latent binary tree z in a bottom-up manner based on Tree-LSTM encoder, called latent Tree-LSTM (Choi et al., 2018; Havrylov et al., 2019).

Given the input sequence x of length T, latent Tree-LSTM merges two nodes into one parent node at each merge step, constructing a binary tree after $T-1$ merge steps. The merge process is implemented by selecting the adjacent node pair which has the highest merging score.

At the t-th ($1 \le t < T$) merge step, we have:

$$\hat{i}_t = \underset{1 \le i \le T-t}{\arg\max}\, \mathrm{Linear}(\text{Tree-LSTM}(\mathbf{r}_i^t, \mathbf{r}_{i+1}^t)) \quad (2)$$

Here "Tree-LSTM" is the standard child-sum tree-structured LSTM encoder (Tai et al., 2015). We use v_i^t to denote the i-th cell at layer t (the t-th merge step is determined by the t-th layer), and use $\mathbf{r}_i^t$ to denote the representation of v_i^t:

$$\mathbf{r}_i^1 = \mathrm{Linear}(\mathrm{Emb}(x_i)) \quad (3)$$

$$\underset{t>1}{\mathbf{r}_i^t} = \begin{cases} \mathbf{r}_i^{t-1} & i < \hat{i}_{t-1} \\ \text{Tree-LSTM}(\mathbf{r}_i^{t-1}, \mathbf{r}_{i+1}^{t-1}) & i = \hat{i}_{t-1} \\ \mathbf{r}_{i+1}^{t-1} & i > \hat{i}_{t-1} \end{cases} \quad (4)$$

Then we can obtain a unlabeled binary tree, in which $\{v_1^1, v_2^1, ..., v_T^1\}$ are leaf nodes, and $\{v_{\hat{i}_1}^2, v_{\hat{i}_2}^3 ..., v_{\hat{i}_{T-1}}^T\}$ are non-leaf nodes.

3.1.2 Abstraction by Nonterminal Symbols

As discussed in Section 2, our hypothesis is that the underlying grammar Γ is context-free. Therefore, each syntactic rule $\gamma \in \Gamma$ can be expressed in the form of:

$$A \to B, \qquad A \in \mathcal{N}, B \in (\mathcal{N} \cup \Sigma)^+$$

where $\mathcal{N}$ is a finite set of nonterminals, and Σ is a finite set of terminal symbols.

Abstraction is an essential property of context-free grammar: each compound expression e will be abstracted as a simple nonterminal symbol $\mathcal{N}(e)$, then it can be combined with other expressions to produce more complex expressions, no matter what details e originally has. This setup may benefit the generalizability, thus we want to incorporate it as an inductive bias into our model.

Concretely, we assume that there are at most N latent nonterminals in language $\mathbf{L}$ (i.e., $\mathcal{N} = \{\mathcal{N}_1, ..., \mathcal{N}_N\}$, where N is a hyper-parameter). For each node v_i^t in tree z, we perform a $(N+1)$-class classification:

$$\hat{c}_{v_i^t} = \underset{0 \le c \le N}{\arg\max}\, \mathrm{Linear}(\mathbf{r}_i^t) \quad (5)$$

We assign the nonterminal $\mathcal{N}_{\hat{c}_{v_i^t}}$ to v_i^t when $\hat{c}_{v_i^t} > 0$. The collection of such nonterminal nodes are denoted as V'_z. Then we modify Equation 4:

$$\underset{t>1}{\mathbf{r}_i^t} = \begin{cases} \mathbf{r}_i^{t-1} & i < \hat{i}_{t-1} \\ \text{Tree-LSTM}(\overline{\mathbf{r}}_i^{t-1}, \overline{\mathbf{r}}_{i+1}^{t-1}) & i = \hat{i}_{t-1} \\ \mathbf{r}_{i+1}^{t-1} & i > \hat{i}_{t-1} \end{cases} \quad (6)$$

$$\overline{\mathbf{r}}_i^t = \begin{cases} \text{Linear}(\text{Emb}(\mathcal{N}(v_i^t))) & v_i^t \in V'_z \\ \mathbf{r}_i^t & v_i^t \notin V'_z \end{cases}$$

Equation 6 means that: in nonterminal nodes, the bottom-up message passing will be reduced from $\mathbf{r}_i^t$ to a nonterminal symbol $\mathcal{N}(v_i^t)$, thus mimicking the abstraction setup in context-free grammar.

3.2 Interpreter

For each nonterminal node $v \in V'_z$, Interpreter $I_\phi(g|x, z)$ assigns a semantic operation g_v to it.

We divide nonterminal nodes into two categories: (1) *lexical nodes*, which refer to those containing no any other nonterminal node in the corresponding sub-trees; (2) *algebraic nodes*, which refer to the rest of nonterminal nodes.

Interpreting Lexical Nodes For each lexical node v, Interpreter assigns a semantic primitive (i.e., 0-ary semantic operation) to it. Take the CFQ benchmark as an example: it uses SPARQL queries to annotate semantic meanings, thus semantic primitives in CFQ are entities (e.g., *m.0gwm_wy*), predicates (e.g., *ns:film.director.film*) and attributes (e.g., *ns:people.person.gender m_05zppz*).

We use a classifier to predict the semantic primitive:

$$g_v = \underset{g \in G_{lex}}{\arg\max}\, \text{Linear}(\mathbf{h}_{v,x}) \quad (7)$$

where G_{lex} is the collection of semantic primitives in the domain, and $\mathbf{h}_{v,x}$ is the contextual representation of the span corresponding to v (implemented using Bi-LSTM). *Contextually conditioned variation* is an important phenomenon in language: the meaning of lexical units varies according to the contexts in which they appear (Allwood, 2003). For example, "*editor*" means a predicate "*film.editor.film*" in expression "*Is M0 an editor of M1?*", while it means an attribute "*film.editor*" in expression "*Is M0 an Italian editor?*". This is the reason why we use contextual representation in Equation 7.

Interpreting Algebraic Nodes For each algebraic node v, Interpreter assigns a semantic operation to it. The collection of all possible semantic operations G_{opr} also depends on the domain. Take the CFQ benchmark as an example[1], this domain has two operations (detailed in Table 1): ∧ (conjunction) and JOIN.

Operation	Args[t_1, t_2]→ Result Type	Example
$\wedge(t_1, t_2)$	[P, P]→P	Who [**direct** and **act**] M0?
	[E, E]→E	Who direct [**M0** and **M1**]?
	[A, A]→A	Is M0 an [**Italian female**]?
	[A, E]→E [E, A]→E	Is [**M0** an **Italian female**]?
	[A, P]→P [P, A]→P	Is M0 M3's [**Italian editor**]?
JOIN(t_1, t_2)	[E, P]→E [P, E]→E	Is M0 an [**editor** of **M1**]?
	[A, P]→E [P, A]→E	Who [**marries** an **Italian**]?

Table 1: Semantic operations in CFQ. A/P/E represents Attribute/Predicate/Entity.

We also use a classifier to predict the semantic operation of v:

$$g_v = \underset{g \in G_{opr}}{\arg\max}\, \text{Linear}(\mathbf{r}_v) \quad (8)$$

where $\mathbf{r}_v$ is the latent Tree-LSTM representation of node v (see Equation 6).

In Equation 8, we do not use any contextual information from outside v. This setup is based on the assumption of **semantic locality**: each compound expression should mean the same thing in different contexts.

4 Training

Denote $\tau = \{z, g\}$ as the trajectory produced by our model where z and g are actions produced from Composer and Interpreter, respectively, and $R(\tau)$ as the reward of trajectory τ (elaborated in Sec. 4.1). Using policy gradient (Sutton et al., 2000) with the likelihood ratio trick, our model can be optimized by ascending the following gradient:

$$\nabla \mathcal{J}(\theta, \phi) = \mathbb{E}_{\tau \sim \pi_{\theta,\phi}}\, R(\tau) \nabla \log \pi_{\theta,\phi}(\tau), \quad (9)$$

where θ and ϕ are learnable parameters in Composer and Interpreter respectively and ∇ is the abbreviation of $\nabla_{\theta,\phi}$. Furthermore, the REINFORCE algorithm (Williams, 1992) is leveraged to approximate Eq. 9 and the mean-reward baseline (Weaver and Tao, 2001) is employed to reduce variance.

---

[1] It is not difficult to define G_{lex} and G_{opr} for each domain, as semantic meanings are always machine-interpretable. The semantic operations of another compositional generalization benchmark, COGS, are listed in the Appendix.

4.1 Reward Design

The reward $R(\tau)$ combines two parts as:

$$R(\tau) = \alpha \cdot R_1(\tau) + (1 - \alpha) \cdot R_2(\tau), \quad (10)$$

Logic-based Reward $R_1(\tau)$. We use $m(x)$ and y to denote the predicted semantic meaning and the ground truth semantic meaning respectively. Each semantic meaning can be converted to a conjunctive normal form[2]. We use $S_{m(x)}$ and S_y to denote conjunctive components in $m(x)$ and y, then define $R_1(\tau)$ based on Jaccard similarity (i.e., intersection over union):

$$R_1(\tau) = \text{Jaccard-Sim}(S_{m(x)}, S_y) \quad (11)$$

Primitive-Based Reward $R_2(\tau)$. We use $S'_{m(x)}$ and S'_y to denote semantic primitives ocurred in $m(x)$ and y. Then we define $R_2(\tau)$ as:

$$R_2(\tau) = \text{Jaccard-Sim}(S'_{m(x)}, S'_y) \quad (12)$$

4.2 Reducing Search Space

To reduce the huge search space of τ, we make two constraints as follows.

Parameter Constraint. Consider v, a tree node with $n (n > 0)$ nonterminal children. Composer will never make v a nonterminal node, if no semantic operation has n parameters.

Phrase Table Constraint. Following the strategy proposed in Guo et al. (2020b), we build a "phrase table" consisting of lexical units (i.e., words and phrases) paired with semantic primitives that frequently co-occur with them[3]. Composer will never produce a lexical node outside of this table, and Interpreter will use this table to restrict candidates in Equation 7.

4.3 Curriculum Learning

To help the model converge better, we use a simple curriculum learning (Bengio et al., 2009) strategy to train the model. Specifically, we first train the model on samples of input length less than a cut-off N_{CL}, then further train it on the full train set.

CFQ

x "Did a male film director edit and direct M0?"

y
```
SELECT count ( * ) WHERE {
    ?x0 ns:film.director.film M0 .
    ?x0 ns:film.editor.film M0 .
    ?x0 ns:people.person.gender m_05zppz }
```

COGS

x "Charlotte was given the cake on a table."

y
```

Avg Input Len (Train/Test)	13.5/15.1	7.5/9.8
Avg Output Len (Train/Test)	27.7/34.0	43.6/67.6
Input Pattern Coverage[a]	0.022	0.783
Output Pattern Coverage	0.045	0.782

Table 2: Dataset statistics.

[a] Input/output pattern coverage is the percentage of test x/y whose patterns occur in the train data. Output patterns are determined by anonymizing semantic primitives, and input patterns are determined by anonymizing their lexical units.

5 Experimental Setup

Benchmarks. We mainly evaluate LEAR on *CFQ* (Keysers et al., 2019) and *COGS* (Kim and Linzen, 2020), two comprehensive and realistic benchmarks for measuring compositional generalization. They use different semantic formulations: CFQ uses SPARQL queries, and COGS uses logical queries (Figure 3 shows examples of them). We list dataset statistics in Table 2. The input/output pattern coverage indicates that: CFQ mainly measures the algebraic recombination ability, while COGS measures both lexical recombination ($\sim 78\%$) and algebraic recombination ($\sim 22\%$).

In addition to these two compositional generalization benchmarks in which utterances are synthesized by formal grammars, we also evaluate LEAR on *GEO* (Zelle and Mooney, 1996), a widely used semantic parsing benchmark, to see whether LEAR can generalize to utterances written by real users. We use the variable-free FunQL (Kate et al., 2005) as the semantic formalism, and we follow the compositional train/test split (Finegan-Dollak et al., 2018) to evaluate compositional generalization.

Baselines. For CFQ, we consider 3 groups of models as our baselines: (1) sequence-to-sequence mod-

---

[2] For example, the semantic meaning of "*Who directed and edited M_0 's prequel and M_1?*" can be converted to a conjunctive normal form with four components: "$x_0 \cdot$ DIRECT $\cdot$ $x_1 \cdot$ PREQUEL $\cdot$ M_0", "$x_0 \cdot$ EDIT $\cdot$ $x_1 \cdot$ PREQUEL $\cdot$ M_0", "$x_0 \cdot$ DIRECT $\cdot$ M_1", and "$x_0 \cdot$ EDIT $\cdot$ M_1".

[3] Mainly based on statistical word alignment technique in machine translation, detailed in the Appendix.

Models	**MCD-MEAN**	**MCD1**	**MCD2**	**MCD3**

Table 3: Accuracy on three splits (MCD1/MCD2/MCD3) of CFQ benchmark.

els based on deep encoder-decoder architecture, including LSTM+Attention (Hochreiter and Schmidhuber, 1997; Bahdanau et al., 2014), Transformer (Vaswani et al., 2017), Universal Transformer (Dehghani et al., 2018) and Evolved Transformer (So et al., 2019); (2) deep models with large pretrained encoder, such as T5 (Raffel et al., 2019); (3) Models that are specially designed for compositional generalization, which include Neural Shuffle Exchange Network (Freivalds et al., 2019), CGPS (Li et al., 2019), and state-of-the-art model HPD (Guo et al., 2020b). For COGS, we quote the baseline results in the original paper (Kim and Linzen, 2020). For GEO, we take the baseline results reported by Herzig and Berant (2020), and also compare with two specially designed methods: SpanBasedSP (Herzig and Berant, 2020) and PDE (Guo et al., 2020c).

Evaluation Metric. We use accuracy as the evaluation metric, i.e., the percentage test samples of which the predicted semantic meaning $m(x)$ is semantically equivalent to the ground truth y.

Hyper-Parameters. We set $N = 3/2/3$ (the number of nonterminal symbols), and $\alpha = 0.5/1.0/0.9$ for CFQ/COGS/GEO respectively. In CFQ, the curriculum cut-off N_{CL} is set to 11, as we statistically find that this is the smallest curriculum that contains the complete vocabulary. We do not apply curriculum learning strategy to COGS and GEO, as LEAR can work well without curriculum learning in both benchmarks. Learnable parameters (θ and ϕ) are optimized with AdaDelta (Zeiler, 2012), and the setting of learning rate is discussed in Section 6.1. We take the model that performs best on the validation set for testing, and all results are obtained by averaging over 5 runs with different random seeds. See Appendix for more implementation details.

Model	**Acc**
Transformer (Kim and Linzen, 2020)	35 ± 6

SpanBasedSP (Herzig and Berant, 2020)	82.2
LEAR	**84.1**

Table 5: Accuracy on GEO benchmark.

6 Results and Discussion

Table 3 shows average accuracy and 95% confidence intervals on three splits of CFQ. LEAR achieves an average accuracy of 90.9% on these three splits, outperforming all baselines by a large margin. We list some observations as follows.

Methods for lexical recombination cannot generalize to algebraic recombination. Many methods for compositional generalization have been proved effective for lexical recombination. Neural Shuffle Exchange and CGPS are two representatives of them. However, experimental results show that they cannot generalize to CFQ, which focus on algebraic recombination.

Knowledge of semantics is important for compositional generalization. Seq2seq models show poor compositional generalization ability ($\sim 20\%$). Pre-training helps a lot ($\sim 20\% \rightarrow\sim 40\%$), but still not satisfying. HPD and LEAR incorporate knowledge of semantics (i.e., semantic operations) into the models, rather than simply model semantic meanings as sequences. This brings large profit.

Exploring latent compositional structure in a bottom-up manner is key to compositional generalization. HPD uses LSTM to encode the input expressions, while LEAR uses latent Tree-LSTM, which explicitly explores latent compositional structure of expressions. This is the key to the large accuracy profit ($67.3\% \rightarrow 90.9\%$).

Table 4 shows the results on COGS benchmark. It proves that LEAR can well generalize to domains which use different semantic formalisms, by specifying domain-specific G_{lex} (semantic primitives) and G_{opr} (semantic operations). Table 5 shows the results on GEO benchmark. It proves that LEAR can well generalize to utterances written by real users (i.e., non-synthetic utterances).

6.1 Ablation Study

Table 3 and 4 also report results of some ablation models. Our observations are as follows.

Abstraction by nonterminal symbols brings profit. We use "*w/o abstraction*" to denote the ablation model in which Equation 6 is disabled. This ablation leads to $5.5\%/3.2\%$ accuracy drop on CFQ/COGS.

Incorporating semantic locality into the model brings profit. We use "*w/o semantic locality*" to denote the ablation model in which a Bi-LSTM layer is added before the latent Tree-LSTM. This ablation leads to $3.0\%/3.7\%$ accuracy drop on CFQ/COGS.

Tree-LSTM contributes significantly to compositional generalization. In the ablation "*w/o Tree-LSTM*", we replace the Tree-LSTM encoder with a span-based encoder, in which each span is represented by concatenating its start and end LSTM representations (similar to Herzig and Berant (2020)). In Table 3 and 4, we can see that span-based encoder severely affects the performance and even much worse than the results of "*w/o abstraction*" and "*w/o semantic locality*". This ablation hints that Tree-LSTM is the main inductive bias of compositionality in our model.

Ratio	MCD-MEAN	MCD1	MCD2	MCD3
1:1:1	87.4±7.1	91.5±2.1	**89.4±2.3**	81.2±17
1:0.5:0.1	**90.9±1.2**	**91.7±1.0**	89.2±1.9	**91.7±0.6**
1:0.1:0.1	86.7±3.9	89.4±1.6	85.8±2.7	84.9±7.5

Table 6: Results of different learning rate ratios of lexical Interpreter, Composer, and algebraic Interpreter.

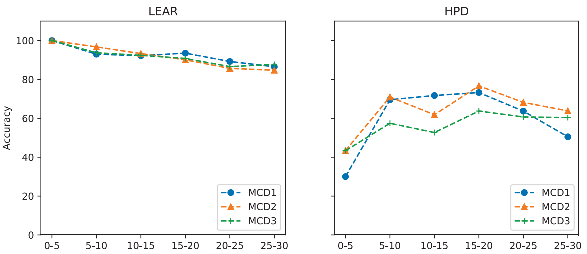

Figure 4: Performance by input length.

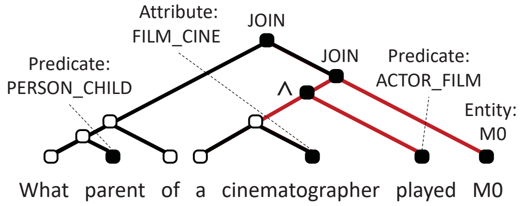
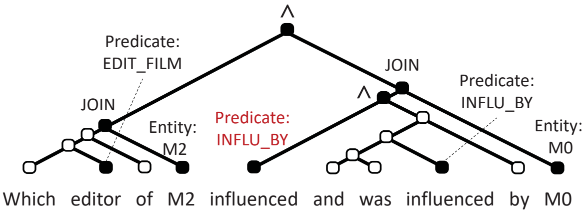
Primitive-based reward helps the model converge better. The ablation "*w/o primitive-based reward*" leads to 5.6% accuracy drop on CFQ, and the model variance has become much larger. The key insight is: primitive-based reward guides the model to interpret polysemous lexical units more effectively, thus helping the model converge better.

Curriculum learning helps the model converge better. The ablation "*w/o curriculum learning*" leads to 19% accuracy drop on CFQ, and the model variance has become much larger. This indicates the importance of curriculum learning. On COGS, LEAR performs well without curriculum learning. We speculate that there are two main reasons: (1) expressions of COGS is much shorter than CFQ; (2) the input/output pattern coverage of COGS is much higher than CFQ.

Higher component with smaller learning rate. Inspired by the differential update strategy used in Liu et al. (2020)(i.e., the higher level the component is positioned in the model, the slower the parameters in it should be updated), we set three different learning rates to three different components in LEAR (in bottom-up order): lexical Interpreter, Composer, and algebraic Interpreter. We fix the learning rate of lexical Interpreter to 1, and adjust the ratio of the learning rates of Composer and algebraic Interpreter to lexical Interpreter. Table 6 shows the results on CFQ. The hierarchical learning rate setup ($1 : 0.5 : 0.1$) achieves the best performance.



(a) Composer error. A correct syntax tree should compose "*parent of a cinematographer*" as a constituent, while the predicted syntax tree incorrectly composes "*a cinematographer played M0*".



(b) Interpreter error. In this expression, the first "*influenced*" should be assigned a semantic primitive "*influence.influence_node.influenced*", while Interpreter incorrectly assigns "*influence.influence_node.influenced_by*" (abbreviated as "*INFLU_BY*" in this figure) to it.

Figure 5: Two error cases. We use solid nodes to denote predicted nonterminal nodes. Incorrect parts are colored red.

6.2 Closer Analysis

We also conduct closer analysis to the results of LEAR as follows.

6.2.1 Performance by Input Length

Intuitively, understanding longer expressions requires stronger algebraic recombination ability than shorter examples. Therefore, we expect that our model should keep a good and stable performance with the increasing of input length.

Figure 4 shows the performance of LEAR and HPD (the state-of-the-art model on CFQ) under different input lengths. Specifically, test instances are divided into 6 groups by length: $[1, 5], [6, 10], ..., [26, 30]$), and we report accuracy on each group separately. The results indicate that **LEAR has stable high performance for different input lengths**, with only a slow decline as length increases. Even on the group with the longest input length, LEAR can maintain an average 86.3% accuracy across three MCD-splits.

6.2.2 Error Analysis

To understand the source of errors, we take a closer look at the failed test instances of LEAR on CFQ. These failed test instances account for 9.1% of the test dataset. We category them into two error types:

Error Type	MCD1	MCD2	MCD3
CE	45.70%	32.05%	39.83%
IE	54.30%	67.95%	60.17%

Table 7: Distribution of CE (Composer Error) and IE (Interpreter Error).

Composer error (CE), i.e., test cases where Composer produces incorrect syntactic structures (only considering nonterminal nodes). Figure 5a shows an example. As we do not have ground-truth syntactic structures, we determine whether a failed test instance belongs to this category based on handcraft syntactic templates.

Interpreter error (IE), i.e., test cases where Composer produces correct syntactic structures but Interpreter assigns one or more incorrect semantic primitives or operations. Figure 5b shows an example, which contains an incorrect semantic primitive assignment.

Table 7 shows the distribution of these two error types. On average, 39.19% of failed instances are composer errors, and the remaining 60.81% are interpreter errors.

6.3 Limitations

Our approach is implicitly build upon the assumption of **primitive alignment**, that is, each primitive in the meaning representation can align to at least one span in the utterance. This assumption holds in most cases of various semantic parsing tasks, including CFQ, COGS, and GEO. However, for robustness and generalizability, we also need to consider cases that do not meet this assumption. For example, consider this utterance "*Obama's brother*", of which the corresponding meaning representation is "$Slibing(People[Obama]) \wedge Gender[Male]$". Neither "$Slibing$" nor "$Gender[Male]$" can align to a span in the utterance, as the composed meaning of them is expressed by a single word ("*brother*"). Therefore, LEAR is more suitable for formalisms where primitives can better align to natural language.

In addition, while our approach is general for various semantic parsing tasks, the collection of semantic operations needs to be redesigned for each task. We need to ensure that these semantic operations are k-ary projections (as described in Section 2), and all the meaning representations are covered by the operations collection. This is tractable, but still requires some efforts from domain experts.

7 Related Work

7.1 Compositional Generalization

Recently, exploring compositional generalization (CG) on neural networks has attracted large attention in NLP community. For SCAN (Lake and Baroni, 2018), the first benchmark to test CG on seq2seq models, many solutions have been proposed, which can be classified into two tracks: data augmentation (Andreas, 2019; Akyürek et al., 2020; Guo et al., 2020a) and specialized architecture (Lake, 2019; Li et al., 2019; Gordon et al., 2020). However, most of these works only focus on lexical recombination. Some works on SCAN have stepped towards algebraic recombination (Liu et al., 2020; Chen et al., 2020), but they do not generalize well to other tasks such as CFQ (Keysers et al., 2019) and COGS (Kim and Linzen, 2020).

Before our work, there is no satisfactory solution on CFQ and COGS. Previous works on CFQ demonstrated that MLM pre-training (Furrer et al., 2020) and iterative back-translation (Guo et al., 2020d) can improve traditional seq2seq models. HPD (Guo et al., 2020b), the state-of-the-art solution before ours, was shown to be effective on CFQ, but still far from satisfactory. As for COGS, there is no solution to it to the best of our knowledge.

7.2 Compositional Semantic Parsing

In contrast to neural semantic parsing models which are mostly constructed under a fully seq2seq paradigm, compositional semantic parsing models predict partial meaning representations and compose them to produce a full meaning representation in a bottom-up manner (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2012; Liang et al., 2013; Berant et al., 2013; Berant and Liang, 2015; Pasupat and Liang, 2015; Herzig and Berant, 2020). Our model takes the advantage of compositional semantic parsing, without requiring any handcraft lexicon or syntactic rule.

7.3 Unsupervised Parsing

Unsupervised parsing (or grammar induction) trains syntax-dependent models to produce syntactic trees of natural language expressions without direct syntactic annotation (Klein and Manning, 2002; Bod, 2006; Ponvert et al., 2011; Pate and Johnson, 2016; Shen et al., 2018; Kim et al., 2019; Drozdov et al., 2020). Comparing to them, our model learns both syntax and semantics jointly.

8 Conclusion

In this paper, we introduce LEAR, a novel end-to-end neural model for compositional generalization in semantic parsing tasks. Our contribution is 4-fold: (1) LEAR focuses on algebraic recombination, thus it exhibits stronger compositional generalization ability than previous methods that focus on simpler lexical recombination. (2) We model the semantic parsing task as a homomorphism between two partial algebras, thus encouraging algebraic recombination. (3) We propose the model architecture of LEAR, which consists of a Composer (to learn latent syntax) and an Interpreter (to learn operation assignments). (4) Experiments on two realistic and comprehensive compositional generalization benchmarks demonstrate the effectiveness of our model.

Acknowledgments

The work was supported by the National Key Research and Development Program of China (No. 2019YFB1704003), the National Nature Science Foundation of China (No. 71690231), Tsinghua BNRist and Beijing Key Laboratory of Industrial Bigdata System and Application.

Ethical Consideration

The experiments in this paper are conducted on existing datasets. We describe the model architecture and training method in detail, and provide more explanations in the supplemental materials. All the data and code will be released with the paper. The resources required to reproduce the experiments is a Tesla P100 GPU, and for COGS benchmark even one CPU is sufficient. Since the compositional generalization ability explored in this paper is a fundamental problem of artificial intelligence and has not yet involved real applications, there are no social consequences or ethical issues.

A Semantic Operations in COGS

The semantic primitives used in COGS benchmark are entities (e.g., *Emma* and *cat(x_1)*), predicates (e.g., *eat*) and propositions (e.g., *eat.agent(x_1, Emma)*). The semantic operations in COGS are listed in Table 8.

The operations with "$^{-1}$" (e.g., ON^{-1}) are right-to-left operations (e.g., ON^{-1}(cake, table)→table.ON.cake) while the operations without "-1" represent the left-to-right operations (e.g., ON(cake, table)→cake.ON.table). For operation FillFrame, the entity in its arguments will be filled into predicate/proposition as an AGENT, THEME or RECIPIENT, which is decided by model.

B Semantic Operations in GEO and Post-process

The semantic primitives used in GEO benchmark are entities (e.g., *var0*), predicates (e.g., *state()*) and propositions (e.g., *state(var0)*). The semantic operations in GEO are listed in Table 9.

To fit the FunQL formalism, we design two post-processing rules for the final semantics generated by the model. First, if the final semantic is a predicate (not a proposition), it will be converted in to a proposition by filling the entity *all*. Second, the predicate *most* will be shifted forward two positions in the final semantics.

C Policy Gradient and Differential Update

In this section, we will show more details about the formulation of our RL training based on policy gradient and how to use differential update strategy on it.

Denoting $\tau = \{z, g\}$ as the trajectory of our model where z and g are actions (or called results) produced from Composer and Interpreter, respectively, and $R(\tau)$ as the reward of a trajectory τ (elaborated in Sec. 4.1), the training objective of our model is to maximize the expectation of rewards as:

$$\max_{\theta,\phi} \mathcal{J}(\theta, \phi) = \max_{\theta,\phi} \mathbb{E}_{\tau\sim\pi_{\theta,\phi}} R(\tau), \tag{13}$$

where $\pi_{\theta,\phi}$ is the policy of the whole model θ and ϕ are the parameters in Composer and Interpreter, respectively. Applying the likelihood ratio trick, θ and ϕ can be optimized by ascending the following gradient:

$$\nabla \mathcal{J}(\theta, \phi) = \mathbb{E}_{\tau\sim\pi_{\theta,\phi}} R(\tau) \nabla \log \pi_{\theta,\phi}(\tau),$$

which is same with Eq. 9.

As described in Sec. 3 that the interpreting process can be divided into two stages: interpreting lexical nodes and interpreting algebraic nodes, the action g can also be split as the semantic primitives of lexical nodes g_l and the semantic operations of algebraic nodes g_a. In our implement, we utilize two independent neural modules for interpreting lexical nodes and interpreting algebraic nodes, with parameters ϕ_l and ϕ_a respectively. Therefore, $\nabla \log \pi_{\theta,\phi}(\tau)$ in Eq. 9 can be expanded via the chain rule as:

$$\begin{aligned} \nabla \log \pi_{\theta,\phi}(\tau) = & \nabla \log \pi_{\theta}(z|x) + \\ & \nabla \log \pi_{\phi_l}(g_l|x, z) + \\ & \nabla \log \pi_{\phi_a}(g_a|x, z, g_l). \end{aligned} \tag{14}$$

With Eq. 14, we can set different learning rates:

$$\begin{aligned} \theta &\leftarrow \theta + \alpha \cdot \mathbb{E}\, R(\tau) \nabla \log \pi_{\theta}(z|x), \\ \phi_l &\leftarrow \phi_l + \beta \cdot \mathbb{E}\, R(\tau) \nabla \log \pi_{\phi_l}(g_l|x, z), \\ \phi_a &\leftarrow \phi_a + \gamma \cdot \mathbb{E}\, R(\tau) \nabla \log \pi_{\phi_a}(g_a|x, z, g_l). \end{aligned} \tag{15}$$

Furthermore, in our experiments, the AdaDelta optimizer (Zeiler, 2012) is employed to optimize our model.

D Phrase Table

The phrase table consists of lexical units (i.e., words and phrases) paired with semantic primitives that frequently co-occur with them. It can be obtained with statistical methods.

For CFQ, we leverage GIZA++[4] (Och and Ney, 2003) toolkit to extract alignment pairs from training examples. We obtain 109 lexical units, each of which is paired with 1.7 candidate semantic primitives on average. Some examples in phrase table are shown in Table 10

As to COGS, for each possible lexical unit, we first filter out the semantic primitives that exactly co-occur with it, and delete lexical units with no semantic primitive. Among the remaining lexical units, for those only contain one semantic primitive, we record their co-occurring semantic primitives

Out of Order: How Important Is The Sequential Order of Words in a Sentence in Natural Language Understanding Tasks?

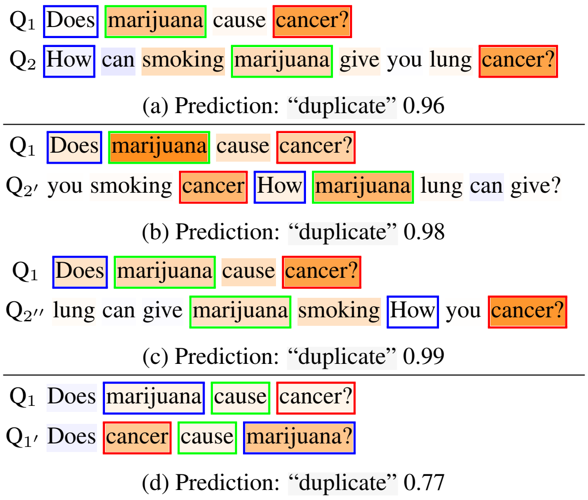
Abstract

Do state-of-the-art natural language understanding models care about word order? Not always! We found 75% to 90% of the correct predictions of BERT-based classifiers, trained on many GLUE tasks, remain constant after input words are randomly shuffled. Although BERT embeddings are famously contextual, the contribution of each individual word to classification is almost unchanged even after its surrounding words are shuffled. BERT-based models exploit superficial cues (e.g. the sentiment of keywords in sentiment analysis; or the word-wise similarity between sequence-pair inputs in natural language inference) to make correct decisions when tokens are randomly shuffled. Encouraging models to capture word order information improves the performance on most GLUE tasks and SQuAD 2.0. Our work suggests that many GLUE tasks are not challenging machines to understand the meaning of a sentence.

1 Introduction

Machine learning (ML) models recently achieved excellent performance on state-of-the-art benchmarks for evaluating natural language understanding (NLU). In July 2019, RoBERTa (Liu et al., 2019) was the first to surpass a human baseline on GLUE (Wang et al., 2019). Since then, 13 more methods have also outperformed humans on the GLUE leaderboard. Notably, at least 8 out of the 14 solutions are based on BERT (Devlin et al., 2019)—a transformer architecture that learns representations via a bidirectional encoder. Given their superhuman GLUE-scores, how do BERT-based models solve NLU tasks? How do their NLU capability differs from that of humans?

We shed light into these important questions by examining model sensitivity to the order of words. Word order is one of the key characteristics of a sequence and is tightly constrained by many linguistic factors including syntactic structures, subcategorization, and discourse (Elman, 1990). Thus, arranging a set of words in a correct order is considered a key problem in language modeling (Hasler et al., 2017; Zhang and Clark, 2015).



Q_1 Does marijuana cause cancer?
Q_2 How can smoking marijuana give you lung cancer?

(a) Prediction: "duplicate" 0.96

Q_1 Does marijuana cause cancer?
$Q_{2'}$ you smoking cancer How marijuana lung can give?

(b) Prediction: "duplicate" 0.98

Q_1 Does marijuana cause cancer?
$Q_{2''}$ lung can give marijuana smoking How you cancer?

(c) Prediction: "duplicate" 0.99

Q_1 Does marijuana cause cancer?
$Q_{1'}$ Does cancer cause marijuana?

(d) Prediction: "duplicate" 0.77

Figure 1: A RoBERTa-based model achieving a 91.12% accuracy on QQP, here, correctly labeled a pair of Quora questions "duplicate" (a). Interestingly, the predictions remain unchanged when all words in question Q_2 is randomly shuffled (b–c). QQP models also often incorrectly label a real sentence and its shuffled version to be "duplicate" (d). We found evidence that GLUE models rely heavily on words to make decisions e.g. here, "marijuana" and "cancer" (more important words are highlighted by LIME). Also, there exist self-attention matrices tasked explicitly with extracting word-correspondence between two input sentences regardless of the position of those words. Here, the top-3 pairs of words assigned the highest self-attention weights at (layer 0, head 7) are inside red, green, and blue rectangles, respectively.

Therefore, a natural question is: **Do BERT-based models trained on GLUE care about the order of words in a sentence?** Lin et al. (2019)

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1145–1160
August 1–6, 2021.

found that pretrained BERT captures word-order information in the first three layers. However, it is unknown whether BERT-based classifiers actually use word order information when performing NLU tasks. Recently, Wang et al. (2020) showed that incorporating additional word-ordering and sentence-ordering objectives into BERT pretraining could lead to text representations (StructBERT) that enabled improved GLUE scores. However, StructBERT findings are inconclusive across different GLUE tasks and models. For example, in textual entailment (Wang et al., 2019, RTE), StructBERT improved the performance for BERT$_{\text{large}}$ but hurt the performance for RoBERTa (Table 2d).

Wang et al. 2020 motivated interesting questions: **Are state-of-the-art BERT-based models using word order information when solving NLU tasks? If not, what cues do they rely on?** To the best of our knowledge, our work is the first to study the above questions for an NLU benchmark (GLUE). We tested BERT-, RoBERTa-, and ALBERT-based (Lan et al., 2020) models on 7 GLUE tasks where the words of only one select sentence in the input text are shuffled at varying degrees. An ideal agent that truly understands language is expected to choose a "reject" option when asked to classify a sentence whose words are randomly shuffled. Alternatively, given shuffled input words, true NLU agents are expected to perform at random chance in multi-way classification that has no "reject" options (Fig. 1b). Our findings include:

1. 65% of the groundtruth labels of 5 GLUE tasks can be predicted when the words in one sentence in each example are shuffled (Sec. 3.1).
2. Although pretrained BERT embeddings are known to be contextual, in some GLUE tasks, the contribution of an individual word to classification is almost unchanged even after its surrounding words are shuffled (Sec. 3.3).
3. In sentiment analysis (SST-2), the polarity of a single salient word is $\geq 60\%$ predictive of an entire sentence's label (Sec. 3.4.1).
4. BERT-based models trained on sequence-pair GLUE tasks used a set of self-attention heads for finding similar tokens shared between the two inputs (Sec. 3.4).
5. Encouraging RoBERTa-based models to be more sensitive to word order improves the performance on SQuAD 2.0 and most GLUE tasks tested (i.e. except for SST-2) (Sec. 3.5).

Despite their superhuman scores, most GLUE-trained models behave similarly to Bag-of-Words (BOW) models, which are prone to naive mistakes (Fig. 1b–d). Our results also suggest that GLUE does not necessarily require syntactic information or complex reasoning.

2 Methods

2.1 Datasets

We chose GLUE because of three reasons: (1) GLUE is a common benchmark for NLU evaluation (Wang et al., 2019); (2) there exist NLU models (e.g. RoBERTa) that outperform humans on GLUE, making an important case for studying their behaviors; (3) it is unknown how sensitive GLUE-trained models are to word order and whether GLUE requires them to be sensitive (Wang et al., 2020).

Tasks Out of 9 GLUE tasks, we chose all 6 binary-classification tasks because they share the same random baseline of 50% accuracy and enable us to compare models' word-order sensitivity across tasks. Six tasks vary from acceptability (CoLA Warstadt et al. 2019), to natural language inference (QNLI Rajpurkar et al. 2016), RTE (Wang et al., 2019), paraphrase (MRPC Dolan and Brockett 2005, QQP Quora 2017), and sentiment analysis (SST-2 Socher et al. 2013).

We also performed our tests on STS-B (Cer et al., 2017)—a regression task of predicting the semantic similarity of two sentences.[1] While CoLA and SST-2 require single-sentence inputs, all other tasks require sequence-pair inputs.

Reject options For all binary-classification tasks (except SST-2), the negative label is considered the reject option (e.g. QQP models can choose "not duplicate" in Fig. 1b to reject shuffled inputs).

Metrics We use accuracy scores to evaluate the binary classifiers (for ease of interpretation) and Spearman correlation to evaluate STS-B regressors, following Wang et al. (2019).

2.2 Classifiers

We tested BERT-based models because (1) they outperformed humans on the GLUE leaderboard; and (2) the pretrained BERT was shown to capture word positional information (Lin et al., 2019).

---

[1] We did not choose WNLI (Levesque et al., 2012) as model performance is not substantially above random baseline.

Pretrained BERT encoders We tested three sets of classifiers finetuned from three different, pretrained BERT variants: BERT, RoBERTa, and ALBERT, downloaded from Huggingface (2020). The pretrained models are the "base" versions i.e. bidirectional transformers with 12 layers and 12 self-attention heads. The pretraining corpus varies from uncased (BERT, ALBERT) to case-sensitive English (RoBERTa).

Classifiers For each of the seven GLUE tasks, we added one classification layer on top of each of the three pretrained BERT encoders and finetuned the entire model. Unless otherwise noted, the mean performance per GLUE task was averaged over three classifiers. Each model's performance matches either those reported on Huggingface (2020) or the original papers (Table A6).

Hyperparameters Following Devlin et al. (2019), we finetuned classifiers for 3 epochs using Adam (Kingma and Ba, 2015) with a learning rate of 0.00002, $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 10^{-8}$. We used a batch size of 32, a max sequence length of 128, and dropout on all layers with a probability of 0.1.

2.3 Constructing sets of real and shuffled examples for experiments

Modifying one sentence As GLUE tasks vary in the number of inputs (one or two input sequences) and the sequence type per input (a sentence or a paragraph), we only re-ordered the words in one *sentence* from only one input while keeping the rest of the inputs unchanged. Constraining the modifications to a single sentence enables us to measure (1) the importance of word order in a single sentence; and (2) the interaction between the shuffled words and the unchanged, real context.

Random shuffling methods To understand model behaviors across varying degrees of word-order distortions, we experimented with three tests: randomly shuffling n-grams where n = $\{1, 2, 3\}$.

Shuffling 1-grams is a common technique for analyzing word-order sensitivity (Sankar et al., 2019; Zanzotto et al., 2020). We split a given sentence by whitespace into a list of n-grams, and re-combined them, in a random order, back into a "shuffled" sentence (see Table 1 for examples). The ending punctuation was kept intact. We re-sampled a new random permutation until the shuffled sentence was different from the original sentence.

As the label distributions, dev-set sizes, and the performance of models vary across GLUE tasks, to compare word-order sensitivity across tasks, we tested each model on two sets: (1) `dev-r` i.e. a subset of the original dev-set (Sec. 2.3.1); and (2) `dev-s` i.e. a clone of version of `dev-r` but that each example has one sentence with re-ordered words (Sec. 2.3.2).

	How can smoking marijuana give you lung cancer?
Q_3	lung cancer marijuana give you How can smoking?
Q_2	smoking marijuana lung cancer give you How can?
Q_1	marijuana can cancer How you smoking give lung?
Q_s	How can smoking cancer give you lung marijuana?

Table 1: A real question on Quora (QQP dataset) and its three modified versions (Q_3 to Q_1) created by randomly shuffling 3-grams, 2-grams, and 1-grams, respectively. Q_s was created by swapping two random nouns.

2.3.1 Selecting real examples

For each pair of (task, classifier), we selected a subset of dev-set examples via the following steps:

1. For tasks with either a single-sequence or a sequence-pair input, we used examples where the input sequence to be modified has only one sentence[2] that has more than 3 tokens (for shuffling 3-grams to produce a sentence different from the original sentence).
2. We only selected the examples that were correctly classified by the classifier (to study what features were important for high accuracy).
3. We balanced the numbers of positive and negative examples by removing random examples from the larger-sized class.

That is, on average, we filtered out ∼34% of the original data. See Table A4 for the total number of examples remaining after each filtering step above.

2.3.2 Creating shuffled sets

For each task, we cloned the `dev-r` sets above and modified each example to create a "shuffled" set (a.k.a. `dev-s`) per shuffling method.

Specifically, a CoLA and SST-2 example contains only a single sentence and we modified that sentence. Each QQP, MRPC and STS-B example has two sentences and we modified the first sentence. An RTE example has a pair of (premise, hypothesis), and we modified the hypothesis since it

---

[2] We used NLTK sentence splitter (Bird et al., 2009) to detect text that has more than one sentence.

is a single sentence while premises are paragraphs. Each QNLI example contains a pair of (question, answer) and we modified the question, which is a sentence, while an answer is often a paragraph.

3 Experiments and Results

3.1 How much is word order information required for solving GLUE tasks?

GLUE has been a common benchmark for evaluating NLU progress. But, do GLUE tasks require models to use word order and syntactic information? We shed light into this question by testing model performance when word order is increasingly randomized.

If a task strictly requires words to form a semantically meaningful sentence, then randomly re-positioning words in correctly-classified sentences will cause model accuracy to drop from 100% to 50% (i.e. the random baseline b for binary-classification tasks with two balanced classes). Thus, to compare model-sensitivity across tasks, we use a Word-Order Sensitivity score (WOS):

$$s = (100 - p)/(100 - b) \tag{1}$$

where $p \in [50, 100]$ is the accuracy of a GLUE-trained model evaluated on a `dev-s` set (described in Sec. 2.3.2) and $s \in [0, 1]$. Here, $b = 50$.

Experiments For each GLUE task, we computed the mean accuracy and confidence score over three classifiers (BERT, RoBERTa, and ALBERT-based) on `dev-s` sets created by shuffling 1-grams, 2-grams, and 3-grams. The results reported in Table 2 were averaged over 10 random shuffling runs (i.e. 10 random seeds) per n-gram type, and then averaged over 3 models per task.

Results We found that for CoLA, i.e. detecting grammatically incorrect sentences, the model accuracy, on average, drops to near random chance i.e. between 50.69% and 56.36% (Table 2b) when n-grams are shuffled. That is, most of examples were classified into "unacceptable" after n-gram shuffling, yielding ~50% accuracy (see Fig. A2 for qualitative examples).

Surprisingly, for the rest of the 5 out of 6 binary-classification tasks (i.e. except CoLA), between 75% and 90% of the originally correct predictions remain constant after 1-grams are randomly reordered (Table 2b; 1-gram). These numbers increase as the shuffled n-grams are longer (i.e. as n increases from 1→3), up to 95.32% (Table 2b; QNLI). Importantly, given an average dev-set accuracy of 86.35% for these 5 tasks, **at least** 86.35% $\times$ 75% $\approx$ **65% of the groundtruth labels of these 5 GLUE tasks can be predicted when all input words in one sentence are randomly shuffled.**

Additionally, on average over three n-gram types, models trained on these five GLUE tasks are from 2 to 10 times more *insensitive* to word-order randomization than CoLA models (Table 2c). That is, if not explicitly tasked with checking for grammatical errors, GLUE models mostly will not care about the order of words in a sentence (see qualitative examples in Figs. 1, A2–A4). Consistently, the confidence scores of BERT-based models for five non-CoLA tasks only dropped ~2% when 1-grams are shuffled (Table 2).

Consistently across three different BERT "base" variants and a RoBERTa "large" model (Table A5), our results suggest that word order and syntax, in general, are not necessarily required to solve GLUE.

2-noun swaps Besides shuffled n-grams, we also repeated all experiments with more syntactically-correct modified inputs where only two random nouns in a sentence were swapped (Table 1; Q_s). This is a harder test for NLU models since the meaning of a sentence with two nouns swapped often changes while its syntax remains correct. We found the conclusions to generalize to this setting. That is, the models hardly changed predictions although the meanings of the original sentence and its swapped version are different (Table 2b; 2-noun swap vs. 1-gram).

3.2 How sensitive are models trained to predict the similarity of two sentences?

An interesting hypothesis is that models trained explicitly to evaluate the semantic similarity of two sentences should be able to tell apart real from shuffled examples. Intuitively, word order information is essential for understanding what an entire sentence means and, therefore, for predicting whether two sentences convey the same meaning.

We tested this hypothesis by analyzing the sensitivity of models trained on QQP and STS-B—two prominent GLUE tasks for predicting semantic similarity of a sentence pair. While QQP is a binary classification task, STS-B is a regression task where a pair of two sentences is given a score $\in [0, 5]$ denoting their semantic similarity.

Experiments We tested the models on `dev-r` and `dev-s` sets (see Sec. 2.3.2) where in each pair, the word order of the first sentence was randomized while the second sentence was kept intact.

QQP results Above 83% of QQP models' correct predictions on real pairs remained unchanged after word-order randomization (see Figs. 1a–c for examples).

STS-B results Similarly, STS-B model performance only drops marginally, i.e. less than 2 points from 89.67 to 87.80 in Spearman correlation (Table 2; STS-B). Since a STS-B model outputs a score $\in [0, 5]$, we binned the scores into 6 ranges. One might expect STS-B models to assign near-zero similarity scores to most modified pairs. However, the distributions of similarity scores for the modified and real pairs still closely match up (Fig. 2). In sum, **despite being trained explicitly on predicting semantic similarity of sentence pairs, QQP and STS-B are surprisingly insensitive to n-gram shuffling, exhibiting naive understanding of sentence meanings**.

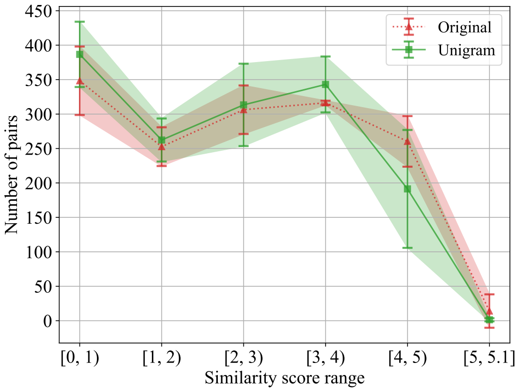


Figure 2: The distribution of similarity scores over 6 ranges for the (real, shuffled) pairs in `dev-s` (green) is highly similar to that for (real, real) STS-B pairs in `dev-r` (red). The statistics in each range were computed over 3 models (BERT, RoBERTa, and ALBERT).

3.3 How important are words to classification after their context is shuffled?

BERT representations for tokens are known to be highly contextual (Ethayarajh, 2019). However, after finetuning on GLUE, would the importance of a word to classification drop after its context is shuffled?

To answer the above question, we used LIME (Ribeiro et al., 2016) to compute word importance.

LIME computes a score $\in [-1, 1]$ for each token in the input denoting how much its presence contributes for or against the network's predicted label (Fig. 1; highlights). The importance score per word w is intuitively the mean confidence-score drop over a set of randomly-masked versions of the input when w is masked out.

Experiments We chose to study RoBERTa-based classifiers here because they have the highest GLUE scores among the three BERT variants considered. We observed that **62.5% (RTE) to 79.6% (QNLI) of the `dev-r` examples were consistently, correctly classified into the same labels in all 5 different random shuffles** (i.e. 5 different random seeds). We randomly sampled 100 such examples per binary-classification task and computed their LIME attribution maps to compare the similarity between the LIME heatmaps before and after unigrams are randomly misplaced.

Results On CoLA and RTE, the importance of words (i.e. mean absolute value of LIME-attribution per word), *decreased* substantially by 0.036 and 0.019, respectively. That is, the individual words become *less important* after their context is distorted—a behavior expected when CoLA and RTE have the highest WOS scores (Table 2). In contrast, for the other 4 tasks, word importance only changed marginally (by 0.008, i.e. 4.5× smaller than the 0.036 change in CoLA). That is, **except for CoLA and RTE models, the contribution of a word to classification is almost unchanged even after the context of each word is randomly shuffled** (Fig. 1a–c). This result suggests that the word embeddings after finetuning on GLUE became much less contextual than the pretrained BERT embeddings (Ethayarajh, 2019).

3.4 If not word order, then what do classifiers rely on to make correct predictions?

Given that all non-CoLA models are highly insensitive to word-order randomization, how did they arrive at correct decisions when words are shuffled?

We chose to answer this question for SST-2 and QNLI because they have the lowest WOS scores across all 6 GLUE tasks tested (Table 2) and they are representative of single-sentence and sequence-pair tasks, respectively.

Task	(a) Perf. on `dev-r`		(b) Performance on `dev-s`				(c) Word-Order Sensitivity			(d) StructBERT improvements		
	Models	Baseline	2-noun swap	1-gram	2-gram	3-gram	1-gram	2-gram	3-gram	BERT$_{\text{base}}$	BERT$_{\text{large}}$	RoBERTa
`CoLA`	100 (0.93)	50	71.75 (0.91)	50.69 (0.95)	53.98 (0.94)	56.36 (0.92)	**0.99**	**0.92**	**0.87**	**+4.9**	+4.8	+1.4

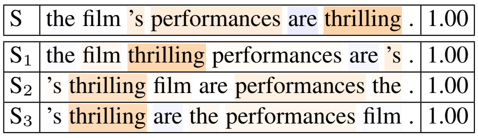
Table 2: All results (a–c) are reported on the GLUE `dev-r` sets i.e. 100% accuracy (a). Shuffling n-grams caused the accuracy to drop (b) the largest for CoLA and the least for QNLI. Each row is computed by averaging the results of 3 BERT-based models and 10 random shuffles. From top to bottom, the Word-Order Sensitivity (WOS) is sorted descendingly (c) and is consistent across three types of n-grams i.e. WOS scores decrease from top down and from left to right. In contrast, the StructBERT results (d), taken from Table 1 and 4 in Wang et al. 2020, showed inconsistent improvements across different tasks. STS-B results are in scaled Spearman correlation. In addition to small accuracy drops, the mean confidence scores of all classifiers—reported in parentheses e.g. "(0.93)"—also changed marginally after words are shuffled (a vs. b).

3.4.1 SST-2: Salient words are highly predictive of sentence labels

As 84.04% of the SST-2 correct predictions did not change after word-shuffling (Table 2b), a common hypothesis is that the models might rely heavily on a few key words to classify an entire sentence.



S	the film 's performances are thrilling .	1.00
S$_1$	the film thrilling performances are 's .	1.00
S$_2$	's thrilling film are performances the .	1.00
S$_3$	's thrilling are the performances film .	1.00

Figure 3: An original SST-2 dev-set example (S) and its three shuffled versions (S$_1$ to S$_3$) were all correctly labeled "positive" by a RoBERTa-based classifier with high confidence scores (right column).

Experiments To test this hypothesis, we took all SST-2 `dev-r` examples whose all 5 randomly shuffled versions were all correctly labeled by a RoBERTa-based classifier (i.e. this "5/5" subset is ∼65% of the dev-set). We used LIME to produce a heatmap of the importance of words in each example.

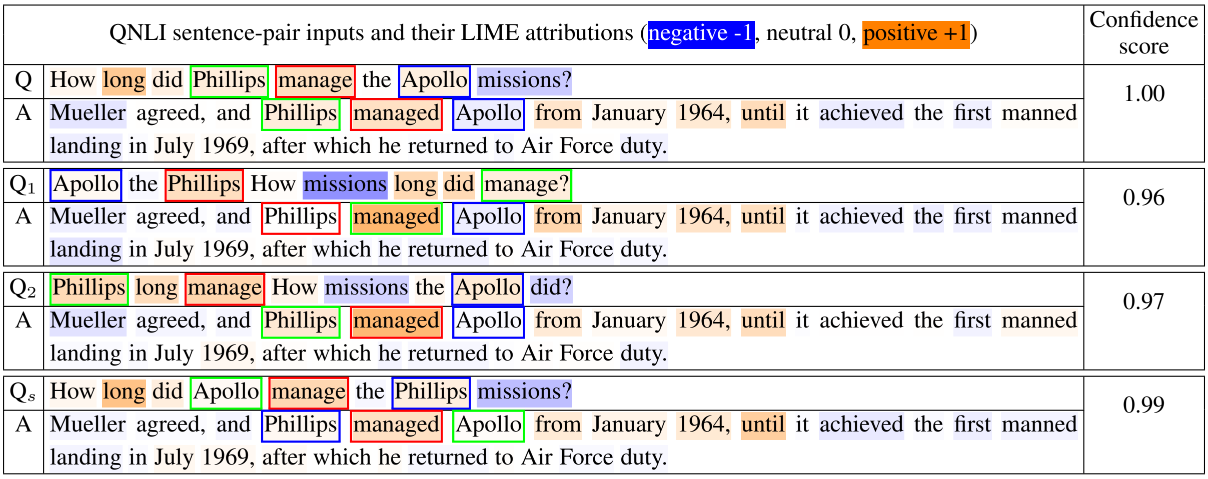
We identified the polarity of each top-1 most important word (i.e. the highest LIME-attribution score) per example by looking it up in the Opinion Lexicon (Hu and Liu, 2004) of 2,006 positive and 4,783 negative words. ∼57% of these top-1 words were found in the dictionary and labeled either "positive" or "negative" (see Table A3).

Results We found that if the top-1 word has a positive meaning, then there is a 100% probability that the sentence's label is "positive". For example, the word "thrilling" in a movie review indicates a "positive" sentence (see Fig. 3). Similarly, the conditional probability of a sentence being labeled "negative" given a negative top-1 word is 94.4%. That is, given this statistics, the SST-2 label distribution and model accuracy, **at least 60% of the SST-2 dev-set examples can be correctly predicted from only a single top-1 salient word.**

We also reached similar conclusions when experimenting with ALBERT classifiers and the SentiWords dictionary (Gatti et al., 2015) (see Table A3).

3.4.2 Self-attention layers matching similar words in both the question and the answer

For sequence-pair tasks, e.g. QNLI, how can models correctly predict "entailment" when the question words are randomly shuffled (Fig. 4; Q$_1$) or when the question syntax is correct but its meaning



QNLI sentence-pair inputs and their LIME attributions (negative -1, neutral 0, positive +1)		Confidence score
Q	How long did Phillips manage the Apollo missions?	1.00
A	Mueller agreed, and Phillips managed Apollo from January 1964, until it achieved the first manned landing in July 1969, after which he returned to Air Force duty.	
Q_1	Apollo the Phillips How missions long did manage?	0.96
A	Mueller agreed, and Phillips managed Apollo from January 1964, until it achieved the first manned landing in July 1969, after which he returned to Air Force duty.	
Q_2	Phillips long manage How missions the Apollo did?	0.97
A	Mueller agreed, and Phillips managed Apollo from January 1964, until it achieved the first manned landing in July 1969, after which he returned to Air Force duty.	
Q_s	How long did Apollo manage the Phillips missions?	0.99
A	Mueller agreed, and Phillips managed Apollo from January 1964, until it achieved the first manned landing in July 1969, after which he returned to Air Force duty.	

Figure 4: A RoBERTa-based model's correct prediction of "entailment" on the original input pair (Q, A) remains unchanged when the question is randomly shuffled (Q_1 & Q_2) or when two random nouns in the question are swapped (Q_s). The salient words in the questions e.g. manage and missions remain similarly important after their context has been shuffled. Also, the classifier harnessed self-attention to detect the correspondence between similar words that appear in both the question and the answer e.g. manage (Q) and managed (A). That is, the top-3 pairs of words that were assigned the largest question-to-answer weights in a self-attention matrix (layer 0, head 7) are inside in the red, green, and blue rectangles.

changes entirely (Fig. 4; Q_s). We hypothesize that inside the model, there might be a self-attention (SA) layer that extracts pairs of similar words that appear in both the question and the answer (e.g. "manage" vs. "managed" in Fig. 4).

Experiments To test this hypothesis, we analyzed the 5,000 QNLI `dev-r` examples (Table A4) of RoBERTa-based classifiers trained on QNLI. For each example, we identified one SA matrix (among all 144 as the base model has 12 layers & 12 heads per layer) that assigns the highest weights to pairs of similar words between the question and the answer, i.e. excluding intra-question and intra-answer attention weights (see the procedure in Sec. A).

Results First, in ∼58% of the examples, we found at least three pairs of words that *match* (i.e. the sum Levenshtein character-level edit-distance for all 3 pairs is ≤ 4). Second, we found, in total, 15 SA heads (out of the 144) which are explicitly tasked with capturing such question-to-answer word correspondence, *regardless* of word order (see Fig. 4).

Remarkably, **87% of the work of matching similar words that appear in both the QNLI question and the answer was handled by only 3 self-attention heads at (layer, head) of (0,7), (1,9), and (2,6)**.

We found consistent results when repeating the same analysis for other three sequence-pair tasks. That is, interestingly, **the three SA heads at exactly the same location of (0, 7), (1, 9), and (2, 6) account for 76%, 89%, and 83% of the "word-matching" task on QQP, RTE, and MRPC, respectively**. This coincidence is likely due to the fact that these classifiers were finetuned for different downstream tasks starting from the same pretrained RoBERTa encoder. See Figs. 1, 4, A3–A4 for qualitative examples of these three tasks.

How important are the 15 word-matching attention heads to QNLI model performance? We found that zero-ing out 15 random heads had almost no effect to correctly-classified predictions–i.e. accuracy dropped marginally (-1% to -3%, Table 3) across different groups of examples. However, ablating the 15 word-matching heads caused the performance to drop substantially i.e. (a) by 9.6% on the 1,453 "positive" examples identified in Sec. A; (b) by 22.1% on a set of 2,906 random, examples including both "positive" and "negative" examples (at 50/50 ratio); and (c) by 24.5% on the entire QNLI 5,000-example `dev-r` set. That is, **the 15 SA heads that learned to detect similar words played an important role in solving QNLI, i.e. enabling at least ∼50% of the correct predictions** (Table 3d; accuracy dropped from 100% to 75.54% when the random chance is 50%). In sum, we found overlap between words in the question and answer of QNLI examples and strong evidence that QNLI models harnessed self-attention to exploit such overlap to make correct decisions in spite of a random word-order.

QNLI `dev-r` examples	Full network	Zero-out 15 attention matrices	
		Random	Ours
a. 1,453 selected 0/5 (+) examples	100	99.31	90.43
b. 1,453 random 0/5 (+) examples	100	99.24	91.05
c. 1,453 random 0/5 (+) examples & 1,453 random 0/5 (-) examples	100	98.18	77.91
d. (+/-) All 5,000 examples	100	96.96	75.54

Table 3: Zero-ing out a set of 15 "word-matching" self-attention matrices (identified via the procedure in Sec. 3.4.2) caused a substantial drop of ∼25% in accuracy (d) while the random baseline is 50%. These 15 matrices played an important role in QNLI because ablating 15 random matrices only caused a ∼1-3% drop in accuracy.

3.5 Does increasing word-order sensitivity lead to higher model performance?

Here, we test whether encouraging BERT representations to be more sensitive to word order (i.e. more syntax-aware) would improve model performance on GLUE & SQuAD 2.0 (Rajpurkar et al., 2018). We performed this test on the five GLUE binary-classification tasks (i.e. excluding CoLA because its WOS score is already at 0.99; Table 2).

Experiments Inspired by the fact that CoLA models are highly sensitive to word order, we finetuned the pretrained RoBERTa on a *synthetic*, CoLA-like task first, before finetuning the model on downstream tasks.

The synthetic task is to classify a single sentence into "real" vs. "fake" where the latter is formed by taking each real sentence and swapping two random words in it. For every downstream task (e.g. SST-2), we directly used its original training and dev sets to construct a balanced, 2-class, synthetic dataset. After finetuning the pretrained RoBERTa on this synthetic binary classification task, we re-initialized the classification layer (keeping the rest unchanged) and continued finetuning it on a downstream task.

For both finetuning steps, we trained 5 models per task and followed the standard BERT finetuning procedure (described in Sec. 2.2).

Results After the first finetuning on synthetic tasks, all models obtained a ∼99% training-set accuracy and a ∼95% dev-set accuracy. **After the second finetuning on downstream tasks, we observed that all models were substantially more sensitive to word order**, compared to the baseline models (which were only finetuned on the downstream tasks). That is, we repeated the 1-gram shuffling test (Sec. 3.1) and found a ∼1.5 to 2× increase in the WOS scores of all models (see Table 4a vs. b).

GLUE `dev-s`	(a) RoBERTa		(b) Ours	
	Accuracy	WOS	Accuracy	WOS
`RTE`	80.76	0.38	64.01	**0.72** (+189%)
`MRPC`	83.86	0.32	72.88	**0.54** (+169%)
`SST-2`	84.26	0.31	76.97	**0.46** (+148%)
`QQP`	87.66	0.25	77.11	**0.46** (+184%)
`QNLI`	91.09	0.18	82.44	**0.35** (+194%)

Table 4: With finetuning on synthetic tasks, all of our models (b) have a larger drop in accuracy on shuffled `dev-s` examples, compared to the standard RoBERTa-based classifiers (a). That is, our models are substantially more sensitive to word-order randomization (i.e. +148% to +194% in WOS scores).

GLUE On GLUE dev sets, on average over 5 runs, our models outperformed the RoBERTa baseline on all tasks except for SST-2 (Table 5). The highest improvement is in RTE (from 72.2% to 73.21% on average, and to 74.73% for the best single model), which is consistent with the fact that RTE has the highest WOS score among non-CoLA tasks (Sec. 3.1).

SQuAD 2.0 Our models also outperformed the RoBERTa baseline on the SQuAD 2.0 dev set, with the highest F1 gain from 80.62% to 81.08% (Table 5).

In sum, leveraging the insights that the original BERT-based models are largely word-order invariant, we showed that increasing model sensitivity via a simple extra finetuning step directly improves GLUE and SQuAD 2.0 performance.

4 Related Work

Pretrained BERT Lin et al. (2019) found that positional information is encoded in the first there layers of BERT$_{\text{base}}$ and fades out starting layer 4. Ettinger (2020) found that BERT heavily relies on word order when predicting missing words in masked sentences from the CPRAG-102 dataset. That is, shuffling words in the context sentence caused the word-prediction accuracy to drop by ∼1.3 to 2×. While all above work studied the

Table 5: Finetuning the pretrained RoBERTa on synthetic tasks (before finetuning on the downstream tasks) improved model dev-set performance on SQuAD 2.0 (b) and all the tested tasks in GLUE (a), except SST-2.

pretrained BERT, we instead study BERT-based models *finetuned* on downstream tasks.

Word-ordering as an objective In text generation, Elman (1990) found that recurrent neural networks were sensitive to regularities in word order in simple sentences. Language models (Mikolov et al., 2010) with long short-term memory (LSTM) units (Hochreiter and Schmidhuber, 1997) were able to recover the original word order of a sentence from randomly-shuffled words even without any explicit syntactic information (Schmaltz et al., 2016). Wang et al. 2020 also observed an increase in GLUE performance after pretraining BERT with two additional objectives of word-ordering and sentence-ordering. Their work differs from ours in three points: (1) they did not study the importance of word order alone; (2) StructBERT improvements were inconsistent across tasks and models (Table 2d) and motivated us to compare the word-order importance between GLUE tasks; and (3) we proposed to improve model performance by finetuning not pretraining.

Word-order insensitivity in other NLP tasks ML models have been shown to be insensitive to word order in several NLP tasks such as reading comprehension (Si et al., 2019; Sugawara et al., 2020), dialog (Sankar et al., 2019), natural language inference (Parikh et al., 2016; Sinha et al., 2020), and essay scoring (Parekh et al., 2020). Zanzotto et al. 2020 found that for several text classification tasks, syntactic information was not always required. In word prediction, LSTMs and pre-trained BERT were found to exhibit a certain degree of insensitivity when the context words are randomly shuffled (Khandelwal et al., 2018; Mitchell and Bowers, 2020; Ettinger, 2020). Compared to the prior work, we are the first to perform a word-order analysis on a NLU benchmark and to contrast this sensitivity across the tasks.

Humans can also be word-order invariant A recent human study interestingly showed that sentences with scrambled word orders elicit a response as high as that elicited by original sentences as long as the local mutual information among words is high enough (Mollica et al., 2020). Gibson et al. 2013 found that humans can also exhibit word-order-invariance effects, especially when one interpretation is much more semantically plausible. Our work therefore documents an important similarity between humans and advanced NLU models.

Invariance to patch-order in computer vision In computer vision, the accuracy of state-of-the-art image classifiers was found to only drop marginally when the patches in an image were randomly shuffled (Chen et al., 2020; Zhang and Zhu, 2019).

5 Discussion and Conclusion

Consistently across three BERT variants and two model sizes, we found that GLUE-trained BERT-based models are often word-order invariant unless explicitly asked for (e.g. in CoLA).

We present a reflection on the progress of NLU by studying GLUE—a benchmark where humans have been surpassed by many models in the past 18 months. As suggested by our work, these models; however, may neither use syntactic information nor complex reasoning. We revealed how self-attention, a key building block in modern NLP, is being used to extract superficial cues to solve sequence-pair GLUE tasks even when words are out of order.

Adversarial NLI We also replicated our shuffling experiments on ANLI (Nie et al., 2020), a task considered challenging to existing models, and where RoBERTa-based models only obtained a 56% accuracy. We found RoBERTa-based models to remain not always sensitive to word-order randomization on ANLI (Table A2; WOS of 0.63), suggesting a common issue in existing benchmarks.

A Self-attention layers that match question-words to similar words in the answer

QNLI models being so insensitive to word shuffling (i.e. 89.4% of the correct predictions remain correct) suggests that inside the finetuned BERT, there might be a self-attention (SA) layer that extract pairs of similar words that appear in both the question and answer.

We started by analyzing all 2,500 "positive" `dev-r` examples (Table A4) of RoBERTa-based classifiers trained on QNLI because there were fewer and more consistent ways for labeling a sentence "positive" than for the "negative" (shown in Sec. 3.3).

Experiment There were 1,776 (out of 2,500) examples whose predictions did not change in 5 random shufflings (a.k.a 5/5 subset). For each such example, we followed the following 4 steps to identify one SA matrix (among all 144 as the base model has 12 layers & 12 heads per layer) that captures the strongest attention connecting the question and answer words.

1. Per example x, we created its shuffled version $\hat{x}$ by randomly shuffling words in the question and fed $\hat{x}$ into the classifier.
2. For each SA matrix obtained, we identified the top-3 highest-attention weights that connect the shuffled question tokens and the real answer tokens (i.e. excluding attention weights between question tokens or answer tokens only).
3. For each shuffled example $\hat{x}$, we identified one matrix M whose the top-3 word pairs are the nearest in Levenshtein character-level edit-distance (NLTK). For instance, the distance is 1 between manage and managed (Fig. 4).
4. For each matrix M identified for $\hat{x}$, we fed the corresponding real example x through the network and re-computed the edit-distance for each of the top-3 word pairs.

Results At step 3, there were 1,590 SA matrices (out of 1,776) whose the top-3 SA weights connected three pairs of *matching* words (i.e. the total edit-distance for 3 pairs together is ≤ 4)[3] that appear in both the shuffled question and original answer (see example top-3 pairs in Fig. 4). At step 4, this number only dropped slightly to 1,453 matrices when replacing the shuffled question by the original one (see Table A1 for detailed statistics).

Sum distance	(a) `dev-s` alone		(b) `dev-s` & `dev-r`	
	# examples	%	# examples	%
≤ 0	749	42.17	392	24.65
≤ 1	1,253	70.55	1,071	67.36
≤ 2	1,440	81.08	1,283	80.69
≤ 3	1,543	86.88	1,391	87.48
≤ 4	**1,590**	**89.53**	**1,453**	**91.38**
≤ 15	1,776	100.00	1,574	98.99
Total	1,776	100.00	1,590	100.00

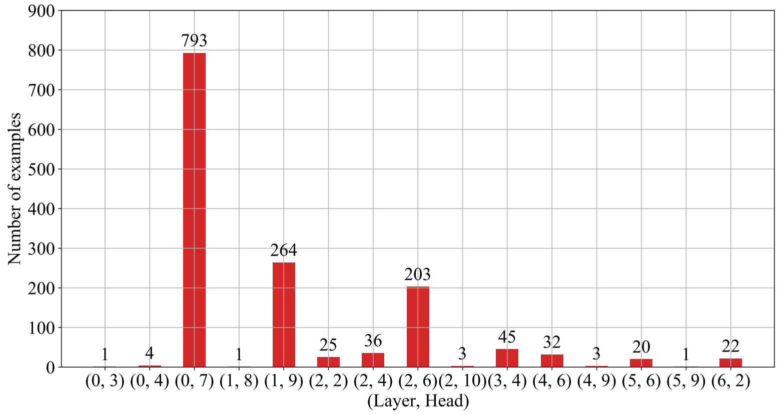
Table A1: The number of QNLI examples where we found $\geq$ one self-attention matrix that the most strongly attends to three pairs of *matching* words when given the `dev-s` examples i.e. (modified question, real answer) (a) or when given both the shuffled and real examples (b). In other words, **the numbers in (b) denote the number of examples where (1) there exist $\geq$ 3 words, regardless of its word order, in the question that can be found in the accompanying real answer; and (2) these correspondences are captured by at least one self-attention matrix.** The sum edit-distance for all 3 pairs of words are less than N where $N = \{0, 1, 2, 3, 4, 15\}$ (left column).

However, there are only 15 unique, RoBERTa self-attention matrices in these 1,453 examples (see Fig. A1). Also at step 4, 83% of the same word pairs remained within the top-3 of the same SA matrices, after question replacement, i.e. 17% of attention changed to different pairs e.g. from ("managed", "manage") to ("it", "it").

First, our results showed that there is a set of 15 self-attention heads explicitly tasked with capturing question-to-answer word correspondence *regardless of word order*. Second, **for ~58% (i.e. 1,453 / 2,500) of QNLI "positive" examples: (1) there exist $\geq$ 3 words in the question that can be found in the accompanying answer; and (2) these correspondences are captured by at least one of the 15 SA matrices.** We also found similar results for 2,500 "negative" `dev-r` examples (data not shown).

---

[3] 4 is a tight budget to account for minor typos or punctuation differences e.g. "Amazon" vs. "Amazon's".



(a) Histogram of self-attention matrices

(Layer, Head)	# Examples	%
(0, 3), (0, 4), (0, 7)	798	54.9%
(1, 8), (1, 9)	265	18.2%
(2, 2), (2, 4), (2, 6), (2, 10)	267	18.4%
(3, 4)	45	3.1%
(4, 6), (4, 9)	35	2.4%
(5, 6), (5, 9)	21	1.5%
(6, 2)	22	1.5%
Total	1,453	100%

(b) Layer-wise comparison

Figure A1: Among 144 self-attention matrices in the RoBERTa-based classifier finetuned for QNLI, there are 15 "word-matching" matrices (a) that explicitly attend to pairs of similar words that appear in both questions and answers regardless of the order of words in the question (see example pairs in Fig. 4). For each QNLI example, we identified one such matrix that exhibits the matching behavior the strongest (a). 92% of the task of attending to duplicate words is mostly handled in the first three layers (b).

Model	Task	(a) Perf. on `dev-r`		(b) Perf. on `dev-s`				(c) Word-Order Sensitivity			
		Models	Baseline	2-noun swap	1-gram	2-gram	3-gram	2-noun swap	1-gram	2-gram	3-gram
RoBERTa$_{\text{base}}$	`ANLI`	100	33.33	74.26	57.74	66.63	69.04	0.39	0.63	0.50	0.46
	`A1`	100	33.33	81.46	63.31	71.52	75.37	0.28	0.55	0.43	0.37
	`A2`	100	33.33	70.83	54.61	64.73	67.02	0.44	0.68	0.53	0.49
	`A3`	100	33.33	70.50	55.29	63.63	64.73	0.55	0.67	0.55	0.53
RoBERTa$_{\text{large}}$	`ANLI`	100	33.33	70.41	54.87	64.11	68.76	0.44	0.68	0.54	0.47
	`A1`	100	33.33	78.06	60.31	70.57	75.86	0.33	0.6	0.44	0.36

Total examples in subset 5/5 ("positive" / "negative")	523 (278 / 245)	506 (228 / 278)	523 (278 / 245)	506 (228 / 278)
Not found in dictionary	223 / 523 (42.64%)	217 / 506 (42.89%)	110 / 523 (21.03%)	104 / 506 (20.55%)
Found in dictionary	300 / 523 (57.36%)	289 / 506 (57.11%)	413 / 523 (78.97%)	402 / 506 (79.45%)
P ("positive" sentence | positive top-1 word)	174 / 174 (100.00%)	143 / 144 (99.31%)	222 / 258 (86.05%)	186 / 215 (86.51%)
P ("negative" sentence | negative top-1 word)	119 / 126 (94.44%)	136 / 145 (93.79%)	145 / 155 (93.55%)	177 / 187 (94.65%)

Table A3: **If the top-1 most important word in an SST-2 5/5 example has a positive meaning, then there is a 100% chance that the sentence is labeled "positive" in SST-2.** Similarly, the conditional probability of a sentence being labeled "negative" given a negative most important word (by LIME Ribeiro et al. 2016) is 94.44%.

LIME attributions (negative -1, neutral 0, positive +1)		
CoLA example. Groundtruth: “acceptable”		
S	Medea denied poisoning the phoenix.	“acceptable” 0.99
S_1	poisoning the phoenix denied Medea.	“acceptable” 0.53
S_2	phoenix Medea denied the poisoning.	“acceptable” 0.99
S_3	Medea the poisoning phoenix denied.	“unacceptable” 0.95
S_4	phoenix Medea denied the poisoning.	“unacceptable” 0.99
S_5	Medea phoenix poisoning the denied.	“unacceptable” 0.96

Figure A2: Each CoLA example contains a single sentence. Here, we shuffled the words in the original sentence (S) five times to create five new sentences (S_1 to S_5) and fed them to a RoBERTa-based classifier for predictions. Words that are important for or against the prediction (by LIME Ribeiro et al. 2016) are in orange and blue, respectively. Most of the shuffled examples were classified into “unacceptable” label (i.e. grammatically incorrect) with even higher confidence score than the original ones.

MRPC example. Groundtruth: “equivalent”		
A	My decision today is not based on any one event . ”	“equivalent” 0.99
B	Governor Rowland said his decision was ” not based on any one event . ”	
A_1	event any is one decision based on My today not . ”	“equivalent” 0.98
B	Governor Rowland said his decision was ” not based on any one event . ”	
A_2	one based today not any My on event is decision . ”	“equivalent” 0.98
B	Governor Rowland said his decision was ” not based on any one event . ”	

Figure A3: Each MRPC example contains a pair of sentences i.e. (A, B). Here, we shuffled the words in the original sentence (A) to create modified sentences (A_1 & A_2) and fed them together with the original second sentence (B) to a RoBERTa-based classifier for predictions. Also, the classifier harnessed self-attention to detect the correspondence between similar words that appear in both sentences. That is, the top-3 pairs of words that were assigned the largest cross-sentence weights in a self-attention matrix (layer 0, head 7) are inside in the red, green, and blue rectangles.

RTE example. Groundtruth: “entailment”		
P	About 33.5 million people live in this massive conurbation. I would guess that 95% of the 5,000 officially foreign-capital firms in Japan are based in Tokyo.	“entailment” 0.90
H	About 33.5 miilion people live in Tokyo.	
P	About 33.5 million people live in this massive conurbation. I would guess that 95% of the 5,000 officially foreign-capital firms in Japan are based in Tokyo.	“entailment” 0.79
H_1	people in miilion 33.5 live Tokyo About.	
P	About 33.5 million people live in this massive conurbation. I would guess that 95% of the 5,000 officially foreign-capital firms in Japan are based in Tokyo.	“entailment” 0.80
H_2	33.5 in people About live Tokyo miilion.	

Figure A4: Each RTE example contains a pair of premises and hypotheses i.e. (P, H). We shuffled the words in the original hypothesis H to create modified hypotheses (H_1 & H_2) and fed them together with the original premise (P) to a RoBERTa-based classifier for predictions. Also, the classifier harnessed self-attention to detect the correspondence between similar words that appear in both the premise and hypothesis. That is, the top-3 pairs of words that were assigned the largest premise-to-hypothesis weights in a self-attention matrix (layer 0, head 7) are inside in the red, green, and blue rectangles.

Task Name	Task Type	Label	GLUE dev-set processing				`dev-r`
			(a) dev set	(b) step 1	(c) step 2	(d) step 3	Total
`CoLA`	Acceptability	"unacceptable" "acceptable"	322 721	287 675	154 638	154 154	308
`RTE`	NLI	"not entailment" "entailment"	131 146	131 145	72 127	72 72	144
`QQP`	Paraphrase	"not duplicate" "duplicate"	25,545 14,885	22,907 14,000	20,943 12,683	12,683 12,683	25,366

`STS-B`	Similarity	N/A	1,500	1,498	N/A	N/A	1,498

Table A4: The number of examples per class before (a) and after each of the three filtering steps to produce `dev-r` sets (described in Sec. 2.3.2) for RoBERTa-based classifiers. For each task, we repeated the same procedure for three sets of classifiers, for BERT-, RoBERTa-, ALBERT-based classifiers, respectively.

Model	Task	`dev-r`	`dev-s`	`dev-s` performance				Word-Order Sensitivity			
		performance	baseline	2-noun swap	1-gram	2-gram	3-gram	2-noun swap	1-gram	2-gram	3-gram
RoBERTa$_{\text{large}}$	`CoLA`	100	50	70.80	51.40	55.62	57.98	**0.58**	**0.97**	**0.89**	**0.84**
	`RTE`	100	50	82.29	73.85	80.42	83.75	0.35	0.52	0.39	0.33
	`SST-2`	100	50	98.24	83.71	88.16	90.43	0.04	0.33	0.24	0.19
	`MRPC`	100	50	98.54	85.53	88.64	90.49	0.03	0.29	0.23	0.19
	`QQP`	100	50	87.13	86.84	90.65	92.60	0.26	0.26	0.19	0.15
	`QNLI`	100	50	95.26	91.12	95.20	96.46	0.09	0.18	0.10	0.07
	`STS-B`	90.43	N/A	88.95	85.47	87.20	87.98	N/A	N/A	N/A	N/A

Table A5: Accuracy of all models on `dev-s` examples (created by shuffling n-grams and swapping 2 nouns) and their Word-Order Sensitivity scores ($\in [0, 1]$) across seven GLUE tasks. STS-B is a regression task and thus not comparable in word-order sensitivity with the other tasks, which are binary classification.

	GLUE dev set						
Task	CoLA (Acc)	RTE (Acc)	QQP (Acc)	MRPC (Acc)	SST-2 (Acc)	QNLI (Acc)	STS-B (Spearman Corr)
RoBERTa$_{\text{base}}$	82.56	72.20	91.12	87.25	94.50	92.57	90.17
ALBERT$_{\text{base}}$	81.21	72.20	90.25	87.99	91.40	91.78	90.82
BERT$_{\text{base}}$	81.89	64.25	90.81	85.54	92.09	91.38	88.49
RoBERTa$_{\text{large}}$	65.30	80.87	91.62	88.48	96.44	94.45	90.44
Average	82.78	72.38	90.95	87.32	93.61	92.55	89.98

Table A6: The dev-set performance of models finetuned from three different BERT "base" variants (12 self-attention layers and 12 heads) and one RoBERTa "large" model (24 self-attention layers and 16 heads) on seven GLUE tasks. These results match either those reported by original papers, Huggingface 2020 or GLUE leaderboard.

RevCore: Review-augmented Conversational Recommendation

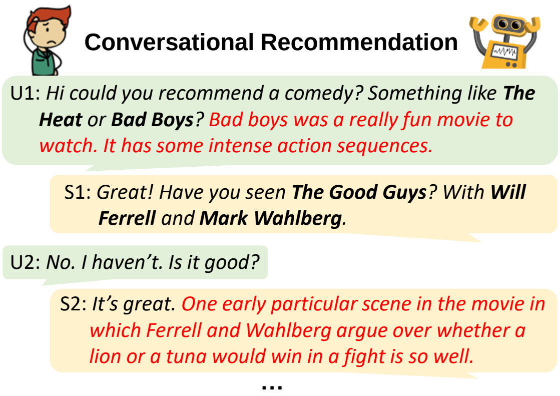
Abstract

Existing conversational recommendation (CR) systems usually suffer from insufficient item information when conducted on short dialogue history and unfamiliar items. Incorporating external information (e.g., reviews) is a potential solution to alleviate this problem. Given that reviews often provide a rich and detailed user experience on different interests, they are potential ideal resources for providing high-quality recommendations within an informative conversation. In this paper, we design a novel end-to-end framework, namely, <u>Rev</u>iew-augmented <u>C</u>onversational <u>Re</u>commender (**RevCore**), where reviews are seamlessly incorporated to enrich item information and assist in generating both coherent and informative responses. In detail, we extract sentiment-consistent reviews, perform review-enriched and entity-based recommendations for item suggestions, as well as use a review-attentive encoder-decoder for response generation. Experimental results demonstrate the superiority of our approach in yielding better performance on both recommendation and conversation responding.[1]



U1: *Hi could you recommend a comedy? Something like* ***The Heat*** *or* ***Bad Boys****? Bad boys was a really fun movie to watch. It has some intense action sequences.*

S1: *Great! Have you seen* ***The Good Guys****? With* ***Will Ferrell*** *and* ***Mark Wahlberg****.*

U2: *No. I haven't. Is it good?*

S2: *It's great. One early particular scene in the movie in which Ferrell and Wahlberg argue over whether a lion or a tuna would win in a fight is so well.*

...

Figure 1: An illustrative example of a user-system conversation on movie recommendation. The additional sentiment-matched reviews are in red. Items (movies) and entities (e.g., actors) are in bold.

1 Introduction

With the increasing popularity of intelligent assistants in users' daily lives, how to effectively help users find information or finish specific tasks, such as recommendation and booking, has tremendous commercial potential. Therefore, conversational recommendation (CR) systems have attracted widespread attention for being a tool providing users potential items of interest through dialogue-based interactions. Though existing studies (Sun and Zhang, 2018; Zhang et al., 2018; Lei et al., 2020) proposed to integrate recommender and dialogue components for providing user-specific suggestions through conversations, CR remains challengeable because (i) typical dialogues are short and lack sufficient item information for user preference capturing (Chen et al., 2019; Zhou et al., 2020), and (ii) difficulties exist in generating informative responses with item-related descriptions (Shao et al., 2017; Ghazvininejad et al., 2018; Wang et al., 2019b). Thus, recently, external information in the form of structured knowledge graphs (KG) is introduced to enhance item representations by using rich entity information in KG (Chen et al., 2019; Zhou et al., 2020). While KG-based methods improve CR to some extent, they are still limited in (i) worse versatility resulted from a high cost of KG construction; and (ii) inadequate integration of knowledge and response generation (Lin et al., 2020).

Given that, nowadays, users are greatly encouraged to share their consumption experience (e.g., restaurant, traveling, movie, etc.), reviews are easily accessed over the internet. Such reviews often provide rich and detailed user comments on different factors of interest, which are crucial in suggest-

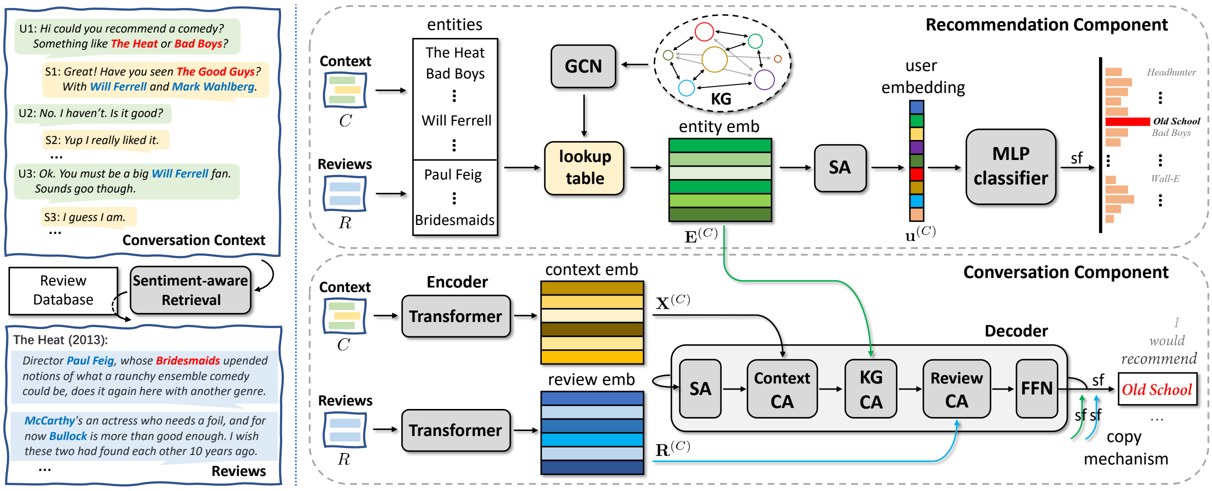

Figure 2: The overview of the proposed method in a movie recommendation scenario, where "emb", "SA", "CA", and "sf" denote embedding, self-attention, cross-attention, and softmax operation, respectively.

ing recommendations to particular users. Thus one can treat reviews as promising external sources for higher-quality recommendations in a conversation. As an example shown in Figure 1, the CR system may be unfamiliar with the mentioned items from the user, resulting in an uninformative response "*It's great.*", thus the chat does not help with recommendation owing to lacking necessary knowledge. In addition, another factor resulting in users' lower acceptance rates to the recommendations is that elaborations on the suggestion are seldom given, which can be alleviated with more explanatory or descriptive utterances after referring to reviews.

Therefore, in better linking external knowledge to recommendation in dialogues, in this paper, we propose a novel framework, Review-augmented Conversational Recommender (**RevCore**), to enhance CR by additional review data. In doing so, we firstly analyze user's utterances with their sentiment polarities and then retrieve reviews for the items mentioned by the user with keeping their sentiment matching the utterances (e.g., they should be both positive or negative). The obtained reviews are thus recommendation-beneficial (He et al., 2015; Hariri et al., 2011) because they are given by the ones who have seen/used and also show interests (or with no interests) in the mentioned items. Afterward, we incorporate the selected reviews into dialogue history, from which the CR system can learn user preference from review-enriched item information. In addition, we also use the sentiment-coordinated reviews to enhance the dialogue response generation, where a review-attentive decoder introduces item information from selected reviews to generate coherent and informative responses. To the best of our knowledge, it is the first time that the aforementioned CR issues have been addressed through incorporating external reviews. Experimental results on a widely used benchmark dataset (Li et al., 2018) show that RevCore is superior on both recommendation accuracy and conversation quality. Further analyses are also performed to confirm the effectiveness of RevCore in an appropriate manner of introducing reviews to CR.

2 The Proposed Framework

We present the proposed Review-augmented Conversational Recommender (**RevCore**) with its overview illustrated in Figure 2, where there are three main components, i.e., the review retrieval module, the recommendation component, and the conversation component. The review retrieval module takes a conversation context C as the input and outputs the selected review set R from the review database $\mathcal{R}_{db}$ which contains all reviews. The context $C = \{s_t\}_{t=1}^{N}$ consists of all utterances s_t of the dialogue history given by the user and system in turns, and the review set R includes all review sentence $r \in \mathcal{R}_{db}$ retrieved according to the contexts in previous turns. With C and R as the input, the recommendation component outputs a set of items from the candidate item set $\mathcal{Z}$ as the recommendation. The dialogue component also accepts C and R as input, and outputs an utterance $s_{t+1} = \{w_i\}_{i=1}^{M}$ as the response, where w_i is the i_{th} word and M the length of s_{t+1}. The output s_{t+1} is added to the context of the next turn.

We first introduce how to retrieve proper reviews from a database in the following Section 2.1. Then our solutions to the recommendation and conversation tasks are described in Section 2.2 and Section 2.3 respectively, along with detailed illustrations of how reviews enhance both two tasks. Without the loss of generality, our method is introduced in a movie recommendation scenario.

2.1 Review Retrieval

To help dialogue with reviews, given $\mathcal{R}_{db}$, it is of great importance to retrieve proper ones. The reasons are two folds: (i) non-relevant reviews may result in harmful effects to the user representation; (ii) reviews with inconsistent altitudes inject noise into the conversation, which impedes generating coherent responses. Then, a preliminary retrieval is to search in $\mathcal{R}_{db}$ for proper reviews according to the mentioned item in the conversation context C. For review filtering, we design a sentiment-aware retrieval module. The sentiment value $v \in [0,1]$ of each review r can be captured by a transformer-based sentiment predictor:

$$v = \mathrm{Sentiment}(r), \; r \in \mathcal{R}_{db}, \tag{1}$$

where $\mathrm{Sentiment}(\cdot)$ denotes sentiment prediction, and v can be viewed as how well the movie is liked in this review r. Similarly, the sentiment of a response to this movie can also be obtained in this way. As a result, reviews that possess similar sentiment polarity v^* with the response are selected.

Considering helpful reviews are usually long paragraphs, we only retain part of them, one sentence, for each mentioned movie. Given a context C, there exist two manners to select the sentences $r^{(C)}$ from the raw reviews, word-wisely (or phrase-wisely) and sentence-wisely. The first one randomly chooses some words or phrases to form each "sentence", and one whole sentence is directly selected at random in a second way. Despite the expense of sentence fluency, the first manner enjoys much variability due to the extensive word/phrase combinations. The process to obtain $r^{(C)}$ can be formulated as follows:

$$r^{(C)} = \mathrm{Retrieve}(\mathcal{R}_{db}, V, v^*), \tag{2}$$

where $\mathrm{Retrieve}(\cdot)$ denotes the retrieval operation and V is the set of all v. The obtained $r^{(C)}$ is added into the review set R.

With the retrieved review sentence, one way of incorporation is to briefly insert it right behind the sentence where the item is, as in Fig. 1. However, it may cause the perturbation to the conversational consistency by interrupting the original dialogue. Thus we seamlessly incorporate the review embedding into the conversation component, which is described in Section. 2.3. More importantly, the review sentence serves as a brief introduction or explanation to the mentioned movie. It enriches user information for personalized recommendations and introduces external knowledge for more informative recommendation responses.

2.2 Review-augmented Recommendation

The recommender component is constructed based on a KG-based framework (Zhou et al., 2020), with all entities in the context are extracted to generate the embedding of a user profile. In our method, the retrieved reviews work on enriching entity information so that the user embedding can be augmented to promote recommendation accuracy.

Similar to the approach in Zhou et al. (2020), a candidate entity embedding dictionary $\mathcal{E}$ is constructed first by using GNN to learn entity representations from KG, e.g., DBpedia (Auer et al., 2007). Given a context C, all entities $E^{(C)}$ in it are extracted. Then the embedding vectors of them are looked up from $\mathcal{E}$ and concatenated into a matrix $\mathbf{E}^{(C)} \in \mathbb{R}^{l^{(C)} \times d}$, where $l^{(C)}$ is the number of entities in the context C, and d denotes the embedding dimension. Next, the entity embedding $\mathbf{E}^{(C)}$ is aggregated into a user embedding vector $\mathbf{u}^{(C)}$, through a self-attention layer (SA) as follows:

$$\begin{aligned} \mathbf{u}^{(C)} &= \mathbf{E}^{(C)} \cdot \boldsymbol{\alpha}, \\ \boldsymbol{\alpha} &= \mathrm{softmax}(\mathbf{b}^\top \cdot \tanh(\mathbf{W}_\alpha \mathbf{E}^{(C)})), \end{aligned} \tag{3}$$

where $\boldsymbol{\alpha}$ is the attention weight vector, and $\mathbf{W}_\alpha$ and $\mathbf{b}$ are the parameter matrix and vector for linear projection and bias. Given $\mathbf{u}^{(C)}$, a multi-layer perceptron (MLP) and a softmax operation are adopted to obtain the recommendation prediction $\mathbf{p} \in \mathbb{R}^L$, where L is the number of candidate movies:

$$\mathbf{p} = \mathrm{softmax}(\mathrm{MLP}(\mathbf{u}^{(C)})). \tag{4}$$

To learn parameters in the recommender component, a cross-entropy loss $\mathcal{L}_{rec}$ between the prediction $\mathbf{p}$ and the target movie category is computed:

$$\mathcal{L}_{rec} = -\frac{1}{M} \sum_{i=1}^{M} \log p_i^*, \tag{5}$$

where M is the number of recommendations and p_i^* is the prediction probability of the target category in the i_{th} recommendation.

The pipeline described above suffers from the entity sparsity in dialogue history, resulted from the dataset construction process, where annotators are inevitably unfamiliar with some movies. Retrieved reviews can act to enrich the $E^{(C)}$ by adding more entity words.The process of obtaining review-enriched entities can be formulated as:

$$\begin{aligned} E_C^{(C)} &= \text{Extract}(C), \\ E_R^{(C)} &= \text{Extract}(R^{(C)}), \\ E^{(C)} &= \{E_C^{(C)}, E_R^{(C)}\}, \end{aligned} \tag{6}$$

where $\text{extract}(\cdot)$ defines the entity extraction operation, and $E_c^{(C)}$, $E_r^{(C)}$ denotes entities extracted from the context and retrieved review, respectively. Based on the review-enriched entities, the user embedding is expected to be better represented to produce a more precise recommendation.

2.3 Review-augmented Response Generation

Reviews can also augment the response generation in the conversation component. We build an encoder-decoder framework to handle the generation task. Retrieved reviews and context are encoded separately first, for the purpose of maintaining the dialog consistency. In the decoding stage, the review embedding is fused via an attention layer to generate informative responses. Considering that a good modeling of the input plays an important role to achieve an outstanding model performance (Mikolov et al., 2013; Song and Shi, 2018; Peters et al., 2018; Devlin et al., 2019; Song et al., 2021) and transformer-based approaches have achieved state-of-the-art in many NLP tasks (Vaswani et al., 2017; Chen et al., 2019; Zhou et al., 2020; Chen et al., 2020a; Joshi et al., 2020; Wang et al., 2020; Tian et al., 2020), we adopt two transformers as the encoders for context and reviews. Given a context C and the retrieved reviews R, the context embedding $\mathbf{X}^{(C)}$ and review embedding $\mathbf{R}^{(C)}$ are first obtained:

$$\begin{aligned} \mathbf{X}^{(C)} &= \text{Transformer}_{\boldsymbol{\theta}_X}(C), \\ \mathbf{R}^{(C)} &= \text{Transformer}_{\boldsymbol{\theta}_R}(R), \end{aligned} \tag{7}$$

where $\boldsymbol{\theta}_X, \boldsymbol{\theta}_R$ are parameters in these two transformers. The decoding stage takes them and the entity embedding $\mathbf{E}^{(C)}$ as inputs of attention layers. These attention layers aim to fuse the external information from KG and reviews R into the context information, inspired by the work of Zhou et al. (2020). Given the decoding output of last time unit $\mathbf{Y}^{i-1}$, the current one $\mathbf{Y}^i$ is generated by:

$$\begin{aligned} \mathbf{A}_0^i &= \text{MHA}(\mathbf{Y}^{i-1}, \mathbf{Y}^{i-1}, \mathbf{Y}^{i-1}), \\ \mathbf{A}_1^i &= \text{MHA}(\mathbf{A}_0^i, \mathbf{X}^{(C)}, \mathbf{X}^{(C)}), \\ \mathbf{A}_2^i &= \text{MHA}(\mathbf{A}_1^i, \mathbf{E}^{(C)}, \mathbf{E}^{(C)}), \\ \mathbf{A}_3^i &= \text{MHA}(\mathbf{A}_2^i, \mathbf{R}^{(C)}, \mathbf{R}^{(C)}), \\ \mathbf{Y}^i &= \text{FFN}(\mathbf{A}_3^i), \end{aligned} \tag{8}$$

where $\text{MHA}(\mathbf{Q}, \mathbf{K}, \mathbf{V})$ represents the multi-head attention function (Vaswani et al., 2017), which takes a query, key, and value as input:

$$\begin{aligned} &\text{MHA}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = [\text{h}_1, \cdots, \text{h}_h] \cdot \mathbf{W}^o, \\ &\text{h}_i = \text{Attention}(\mathbf{QW}_i^{(q)}, \mathbf{KW}_i^{(k)}, \mathbf{VW}_i^{(v)}), \end{aligned} \tag{9}$$

where $[\cdot]$ represents the concatenation operation, h is the number of heads, and $\mathbf{W}_i$ is the parameter matrix to learn. $\text{FFN}(\cdot)$ in Equation 8 defines a fully-connected feed-forward network, which comprises of two linear layers with one ReLU activation layer in between:

$$\text{FFN}(\boldsymbol{x}) = \text{ReLU}(\boldsymbol{x}\mathbf{W}_1 + \mathbf{b}_1)\mathbf{W}_2 + \mathbf{b}_2. \tag{10}$$

As presented above, information is injected progressively into the decoding stage, from the original context at first, then related entity information in KG, and finally reviews, which contain detailed item-related information.

To complete the generation, the decoder output $\mathbf{Y}^i$ is processed through a softmax operation to predict the token distribution. Apart from the conversational consistency required in the chit-chat task, the CR system also expects recommendation-related responses, which usually contain relevant entities and descriptive keywords. So a copy mechanism is further adapted to introduce vocabulary bias and thus increase the informativeness in the generation. Given the previous generated sub-sequence $\{y_{i-1}\} = y_1, y_2, \cdots, y_{i-1}$, the generation probability y_i of the next token can be computed as:

$$\begin{aligned} \Pr(y_i|\{y_{i-1}\}) = \Pr_1(y_i|\mathbf{Y}_i) + \Pr_2(y_i|\mathbf{Y}_i, G) + \\ \Pr_3(y_i|\mathbf{Y}_i, R), \end{aligned} \tag{11}$$

where $\Pr_1(\cdot)$ is a generation probability function over the vocabulary, with $\mathbf{Y}^i$ as the input. G and R represents the knowledge graph and reviews we use. $\Pr_2(\cdot)$, $\Pr_3(\cdot)$ are copy probability functions from KG entities and reviews, respectively, implemented by a standard copy mechanism (Gulcehre et al., 2016) (computing the distributions over the KG words or review words). Both probability functions are implemented with a softmax operation. To learn the response generation in the dialogue component, we set a cross-entropy loss:

$$\mathcal{L}_{gen} = -\frac{1}{N}\sum_{t=1}^{N} \log\big(\Pr(s_t|s_1, \cdots, s_{t-1})\big), \quad (12)$$

where N is the number of turns, s_t represents the t_{th} utterance in the conversation.

To train the whole model, it includes three steps: (i) pre-training the sentiment predictor in the review retrieval module; (ii) training the recommender component by minimizing $\mathcal{L}_{rec}$; (iii) training the dialogue component by minimizing $\mathcal{L}_{gen}$.

3 Experiment Settings

3.1 Dataset

REDIAL (Li et al., 2018) is a widely-used dataset of real-world conversations around the theme of providing movie recommendations generated by the human in seeker-recommender pairs. REDIAL contains 10,021 conversations related to 64,362 movies, split into training, validation, and test sets using a ratio of 8:1:1[2]. To construct a review database, we crawled 30 reviews for each movie from IMDb[3] website, which is one of the most popular and authoritative movie databases. Each review can be queried according to the corresponding movie along with its rating and helpful score provided by IMDb. In practice, we select the 30 reviews with the highest helpful scores for each movie to guarantee the high quality of collected reviews. Other manners of selecting the 30 reviews are described and compared in the second part of Section 4.4.

3.2 Implementation Details

The maximum lengths of context and response are set to 256 and 30, respectively. Transformers for review encoding in dialogue generation and sentiment prediction use the same hyper-parameters with the context encoder. For sentiment polarity in the reviews, we threshold on the star-rating to getting sentiment polarity with the threshold set to 5. In the dialogue context, the sentiment polarity is obtained according to users' attitude to the mentioned entity in utterances, which is provided by the REDIAL dataset. Other settings are kept consistent with Zhou et al. (2020) for fair comparison[4]. Besides, the "review sentence" is selected according to the sentiment value and in a sentence-wise manner, and the token number of incorporated review sentences is set to 20, considering the balance between the original source and external source. We add the retrieved review sentences after the mentioned items in the dialogue component training to guide it to generate review-aware responses. The sentiment predictor for reviews is trained on the collected reviews. The sentiment predictor for dialog context is trained on the IMDb Movie Reviews Dataset (Maas et al., 2011) and then finetuned on the REDIAL dataset.

3.3 Baselines

Evaluated on the REDIAL dataset, we compare our approach with a variety of competitive baselines from previous studies listed as follows:

- **Trans** (Vaswani et al., 2017) applies a encoder-decoder framework based on transformer for generation, and applies a transformer encoder to encode context information for recommendation.
- **Redial** (Li et al., 2018) builds a conversation component based on a hierarchical encoder-decoder architecture, and its recommender component is implemented by an auto-encoder extended with a RNN-based sentiment analysis module.
- **KBRD** (Chen et al., 2019) adopts DBpedia-enhanced contextual items or entities to construct user profile for recommendation. The KG-enhanced user profile also serves as word bias for the transformer-based generation module.
- **KGSF** (Zhou et al., 2020) uses MIM (Viola and Wells III, 1997) to align the semantic spaces of two KGs. The user embedding is obtained from the aligned representations of words and items for recommendation. The generation module follows a transformer encoder and a fused KG enhanced decoder.

3.4 Evaluation Metrics

Our method is evaluated on both the recommendation and conversation tasks. The evaluation metric for recommendation is Recall@k (R@k, k = 1, 10, 50), which indicates whether the predicted top-k items contain the ground truth recommendation

---

[2] More statistics presents in appendix A.

[3] `https://www.imdb.com/`

[4] More details of hyper-parameters and training strategies are described in Appendix B; the size of different models and their inference speed are reported in Appendix C.

Models	**R@1**	**R@10**	**R@50**

RevCore (−KG)	0.373	0.527	**0.615**	10.7
RevCore (+KG)	**0.424**	**0.558**	0.612	10.2

Table 2: Results on the conversation task. Best results are in bold.

provided by human recommenders. Conversation evaluation comprises automatic and human evaluation. The metrics for automatic evaluation are perplexity (PPL) (Jelinek et al., 1977) and distinct n-gram (Dist-n, $n = 2, 3, 4$) (Li et al., 2016). Perplexity is a measurement for the fluency of natural language, where lower perplexity refers to higher fluency. Distinct n-gram is a measurement for the diversity of generated utterances. Specifically, we use distinct 3-gram and 4-gram at the sentence level to evaluate the diversity. The main purpose of our dialog component is a successful recommendation rather than imitating the ground truth responses. Therefore, we provide annotators to manually evaluate the results instead of using BLEU scores. The annotators evaluate the quality of generated dialogue responses from 3 aspects, i.e., coherence, fluency, and informativeness, with each score ranging from 0 to 1.

4 Results and Analysis

4.1 Evaluation on Recommendation Task

For the recommendation task, we adopt Recall@k (R@1, R@10, R@50) for evaluation. As the results summarized in Table 1, our approach outperforms all competitive baselines and achieves 5.9% R@1, 24.0% R@10, and 41.3% R@50, which is the state-of-the-art performance on the REDIAL dataset.[5] Compared with KGSF, RevCore (+KG) achieves significant improvements, with R@1 score improved about 156% (absolutely 2.2), R@50 score improved about 129% (absolutely 4.5), and R@50 score improved about 120% (absolutely 7.6).

We also evaluate the performance of RevCore (−KG), which means the construction of $\mathcal{E}$ removes relation between entities. Instead, an embedding matrix is randomly initialized and learned to represent each entity, without using the GNN-based embedding. In this version, the external knowledge source we introduce is reduced to review only. As the result in the last two rows of Table 1, RevCore (−KG) can achieve competitive results with RevCore (+KG), and outperform KGSF that uses two KGs. According to our observation, although the learning of entity representation is made harder without structured knowledge graphs, the enrichment of dialogue history by reviews makes up the embedding learning. It demonstrates that incorporating reviews is a meaningful method to improve the recommendation in the conversation. We hope this result inspire further research.

4.2 Evaluation on Conversation Task

Automatic Evaluation The results of automatic evaluation on the REDIAL dataset summarize in Table 2. The proposed RevCore outperforms all competitive baselines and achieves significant improvements over most of the automatic metrics. Compared with KGSF, all of the Dist-n scores are significantly lifted, namely, by +0.14 for Dist-2, +0.11 for Dist-3, and +0.08 for Dist-4, which demonstrates our method is effective to generate diverse utterances. Besides, RevCore (+KG) achieves a comparable PPL score with KGSF. It validates our claim that the review incorporation in our method does not cause a decline in generation fluency. The lower PPL score of RevCore (+KG) possibly relates to the high fluency contained in incorporated reviews that carefully induct by website users. For the version of RevCore (−KG), it achieves higher Dist-n scores than KGSF and only results in a slight drop compared with RevCore (+KG). It demonstrates that reviews compared with KG bring more diversity as a richer and more accessible external source.

Human Evaluation We adopt human evaluation on a random selection of 100 multi-turn dialogues

---

[5] We report the performance of different models on the validation sets in Appendix D and the mean and standard deviation of the test set results in Appendix E.

Models	**Coherence**	**Fluency**	**Informat**
Trans	0.189	0.226	0.115
Redial	0.225	0.455	0.228
KBRD	0.263	0.468	0.283
KGSF	0.324	0.502	0.332
RevCore (−KG)	0.556	0.493	0.682

−revEN	0.394	0.534	0.586	10.8

Table 4: Ablation study on the conversation task.

from the testing set. Given one dialogue context, each generated response is scored ranging from 0 to 1, with a higher value indicating a more coherent, fluent, and informative utterance. The final result is calculated as the average score of three annotators, as summarized in Table 3. The proposed RevCore (with or without KG) is consistently better than all the baselines, especially on the metric of informativeness in a large margin. It further proves the effectiveness of our method, and also verifies its superiority in numerical results.

Ablation Study We demonstrate the contribution of each part on the conversation task by constructing an ablation study based on three variants of our complete model, including: (1) RevCore (−revCP) by removing the copy mechanism for reviews, (2) RevCore (−revRA) by removing the review attention layers from the transformer decoder, and (3) RevCore (−revEN) by removing the sentiment-aware review encoder (the reviews share the same encoder with the context). As shown in Table 4, first, all the techniques are useful to improve the final performance in generating diversified utterances. Besides, the copy mechanism and the review attention layers seem to be more important in conversation diversity. One of the potential reasons is that these two components are directly related to the decoding stage. Separated encoders for review and context lead to a slight increment, which shows that sharing a common encoder is an alternative solution.

Len	Recommendation			Conversation		
	R@1	**R@10**	**R@50**	**Dist-3**	**Dist-4**	**PPL**
10	4.5	21.8	37.0	0.491	0.564	**10.2**
20	**6.1**	**23.6**	**45.4**	**0.558**	**0.612**	**10.2**
30	4.7	22.0	41.3	0.263	0.426	13.1
40	5.8	21.3	41.3	0.289	0.439	14.0
50	5.1	22.3	40.8	0.304	0.520	13.8

Table 5: Performance of RevCore when incorporating review sentences with different length (Len). Best results are in bold.

4.3 Case Study

In this part, we present a visualized example to illustrate how our model works in practice, as shown in Figure 3. First, the sentiment-aware review retrieval module guarantees the coherence of incorporating reviews to some extent, for example in Figure 3, negative comments (the last row for the movie *The Notebook*) are filtered out considering the positive attitude in the original utterance. Secondly, incorporated reviews exactly enrich the context for better recommendation. As seen in the first yellow frame, many entities like "*Roshan Andrews*" mentioned in the review are added into the entity set. Note that some other entities are also added from the reviews that are incorporated into users' utterances as described in Section 2, which is not visualized here but brings recommendation accuracy improvement as well. Last but not least, the generated responses are more informative to use more varied expressions like "*the magic spell*" and "*the sultry dance*". Besides, they uncover more details related to the movie that acts as explanatory sentences that make recommendations accepted more easily and naturally.

4.4 Discussion

Longer Review, Better Performance? In our basic setting, each retrieved review sentence is formed by 20 words. We conduct a series of experiments by setting the length of retrieved review sentences as 10, 20, 30, 40, and 50 to inspect the effect of review length. The results of using different lengths are shown in Table 5, among which 20 is the best across all metrics. An interesting finding is that continually increasing the review length makes no benefits after reaching 20. Over introducing external text may suppress original text, thus 20 is a better choice to keep the balance between them.

Figure 3: Case study. $U(i)$ (green) and $S(i)$ (yellow) represent user and system, respectively. In the "Dialogue Generation", items are marked in blue font, explanatory sentences are in red. Items are in bold font in "Entities" frames. In "Recommend" frames, a darker color represents a higher probability. "Review Retrieval" gives retrieved review examples, with their sentiment value (0-9) at the most left, and the selected reviews are in bold.

Method	Recommendation			Conversation		
	R@1	**R@10**	**R@50**	**Dist-3**	**Dist-4**	**PPL**
iCorpus	2.1	8.5	20.3	0.430	0.555	11.2
R-H-W	2.3	10.7	25.2	0.307	0.347	10.9
C-H-W	5.4	23.3	42.9	0.471	0.559	13.1
C-H-S	4.2	22.4	39.4	0.534	0.586	11.4
C-S-S	**6.1**	**23.6**	**45.4**	**0.558**	**0.612**	**10.2**

Table 6: Results of various retrieval strategies. Three characters from left to right represent three factors: (i) C/R: correctly/randomly matched movie-review pairs; (ii) S/H: ranking by sentiment value or helpful score respectively; (iii) S/W: sentence/word-wise manner. "iCorpus" indicates using irrelevant corpus. Best results are in bold.

Appropriate Reviews Help More? The "review sentence" are obtained from a 3-stage process, namely, searching item-matched reviews from the database, ranking them by the helpful score or sentiment value, and constructing "review sentence" word-wisely or sentence-wisely. Therefore, we conduct control experiments to inspect these three factors. As shown in Table 6, (i) using reviews randomly matched with items (R-H-W) results in significantly lower R@k and Dist-n scores; (ii) ranking by sentiment value (C-S-S) leads to better performance across all metrics than by helpful score (C-H-S), which demonstrates the necessity of using sentiment-aware review retrieval; (iii) the sentence-wise manner (C-H-S) gets a lower PPL than the word-wise one (C-H-W), which is reasonable because the incorporated reviews made up of random words causes the fluency loss. Besides, another experiment is conducted to verify the necessity of using a movie-review database. A food-review database is constructed as a topic-irrelevant corpus (iCorpus), which results in the lowest R@k yet not bad Dist-n scores. It shows that despite the response diversity brought by the external corpus, the unrelated entities from another domain have negative impacts on the recommendation accuracy.

5 Related Work

Recommender systems have emerged as a separate research area and now play an indispensable role in daily social lives. Traditional recommender systems tend to work statically, primarily relying on content-based approaches or the collaborative filtering hypothesis (Resnick et al., 1994; Pazzani and Billsus, 2007; Wang et al., 2019b), which assumes that similar users may have similar interests. Afterward, more sophisticated methods using neural networks are proposed and prove effective. For instance, neural factorization machines (He and Chua, 2017) and deep interest networks (Zhou et al., 2018) are used to estimate user preferences based on historical user-item interactions. Graphs are adopted in Wang et al. (2019b,a) to model complex relations among users, items, and attributes for a better representation of data.

In recent years, major advances made in dialog systems (Dodge et al., 2016; Yan et al., 2016; Benni et al., 2016; Bordes et al., 2017; Song et al., 2020) and structured knowledge-based info-seeking technics including question answering (Bao et al., 2014, 2016; Yin et al., 2015; Yih et al., 2015; Shao et al., 2019) and question generation (Serban et al., 2016; Bao et al., 2018; Dušek et al., 2020) have encouraged the development of *conversational recommendation* systems, which dynamically obtain user preferences through interactive conversation with users. Multiple datasets have been constructed (Dodge et al., 2016; Li et al., 2018; Kang et al., 2019) to facilitate the study of this task. Li et al. (2018) collect a standard human-to-human multi-turn dialog dataset focusing on providing movie recommendations. Based on these datasets, various approaches are proposed to address different issues in CR systems. Specifically, external information is introduced to alleviate the cold-start problem, including knowledge bases (Wang et al., 2018), social networks (Daramola et al.), and knowledge graphs (Chen et al., 2019). Christakopoulou et al. (2016) use bandit-based explore-exploit strategy to minimize the number of user queries. Liu et al. (2020) conduct multi-goal planning to make a proactive conversational recommendation over multi-type dialogues. A multi-view method is proposed in Chen et al. (2020b) for the explainable conversational recommendation. The work of Pecune et al. (2020) builds a socially aware CR system engaging its users through a rapport-building dialogue to improve users' perception.

Different from all aforementioned previous work, we offer an alternative to AIG with an augmented conversational recommendation system by incorporating reviews that highly relevant to items. Particularly, our model is able to learn better user representations from a review-enriched dialogue context, which enables a high-quality recommendation and response generation.

6 Conclusion

In this paper, we proposed a novel CR framework with review augmentation, including a sentiment-aware retrieval module, a recommender exploiting the review-enriched user profile, an encoder for enhancing semantic embedding of selected reviews, and a review attentive decoder to integrate review information for dialogue response generation. Experimental results show that our approach achieves consistent and significant improvements of both recommendation and dialogue responding over baselines, and is able to generate informative responses without losing fluency and coherence.

A Statistics for Conversation Dataset and Reviews

Conversations in the REDIAL dataset consist of 163,820 utterances, of which 15.80% have reviews added. The vocabulary size of REDIAL is increased by 13.14% (from 23,356 to 26,427). Among the mentioned 6,927 movies in all conversations, 40% of them are randomly chosen and linked with reviews to keep the balance between the original source and external source. We count the ratio of "disliked" movies by the recommender to explain the improvements brought by doing sentiment-aware retrieval when incorporating reviews. We also show the ratio of unseen movies by the recommender to show the need of introducing reviews to "talk more". Comprehensive statistics are listed in Table 7.

B Experiment Details

Hyper-parameter Settings For a fair comparison, most hyper-parameters are kept consistent with KGSF. We did not search for more hyper-parameters combinations to achieve additional improvements apart from our main idea. The shared hyper-parameters include: embedding dimension

Items	Statistic	Items	Statistic
Dialogues	10,021	Cnd Movies	64,368
Utterances	163,820	Mnt Movies	6,924
+reviews	25,884	+reviews	2,711
Disliked	4.9%	Not Seen	31.9%
Liked	81.2%	Seen	61.3%
Did not say	13.9%	Did not say	6.8%

Table 7: Statistics for the REDIAL dataset with incorporated reviews. “Cnd” denotes “Candidate”, and “Mnt” denotes “Mentioned” to indicate the movies that mentioned in the conversations.

Models	Param	Tra Time	Inf Time
KGSF	130.51	4979.88	65.30
RevCore (−KG)	71.12	1045.65	59.57
RevCore (+KG)	133.30	3308.28	51.46

Table 8: Comparison of three models on the number of parameters (million), training (“Tra”) time for 30 epochs (second), and inference (“Inf”) time (second).

set as 128 in the recommender component and 300 in the dialogue component, the layer number of both GNN in the KG module as 1, the batch size as 32, word embedding initialization via word2vec[6], the optimizer as Adam, the learning rate as 0.001, the epoch number as 30, etc.

Training Strategies To train the whole model, three steps are included: (i) pre-training the sentiment predictor in the review retrieval module; (ii) training the recommender component by minimizing $\mathcal{L}_{rec}$; (iii) training the dialogue component by minimizing $\mathcal{L}_{gen}$. In the first step, the predictor takes each sentence in the review as input and outputs the sentiment, with the corresponding rating set as the label. In the second and third steps, our implementation refers to the training algorithm for the KGSF model. It first pre-trains the parameters in KG for entity representation by minimizing the Mutual Information Maximization loss between two KG embedding, then trains the recommender component by minimizing the recommendation loss and also updating the parameters in the KG module, and finally the dialogue component by minimizing the generation loss with all other modules' parameters “frozen”.

Metrics	RevCore (+KG)		RevCore (−KG)	
	Val	**Test**	**Val**	**Test**
R@1	6.13	6.11	4.55	4.19
R@10	23.49	23.62	23.35	22.71

Dist-2	0.418	0.424	0.410	0.373
Dist-3	0.582	0.558	0.582	0.527
Dist-4	0.675	0.612	0.668	0.615
PPL	10.89	10.24	10.14	10.69

Table 9: Validation (Val) and test results on the REDIAL dataset of RevCore (+KG) and RevCore (−KG).

Metrics	RevCore (+KG)		RevCore (−KG)	
	Mean	**Devi**	**Mean**	**Devi**
R@1	5.70	± 0.67	3.75	± 0.13
R@10	22.80	± 1.81	21.53	± 0.68
R@50	40.75	± 2.18	44.68	± 0.43
Dist-2	0.394	± 0.039	0.373	± 0.031
Dist-3	0.551	± 0.062	0.527	± 0.051
Dist-4	0.633	± 0.073	0.616	± 0.062

Table 10: Mean and deviation of recall rates (%) and distance scores for RevCore (+KG) and RevCore (−KG).

C Model Size and Running Speed

The model size and running speed of KGSF, RevCore (+KG), and RevCore (−KG) are all listed in Table 8. Note that all three models are implemented with Pytorch[7], trained for 30 epochs, and experimented on NVIDIA A100-SXM4 for 5 times to compute the average running time.

D Results on the Validation Set

We present the validation result of RevCore with and without KG on the REDIAL dataset as a reference for reproducing. All validation results are shown in Table 9, with test results as well.

E Mean and Standard Deviation

We implement the major experiment 4 times to inspect the mean and standard deviation of the performance of RevCore across all metrics. The reported results in the paper of both recommendation accuracy and conversation quality are the mean results. Results are shown in Table 10.

Abstract

Recent years pretrained language models (PLMs) hit a success on several downstream tasks, showing their power on modeling language. To better understand and leverage what PLMs have learned, several techniques have emerged to explore syntactic structures entailed by PLMs. However, few efforts have been made to explore grounding capabilities of PLMs, which are also essential. In this paper, we highlight the ability of PLMs to discover which token should be grounded to which concept, if combined with our proposed erasing-then-awakening approach. Empirical studies on four datasets demonstrate that our approach can awaken latent grounding which is understandable to human experts, even if it is not exposed to such labels during training. More importantly, our approach shows great potential to benefit downstream semantic parsing models. Taking text-to-SQL as a case study, we successfully couple our approach with two off-the-shelf parsers, obtaining an absolute improvement of up to 9.8%.

1 Introduction

Recent breakthroughs of **P**retrained **L**anguage **M**odels (**PLMs**) such as BERT (Devlin et al., 2019) and GPT3 (Brown et al., 2020) have demonstrated the effectiveness of self-supervised learning for a range of downstream tasks. Without being guided by structural information in training, PLMs show the potential for learning implicit syntactic structures and language semantic, which can be transferred to other tasks. To better understand and leverage what PLMs have learned, several work has emerged to probe or induce syntactic structures from PLMs. According to prior studies (Rogers et al., 2020), most existing work focuses on syntactic structures such as part of speech (Liu et al., 2019), constituency tree (Wu et al., 2020) and dependency tree (Hewitt and Manning, 2019; Jawahar et al., 2019), paying much less attention on language semantics (Tenney et al., 2019). However, as well known, semantic information is essential for high-level tasks like machine reading comprehension (Wang and Jiang, 2019).

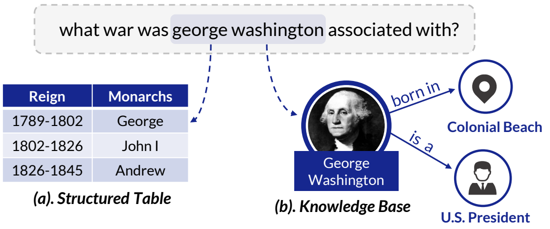

Figure 1: Typical scenarios for grounding, here the linguistic tokens "george washington" can be grounded into different real-world concepts.

Regarding to language semantics, an important branch is grounding, which is overlooked by most previous work. Broadly speaking, grounding means "*connecting linguistic symbols to real-world perception or actions*" (Roy, 2005). It is generally thought to be important for a variety of tasks, such as video descriptions (Zhou et al., 2019), visual question answering (Zhu et al., 2016) and semantic parsing (Guo et al., 2019). In this paper, we focus on single-modal scenarios, where grounding refers more specifically to mapping linguistic tokens into a real-world concept described in natural language. As shown in Figure 1, "george washington" can be grounded into either a cell value in a structured table, or an entity in knowledge bases.

In single-modal scenarios, grounding is especially important for semantic parsing, the task of translating a natural language sentence into its corresponding executable logic form. For earlier work, grounding is essential since earlier work almost conceptualized semantic parsing as grounding an

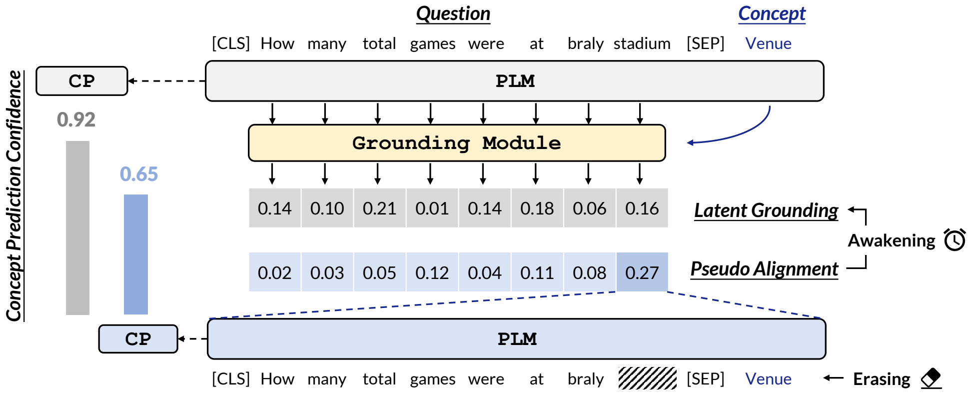

Figure 2: The illustration of ETA, which consists of a PLM module, a **C**oncept **P**rediction (CP) module and a grounding module. Two models (gray and blue) are drawn here for illustration purposes, and they are indeed the same. The model training involves three steps: (1) The concept prediction module is trained to predict the confidence of any concept occurring in a given question (**Left**). (2) The erasing mechanism erases tokens in the question sequentially, feeds them into CP, and obtains the confidence differences (e.g., $0.92 - 0.65 = 0.27$) as the pseudo alignment. Here we only demonstrate the process related to "stadium" (**Bottom Right**). (3) The pseudo alignment is employed to awaken the latent grounding, i.e., to supervise the grounding module (**Top Right**). We show only one concept "Venue" for the sake of brevity, which in practice is a sequence of concepts.

utterance to a task-specific meaning representation (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Liang et al., 2013; Cheng et al., 2017). As for modern approaches based on the encoder-decoder architecture, grounding also plays an important role and considerable work has demonstrated the positive effect of it (Guo et al., 2019; Dong et al., 2019; Liu et al., 2020a; Wang et al., 2020b; Chen et al., 2020). Despite its success, existing grounding methods mainly relied on heavy manual efforts like high-quality lexicons (Reddy et al., 2016) or ad-hoc heuristic rules like n-gram matching (Guo et al., 2019), suffering from poor flexibility. To explore more flexible methods, researchers recently tried a data-driven way: they collected grounding annotations as supervision to train grounding models (Li et al., 2020a; Lei et al., 2020; Shi et al., 2020). However, this modeling flexibility in their approaches requires expensive annotations of grounding, which most of the time are not available.

To alleviate the above issues, we present a novel approach **E**rasing-**t**hen-**A**wakening (ETA)[1]. It is inspired by recent advances in interpretable machine learning (Samek et al., 2017), where the importance of individual pixels can be quantified with respect to the classification decision. Similarly, our approach firstly quantifies the contribution of each word with respect to each concept, by erasing it and probing the variation of concept prediction decisions (elaborated later). Then it employs these contributions as pseudo labels to awaken latent grounding from PLMs. In contrast to prior work, our approach only needs supervision of concept prediction, which can be easily derived by downstream tasks (e.g., text-to-SQL) instead of full grounding supervision. Empirical studies on four datasets demonstrate that our approach can awaken latent grounding which is understandable to human experts. It is highly non-trivial because our approach is not exposed to any human-annotated grounding label in training. More importantly, we find that the grounding can be easily coupled with downstream models to boost their performance, and the absolute improvement is up to 9.8%. In summarization, our contribution is as three-fold:

1. To the best of our knowledge, we are the first one to highlight and demonstrate the possibility of awakening latent grounding from PLMs.

2. We propose a novel weakly supervised approach erasing-then-awakening, to awaken latent grounding from PLMs. Empirical studies on four datasets demonstrate that our approach can awaken latent grounding which is understandable to human experts.

3. Taking text-to-SQL as a case study, we successfully couple our approach with two off-the-shelf parsers. Experimental results on two benchmarks show the effectiveness of our approach on boosting downstream performance.

---

2 Method: Erasing-then-Awakening

In the task of grounding, we are given a question $\mathbf{x} = \langle x_1, \cdots, x_N \rangle$ and a concept set $\mathcal{C} = \{c_1, \cdots, c_K\}$, where each concept consists of several tokens. The goal of grounding is to find out tokens (also known as mentions) in $\mathbf{x}$ which are relevant to concepts in $\mathcal{C}$. Generally, the grounding procedure learns to create a $N \times K$ matrix, which we call *latent grounding*. In some cases, a set of pairs is needed, of which each one explicitly shows a token and a concept is grounded. We call this kind of pairs as *grounding pairs* below.

As illustrated in Figure 2, our model consists of a PLM module, a CP module and a grounding module. In this section, we first present the training procedure of ETA, which at a high-level involves three steps: (1) Train an auxiliary concept prediction module. (2) Erase tokens in a question to obtain the concept prediction confidence differences as pseudo alignment. (3) Awaken latent grounding from PLMs by applying pseudo alignment as supervision. Then we introduce the procedure to produce grounding pairs in inference.

2.1 Training a Concept Prediction Module

Given $\mathbf{x}$ and $\mathcal{C}$, the goal of the concept prediction module is to identify if each concept $c_k \in \mathcal{C}$ is mentioned or not in the question $\mathbf{x}$. Although it does not seem to be directly related to grounding, it is a pre-requisite for the erasing mechanism, which will be elaborated later. As for c_k's supervision $l_k \in \{0, 1\}$, it is the weak supervision ETA relies on, and can be readily obtained through downstream task signals. Taking text-to-SQL as an illustration, each database schema (i.e., table, column and cell value) in an annotated SQL can be considered as mentioned in the question ($l_k = 1$), with others as negative examples ($l_k = 0$).

Once the supervision is prepared, the CP module is trained to conduct binary classification over the representation of each concept. As done in previous work (Hwang et al., 2019), we first concatenate the question and all concepts into a sequence as input to the PLM module. As illustrated in Figure 2, the input sequence starts with `[CLS]`, with the question and each concept being separated by `[SEP]`. Then, the sequence is fed into the PLM module to produce deep contextual representations over each position. Denoting $\langle \mathbf{q}_1, \mathbf{q}_2, ..., \mathbf{q}_N \rangle$ and $\langle \mathbf{e}_1, \mathbf{e}_2, ..., \mathbf{e}_K \rangle$ as the token representations and concept representations, they can be obtained by:

$$\{\mathbf{q}_n\}_{n=1}^{N}, \{\mathbf{e}_k\}_{k=1}^{K} = \mathrm{PLM}\big(\texttt{[CLS]}, \mathbf{x}, \{\texttt{[SEP]}, c_k\}_{k=1}^{K}\big), \quad (1)$$

where $\mathbf{q}_n$ and $\mathbf{e}_k$ correspond to the representations at the position of n-th question token and the first token in c_k respectively. Finally, each concept representation $\mathbf{e}_k$ is passed to a classifier to predict if it is mentioned in $\mathbf{x}$ as:

$$p_k = \texttt{Sigmoid}(\mathbf{W}_l\, \mathbf{e}_k), \quad (2)$$

where $\mathbf{W}_l$ is a learnable parameter. p_k is the probability of c_k mentioned in the question, which is referred to by *concept prediction confidence* below.

2.2 Erasing Question Tokens

Once the concept prediction module is converged, we apply an erasing mechanism to assist in the following awakening phase. It follows a similar idea from the interpretable document classification (Arras et al., 2016), where a word is considered important for the document classification if removing it and classifying the modified document results in a strong decrease of the classification score. In our case, a token is considered highly relevant to certain concepts if there is a large drop in these concept prediction confidences after erasing the token. Therefore, we need the above mentioned concept prediction module to provide a reasonable concept prediction confidence.

Concretely, as shown in Figure 2, the erasing mechanism erases the input sequentially, and feeds each erased input into the PLM module and the subsequent CP module. For example, with x_n being substituted by a special token `[UNK]`, we can obtain an erased input as $\texttt{[CLS]}, x_1, \cdots, x_{n-1}, \texttt{[UNK]}, x_{n+1}, \cdots, c_K$. Denoting $\hat{p}_{n,k}$ the concept prediction confidence for c_k after erasing x_n, we believe the difference between $\hat{p}_{n,k}$ and p_k reveals c_k's relevance to x_n from a PLM's view. The confidence difference $\Delta_{n,k}$ can be obtained by $\Delta_{n,k} = l_k \cdot \max(0, p_k - \hat{p}_{n,k})$. Repeating the above procedure on the input question sequentially, $\Delta \in \mathbb{R}^{N \times K}$ is filled completely.

2.3 Awakening Latent Grounding

As mentioned above, we believe Δ reflects the relevance between each token and each concept from a PLM's view. Therefore, we could directly use Δ as ETA's output. However, according to our preliminary study, the method performs poorly and cannot produce high-quality alignment[2]. Different from directly using Δ, we employ it to "awaken" the latent grounding. To be specific, we introduce a grounding module upon representations of the PLM module and train it using Δ as pseudo labels (i.e., pseudo alignment). The grounding module first obtains grounding scores $g_{n,k}$ between each question token x_n and each concept c_k based on their deep contextual representations $\mathbf{q}_n$ and $\mathbf{e}_k$ as:

$$g_{n,k} = \frac{\mathbf{W}_e \mathbf{e}_k \cdot (\mathbf{W}_q \mathbf{q}_n)^T}{\sqrt{d}}, \quad (3)$$

where $\mathbf{W}_e, \mathbf{W}_q$ are learnable parameters and d is the dimension of $\mathbf{e}_k$. Then it normalizes the grounding scores into latent grounding $\boldsymbol{\alpha}$ as:

$$\boldsymbol{\alpha}_{n,k} = \frac{\exp(g_{n,k})}{\sum_i \exp(g_{i,k})}. \quad (4)$$

Finally, the grounding module is trained to maximize the likelihood with Δ as the weight:

$$\sum_n \sum_k \Delta_{n,k} \cdot \log \boldsymbol{\alpha}_{n,k}. \quad (5)$$

2.4 Producing Grounding Pair

Repeating erasing and awakening iteratively for epochs until the grounding module converges, we can readily produce grounding pairs. Formally, we aim to obtain a set of pairs, where each pair $\langle x_n, c_k \rangle$ indicates that x_n is grounded to c_k. Noticing c_k may contain several tokens, we keep all probabilities in $\boldsymbol{\alpha}_{\cdot,k}$ which exceeds $\tau/|c_k|$, where τ is a threshold and $|c_k|$ is the number of tokens in c_k. Also, taking into account that x_n should be grounded to only one concept, we keep only the highest probability over $\boldsymbol{\alpha}_{n,\cdot}$. Finally, for each pair $\langle x_n, c_k \rangle$, it is thought to be a grounding pair if $\boldsymbol{\alpha}_{n,k}$ is kept and $p_k \geq 0.5$, otherwise it is not.

3 Experiments

In this section, we conduct experiments to evaluate if the latent grounding awakened by ETA is understandable to human experts. Here we accomplish the evaluation by comparing the grounding pairs produced by ETA with human annotations.

3.1 Experimental Setup

Datasets We select two representative grounding tasks where human annotations are available: *schema linking* and *entity linking*. Schema linking is to ground questions into database schemas, while entity linking is to ground questions into entities of knowledge bases. For schema linking, we select SPIDER-L (Lei et al., 2020) and SQUALL (Shi et al., 2020) as our evaluation benchmarks. As mentioned in §2.1, the supervision for our model is obtained from SQL queries. As for entity linking, we select WebQSP$_{\text{EL}}$and GraphQ$_{\text{EL}}$(Sorokin and Gurevych, 2018). The supervision for our model is obtained from SPARQL queries in a similar way.

Evaluation For schema linking, as done in previous work (Lei et al., 2020), we report the micro-average precision, recall and F1-score for both columns (Col$_P$, Col$_R$, Col$_F$) and tables (Tab$_P$, Tab$_R$, Tab$_F$). For entity linking, we report the weak matching precision, recall and F1-score for entities (Ent$_P$, Ent$_R$, Ent$_F$). The weak matching metric is a commonly used metric in previous work (Sorokin and Gurevych, 2018), which considers a prediction as correct whenever the correct entity is identified and the predicted mention boundary overlaps with the ground truth boundary. More details can be seen in §A.

Baselines For schema linking, we consider four strong baselines. (1) **N-gram Matching** enumerates all n-gram ($n \leq 5$) phrases in a natural language question, and links them to database schemas by fuzzy string matching. (2) **SIM** computes the dot product similarity between each question token and schema using their PLM representations without fine-tuning, to explore grounding capacities of unawakened PLMs. (3) **CONTRAST** learns by comparing the aggregated grounding scores of mentioned schemas with unmentioned ones in a contrastive learning style, as done in Liu et al. (2020b). Concretely, in training, CONTRAST is trained to accomplish the same concept prediction task as our approach. With a similar architecture to the Receiver used in Liu et al. (2020b), it first computes the similarity score between each token and each concept, and then uses max pooling to aggregate the similarity scores of a concept over an utterance into a concept prediction score. Finally, a margin-based loss is used to encourage the baseline to give higher concept prediction scores on mentioned concepts than unmentioned concepts. (4) **SLSQL$_{\text{L}}$ & ALIGN$_{\text{L}}$**. SLSQL$_{\text{L}}$ (ALIGN$_{\text{L}}$) is a learnable schema linking module[3] proposed in

---

[2] More experimental results can be found in §3.3.

[3] SLSQL and ALIGN use multi-task learning to simultaneously learn schema linking and SQL generation.

Model	SPIDER-L						SQUALL		
	Col$_P$	Col$_R$	Col$_F$	Tab$_P$	Tab$_R$	Tab$_F$	Col$_P$	Col$_R$	Col$_F$
N-gram Matching	61.4	69.1	65.1	78.2	69.6	73.6	71.6	50.8	59.4
SIM + BERT	16.6	8.0	10.8	8.5	11.6	9.8	13.9	18.0	15.7
CONTRAST + BERT	83.7	68.4	75.3	**84.0**	76.9	80.3	47.9	31.2	37.8
ETA + BERT	**86.1**	**79.3**	**82.5**	81.1	**85.3**	**83.1**	**77.3**	**62.4**	**69.0**
SLSQL$_{\text{L}}$ + BERT$^{\heartsuit}$ (Lei et al., 2020)	82.6	82.0	82.3	80.6	84.0	82.2	–	–	–
ALIGN$_{\text{L}}$ + BERT$^{\heartsuit}$ (Shi et al., 2020)	–	–	–	–	–	–	79.2	72.8	75.8

Table 1: Experimental results on schema linking dev sets. $^{\heartsuit}$ means the model uses schema linking supervision, while other learnable models use weak supervision. +BERT means using BERT as encoder, the same for Table 2.

Model	WebQSP$_{\text{EL}}$			GraphQ$_{\text{EL}}$(zero-shot)		
	Ent$_P$	Ent$_R$	Ent$_F$	Ent$_P$	Ent$_R$	Ent$_F$
Heuristic (Sorokin and Gurevych, 2018)	30.2	60.8	40.4	-	-	-
ETA + BERT	**76.6**	**72.5**	**74.5**	**43.1**	**42.1**	**42.7**
VCG$^{\heartsuit}$ (Sorokin and Gurevych, 2018)	82.4	68.3	74.7	54.1	30.6	39.0
ELQ + BERT$^{\heartsuit}$ (Li et al., 2020a)	90.0	85.0	87.4	60.1	57.2	58.6

Table 2: Experimental results on entity linking test sets. $^{\heartsuit}$ means the model uses entity linking supervision from WebQSP$_{\text{EL}}$, while ETA uses the weak supervision derived from WebQSP. Following previous work (Sorokin and Gurevych, 2018), we use GraphQ$_{\text{EL}}$only in the evaluation phase to test the generalization ability of our model.

SLSQL (ALIGN). Unlike our method, these two methods are trained with the full schema linking supervision. Please refer to Shi et al. (2020) and Lei et al. (2020) for more details. Notably, for baselines which require a threshold, we tuned their thresholds based on dev sets for fair comparison.

For entity linking, we compare ETA with three powerful methods. (1) **Heuristic** picks the most frequent entity among the candidates found by string matching over Wikidata. (2) **VCG** (Sorokin and Gurevych, 2018) aggregates and mixes contexts of different granularities to perform entity linking. (3) **ELQ** (Li et al., 2020a) uses a bi-encoder to perform entity linking in one pass, achieving state-of-the-art performance on WebQSP$_{\text{EL}}$and GraphQ$_{\text{EL}}$. VCG and ELQ utilize entity linking supervision in training, while ETA does not.

Implementation For schema linking we follow the procedure in §2.4 to produce grounding pairs to evaluate, while for entity linking we further merge adjacent grounding pairs to produce span-level grounding pairs. We implement ETA in Pytorch (Paszke et al., 2019). With respect to PLMs in experiments, we use the uncased BERT-base (BERT)[4] and BERT-large (BERT$_{\text{L}}$) from Transformers library (Wolf et al., 2020). As for the optimizer, we employ AdamW (Loshchilov and Hutter, 2019). More details (e.g., learning rate) of each experiment can be found in §C.1.

3.2 Experimental Results

Table 1 shows the experimental results on the schema linking task. As shown, our method outperforms all weakly supervised methods and heuristic-based methods by a large margin. For example, on SPIDER-L, ETA + BERT achieves an absolute improvement of 7.2% Col$_F$ and 2.8% Tab$_F$ over the best baseline CONTRAST. The same conclusion can be drawn from the experimental results on the entity linking task shown in Table 2. For instance, ETA + BERT can obtain a high Ent$_F$ up to 74.5% on WebQSP$_{\text{EL}}$, which is a satisfying performance for downstream tasks. All results above demonstrate the superiority of our approach on awakening latent grounding from PLMs. With respect to the reason that PLMs work well on both schema linking and entity linking, it may be because both schema linking and entity linking require text-based semantic matching (e.g., synonyms), which PLMs excel at.

Furthermore, it is very surprising that although not trained under fine-grained grounding supervision, our model is comparable with or slightly worse than the fully supervised models across

---

[4] Our approach is theoretically applicable to different PLMs. In this paper, we chose BERT as a representative and we leave exploration of different PLMs for future work.

Error Type	**Example Error**
Missed Grounding (43.1%)	How many **points** did arnaud demare receive? `GOLD:` **points**→ "`UCI world tour points`" `PRED:`
Technically Correct (21.0%)	Total **population** of millbrook first **nation**? `GOLD:` **population**→ "`Population`" `PRED:` **population**→ "`Population`"; **nation**→ "`Community`"
Partially Correct (15.8%)	Who was **the first winning captain**? `GOLD:` **the first**→ "`Year`"; **winning captain**→ "`Winning Captain`" `PRED:` **first**→ "`Year`"; **winning captain**→ "`Winning Captain`"
Wrong Grounding (10.1%)	Were the **matinee** and evening performances held **earlier** than the 8th anniversary? `GOLD:` **earlier**→ "`Date`" `PRED:` **matinee**→ "`Performance`"; **earlier**→ "`Date`"

Table 3: Four main error types made by Eta along with their proportions on Squall dataset.

datasets. For instance, on Spider-L, our model exceeds the fully supervised baseline SLSQL$_\text{L}$ by 0.9 points on Tab$_F$. On Squall, our model holds a slightly worse performance than the fully supervised baseline ALIGN$_\text{L}$. It is highly nontrivial since Contrast, the best weakly supervised baseline on Spider-L, is far from the fully supervised model on Squall, while our model has only a small drop. Besides, on WebQSP$_\text{EL}$and GraphQ$_\text{EL}$, although our model is inferior to the state-of-the-art model ELQ, it also achieves a comparable performance with the fully supervised baseline VCG. These results provide strong evidence that PLMs do have very good grounding capabilities, and our approach can awaken them from PLMs.

3.3 Model Analysis

In this section, we try to answer four interesting research questions via a thorough analysis: **RQ1.** Does the grounding capability come mainly from the PLM? **RQ2.** Is the awakening phase necessary? **RQ3.** Do larger PLMs have better grounding capabilities? **RQ4.** What are the remaining errors?

RQ1 There is a long term debate in literature about if knowledge is primarily learned by PLMs, when extra parameters are employed in analysis (Hewitt and Liang, 2019). Similarly, since our approach depends on extra modules (e.g., grounding module), it faces the same dilemma: how can we know whether the latent grounding is learnt from PLMs or extra modules? Therefore, we apply our approach to a randomly initialized Transformer encoder (Vaswani et al., 2017), to probe the grounding capability of a model that has not been pretrained. To make it comparable, the encoder has the same architecture as BERT. However, it only gets a 40% Col$_F$ on Squall, not even as good as the N-gram baseline. Considering it contains the same extra modules as Eta + BERT, the huge gap between it and Eta + BERT supports the opinion that the latent grounding is mainly learnt from PLMs. Meanwhile, one concern shared by our reviewers is the risk of supervision exposure during training of the concept prediction module. In other words, our approach may "steal" some supervision in the concept prediction module to achieve good performance on grounding. However, the above experiment demonstrates that a non-pretrained model is far from strong grounding capability even with the same concept prediction module. We hope the finding will alleviate the concern.

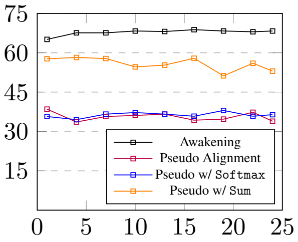

Figure 3: Col$_F$ score on the dev set of Squall at different training epochs. "Pseudo w/ `Softmax`" means normalizing pseudo alignment with `Softmax`, while "Pseudo w/ `Sum`" means normalizing through dividing each number by the sum of them.

RQ2 As mentioned in §2.3, the pseudo alignment Δ can also be employed as the model prediction. Therefore, we conduct experiments to verify if our proposed awakening phase is necessary. As shown in Figure 3, even with various normalization methods (e.g., `Softmax`), Δ does not produce satisfactory alignment. In contrast, our model consistently performs well. To investigate deeper, we conduct a careful analysis on Δ, and we are surprised to

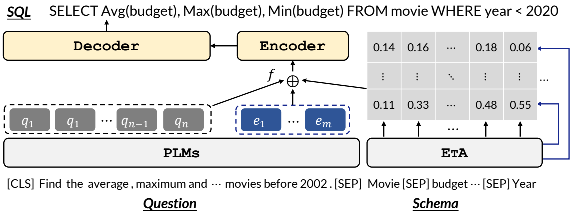

Figure 4: The illustration of the solution to couple ETA with downstream text-to-SQL parsers.

find that values of Δ are generally small and not as significantly different with each other as we would expect. Therefore, we believe the success of our approach stems from the fact that it encourages the grounding module to capture subtle differences and strength them.

RQ3 We apply our approach on BERT-large (BERT_L) and conduct experiments on SPIDER-L. The results show BERT_L brings an improvement of 2.5% Col_F and 0.5% Tab_F, suggesting the possibility of awakening better latent grounding from larger PLMs. Nevertheless, the improvement may also come from more parameters, so the conclusion needs further investigation.

RQ4 We manually examine 20% of our model's errors on the SQUALL dataset and summarize four main error types: (1) missed grounding - where our model did not ground any token to a concept, (2) technically correct - where our model was technically correct but the annotation was missing, (3) partially correct - where our model did not find all tokens of a concept, (4) wrong grounding - where the model produced incorrect grounding. As shown in Table 3, only a small fraction of errors are wrong grounding, indicating that the main challenge of our approach is recall rather than precision.

4 Case Study: Text-to-SQL

The ETA model is proposed for general-purpose uses and intends to enhance different downstream semantic parsing models. To verify it, we take the text-to-SQL task as a case study. In this section, we first present a general solution to couple ETA with different text-to-SQL parsers. Then, we conduct experiments on two off-the-shelf parsers to verify the effectiveness of ETA.

4.1 Coupling with Text-to-SQL Parsers

Inspired by Lei et al. (2020), we present a general solution to couple ETA with downstream parsers in Figure 4. As shown, we first obtain a schema-aware representation for each question token, by fusing the token representation and its related schema representation according to the latent grounding $\boldsymbol{\alpha} \in \mathbb{R}^{N \times K}$ (gray matrix in Figure 4). Specifically, given a token representation $\mathbf{q}_n$ and all schema representations $\langle \mathbf{e}_1, \mathbf{e}_2, ..., \mathbf{e}_K \rangle$, the schema-aware representation $\tilde{\mathbf{q}}_n$ for $\mathbf{q}_n$ can be computed as:

$$\tilde{\mathbf{q}}_n = \mathbf{q}_n \oplus \sum_k \boldsymbol{\alpha}_{n,k}\, \mathbf{e}_k. \tag{6}$$

Then we feed every $\tilde{\mathbf{q}}_n$ into a question encoder to generate hidden states, which are attended by a decoder to decode the SQL query. By contributing to the schema-aware representation, ETA is able to prompt the decoder to predict appropriate schemas during decoding. Notably, the encoder and decoder are not limited to specific modules, and we follow the paper settings in subsequent experiments.

Model	Dev		Test
	Ex.Match	Ex.Acc	Ex.Acc
ALIGN_P	37.8 ± 0.6	56.9 ± 0.7	46.6 ± 0.5
ALIGN_P + BERT	44.7 ± 2.1	63.8 ± 1.1	51.8 ± 0.4
ETA + BERT	$\mathbf{47.6} \pm 2.5$	$\mathbf{66.6} \pm 1.7$	$\mathbf{53.8} \pm 0.3$
$\text{ALIGN}^\heartsuit$	42.2 ± 1.5	61.3 ± 0.8	49.7 ± 0.4
$\text{ALIGN} + \text{BERT}^\heartsuit$	47.2 ± 1.2	66.5 ± 1.2	54.1 ± 0.2

Table 4: Ex.Match and Ex.Acc results on the dev and test set of WTQ. + BERT means using BERT to enhance encoder. $^\heartsuit$ means the model uses extra schema linking supervision. Both are the same for Table 5.

4.2 Experimental Setup

Datasets and Evaluation We conduct experiments on two text-to-SQL benchmarks: WikiTableQuestions(WTQ) (Pasupat and Liang, 2015)[5] and Spider (Yu et al., 2018b). Following previous work, we employ three kinds of evaluation metrics: *Exact Match* (Ex.Match), *Exact Set Match* (Ex.Set) and *Execution Accuracy* (Ex.Acc). Ex.Match evaluates the predicted SQL correctness by checking if it is equal to the ground-truth, while Ex.Set evaluates the structural correctness by checking the set match of each SQL clause in the predicted query with respect to the ground-truth. Ex.Acc evaluates the functional correctness of the predicted SQL by checking whether it yields the ground-truth answer.

---

[5] Note that the original WTQ only contains answer annotations, and here we use the version with SQL annotations provided by Shi et al. (2020). Our training data is a subset of the original train set, while the test data keeps the same.

Model	Dev	Test
GlobalGNN + BERT (Bogin et al., 2019)	52.7	47.4
EditSQL + BERT (Zhang et al., 2019)	57.6	53.4

IRNet v2 + BERT (Guo et al., 2019)	63.9	55.0
BRIDGE + BERT (Lin et al., 2020)	65.5	59.2
BRIDGE + BERT$_L$ (Lin et al., 2020)	70.0	65.0
RATSQL + BERT$_L$ (Wang et al., 2020a)	69.7	**65.6**
SLSQL$_P$ + BERT	57.4	-
SLSQL$_P$ + BERT$_L$	61.0	-
ETA + BERT	64.5	59.5
ETA + BERT$_L$	**70.8**	65.3
SLSQL + BERT$^{\heartsuit}$	60.8	55.7
SLSQL + BERT$_L$$^{\heartsuit}$	65.1	-
SLSQL + BERT (Oracle)$^{\heartsuit}$	72.4	-

Table 5: Ex.Set results on the dev and test set of Spider.

Baselines On WTQ, our baselines include ALIGN$_P$ and ALIGN, where the former is a vanilla attention based sequence to sequence model and the latter enhances ALIGN$_P$ with an additional schema linking task (Shi et al., 2020). Similarly, on Spider, our main baselines are SLSQL$_P$ and its schema linking enhanced version SLSQL (Lei et al., 2020). SLSQL$_P$ is made up of a question encoder and a two-step SQL decoder. In the first decoding step, a coarse SQL (i.e., without aggregation functions) is generated. Then the coarse SQL is used to synthesize the final SQL in the second decoding step. Here we also report the performance of SLSQL + BERT (Oracle), where the learnable schema linking module is replaced with human annotations in inference. It represents the maximum potential benefit of schema linking for the text-to-SQL task. Meanwhile, for a comprehensive comparison, we also compare our model with state-of-the-art models on the Spider benchmark[6]. We refer readers to their papers for details.

Implementation As for our approach, on WTQ, we employ ALIGN$_P$[7] as our base parser, while on Spider we select SLSQL$_P$[8] as our base parser. For both parsers, we try to follow the same hyperparameters as described in the paper to reduce other factors that may affect the performance. More implementation details can be found in §C.2.

4.3 Experimental Results

Table 4 and Table 5 show the experimental results of several methods on WTQ and Spider respectively. As observed, introducing ETA dramatically improves the performance of both base parsers, demonstrating its effectiveness on downstream tasks. Taking Spider as an illustration, our model ETA + BERT boosts SLSQL$_P$ + BERT by an absolute improvement 7.1% on the Ex.Set metric. As the PLM becomes larger (e.g., BERT$_L$), the improvement becomes more significant, up to 9.8%. Compared with state-of-the-art methods, our model ETA + BERT$_L$ also obtains a competitive performance, which is extremely impressive since it is based on a simple parser.

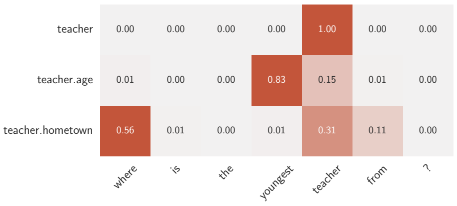

Figure 5: The latent grounding produced by ETA + BERT$_L$ for the question "*Where is the youngest teacher from?*".

More interestingly, on both datasets, our model can achieve similar even better performance compared to methods which employ extra grounding supervision. For instance, in comparison with SLSQL + BERT on Spider, our ETA + BERT outperforms it by 3.7%. Taking into account that SLSQL utilizes additional supervision, the performance gain is very surprising. We attribute the gain to two possible reasons: (1) The PLMs already learn latent grounding which is understandable to human experts. (2) Compared with training with strong schema linking supervision, training with weak supervision alleviates the issue of exposure bias, and thus enhance the generalization ability of ETA.

Table 6 presents the model predictions of ETA + BERT$_L$ on three real cases. As observed, ETA has learned the grounding about adjective (e.g., oldest → age), entity (e.g., where → hometown) and semantic matching (e.g., registered → student_enrolment). Meanwhile, grounding pairs provide us a useful guide to better understand the model predictions. Figure 5 visualizes the latent grounding for Q2 in Table 6, and more visualization can be found in §D.

els. According to the knowledge category, there are mainly two kinds of methods: one focuses on syntactic knowledge and the other pays attention to semantic knowledge. Under the category of syntactic knowledge, several work showed that BERT embeddings encoded syntactic information in a structural form and can be recovered (Lin et al., 2019b; Warstadt and Bowman, 2020; Hewitt and Manning, 2019; Wu et al., 2020). However, recent work also showed that BERT did not rely on syntactic information for downstream task performance, and thus doubted the role of syntactic knowledge (Ettinger, 2020; Glavas and Vulic, 2020). As for semantic knowledge, although it is less explored than syntactic knowledge, previous work showed that BERT contained some semantic information, such as entity types (Ettinger, 2020), semantic roles (Tenney et al., 2019) and factual knowledge (Petroni et al., 2019). Different from the above work, we focus on the grounding capability, an under-explored branch of language semantics.

Our work is also closely related to entity linking and schema linking, which can be viewed as subareas of grounding on specific scenarios. Given an utterance, entity linking aims at finding all mentioned entities in it using a knowledge base as candidate pool (Tan et al., 2017; Chen et al., 2018; Li et al., 2020a), while schema linking tries to find all mentioned schemas related to specific databases (Dong et al., 2019; Lei et al., 2020; Shi et al., 2020). Previous work generally either employed full supervision to train linking models (Li et al., 2020a; Lei et al., 2020; Shi et al., 2020), or treated linking as a minor pre-processing(Yu et al., 2018a; Guo et al., 2019; Lin et al., 2019a) and used heuristic rules to obtain the result. Our work is different from them since we optimize the linking model with weak supervision from downstream signals, which is flexible and practicable. Similarly, Dong et al. (2019) utilized downstream supervision to train their linking model. Compared with them using policy gradient, our method is more efficient since it directly learns the grounding module using pseudo alignment as supervision.

6 Conclusion & Future Work

In summary, we propose a novel weakly supervised approach to awaken latent grounding from pretrained language models via erasing. Only with downstream signals, our approach can induce latent grounding from pretrained language models which is understandable to human experts. More importantly, we demonstrate that our approach could be applied to off-the-shelf text-to-SQL parsers and significantly improve their performance. For future work, we plan to extend our approach to more downstream tasks such as visual question answering. We also plan to utilize our approach to improve the error locator module in existing interactive semantic parsing systems (Li et al., 2020b).

Acknowledgement

We would like to thank all the anonymous reviewers for their constructive feedback and useful comments. We also thank Tao Yu and Bo Pang for evaluating our submitted models on the test set of Spider. The first author Qian is supported by the Academic Excellence Foundation of Beihang University for PhD Students.

Ethical Considerations

This paper conducts experiments on several existing datasets covering the areas of entity linking, schema entity and text-to-SQL. All claims in this paper are based on the experimental results. Every experiment can be conducted on a single Tesla P100 or P40 GPU. No demographic or identity characteristics information is used in this paper.

A Evaluation Details

A.1 Schema Linking

Let Ω_{col} be a set $\{(c, q)_i | 1 \leq i \leq N\}$ which contains N gold (column-question token) tuples. Let $\overline{\Omega}_{col}$ be a set $\{(\overline{c}, \overline{q})_j | 1 \leq j \leq M\}$ which contains M predicted (column-question token) tuples. We define the precision(Col$_P$), recall(Col$_R$), F1-score(Col$_F$) as:

$$\frac{|\Gamma_{col}|}{|\overline{\Omega}_{col}|}, \frac{|\Gamma_{col}|}{|\Omega_{col}|}, \frac{2\mathrm{Col}_P\mathrm{Col}_R}{\mathrm{Col}_P + \mathrm{Col}_R}$$

where $\Gamma_{col} = \Omega_{col} \bigcap \overline{\Omega}_{col}$. The definitions of Tab$_P$, Tab$_R$, Tab$_F$ are similar. Note that the result reported in Table 8 of Shi et al. (2020) use a different evaluation metrics. Here we re-evaluate their model by the above mentioned metrics for fair comparison.

A.2 Entity Linking

Let $\Omega = \{(e, [q_s, q_e])_i | 1 \leq i \leq N\}$ be the gold entity-mention set and $\overline{\Omega} = \{(\overline{e}, [\overline{q_s}, \overline{q_e}])_j | 1 \leq j \leq M\}$ be the predicted entity-mention set, where e is the entity, q_e, q_s are the mention boundaries in the question q. In the weak matching setting, a prediction is correct only if the ground-truth entity is identified and the predicted mention boundaries overlap with the ground-truth boundaries. Therefore, the True-Positive prediction set is defined as:

$$\begin{aligned} \Gamma = \{e | (e, [q_s, q_e]) \in \Omega, (e, [\overline{q_s}, \overline{q_e}]) \in \overline{\Omega}, \\ [q_s, q_e] \bigcap [\overline{q_s}, \overline{q_e}] \neq \emptyset\}. \end{aligned}$$

The corresponding precision(Ent$_P$), recall(Ent$_R$) and F1(Ent$_F$) are:

$$\frac{|\Gamma|}{|\overline{\Omega}|}, \frac{|\Gamma|}{|\Omega|}, \frac{2\mathrm{Ent}_P\mathrm{Ent}_R}{\mathrm{Ent}_P + \mathrm{Ent}_R}$$

B Dataset Statistic

All details of datasets used in this paper are shown in Table 7.

C Implementation Details

For all experiments, we employ the AdamW optimizer and the default learning rate schedule strategy provided by Transformers library (Wolf et al., 2020).

C.1 Experiments on Grounding

SQUALL We use uncased BERT-base as the encoder. The learning rate is 3×10^{-5}. The training epoch is 50 with a batch size of 16. The dropout rate and the threshold τ are set to 0.3 and 0.2 respectively. The training process lasts 6 hours on a single 16GB Tesla P100 GPU.

SPIDER-L We implement two versions: uncased BERT-base and uncased BERT-large. For both versions, the learning rate is 5×10^{-5} and the training epoch is 50. For BERT-base (BERT-large) version, the batch size and gradient accumulation step are set to 12 (6) and 6 (4). The dropout rate and the threshold τ are set to 0.3 and 0.2 respectively. As for training time, BERT-base (BERT-large) version is trained on a 24GB Tesla P40 and it takes about 16 (48) hours to finish the training process.

WebQSP$_{\text{EL}}$& GraphQ$_{\text{EL}}$ Due to the large amount of entity candidates, we first use the candidate retrieval method proposed in (Sorokin and Gurevych, 2018) to reduce the number of candidates. After that, we still can not feed all candidates along with the question due to the maximum encoding length of BERT. Therefore, we divide the candidates into multiple chunks and feed each chunk (along with the question) into BERT sequentially.

In implementation, we use uncased BERT-base as the encoder. The learning rate is 1×10^{-5} The training epoch is 50 with a batch size of 16. The dropout rate and the threshold τ are set to 0.3 and 0.3 respectively. The training procedure finishes within 10 hours on a single Tesla M40 GPU.

C.2 Experiments on Text-to-SQL

For experiments of the text-to-SQL task, we employ the official code released along with Shi et al. (2020) (on WTQ) and Lei et al. (2020) (on Spider). When coupling ETA with these models, we first produce a one-hot grounding matrix derived by grounding pairs and then feed it into them as described in §4.

WTQ We use uncased BERT-base as the encoder. The training epoch is 50 with a batch size of 8. The learning rate is 1×10^{-5} for the BERT module and 1×10^{-3} for other modules. The dropout rate is set to 0.2. The training process finishes within 16 hours on a single 16GB Tesla P100 GPU.

Meanwhile, we follow the previous work (Shi et al., 2020) to employ 5-fold cross-validation, and

Dataset	Train		Dev		Test	
	#Q	#C	#Q	#C	#Q	#C
SQUALL	9,030	19,185	2,246	4,774	–	–
SPIDER-L	7,000	28,848	1,034	4,360	–	–
WTQ	9,030	–	2,246	–	4,344	–
Spider	7,000	–	1,034	–	2,147	–
WebQSP$_{\mathrm{EL}}$	2,974	3,242	–	–	1,603	1,806
GraphQ$_{\mathrm{EL}}$	2,089	2,253	–	–	2,075	2,229

Table 7: Statistics for all datasets used in our experiments. For SQUALL and WTQ, we only show the size of Split-0, and details of other splits can be found in Table 8. #Q represents the number of questions, #C represents the number of concepts.

Split	Train	Dev
0	9,030	2,246
1	9,032	2,244
2	9,028	2,248
3	8,945	2,331
4	9,069	2,207

Table 8: The size of train set and dev set of five splits on SQUALL and WTQ.

Split	Dev		Test
	Ex.Match	Ex.Acc	Ex.Acc
0	45.10	64.43	53.57
1	47.39	67.01	54.17
2	47.24	65.93	53.61
3	45.99	65.72	53.41
4	52.38	69.73	52.41

Table 9: The experimental results of all splits on WTQ.

experimental results of all five splits on WTQ using ETA + BERT are shown in Table 9.

Spider We implement two versions: uncased BERT-base and uncased BERT-large. For BERT-base (BERT-large), the learning rate is 1.25×10^{-5} (6.25×10^{-6}) for the BERT module and 1×10^{-4} (5×10^{-5}) for other modules. The batch size and gradient accumulation step are set to 10 (6) and 5 (4) for BERT-base (BERT-large) version. The dropout rate is set to 0.3. As for training time, BERT-base (BERT-large) version is trained on a 24GB Tesla P40 and it takes about 36 (56) hours to finish the training process.

D Latent Grounding Visualization

Figure 6 and Figure 7 show the latent grounding visualization corresponding to examples in Table 6.

Abstract

In multi-label text classification (MLTC), each given document is associated with a set of correlated labels. To capture label correlations, previous classifier-chain and sequence-to-sequence models transform MLTC to a sequence prediction task. However, they tend to suffer from label order dependency, label combination over-fitting and error propagation problems. To address these problems, we introduce a novel approach with multi-task learning to enhance label correlation feedback. We first utilize a joint embedding (JE) mechanism to obtain the text and label representation simultaneously. In MLTC task, a document-label cross attention (CA) mechanism is adopted to generate a more discriminative document representation. Furthermore, we propose two auxiliary label co-occurrence prediction tasks to enhance label correlation learning: 1) Pairwise Label Co-occurrence Prediction (PLCP), and 2) Conditional Label Co-occurrence Prediction (CLCP). Experimental results on AAPD and RCV1-V2 datasets show that our method outperforms competitive baselines by a large margin. We analyze low-frequency label performance, label dependency, label combination diversity and coverage speed to show the effectiveness of our proposed method on label correlation learning. Our code is available at `https://github.com/EiraZhang/LACO`.

1 Introduction

Multi-label text classification (MLTC) is an important natural language processing task with applications in text categorization, information retrieval, web mining, and many other real-world scenarios (Zhang and Zhou, 2014; Liu et al., 2020). In MLTC, each given document is associated with a set of labels which are often related statistically and semantically. Label correlations should be sufficiently utilized to build multi-label classification models with strong generalization performance (Tsoumakas et al., 2009; Gibaja and Ventura, 2015). In particular, learning the dependencies between labels might be helpful in modeling the low-frequency labels, because real-world classification problems tend to exhibit *long-tail* label distribution, where low-frequency labels are associated with only a few instances and are difficult to learn (Menon et al., 2020).

Previous sequence-to-sequence (Seq2Seq) based methods (Nam et al., 2017; Yang et al., 2018) have been shown to have a powerful ability to capture label correlations with using the current hidden state of the model and the prefix label predictions. However, exposure bias phenomenon (Bengio et al., 2015) may cause the models overfit to the frequent label sequence in training set, thus lead to several problems. First, Seq2Seq-based methods heavily rely on a predefined ordering of labels and perform sensitively to the label order (Vinyals et al.; Yang et al., 2019; Qin et al., 2019). Actually, labels are essentially an order-independent set in the MLTC task. Second, the Seq2Seq-based methods suffer from low generalization ability problem since they tend to overfit the label combinations in the training set and have difficulty to generate the unseen label combination. Third, Seq2Seq-based methods rely on the previous potentially incorrect prediction results. The errors may propagate during the inference stage where true previous target labels are unavailable and are thus replaced by labels generated by the model itself.

To circumvent the potential issues mentioned above, we introduce a multi-task learning based approach that does not rely on Seq2Seq architecture. The approach contains a shared encoder, a MLTC task specific module and a label correla-

August 1–6, 2021.

tion enhancing module. In the shared parameter layers, we introduce a joint embedding (JE) mechanism which takes advantage of a transformer-based encoder to obtain document and label representation jointly. Correlations among labels are learned implicitly through the self-attention mechanism, which is different from previous label embedding methods (Wang et al., 2018; Xiao et al., 2019) that treat labels independently. In MLTC task specific module, we generate the label-specific document representation by the document-label cross attention (CA) mechanism, which retains discriminatory information. The shared encoder and the MLTC task specific module form the basic model called **LACO**, i.e. LAbel COrrelation aware multi-label text classification.

The co-occurrence relationship among labels is one of the important signal that can reflect label correlations explicitly, which can be obtained without additional manual annotation. In label correlation enhancing module, we propose two label co-occurrence prediction tasks, which are jointly trained with the MLTC task. The one is the *Pairwise Label Co-occurrence Prediction* (PLCP) task for capturing second-order label correlations through the two-by-two combinations to distinguish whether they appear together in the set of relevant labels. The other one is the *Conditional Label Co-occurrence Prediction* (CLCP) task for capturing high-order label correlations through a given partial relevant label set to predict the relevance of other unknown labels.

We conduct experiments on AAPD and RCV1-V2 datasets, and show that our method outperforms competitive baselines by a large margin. Comprehensive experimental results are provided to analysis low-frequency label performance, label dependency, label combination diversity and coverage speed, which are essential to measure the ability of label correlation learning. We highlight our contributions as follows:

1. We propose a novel and effective approach for MLTC, which not only sufficiently learns the features of documents and labels through the joint space, but also reinforces correlations through multi-task design without depending on the label order.

2. We propose two feasible tasks (PLCP and CLCP) to enhance the feedback of label correlations, which is beneficial to help induce the multi-label predictive model with strong generalization performance.

3. We compare our approach with competitive baseline models on two multi-label classification datasets and systematically demonstrate the superiority of the proposed models.

2 Related Work

Our work mainly relates to two fields of MLTC task: label correlation learning and document representation learning.

2.1 Label Correlation Learning

For MLTC task, a simple but widely used method is binary relevance (BR) (Boutella et al., 2004), which decomposes the MLC task into multiple independent binary classification problem without considering the correlations between labels.

To capture label correlations, label powerset (LP) (Tsoumakas and Katakis, 2007) take MLTC task as a multi-class classification problem by training a classifier on all unique label combinations. Classifier Chains (CC) based method (Read et al., 2011) exploits the chain rule and predictions from the previous classifiers as input. Seq2Seq architectures are proposed to transform MLTC into a label sequence generation problem by encoding input text sequences and decoding labels sequentially (Nam et al., 2017). However, both CC and Seq2Seq-based methods heavily rely on a predefined ordering of labels and perform sensitively to the label order. To tackle the label order dependency problem, various methods have been explored: by sorting heuristically (Yang et al., 2018), by dynamic programming (Liu and Tsang, 2015), by reinforcement learning (Yang et al., 2019), by multi-task learning (Tsai and Lee, 2020; Zhao et al., 2020). Different from these works, our method learns the label correlations through a non-Seq2Seq-based approach without suffering the above mentioned problems.

More recently, researchers have proposed a variety of label correlation modeling methods for MLTC that are not based on Seq2Seq architecture. Wang et al. (2020) propose a multi-label reasoner mechanism that employs multiple rounds of predictions, and relies on predicting multiple rounds of results to ensemble or determine a proper order, which is computationally expensive. CorNet-BertXML (Xun et al., 2020) utilizes BERT (Devlin et al., 2019) to obtain the joint representation of text and all candidate labels and extra exponential linear units (ELU) at the prediction layer to make use of label correlation knowledge. Different from the above works, we exploit extra label co-occurrence prediction tasks to explicitly model the label correlations in a multi-task framework.

2.2 Document Representation Learning

Text representation plays a significant role in text classification tasks. It is crucial to extract essential hand-crafted features for early models (Joachims, 1998). Deep neural network based MLTC models have achieved great success such as CNN (Kurata et al., 2016; Liu et al., 2017), RNN (Liu et al., 2016), CNN-RNN (Chen et al., 2017; Lai et al., 2015), attention mechanism (Yang et al., 2016; You et al., 2018; Adhikari et al., 2019) and etc. (Devlin et al., 2019) is an important turning point in the development of text classification task and it works by generating contextualized word vectors using Transformer. The reason why deep learning methods have become so popular is their ability to learn sophisticated semantic representations from text, which are much richer than hand-crafted features(Guo et al., 2020). However, these methods tend to ignore the semantics of labels while focusing only on the representation of the document.

Recently, label embedding is considered to improve multi-label text classification tasks. (Liu et al., 2017) is the first DNN-based multi-label embedding method that seeks a deep latent space to jointly embed the instances and labels. LEAM (Wang et al., 2018) applies label embedding in text classification, which obtains each label's embedding by its corresponding text descriptions. LSAN (Xiao et al., 2019) makes use of document content and label text to learn the label-specific document representation with the aid of self-attention and label-attention mechanisms. Our work differs from these works in that the goal of our work is to consider not only the relevance between the document and labels but also the correlations between labels.

3 Methodology

The framework of LACO is shown in Figure 1. The lower layers are shared across all tasks, while the top layers are task-specific. In this section, we first introduce the standard formal definition of MLTC. After that, we present the detailed technical implementation of LACO.

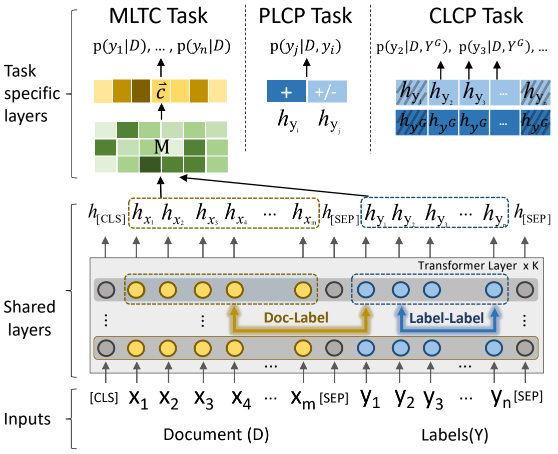

Figure 1: The framework of our proposed approach. Note that the shaded square in the CLCP task is the embedding of given labels, and $+$, $-$ represent related label and unrelated label respectively.

3.1 Problem Formulation

Multi-label task studies the classification problem where each single instance is associated with a set of labels simultaneously. Given a training set $S = \{(D_i, Y_i^+)|1 \leq i \leq N\}$ of multi-label text classification data, D_i is the text sequence and Y_i^+ is its corresponding labels. Specifically, a text sequence D of length m is composed of word tokens $D = \{x_1, x_2, ..., x_m\}$, and $Y = \{y_1, y_2, ..., y_n\}$ denote the label space consisting of n class labels. The aim of MLTC is to learn a predictive function $f : D \rightarrow 2^Y$ to predict the associated label set for the unseen text. For such, the model must optimize a loss function which ensures that the relevant and irrelevant labels of each training text are predicted with minimal misclassification.

3.2 Document-Label Joint Embedding (JE)

Following BERT (Devlin et al., 2019), the first token is always the [CLS] token. The output vector corresponding to the [CLS] token aggregates the features of the whole document and can be used for classification. Different from this habitual operation, we propose a novel input structure to directly use label information in constructing the token-level representations.

As shown in Figure 1, the inputs are packed by a sequence pair (D, Y), we separate the text sequence D and the label sequence Y with a special token [SEP]. Note that the label sequence is to concatenate all label tokens. The shared layers map the inputs into a sequence of embedding vectors, one for each token, called token-level representations. Formally, let $\{[CLS], x_1, ..., x_m, [SEP], y_1, ..., y_n, [SEP]\}$ be the input sequence of the encoder, we obtain the output contextualized token-level representations $\{h_{[CLS]}, h_{x_1}, ..., h_{x_m}, h_{[SEP]}, h_{y_1}, ..., h_{y_n}, h_{[SEP]}\}$. The input structure is designed to guarantee that words and labels are embedded together in the same space. With the joint embedding mechanism, our model could pay more attention to two facets: 1) The correlations between document and labels. Different document have different influences on a specific label, while the same document fragment may affect multiple labels. 2) The correlations among labels. The semantic information of labels is interrelated, and label co-occurrence indicates strong semantic correlations between them.

3.3 Multi-Label Text Classification

In this subsection, we introduce the MLTC task specific module, including *Document-Label Cross Attention* (CA) and *Label Predication*.

3.3.1 Document-Label Cross Attention (CA)

To explicitly model the semantic relationship between each word and label token, we measure the compatibility of label-word pairs via dot product:

$$M = H_D H_Y^T \tag{1}$$

where $H_D = [h_{x_1}, ..., h_{x_m}]$ is the text sequence embedding, $H_Y = [h_{y_1}, ..., h_{y_n}]$ is the label sequence embedding and $M \in \mathcal{R}^{m \times n}$. Considering the semantic information among consecutive words, we further generalize M through non-linearity network. Specifically, for a text fragment of length $2r + 1$ centered at i, the local matrix block $M_{i-r;i+r}$ in M measures the correlation for the label-phrase pairs. To improve the effectiveness of the sparse regularization, we use CNN with ReLU activation in the hidden layers, and perform max-pooling and hyperbolic tangent sequentially in the function Ω:

$$\overrightarrow{c} = \Omega(M_{i-r;i+r}) \cdot H_D \tag{2}$$

Note that the final document representation $\overrightarrow{c}$ is generated by aggregation of word representations H_D, and weighted by the label-specific attention vector $\Omega(\cdot)$.

3.3.2 Label Predication

Once having the discriminative document representation, we build the multi-label text classifier via a fully connected layer that captures more fine-grained features from different regions of the document:

$$\overrightarrow{p} = sigmoid(W_1 \overrightarrow{c}^T + b_1) \tag{3}$$

where $W_1 \in \mathcal{R}^{n \times k}$ and $b_1 \in \mathcal{R}^n$. We use Binary Cross Entropy as the loss function for the multi-label classification problem:

$$\mathcal{L}_{mlc} = -\sum_{i=1}^{n} [q_i \ln p_i + (1 - q_i) \ln(1 - p_i)] \tag{4}$$

where $p_i = P(y_i|D)$ is the probability of y_i predicted by the model, and $q_i \in \{0, 1\}$ is the categorical information of y_i. We train the model by minimizing the cross-entropy error.

3.4 Multi-Task Learning with Label Correlations

In this subsection, we introduce two auxiliary tasks, *Pairwise Label Co-occurrence Prediction* (PLCP) and *Conditional Label Co-occurrence Prediction* (CLCP), to explore the second-order and high-order label relationships, respectively.

3.4.1 PLCP Task

Suppose that each document D contains the corresponding label set Y^+ and the uncorresponding label set Y^-. In order to train the model to understand second-order label relationships, we propose a binarized label-pair prediction task named as PLCP that can be trivially generated from the multi-label classification corpus. The strategy of selecting label pairs for co-occurrence prediction is straightforward. One part is sampled only from Y^+, which is marked as *IsCo-occur*, and the other part is sampled from Y^+ and Y^-, respectively, which is marked as *NotCo-occur*. To construct the manual training dataset, we empirically set the ratio of *IsCo-occur* and *NotCo-occur* to γ. As Figure 1 shows, we concat the embedding of the two labels $[y_i, y_j]$ together as the input features. The additional binary classifier is used to predict whether the state of the two labels is *IsCo-occur* or *NotCo-occur*. The loss function is as followed:

$$\mathcal{L}_{plcp} = -[q_{ij} \ln p_{ij} + (1 - q_{ij}) \ln(1 - p_{ij})] \tag{5}$$

where $p_{ij} = p(y_j|D, y_i)$ denotes the output probability of the the co-occurrance of the label-pair, and q is the ground-truth where $q_{ij} = 1$ means *IsCo-occur* and $q_{ij} = 0$ means *NotCo-occur*.

3.4.2 CLCP Task

To further learn the high-order label relationships, we propose the conditional label co-occurrence prediction (CLCP) task. We first randomly pick s labels from Y^+ to form Y^G, i.e. $Y^G \subseteq Y^+$, and then predict whether the remaining labels of Y are relevant with them. Specifically, we introduce an additional position vector $E_Y = [e_{y_1}, ..., e_{y_n}]$, where $e_{y_i} = 0$ indicates that y_i at that position is the sampled label, i.e. $y_i \in Y^G$, and $e_{y_i} = 1$ indicates $y_i \in Y - Y^G$. The average of the embedding of the zero-position labels h_{y^G} is concatenated to each nonzero-position label embedding as the input features to predict whether each of remaining labels should be co-occurrence when knowing the sampled labels. In Figure 1, $p(y_i|D, Y^G)$ denotes the probability of y_i predicated by the additional sigmoid classifier. The loss for the classification is the sum of binary cross-entropy loss of each nonzero-position:

$$\mathcal{L}_{clcp} = -\sum_{i=1}^{n-s}[q_i \ln p_i + (1 - q_i)\ln(1 - p_i)] \quad (6)$$

where $q_i \in \{0, 1\}$ is the ground-truth to denote whether the label y_i should be co-occurrence with Y^G, and $p_i = p(y_i|D, Y^G)$ is the output probability of each masked label y_i.

3.4.3 Training Objectives

The same inputs are first fed into the shared layers, then each sub-task module takes the contextualized token-level representations generated by joint embedding and produces a probability distribution for its own target labels. The overall loss can be calculated by:

$$\mathcal{L} = \mathcal{L}_{mlc} + \alpha\mathcal{L}_{plcp} + (1 - \alpha)\mathcal{L}_{clcp} \quad (7)$$

where α is a hyperparameter in (0, 1), $\mathcal{L}_{plcp}$ and $\mathcal{L}_{clcp}$ are task-specific Cross-Entropy loss for PLCP task and CLCP task, respectively. [1]

4 Experimental Setup

4.1 Datasets

We validate our proposed model on two multi-label text classification datasets: **Arxiv Academic Paper Dataset (AAPD)** (Yang et al., 2018) collected 55,840 abstracts of papers in the field of computer science, which is organized into 54 related topics. In AAPD dataset, each paper is assigned multiple topics. **Reuters Corpus Volume I (RCV1-V2)** (Lewis et al., 2004) is composed of 804,414 manually categorized newswire stories for research purposes. Each story in the dataset can be assigned multiple topics, and there are 103 topics in total.

Dataset	$\lvert\mathcal{D}\rvert$	$\lvert Y\rvert$	$\overline{\lvert D_i\rvert}$	$\overline{\lvert Y_i^+\rvert}$
AAPD	55,840	54	163.42	2.41
RCV1-V2	804,414	103	123.94	3.24

Table 1: Statistics of datasets. Here, $|\mathcal{D}|$ and $|Y|$ denote the total number of documents and labels. $\overline{|D_i|}$ is the average length of all documents. $\overline{|Y_i^+|}$ means the average number of labels associated with the document.

Tabel 1 shows statistics of datasets. Each dataset is divided into a training set, a validation set, and a test set. We followed the division of these two datasets by Yang et al. (2018).

4.2 Evaluation Metrics

Multi-label classification can be evaluated with a group of metrics, which capture different aspects of the task (Zhang and Zhou, 2014). Following the previous works (Yang et al., 2018; Tsai and Lee, 2020), we adopt hamming loss, Micro/Macro-F1 scores as our main evaluation metrics. Micro/Macro-P and Micro/Macro-R are also reported to assist analysis. A Macro-average will treat all labels equally, whereas a Micro-average will weighted compute each label by its frequency.

4.3 Comparing Algorithms

We adopt a various of methods as baselines, which can be divided into two groups according to whether the label correlations are considered.

The first group of approaches do not consider label correlations. Binary Relevance (BR) (Boutella et al., 2004) amounts to independently training one binary classifier (linear SVM) for each label. CNN (Kim, 2014) utilizes multiple convolution kernels to extract text features and then output the probability distribution over the label space. LEAM (Wang et al., 2018) involves label embedding to obtain a more discriminative text representation in text classification. LSAN (Xiao et al., 2019) learns the label-specific text representation with the help of attention mechanisms. We also implement a BERT (Devlin et al., 2019) classifier which first encodes a document into vector space and then outputs the probability for each label independently.

---

[1] We also implement it with three tasks together. Since the two auxiliary tasks have the similar goal, there is no performance gain.

Table 2: Predictive performance of each comparing algorithm on two datasets. Hamming Loss (HL), Micro (Mi-) and Marco (Ma-) average Precision (P), Recall (R), F1-Score (F1) are used as evaluation metrics. The ↓ represents the lower score the better performance, and the ↑ is the opposite. Models with † denote for its results are quoted from previous papers. Models with ♣ are the Seq2Seq-based models.

The second group of methods consider label correlations. Classifier Chains (CC) (Read et al., 2011) transforms the MLTC problem into a chain of binary classification problems. SGM (Yang et al., 2018) proposes the Seq2Seq model with global embedding mechanism to capture label correlations. Seq2Set (Yang et al., 2019) presents deep reinforcement learning to improve the performance of the Seq2Seq model. We also implement a Seq2Seq baseline with 12-layer transformer, named with Seq2Seq$_T$. More recently, OCD (Tsai and Lee, 2020) proposes a framework including one encoder and two decoders for MLTC to alleviate exposure bias. ML-Reasoner (Wang et al., 2020) employs a binary classifier to predict all labels simultaneously and applies a novel iterative reasoning mechanism. Besides, we also provide another strong baseline: SeqTag$_{Bert}$ transforms multi-label classification task into sequential tagging task, which first obtain embeddings of each label (H_Y in Sec 3.3) by our shared encoder and then output a probability for each label sequentially by a BiLSTM-CRF model (Huang et al., 2015).

Results of BR, CNN, CC, SGM, Seq2Set, OCD and ML-R are cited in previous papers and results of other baselines are implemented by us. All algorithms follow the same data division.

4.4 Experimental Setting

We implement our model in Tensorflow and run on NVIDIA Tesla P40. We fine-tune models on the English base-uncased versions of BERT [2]. The batch size is 32, and the maximum total input sequence length is 320. The window size of the additional layer is 10, and we set γ as 0.5. We use Adam (Kingma and Ba, 2015) with learning rate of 5e-5, and train the models by monitoring Micro-F1 score on the validation set and stopping the training if there is no increase in 50,000 consecutive steps.

5 Results and Analysis

In this section, we report the main experimental results of the baseline models and the proposed method on two text datasets. Besides, we analyze the performance on different frequency labels, and further evaluate whether our method effectively learns the label correlations through label-pair confidence distribution learning and label combination prediction. Finally, we give a detailed analysis of the convergence study which demonstrates the generalization ability of our method.

5.1 Experiment Results

We report the experimental results of all comparing algorithms on two datasets in Table 2. The first block includes methods without learning label correlations. The second block is the methods considering label correlations, and the third block is our proposed LACO methods. As shown in Table 2, the LACO-based models outperform all

Model	AAPD HL	AAPD Mi-F1	RCV1-V2 HL	RCV1-V2 Mi-F1
BERT	9.39e-09	3.80e-10	4.95e-04	3.67e-08
SeqTag$_{Bert}$	7.76e-16	1.86e-07	4.95e-04	3.67e-08

Table 3: Statistical analysis results. The P-values of LACO on significant test comparing with the two strong baselines BERT and SeqTag$_{Bert}$.

baselines by a large margin in the main evaluation metrics. The following observations can be made according to the results:

- Our basic model LACO training only by the MLTC task significantly improves previous results on hamming loss and Micro-F1. Specifically, on the AAPD dataset, comparing to Seq2Set which considers modeling the label correlations, our basic model decreases by 13.8% on hamming loss and improves by 5.67% on Micro-F1. Comparing with the label embedding method like LSAN, LACO achieves a reduction of 4.00% hamming loss score and an improvement of 0.69% Micro-F1 score on the RCV1-V2 dataset. Also, BERT is still a strong baseline, which shows that obtaining a high-quality discriminative document representation is important for the MLTC task. Here, we train the LACO with 3 random seeds and calculate the mean and the standard deviation. We perform a significant test with LACO and the two strong baselines BERT and SeqTag$_{Bert}$ in Table 3. Comparing with the two strong baseline models, all of the P-values of LACO are below the threshold ($p < 0.05$), suggesting that the performance is statistically significant. In addition, we implement Friedman test (Demšar, 2006) for hamming loss and Micro-F1 metrics. The Friedman statistics F_F for hamming loss is 7.875 and for Micro-F1 is 6.125, when the corresponding critical value is 2.8179 (# comparing algorithms $k = 12$, # datasets $N = 2$). As a result, the null hypothesis of indistinguishable performance among the compared algorithms is clearly rejected at 0.05 significance level.
- Compared with SGM, Seq2Seq$_T$ does not achieve significantly improvements, but SeqTag$_{Bert}$ shows good performance based on the shared Transformer encoder between document and labels. Notably, the result of SeqTag$_{Bert}$ on Micro-F1 is comparable to BERT, but the result on Macro-F1 is observably higher. The above illustrates that label correlation information is more important for learning low frequency labels.

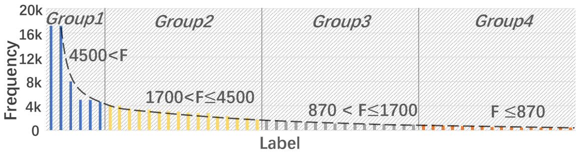
Table 4: Ablation over the proposed joint embedding (JE) and cross attention (CA) mechanisms using the LACO model on AAPD and RCV1-V2 datasets.

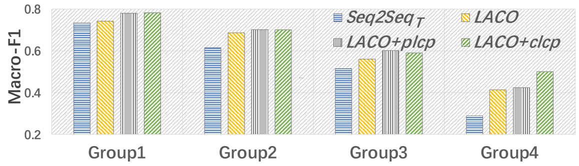
- As for the results of the multi-task learning methods, the two subtasks introduced by our method have a certain degree of improvement on the main metrics of the two datasets. Specifically, we observe that the PLCP task shows better performance and presents the best score of 74.9 on Micro-F1 for AAPD dataset, while the CLCP task presents the best performance on Micro-F1 for RCV1-V2 dataset as 88.5. Furthermore, the proposed multi-task framework shows great improvements than the basic model LACO on Macro-F1, which demonstrates that the performance on low-frequency labels can be greatly improved through our label correlation guided subtasks. There are more detailed analysis in Section 5.3 and 5.5. Notably, the CLCP task performs better on Marco-F1 by considering the high-order correlations. We also implement the experiment using the losses of three tasks together, while the combination of the two subtasks can not further improve the model performance comparing to LACO$_{+plcp}$ or LACO$_{+clcp}$, which we consider is due to the strong relevance between the two tasks.

5.2 Ablation Study

In this section, we will demonstrate the effectiveness of two cores of the proposed LACO model, that is a document-label joint embedding (JE) mechanism, and a document-label cross attention (CA) mechanism. Note that, the setting of **w/o JE & CA** is equivalent to the BERT baseline in Tabel 2, which encode document only and predict the probability for each label based on [CLS]. In the **w/o JE** setting, document embedding is encoded by BERT while each label embedding is a learnable random initialized vector. Its label prediction layer is the same with LACO. In the **w/o CA** setting, document and label embedding are obtained by BERT jointly, and probability for each label is predicted based on [CLS]. Tabel 4 shows that JE and CA are both important to obtain a more discriminative text rep-



(a) The label distribution of AAPD



(b)Macro-F1 for the four groups on AAPD

Figure 2: Label classification performance on different frequency distributions. Subfigure(a) shows the label frequency distribution of each label on AAPD training set. Subfigure(b) illustrates the Macro-F1 performance of different methods in the four groups.

resentation. After removing JE and CA mechanism, the performance drops more in the AAPD dataset than RCV1-V2 dataset. We believe that is mainly due to the less of training instance in AAPD, which is more difficult to learn relevant features especially for those low-frequency labels.

5.3 Low-frequency Label Performance

Figure 2(a) illustrates the label frequency distribution on AAPD training set, which is a typical big-head-long-tail distribution. We divide all the labels into four groups according to the frequency, the big-head group (Group1), the high-frequency group (Group2), the middle-frequency group (Group3), and the low-frequency group (Group4). As shown in Figure 2(b), we find the performance of all methods decreases with the label frequency of occurrence. The performance gap between Seq2Seq$_T$ and LACO based methods increases as the frequency decreases, especially in Group 4, LACO$_{+clcp}$ achieves a 74.5% improvement comparing to the Seq2Seq$_T$ model, which demonstrates that the performance on low-frequency labels can be enhanced by the conditional label co-occurrence prediction task.

5.4 Label Correlation Analysis

The co-occurrence relationship between labels is one of the important aspects that can reflect label correlation. In this experiment, we utilize the conditional probability $p(y_b|y_a)$ between label y_a and y_b to represent their dependency quantitatively. Furthermore, we calculate the Conditional Kullback-Leibler Divergence of $p(y_b|y_a)$ to measure the “distance” between model prediction distribution (P^p) and the ground-truth distribution on training/testing dataset (P^g). The score is calculate as:

	AAPD		RCV1-V2	
Model	**train**	**test**	**train**	**test**
Seq2Seq$_T$	**1.27**	1.30	0.08	0.94
SeqTag$_{Bert}$	1.40	1.28	0.09	0.95
LACO	1.40	1.27	0.09	0.94
LACO$_{+plcp}$	1.35	1.28	0.08	**0.76**
LACO$_{+clcp}$	1.32	**1.10**	0.08	0.91

Table 5: $KL(P^g||P^p)$ for different models on AAPD and RCV1-V2 datasets. Note that P^g is the ground truth distribution of datasets and P^p is the model distribution. Smaller scores indicate that two distributions are closer.

$$KL(P^g||P^p) = \sum_{y_a,y_b \in Y} (p^g(y_b|y_a) log \frac{p^g(y_b|y_a)}{p^p(y_b|y_a)}$$
$$p(y_b|y_a) = \#(y_a, y_b)/\#(y_a) \tag{8}$$

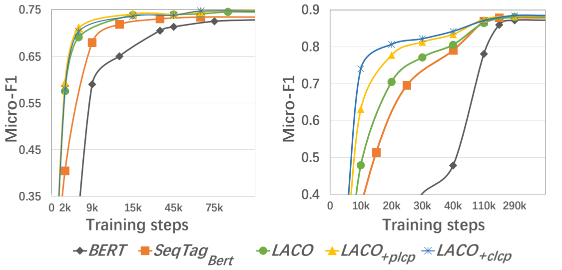
where # means the number of the single label or the label combination in the training/testing dataset. The KL-distances on the AAPD and RCV1-V2 datasets are shown in Table 5. On the testing set settings, we can find that LACO has much better fitting ability for the dependency relationship between labels, especially after introducing the co-occurrence relationship prediction task. The Seq2Seq$_T$ model achieves the lowest KL distance with training set on both AAPD and RCV1-V2 but achieve larger scores on the test set. This conclusion further proves that the Seq2Seq-based model is prone to over-fitting label pairs during training. It should be emphasized that this KL distance just quantify how much interdependence between label pairs the model have learned, but it cannot directly measure the prediction accuracy of the model.

5.5 Label Combination Diversity Analysis

Table 6 shows the number of different predicted label combinations (C_{Test}) and subset accuracy (Acc), which is a strict metric that indicates the percentage of samples that have all their labels classified correctly. Seq2Seq$_T$ produces fewer kinds of label combinations on the two datasets. As they tend to “remember” label combinations, the generated label sets are most alike, indicating a poor generalization ability to unseen label combinations. Because Seq2Seq$_T$ is conservative and only generates label combinations it has seen in the training set, it achieves high Acc values, especially on

Model	AAPD		RCV1-V2	
	C_{Test}	Acc	C_{Test}	Acc
Ground Truth	392	1.000	278	1.000
Seq2Seq$_T$	214	0.392	87	0.669
OCD†	302	0.403	-	-
SeqTag$_{Bert}$	289	0.410	187	0.637
LACO	315	0.425	241	0.642
LACO$_{+plcp}$	320	0.439	241	0.644
LACO$_{+clcp}$	321	0.427	239	0.660

Table 6: Statistics on the number of label combinations. C_{Test} is the number of different predicted label combinations. Acc is the subset accuracy on the testing set.



(a) Covergence speed of AAPD (b) Covergence speed of RCV1-V2

Figure 3: The convergence speed of five BERT-based methods. The x-axis refers to the training steps, and the y-axis refers to the Micro-F1 score performance.

RCV1-V2 dataset. For our models, they produce more diverse label combinations while obtaining good Acc since we do not regard multi-label classification as a sequence generation task that uses a decoder to model the relationship between labels. Instead, we learn the correlations among labels on the encoding side, and the scoring between labels does not interfere with each other, which leads to a higher probability of generating label combinations not seen during training than the Seq2Seq-based models.

5.6 Coverage Speed

The convergence speed of five BERT-based models are shown in Figure 3. Our basic model LACO outperforms other BERT-based models in terms of convergence speed, and the proposed multi-task mechanisms are able to enhance LACO to converge much faster. The main reason might be that the feature exchanging through multi-tasks accelerates the model to learn a more robust and common representation.

6 Conclusions and Future Work

In this paper, we propose a new method for MLTC based on document-label joint embedding and correlation aware multi-task learning. Experimental results show that our method outperforms competitive baselines by a large margin. Detailed analyses show the effectiveness of our proposed architecture using semantic connections between document-label and label-label, which helps to obtain a discriminative text representation. Furthermore, the multi-task framework shows strong capability on low-frequency label predicting and label correlation learning.

Considering the Extreme Multi-label Text Classification that contains an extremely large label set, LACO could be further exploited through scheduled label sampling, hierarchical label embedding strategy, and so on. We hope that further research could get clues from our work.

Abstract

Commonsense question answering (QA) requires a model to grasp commonsense and factual knowledge to answer questions about world events. Many prior methods couple language modeling with knowledge graphs (KG). However, although a KG contains rich structural information, it lacks the context to provide a more precise understanding of the concepts. This creates a gap when fusing knowledge graphs into language modeling, especially when there is insufficient labeled data. Thus, we propose to employ external entity descriptions to provide contextual information for knowledge understanding. We retrieve descriptions of related concepts from Wiktionary and feed them as additional input to pre-trained language models. The resulting model achieves state-of-the-art result in the CommonsenseQA dataset and the best result among non-generative models in OpenBookQA.

1 Introduction

One critical aspect of human intelligence is the ability to reason over everyday matters based on observation and knowledge. This capability is usually shared by most people as a foundation for communication and interaction with the world. Therefore, commonsense reasoning has emerged as an important task in natural language understanding, with various datasets and models proposed in this area (Ma et al., 2019; Talmor et al., 2018; Wang et al., 2020; Lv et al., 2020).

While massive pre-trained models (Devlin et al., 2018; Liu et al., 2019) are effective in language understanding, they lack modules to explicitly handle knowledge and commonsense. Also, structured data like knowledge graph is much more efficient in representing commonsense compared with unstructured text. Therefore, there have been multiple methods coupling language models with various forms of knowledge graphs (KG) for commonsense reasoning, including knowledge bases (Sap et al., 2019; Yu et al., 2020b), relational paths (Lin et al., 2019), graph relation network (Feng et al., 2020) and heterogeneous graph (Lv et al., 2020). These methods combine the merits of language modeling and structural knowledge information and improve the performance of commonsense reasoning and question answering.

However, there is still a non-negligible gap between the performance of these models and humans. One reason is that, although a KG can encode topological information between the concepts, it lacks rich context information. For instance, for a graph node for the entity "Mona Lisa", the graph depicts its relations to multiple other entities. But given this neighborhood information, it is still hard to infer that it is a painting. On the other hand, we can retrieve the precise definition of "Mona Lisa" from external sources, e.g. the definition of Mona Lisa in Wiktionary is "*A painting by Leonardo da Vinci, widely considered as the most famous painting in history*". To represent structured data that can be seamlessly integrated into language models, we need to provide a panoramic view of each concept in the knowledge graph, including its neighboring concepts, relations to them, and a definitive description of it.

Thus, we propose the DEKCOR model, i.e. DEscriptive Knowledge for COmmonsense question answeRing, to tackle multiple choice commonsense questions. Given a question and a choice, we first extract the contained concepts. Then, we extract the edge between the question concept and the choice concept in ConceptNet (Speer et al., 2017). If such an edge does not exist, we compute a relevance score for each knowledge triple (subject, relation, object) containing the choice concept, and select the one with the highest score. Next, we

---

[*] Equal contribution

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1201–1207
August 1–6, 2021.

retrieve the definition of these concepts from Wiktionary via multiple criteria of text matching. Finally, we feed the question, choice, selected triple and definitions into the language model ALBERT (Lan et al., 2019) to produce a score indicating how likely this choice is the correct answer.

We evaluate our model on CommonsenseQA (Talmor et al., 2018) and OpenBookQA (Mihaylov et al., 2018). On CommonsenseQA, it outperforms the previous state-of-the-art result by 1.2% (single model) and 3.8% (ensemble model) on the test set. On OpenBookQA, our model outperforms all baselines other than two large-scale models based on T5 (Raffel et al., 2019). We further conduct ablation studies to demonstrate the effectiveness of fusing context into the knowledge graph.

2 Related work

Several different approaches have been investigated for leveraging external knowledge sources to answer commonsense questions. Min et al. (2019) addresses open-domain QA by retrieving from a passage graph, where vertices are passages and edges represent relationships derived from external knowledge bases and co-occurrence. Sap et al. (2019) introduces the ATOMIC graph with 877k textual descriptions of inferential knowledge (e.g. if-then relation) to answer causal questions. Lin et al. (2019) projects questions and choices to the knowledge-based symbolic space as a schema graph. It then utilizes path-based LSTM to give scores. Feng et al. (2020) adopts the multi-hop graph relation network (MHGRN) to perform reasoning unifying path-based methods and graph neural networks. Lv et al. (2020) proposes to extract evidence from both structured knowledge base such as ConceptNet and Wikipedia text and conduct graph-based representation and inference for commonsense reasoning. Wang et al. (2020) employs GPT-2 to generate paths between concepts in a knowledge graph, which can dynamically provide multi-hop relations between any pair of concepts.

Several studies have utilized knowledge descriptions for different tasks. Yu et al. (2020a) uses description text from Wikipedia for knowledge-text co-pretraining. Xie et al. (2016) encodes the semantics of entity descriptions in knowledge graphs to improve the performance on knowledge graph completion and entity classification. Chen et al. (2018) co-trains the knowledge graph embeddings and entity description representation for cross-lingual entity alignment. Concurrent with our work, Chen et al. (2020) also insert knowledge descriptions into commonsense question answering. Compared with our work, the proposed method in Chen et al. (2020) is much more complex, e.g. involving training additional rankers on retrieved text, while our result outperforms Chen et al. on CommonsenseQA.

3 Method

3.1 Knowledge Retrieval

Problem formulation. In this paper, we focus on the following QA task: given a commonsense question q, select the correct answer from several choices $c_1, ..., c_n$. In most cases, the question does not contain any mentions of the answer. Therefore, external knowledge sources can be used to provide additional information. We adopt ConceptNet (Speer et al., 2017) as our knowledge graph $G = (V, E)$, which contains over 8 million entities as nodes and over 21 million relations as edges. In the following, we use triple to refer to two neighboring nodes and the edge connecting them, i.e. $(u \in V, p = (u, v) \in E, v \in V)$, with u being the subject, p the relation, and v the object.

Suppose the question mentions an entity $e_q \in V$ and the choice contains an entity $e_c \in V$[1]. We then employ the KCR method (Lin, 2020) to select relation triples. If there is a direct edge r from e_q to e_c in G, we choose this triple (e_q, r, e_c). Otherwise, we retrieve all the N triples containing e_c. Each triple j is assigned a score s_j which is the product of its triple weight w_j provided by ConceptNet and relation type weight t_{r_j}:

$$s_j = w_j \cdot t_{r_j} = w_j \cdot \frac{N}{N_{r_j}} \tag{1}$$

Here, r_j is the relation type of the triple j, and N_{r_j} is the number of triples among the retrieved triples that have the relation type r_j. In other words, this process favors rarer relation types. Finally, the triple with the highest weight is chosen.

3.2 Contextual information

The retrieved entities and relations from the knowledge graph are described by their surface form. Without additional context, it is hard for the language model to understand its exact meaning, especially for proper nouns.

---

[1] CommonsenseQA provides the question/choice entity. For OpenBookQA, we choose from the extracted entities that are most frequent in retrieved facts. See Appendix for details.

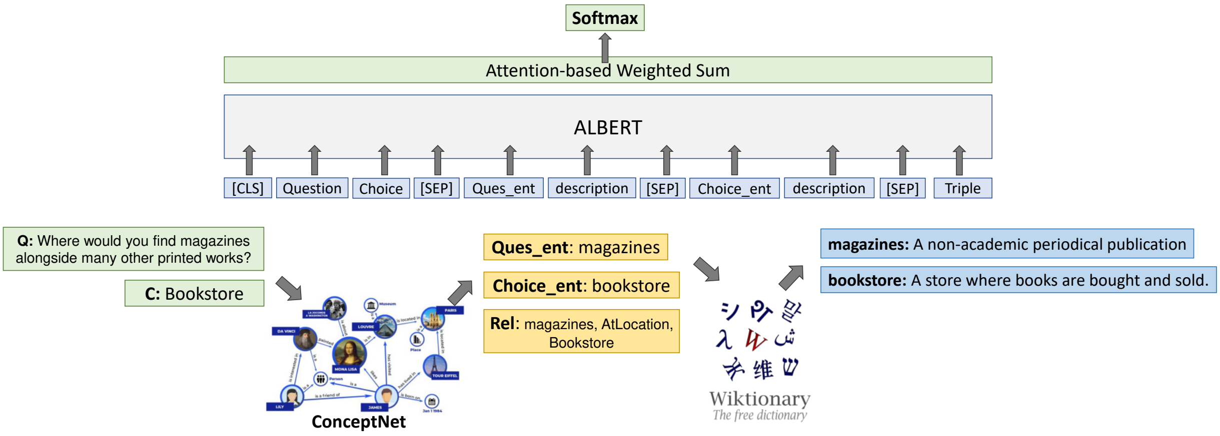

Figure 1: In our model, the input to ALBERT includes the question, choice, entity names, description text and triple. An attention-based weighted sum and a softmax layer process the output from ALBERT to produce the prediction.

Therefore, we leverage large-scale online dictionaries to provide definitions as context. We use a dump of Wiktionary[2] which includes definitions of 999,614 concepts. For every concept, we choose its first definition entry in Wiktionary as the description. For every question/choice concept, we find its closest match in Wiktionary by using the following forms in order: i) original form; ii) lemma form by Spacy (Honnibal and Montani, 2017); iii) base word (last word). For example, the concept "taking notes" does not appear in its original form in Wiktionary, but its lemma form "take notes" is in Wiktionary and we get its description text: "*To make a record of what one hears or observes for future reference*". In this way, we find descriptions of all entities in our experiments. The descriptions of the question and choice concept are denoted by d_q and d_c, respectively.

Finally, we feed the question, choice, descriptions and triple (from Section 3.1) into the ALBERT model (Lan et al., 2019) in the following format: [CLS] q c [SEP] e_q: d_q [SEP] e_c: d_c [SEP] triple.

3.3 Reasoning

On top of ALBERT, we leverage an attention-based weighted sum and a softmax layer to generate the relevance score for the question-choice pair. In detail, suppose the output representations of ALBERT is $(\boldsymbol{x}_0, ..., \boldsymbol{x}_m)$, where $\boldsymbol{x}_i \in R^d$. We compute a weighted sum of these embeddings based on attention:

Table 1: Statistics of CommonsenseQA (CSQA) and OpenBookQA (OBQA).

Dataset	Train	Dev	Test	Choices
CSQA	9,741	1,221	1,140	5
OBQA	4,957	500	500	4

$$q_i = \boldsymbol{u}^T \boldsymbol{x}_i \tag{2}$$

$$\alpha_i = \text{softmax}(q_i) \tag{3}$$

$$\boldsymbol{v} = \sum_{i=0}^{m} \alpha_i \boldsymbol{x}_i, \tag{4}$$

where $\boldsymbol{u}$ is a parameter vector. The relevance score between the question and the choice is then $s = \text{softmax}(\boldsymbol{v}^T \boldsymbol{b})$, where $\boldsymbol{b} \in R^d$ is a parameter vector and the softmax is computed over all choices for the cross-entropy loss function.

The architecture of our model DEKCOR and the construction of input is shown in Fig. 1.

4 Experiments

4.1 Datasets and baselines

We evaluate our model on two benchmark datasets of multiple-choice questions for commonsense question answering: CommonsenseQA (Talmor et al., 2018) and OpenBookQA (Mihaylov et al., 2018). CommonsenseQA creates questions from ConceptNet entities and relations; OpenBookQA probes elementary science knowledge from a book of 1,326 facts. The statistics of the datasets is provided in Table 1. For OpenBookQA, we follow prior approaches (Wang et al., 2020) to append top

5 retrieved facts provided by Aristo team (Clark et al., 2019) to the input. We also pre-train our OpenBookQA model on CommonsenseQA's training set as we find it helps to boost the performance.

We compare our models with state-of-the-art baselines, which all employ pre-trained models including RoBERTa (Liu et al., 2019), XLNet (Yang et al., 2019), ALBERT (Lan et al., 2019) and T5 (Raffel et al., 2019) and some adopt additional modules to process knowledge information. A detailed description of the baselines is in the Appendix.

4.2 Results

CommonsenseQA. Table 2 shows the accuracy on the test set of CommonsenseQA. For a fair comparison, we categorize the results into single models and ensemble models. Our ensemble model consists of 7 single models with different initialization random seeds, and its output is the majority of choices selected by these single models. More implementation details are shown in the Appendix.

Table 4: Ablation results on the dev sets of CommonsenseQA and OpenBookQA.

Methods	CSQA	OBQA
DEKCOR	84.7	82.2
Triple Only	82.0	80.0
Description Only	80.3	81.8
No Context	78.9	80.0

Our proposed DEKCOR outperforms the previous state-of-the-art result by 1.2% (single model) and 3.8% (ensemble model). This demonstrates the effectiveness of the usage of knowledge description to provide context.

Furthermore, we notice two trends based on the results. First, the underlying pre-trained language model is important in commonsense QA quality. In general, we observe this order of accuracy among these language models: BERT<RoBERTa<XLNet<ALBERT<T5. Second, the additional knowledge module is critical to provide external information for reasoning. For example, RoBERTa+KEDGN outperforms the vanilla RoBERTa by 1.9%, and our model outperforms the vanilla ALBERT model by 6.8% in accuracy.

OpenBookQA. Table 3 shows the test set accuracy on OpenBookQA. All results are from single models. Note that the two best-performing models, i.e. UnifiedQA (Khashabi et al., 2020) and TTTTT (Raffel et al., 2019), are based on the T5 generation model, with 11B and 3B parameters respectively. Thus, they are computationally very expensive. Except these T5-based systems, DEKCOR achieves the best accuracy among all baselines.

Ablation study. Table 4 shows that the usage of concept descriptions from Wiktionary and triple from ConceptNet can help improve the accuracy of DEKCOR on the dev set of CommonsenseQA by 2.7% and 4.4% respectively. We observe similar results on OpenBookQA. This demonstrates that additional context information can help with fusing knowledge graph into language modeling for commonsense question answering.

Case Study. Table 5 shows two examples from CommonsenseQA and OBQA respectively. In the first example, without additional description the model would not know relevant information about bats, like they are insectivorous, leading to the wrong answer "eating bugs". With the description, the model knows that bats eat bugs, so it chooses "laying eggs" as the answer. Similarly, for the sec-

CommonsenseQA Question:
Bats have many quirks, with the exception of ___ .
Question entity description:
bat: Any of the flying mammals of the order Chiroptera, usually small and nocturnal, insectivorous or frugivorous.

Model w/o description chooses: eating bugs
Model w/ description chooses: laying eggs

OBQA Question:
Alligators ___ .
Question entity description:
alligator: Either of two species of large amphibious reptile, ..., which have sharp teeth and very strong jaws...

Model w/o description chooses: eat gar
Model w/ description chooses: are warm-blooded

Table 5: Examples from CommonsenseQA and OBQA dataset showing the effectiveness of entity descriptions.

ond question, the "sharp teeth and very strong jaws" in the description hint that alligators are likely carnivorous, and reptiles are likely cold-blooded. The entity description leads to the correct answer of "eat gar".

5 Conclusions

In this paper, we propose to fuse context information into knowledge graphs for commonsense question answering. As a knowledge graph often lacks descriptions for the contained entities and relations, we leverage Wiktionary to provide definitive text for each entity as additional input to the pre-trained language model ALBERT. The resulting DEKCOR model achieves state-of-the-art results on the benchmark datasets CommonsenseQA and OpenBookQA. Ablation studies demonstrate the effectiveness of the proposed usage of knowledge description and knowledge triple information in commonsense question answering.

A Implementation Details

Identification of e_q and e_c. CommonsenseQA specifies the question entity in each question and each answer choice is also an entity in ConceptNet. We use them as e_q and e_c. For OpenBookQA, we identify all ConceptNet entities in the question and answer text and count their number of occurrences in the retrieved text. For a triple (e_q, r, e_c), we define its weight as $n_{e_q} + n_{e_c}$, where n_e is the number of occurrences in retrieved text. The edge with the largest weight is picked. If no edge is found between question and answer entities, we use the answer entity with the most occurrences to find triples. For Wiktionary descriptions, we find descriptions for e_q and e_c with the most occurrences as well.

Using ConceptNet. Since ConceptNet contains a lot of weak relations, we only use the following relations for our triples: CausesDesire, HasProperty, CapableOf, PartOf, AtLocation, Desires, HasPrerequisite, HasSubevent, Antonym, Causes.

Optimization. We use the AdamW (Loshchilov and Hutter, 2017) optimizer with a learning rate of 2e-5. The batch size is 8. We limit the maximum length of the input sequence to 192 tokens. The model is trained for 10 epochs. We use the Huggingface (Wolf et al., 2019) implementation for the ALBERT model.

B Baseline Methods

GraphReason (Lv et al., 2020) retrieves knowledge from both structured knowledge base and plain text.

PG-FULL (Wang et al., 2020) fine-tunes GPT-2 on ConceptNet to generate knowledgeable paths between knowledge graph concepts.

UnifiedQA (Khashabi et al., 2020) pre-trains T5 on a variety of QA datasets for general QA tasks.

MHGRN (Feng et al., 2020) adopts the multi-hop graph relation network to perform reasoning.

HyKAS (Ma et al., 2019) employs an option comparison network to consume ConceptNet triples.

ALBERT+KRD retrieves commonsense knowledge from Open Mind Common Sense and then uses a self-attention module to compute a weighted sum of these triple representations.

BERT + Selection (Banerjee et al., 2019) improves the result on OpenBookQA via abductive information retrieval , information gain based re-ranking, passage selection and weighted scoring.

ALBERT+KB also improves retrieval results on OpenBookQA by token-based and embedding-based retrieval. TTTTT (Raffel et al., 2019) fine-tunes the T5 language generation model on OpenBookQA.

Unsupervised Energy-based Adversarial Domain Adaptation for Cross-domain Text Classification

Abstract

Transferring knowledge from a label-rich domain (source domain) to a label-scarce domain (target domain) for pervasive cross-domain Text Classification (TC) is a non-trivial task. To overcome this issue, we propose EADA, a novel unsupervised energy-based adversarial domain adaptation framework. First, a deep pre-trained language model (e.g. RoBERTa) is leveraged as a shared feature extractor that maps the text sequences from both source and target domains to a feature space. Since the source features maintain good feature discriminability because of the full supervised training, we design a method that encourages target features towards the source ones via adversarial learning. An autoencoder is designed as an energy function that focuses on reconstructing source feature embeddings, while the feature extractor aims to generate source-like target feature embeddings to deceive the autoencoder. In this manner, the target feature embeddings become domain-invariant and inherit great discriminability. Extensive experiments on multi-domain sentiment classification (Amazon review dataset) and Yes/No question-answering classification (BoolQ and MARCO dataset) are conducted. The experimental results validate that EADA largely alleviates the domain discrepancy while maintaining excellent discriminability and achieves state-of-the-art cross-domain TC performance.

1 Introduction

With the booming development of Natural Language Processing (NLP) in recent years, text classification (TC) is playing a vital role in a myriad of services in our daily lives, such as online recommendations, email spam detection, sentiment classification and social media analysis. Large pre-trained language models, e.g. BERT (Devlin et al., 2019), XLNet (Yang et al., 2019) and RoBERTa (Liu et al., 2019b), achieve outstanding results on challenging NLP benchmarks, i.e. GLUE (Wang et al., 2018), RACE (Lai et al., 2017), and SQuAD (Rajpurkar et al., 2016). These models enable numerous downstream NLP tasks with compelling performance, including TC, where the model is further fine-tuned with annotated data.

TC tasks are usually domain dependent in real-world. Thus, the performance of these powerful deep models is still fluctuated and even degraded when directly implementing them in a unseen domain (target domain), where the task topic or the data distributions are different from the domain during training (source domain). Although their performance can be improved via fine-tuning with full supervision in the target domain, a significant amount of labeled target data is required. Collecting high-quality data is usually difficult and expensive in many real-world domains. Furthermore, the annotating process is extremely time-consuming and labor-intensive. To overcome these issues, unsupervised domain adaptation (UDA), which aims to transfer the knowledge from a label-rich domain (source domain) to a label-scarce or unlabeled domain (target domain) is proposed (Li et al., 2017; Chen et al., 2018; Guo et al., 2018; Zhang et al., 2019).

The intuitive objective of UDA is to align the marginal distribution of features across source and target domains. In general, UDA methods can be classified into two categories. One line of research focuses on reducing the discrepancy by minimizing statistical measurements, e.g. maximum mean discrepancy (Tzeng et al., 2014a). Another category leverages adversarial learning to alleviate the domain shift. Motivated by Generative Adversarial Network (GAN) (Goodfellow et al., 2014), adversarial domain adaptation (ADA) introduces a binary domain discriminator to identify the domain

label of the data, while an encoder learns to fool the discriminator. ADA has achieved encouraging results on nontrivial DA problems across various applications, such as image classification (Vu et al., 2019; Yang et al., 2020b), human activity recognition (Zou et al., 2019; Yang et al., 2018; Zou et al., 2018), Internet of Things (Yang et al., 2020a), and also text classification (Li et al., 2017; Zhang et al., 2019). For instance, AMN (Li et al., 2017) trains a sentiment classifier and a domain discriminator to reduce the domain discrepancy. ADAN (Chen et al., 2018) exploits adversarial learning for cross-lingual sentiment classification. HAGAN (Zhang et al., 2019) integrates the hierarchical attention mechanism with ADA to obtain features that are sentiment distinguishable but domain indistinguishable.

Although these ADA methods achieve good results in certain cross-domain TC tasks, one major issue is the unstable prediction performance in the target domain (Xie et al., 2018; Saito et al., 2018). After the adversarial training achieves convergence, the conventional binary domain discriminator cannot distinguish the domain label of the feature representations, which means these representations obtain good transferability. However, there is no constraint on the discriminability in the target domain. The model can generate trivial but useless target feature representations as long as they can fool the domain discriminator. Thus, this uncertainty in adversarial training deteriorates the discriminability of the target feature representations and ignores the decision boundary learned in the source domain, which leads to unstable and even poor prediction performance in the target domain (Chen et al., 2019a; Cui et al., 2020). Some works aim to adjust the decision boundary of the label classifier (Saito et al., 2018; Shu et al., 2018) or align additional semantic information (Xie et al., 2018) to overcome this issue during adversarial training. However, these additional learning steps either require a sophisticated hyper-parameter tuning process or increase the computational overhead, that limits the generalization capability of the ADA methods for NLP tasks. Therefore, a simple yet efficient solution is urgently desired.

In this paper, we propose EADA, an energy-based adversarial domain adaptation framework that tackles the uncertainty issue during adversarial learning and dedicates for text classification tasks. EADA consists of three modules, a shared feature extractor, a label predictor, and an autoencoder. We employ a deep pre-trained language model (RoBERTa) as a shared feature extractor that maps the text sequences from both source domain and target domain into a latent feature space. With the labeled source data, the feature extractor and the label predictor are fine-tuned under full supervision. Since the source feature representations generated from the feature extractor contain superb discriminability, the innovative goal of EADA is to fix these source features by adding constrains in the objective and only force the target feature distribution to align the source feature distribution through adversarial training so that the target features could remain discriminative, and the label predictor could also perform well in the target domain. Since autoencoder is acknowledged as an energy function that learns to map the observed sample to the low-energy space (LeCun et al., 2006), we design an autoencoder that leverages this property to fix the source features by associating lower energies to it while pushing the target domain to the low-energy space by minimizing the margin loss of the autoencoder. Meanwhile, it can also cluster similar data to form a high-density manifold, which helps to preserve more semantic information. We train the autoencoder to reconstruct the source features and train the feature extractor to generate source-like target features to deceive the autoencoder via a minimax with a margin loss. In summary, we make the following contributions:

- To address the problem of conventional binary domain discriminator that deteriorates the discriminability of the target feature presentation, we propose a novel autoencoder module, which forces the target feature representations to simulate source feature representations such that good discriminability can be inherited.

- As an energy function, the autoencoder maps features from both domains to the low-energy space, which motivates the feature clusters to be tight in an unsupervised manner. It improves the label classification accuracy in the target domain.

- Extensive experiments on public cross-domain TC benchmark datasets, including multi-domain sentiment classification (Amazon review dataset) and cross-domain

Yes/No question-answering (QA) classification (BoolQ and MARCO dataset), are conducted. The experimental results demonstrate that EADA alleviates the uncertainty during adversarial training and enhances the feature discriminability in the target domain. This enables EADA to outperform existing methods and achieve new state-of-the-art ADA results for cross-domain TC tasks without requiring any labeled data in the target domain.

The rest of the paper is organized as follows. Section 2 summarizes the existing domain adaptation methods for TC tasks. The limitation of existing ADA Methods is elaborated in Section 3. Section 4 presents the framework architecture of EADA. In Section 5, we present the experimental results and performance evaluation. We conclude our work in Section 6.

2 Related Work

Domain Adaptation aims to tackle the domain shift issue when the data distribution in the source domain and target domain are different (Ben-David et al., 2010). Unsupervised domain adaptation (UDA) aims to learn a model that is able achieve good classification accuracy without any annotation in the target domain (Tzeng et al., 2017; Zhao et al., 2019). Certain statistical measurements, such as maximum mean discrepancy (MMD) (Tzeng et al., 2014b; Ma et al., 2019), are leveraged to quantify the distribution differences.

Inspired by the recent success of Generative Adversarial Network (GAN) (Goodfellow et al., 2014) for data generation, researchers have proposed adversarial domain adaptation (ADA), that constructs an adversarial loss to accommodate the domain shift. It consists of an encoder and a domain discriminator. The generator aims to fool the discriminator to make the target domain samples look like the source domain ones, while the discriminator tries to identify the domain labels (source or target). ADDA (Tzeng et al., 2017) learns a discriminative representation using the labels in the source domain and then a separate encoder that maps the target data to the same space using an asymmetric mapping learned through a standard GAN loss without weights sharing. CoGAN (Liu and Tuzel, 2016) trains 2 GANs to synthesize both source and target images and achieves a domain invariant feature space by tying the high-level layer parameters of the 2 GAN to solve the domain transfer problem.

ADA has been adopted for cross-domain NLP tasks as well (Peng et al., 2018; Li et al., 2017; Shah et al., 2018; Chen and Cardie, 2018; Cai and Wan, 2019; Wang et al., 2019). AMN (Li et al., 2017) is an end-to-end adversarial memory network for cross-domain sentiment classification, which is the pioneering work for ADA in NLP. An adversarial deep averaging network is proposed in (Chen et al., 2018) for cross-lingual sentiment classification. A dedicated ADA framework for machine reading comprehension is proposed in (Wang et al., 2019). (Chen and Cardie, 2018) designed an ADA model that learns domain invariant representation across multiple domains for text classification. Target domain-specific information is being exploited in (Peng et al., 2018) to further improve the DA performance, while labeled data in the target domain is required.

Large deep pre-trained language models pioneered by BERT (Devlin et al., 2019), have been employed as feature encoders to embed text sequences into a latent feature space. Then, the encoder is further fine-tuned with the discriminator via adversarial learning using the labeled source data and unlabeled target data (Lee et al., 2019; Ma et al., 2019). For instance, BERT and ADA were adopted in (Lee et al., 2019) for domain-agnostic question-answering. A similar framework that integrates BERT and MMD is proposed in (Ma et al., 2019) for cross-domain sentiment classification. However, all these approaches leverage the binary domain discriminator which has failed to consider the discriminative features during feature learning. This leads to severe performance degradation since the decision boundary of the label predictor trained with source data is no longer valid in the target domain due to the domain shift.

3 Limitation of Existing ADA Methods

In this section, we analyze the learning process of conventional ADA methods and reveal their limitations. In common UDA setup, N_s labeled examples from a source domain $\mathcal{D}_S = \{\mathbf{x}_i^s, y_i^s\}$ and N_t unlabeled examples from a target domain $\mathcal{D}_T = \{x_i^t\}$ are available. The distributions of $\mathcal{D}_S$ and $\mathcal{D}_T$ are different due to the domain discrepancy. UDA aims to build up a model that provides good class prediction in both source and target domain. Discriminability of the feature representation is the clustering capacity in the feature manifold, that controls the easiness of class category separation

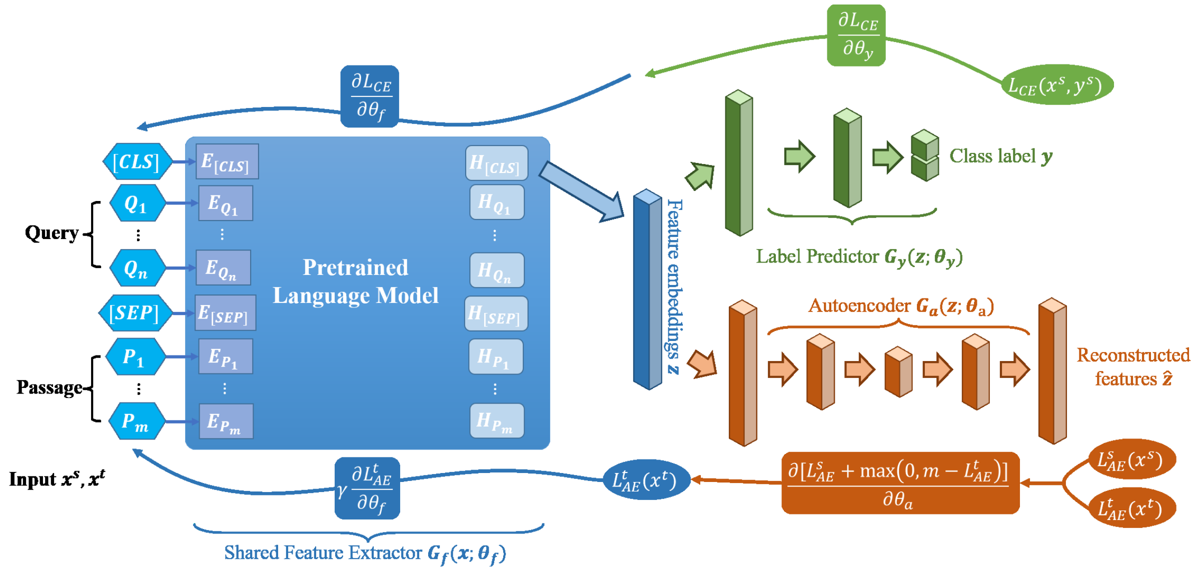

Figure 1: EADA constitutes: a pre-trained language model as shared feature extractor G_f, a label predictor G_y and an autoencoder G_a. In addition to the full supervised learning of G_f and G_y with the labeled source data, the autoencoder G_a serves as a domain classifier to learn reconstructing the source feature representations and push the target feature representations away. The feature extractor G_f aims to generate source-like target feature representations to deceive the autoencoder. This objective is realized by forcing the target feature representations towards the those from the source domain in the feature space via adversarial learning.

(Chen et al., 2019b). Excellent discriminability can be achieved for the source features due to the full supervision learning in the source domain. The objective of UDA is to transfer and ensure the model maintains this discriminability in the target domain.

ADA method, as one category of UDA, which is pioneered by Domain-Adversarial Training of Neural Networks (DANN) (Ganin et al., 2016) and Adversarial Memory Network (AMN) (Li et al., 2017) have shown promising performance in numerous NLP tasks in recent years (Chen and Cardie, 2018; Shah et al., 2018; Cai and Wan, 2019; Wang et al., 2019). It usually consists of a shared feature extractor $\mathbf{f} = G_f(x)$, a label predictor $\mathbf{y} = G_y(x)$ and a domain discriminator $\mathbf{d} = G_d(x)$. In addition to the standard full supervision learning process in the source domain, a minimax game is designed between $\mathbf{f}$ and $\mathbf{d}$. The domain discriminator $\mathbf{d}$ aims to distinguish the domain label between source and target, meanwhile the feature extractor $\mathbf{f}$ is trained to deceive $\mathbf{d}$. This adversarial training process can be formulated as

$$\min_{G_f, G_y} \mathcal{L}_y(\mathbf{X}_s, Y_s) - \gamma \mathcal{L}_f(\mathbf{X}_s, \mathbf{X}_t), \quad (1)$$

$$\min_{G_d} \mathcal{L}_d(\mathbf{X}_s, \mathbf{X}_t), \quad (2)$$

where $\mathcal{L}_y$ is the cross-entropy classification loss. In this manner, the model can learn domain-invariant features and transfer them across domains when the Nash Equilibrium is achieved (Zhao et al., 2017). The hyper-parameter γ controls the significance of adversarial training that improves transferability. As shown in Eq(1), the training process of feature extractor $\mathbf{f}$ of conventional ADA methods aims to achieve two tasks: (1) learn source representations with good discriminability; (2) train representations that are indistinguishable to the domain discriminator $\mathbf{d}$. Since both source domain and target domain data are involved in the adversarial feature learning as presented in the second term of Eq(1), the objective is equivalent to move two domains closer in the feature space to deceive $\mathbf{d}$. However, this process does not impose any constraint on the discriminability in the target domain. The feature extractor $\mathbf{f}$ can generate trivial but useless target representations as long as they can fool the discriminator $\mathbf{d}$. Therefore, these ADA methods cannot guarantee that the good decision boundary learned via full supervision in the source domain can still separate the categorical clusters in the target domain (Chen et al., 2019b; Liu et al., 2019a). This degradation of discriminability in the target domain is the major reason that hinders the performance of existing ADA methods.

4 Energy-based Adversarial Domain Adaptation

It is not a trivial task to maintain the source manifolds during adversarial training. Our solution is to decouple the adversarial training process of source and target feature representations. To be specific, we fix the source representation in the feature space and only encourage the target representations align to the source representations. Therefore, the superb discriminability learned in the source domain can be preserved and a label predictor that performs well in both source and target domain can be obtained.

To achieve this goal, we propose Energy-based Adversarial Domain Adaptation (EADA), which innovatively utilizes an autoencoder structure as a domain discriminator during adversarial training. Figure 1 demonstrates the model structure of EADA. It consists of three modules, a pre-trained language model as a shared feature extractor G_f parameterized by θ_f to embed input sample to feature embedding z. After that, a label predictor G_y parameterized by θ_y, which consists of several fully connected layers, further maps the feature embedding z to the predicted label $\hat{y}$. Another module is an autoencoder G_a parameterized by θ_a, that reconstructs a feature embedding z to $\hat{z}$. The detailed functionality of each module is elaborated as follows.

4.1 Shared Feature Extractor

Large pre-trained language models (e.g. BERT (Devlin et al., 2019), XLNet (Yang et al., 2019) and RoBERTa (Liu et al., 2019b)) have achieved a series of state-of-the-art results on NLP benchmarks. These powerful pre-trained language models are built up on bidirectional transformer architecture, and pre-trained on large corpora with a masked language model, that enable various downstream NLP tasks, including text classification.

In this work, we employ RoBERTa as the shared feature extractor G_f (highlighted in blue in Figure 1) that embeds both labeled text data $(\mathbf{X}_s)$ from the source domain, as well as the unlabeled text data $(\mathbf{X}_t)$ from the target domain into a latent feature space. To be specific, as a QnA classification problem, the input for the G_f are sequence pairs <query **Q**, passage **P**> as depicted in Figure 1 in the format of [CLS] <s> Q </s> <s> P </s>, where [CLS] is a dummy token for classification and <s> </s> are separator tokens. We leverage the roberta.base architecture (12-layer, 768-hidden, 12-heads, 125M parameters) (Liu et al., 2019b) as the shared feature extractor G_f. Since our objective is text classification, the last hidden representation of the [CLS] token, $H_{[CLS]} \in \mathbf{R}^{768\times 1}$ (feature embedding z) serves as the output of G_f. These embeddings $\mathbf{z}$ are utilized by both classifier G_y and autoencoder G_a.

4.2 Class Label Predictor

The class label predictor G_y consists of several fully connected layers that map the feature embedding z to the predicted label $\hat{y}$. Since the source domain is label-rich by default, we assume that n labeled samples $\mathcal{D}_S = \{\mathbf{x}_i^s, y_i^s\}$ are available from the source domain for finetuning of the shared feature extractor (language model) G_f (blue part in Figure 1) and the label predictor G_y (green part in Figure 1). The good classification accuracy of G_y is achieved by minimizing the cross-entropy loss via back-propagation under full supervision:

$$\begin{aligned}&\min_{G_f,G_y} \mathcal{L}_{CE}(\mathbf{X}_s, Y_s) = \\ &- \mathbb{E}_{(\mathbf{x}_s,y_s)\sim(\mathbf{X}_s,Y_s)} \sum_{n=1}^{N_s} [\mathbb{I}_{[l=y_s]} \log G_y(G_f(\mathbf{x}_s))].\end{aligned} \tag{3}$$

4.3 Autoencoder as Domain Discriminator

After obtaining the source feature representation with good discriminability, the next task is to learn transferable features with k unlabeled samples from a target domain $\mathcal{D}_T = \{x_i^t\}$. To ensure both transferability and discriminability of the feature representation, we design an autoencoder G_a with a margin Mean Squared Error (MSE) loss to replace the conventional binary domain discriminator. The MSE loss of the autoencoder is defined as:

$$\mathcal{L}_{AE}(\mathbf{x}_i) = ||G_a(G_f(\mathbf{x};\theta_f);\theta_a) - \mathbf{x}_i||_2^2, \tag{4}$$

where $||\cdot||_2^2$ denotes the squared L_2-norm. Since the source embeddings z_s always contain superb discriminability due to full supervision during the training of the classifier, z_s should be fixed to preserve the good decision boundary, while the target embeddings z_t should be encouraged to align with the distribution of z_s. To achieve this goal, the autoencoder G_a is designed to be able to only reconstruct features in the source domain but not features in the target domain. Namely, when two domains distribute similarly, the autoencoder will incur the same reconstruction loss in both domains. The training process of the autoencoder is formulated as:

$$\min_{G_a} \mathcal{L}_{AE}(\mathbf{X_s}) + \max(0, m - \mathcal{L}_{AE}(\mathbf{X_t})), \quad (5)$$

where m is the margin between the representations from the source domain and the target domain. The autoencoder G_a can be considered as an energy function that associates lower energies to the observed samples in a binary classification problem (LeCun et al., 2006). With the inspiration of Energy-based GAN which theoretically proves that using an energy function in GAN, the true distribution can be simulated by the generator at *Nash Equilibrium* (Zhao et al., 2017). In EADA, the autoencoder module G_a provides similar functionality that associates low energies to the source features (focuses on reconstructing source embeddings z_s). As presented in Eq(5), the training goal of the autoencoder is to have $\mathcal{L}_{AE}(\mathbf{X_s}) = 0$ and $\mathcal{L}_{AE}(\mathbf{X_t}) = m$. It behaves proportionally similar to a binary domain discriminator. But G_a includes more domain information and can transfer it during adversarial training.

4.4 The Learning Framework

The adversarial training objective of three modules forms a minimax game, that is defined by:

$$\begin{aligned} &\min_{G_f, G_y} \mathcal{L}_{CE}(\mathbf{X}_s, Y_s) + \gamma \mathcal{L}_{AE}(\mathbf{X_t}), \\ &\min_{G_a} \mathcal{L}_{AE}(\mathbf{X_s}) + \max(0, m - \mathcal{L}_{AE}(\mathbf{X_t})), \end{aligned} \quad (6)$$

where γ is a hyper-parameter to control the effectiveness of G_a. The shared feature extractor G_f maps both labeled source data $\mathbf{X_s}$ and unlabeled target data $\mathbf{X_t}$ to a latent feature space. Both G_f and the label predictor G_y are trained with full supervision using the labeled data in the source domain. Another key role of the feature extractor G_f is to deceive the autoencoder G_a by generating source-like features for unlabeled target samples. Therefore, we only incorporate the $\mathcal{L}_{AE}(\mathbf{X_t})$ term into the training of G_f. The adversarial training of G_f is formulated by:

$$\min_{G_f} \mathcal{L}_{AE}(\mathbf{X_t}). \quad (7)$$

In the minimax game, the autoencoder G_a aims to maximize the domain divergence by pushing two domains away from a margin m, while the objective of the feature extractor G_f is to minimize the domain divergence by deceiving the autoencoder. When the model achieves convergence, the target feature representations inherit excellent discriminability from the source domain so that the generalization capability of the label predictor G_y is improved and performs well not only in the source domain but also in the target domain.

5 Experiments

We evaluate the domain adaptation performance of EADA on two public real-world cross-domain text classification benchmarks: 1) sentiment classification (Amazon reviews dataset); 2) Natural QA Yes/No classification (BoolQ ⇔ MS Marco), and compared it with state-of-the-art baselines.

5.1 Evaluation on Sentiment Classification

Amazon reviews dataset (Pan et al., 2010) is the standard and well-known benchmark for sentiment classification domain adaptation. It contains reviews on four domains: Books (B), DVDs (D), Electronics (E), and Kitchen (K). Each domain contains 1000 positive reviews (higher than 3 stars) and 1000 negative reviews (3 stars or lower). 12 cross-domain sentiment classification tasks: D→B, E→B, K→B, K→E, D→E, B→E, B→D, K→D, E→D, B→K, D→K, E→K, where the letter before the arrow represents the source domain and the letter after the arrow indicates the target domain by following (Li et al., 2017). For each pair of domain adaptation, 800 labeled positive (Pos) and 800 labeled negative (Neg) reviews from the source domain (src), together with 1600 unlabeled reviews from the target domain (tgt) are randomly selected for training. The rest of 200 positive and 200 negative reviews from the target domain are used for testing.

We configured the feature extractor module G_f as RoBERTa.base for single sequences task since each review is one sequence passage. The input is tokenized as [CLS] <s> Review </s>. The maximum input sequence length is set to 256 tokens. The autoencoder module G_a consists of 5 fully connected layers (768-384-96-384-768). The entire EADA framework is implemented in PyTorch. The Adam optimizer with the constant learning rate $\mu = 1e^{-5}$ with a batch size of 24 was adopted and we used 5-fold cross-validation to tune the hyperparameter $m = 4$ and $\gamma = 1e^{-2}$ during the training.

Table 1: Cross-domain classification accuracy of different methods on Amazon review dataset.

Tasks	Source-only RoBERTa	AMN	ADAN	HAGAN	HAGAN-C	MoE	ADA RoBERTa	EADA
D→B	85.55	81.52	81.70	81.22	81.69	81.70	86.80	**88.10**
E→B	81.95	77.80	78.55	79.05	79.23	79.65	82.10	**85.25**
K→B	72.65	79.37	79.25	78.52	78.99	80.94	77.60	**81.20**
B→D	81.95	81.32	82.30	82.07	82.38	84.60	82.47	**86.05**
E→D	82.50	77.51	79.70	81.00	80.65	84.20	83.70	**85.35**
K→D	80.00	80.03	80.45	80.83	80.91	**81.22**	80.58	80.35
B→E	85.95	80.07	77.60	79.87	80.12	84.66	86.00	**89.35**
D→E	82.75	80.00	79.70	80.57	80.99	84.10	82.99	**87.15**
K→E	82.45	81.97	86.85	85.94	85.23	**85.81**	84.32	85.11
B→K	86.80	81.00	76.10	81.25	82.00	86.32	87.00	**89.65**
D→K	85.75	83.88	77.35	81.73	81.50	86.33	86.55	**89.20**
E→K	86.95	87.10	83.95	84.30	84.99	85.40	87.10	**90.50**
Average	*82.94*	*80.96*	*80.29*	*81.36*	*81.56*	*83.74*	83.93	***86.44***

The performance of EADA is compared with the following state-of-the-art baselines: *Source-only RoBERTa* directly applies the finetuned RoBERTa model from source domain in target domain; *AMN* (Li et al., 2017) adopts attention mechanism and ADA for cross-domain sentiment classification; *ADAN*(Chen et al., 2018) employs ADA to transfer the knowledge of resource-rich source language to low-resource language; *HAGAN* and *HAGAN-C* (Zhang et al., 2019) incorporate hierarchical attention into ADA for cross-domain sentiment classification; *MoE* (Guo et al., 2018) utilizes a mixture of experts from different source domains to further enhance the DA performance in target domain; *ADA RoBERTa* uses RoBERTa as a shared feature extractor and a conventional binary domain discriminator as the domain classifier for ADA.

Table 1 presents the mean accuracy with 5 runs of each method on the 12 DA tasks. One observation is that the accuracy of source-only RoBERTa (82.94%) is even worse than MoE (83.74%). This indicates that the problem of DA cannot be solved by just solely using large pre-trained language models. It can be observed that EADA provides 86.44% classification accuracy on average, which outperforms all the baselines. It achieves the best DA performance in 10 out of the 12 tasks. Although ADA-RoBERTa and EADA both adopted RoBERTa as the feature extractor, the accuracy of EADA is still 2.5% higher than ADA-RoBERTa, which validates the advantage of the proposed energy-based ADA method. Moreover, the variance of EADA is the smallest among all the methods, which indicates its performance is more stable in general. By learning a source-like representation for the target feature embeddings, EADA successfully performs cross-domain sentiment classification without any annotated data in target domain.

5.2 Evaluation on Yes/No QA classification

We also validated the performance of EADA on cross-domain naturally occurring yes/no questions between BoolQ dataset (Clark et al., 2019) and Marco dataset (Nguyen et al., 2016). Each example is a triplet of (query, passage, answer). Thus, feature extractor module G_f (RoBERTa) is configured for sequence pairs task, which means the input is tokenized in the format as [CLS] <s> query </s> <s> passage </s>. BoolQ dataset contains 5874 Yes and 3553 No samples for training and 2033 Yes and 1237 No samples for evaluation from Wikipedia. Samples in Marco dataset are web snippets from Bing Search. There are 17339 Yes and 10550 No samples for training and 2033 Yes and 1237 No samples for testing. The data distributions at both domain level and categorical level are imbalanced, which is a common situation in many real-world applications. The number of training samples in BoolQ is only 33.8% of those in Marco, indicating that the data are imbalanced across domains. Moreover, the data categorical distribution is imbalanced because the number of No-samples is at least 39.1% less than the number of Yes-samples in both domains. Since the samples from the two domains are collected from different sources, there is a huge domain shift between the two datasets.

The domain adaptation performance is reported in Table 2. The 2^{nd} column shows the accuracies

Table 2: Cross-domain adaptation for Yes/No QA classification between BoolQ and Marco datasets.

Tasks	Source only	AMN	HAGAN	ADA-RoBERTa	MoE	EADA	Target full supervision
BoolQ → Marco	67.63	72.95	73.11	73.86	74.01	**78.38**	82.51
Marco → BoolQ	69.30	74.34	74.73	75.11	75.23	**79.51**	84.31

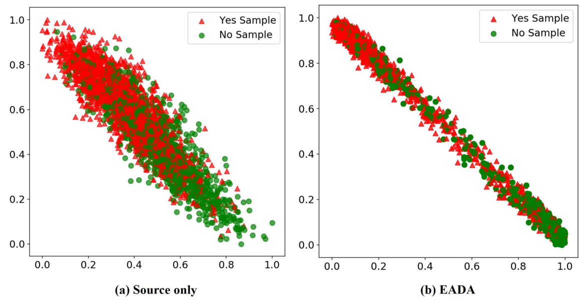

Figure 2: The t-SNE visualization of features embedded using distinct feature extractor in target domain. (Marco → BoolQ).

when the non-adapted source feature extractors and classifiers are directly applied in the target domain, which serves as the lower-baseline. The last column reports the accuracies when the feature extractors and classifiers are trained with full-supervision that all the target training data are labeled (as the upper-baseline). As shown in Table 2, the source-only classifiers can only provide 68% accuracy, which verifies that the domain shift hurts the classification accuracy even when a powerful deep language model is adopted. On the other hand, it can be easily observed from Table 2 that EADA enhances the accuracy in both adaptation directions by at least 15% compared to the lower-baseline in an unsupervised manner, and outperforms all the state-of-the-art baselines. It elevates the performance closer to the target full supervision as well.

We leverage t-Distributed Stochastic Neighbor Embedding (t-SNE) to map the embedded feature representations through different feature extractors to a 2-D space for better visualization and analysis. Figure 2(a) and Figure 2(b) depict the embedded features using the non-adapted source feature extractor and the EADA's feature extractor learned, respectively (Yes sample - red, No sample - Green). If we directly apply the non-adapted source feature extractor in the target domain, as shown in Figure 2(a), a large amount samples with different categorical labels overlap with each other, which leads to corresponding huge misclassification as presented in the 2^{nd} column of Table 2. After employing EADA, the common confusions are further separated in the latent feature space and two clusters are formulated as depicted in Figure 2(b). These observations further validate that the feature embeddings constructed via EADA are not only domain-invariant but also preserve excellent discriminability in both the source domain and the target domain.

We also conducted a sensitivity study of the two hyperparameters: m and γ in Eq(6). We evaluated the impact of margin m with different values from 0 to 10 in both experiments. EADA's accuracy increases while m is increasing. The reason is that the degree of transferability is limited when m is small. The performance becomes stable when $m \geqslant 4$ in both experiments. In general, the objective of γ is to control the weight of the adversarial loss during feature learning of ADA as shown in Eq(1). γ in EADA aims to control the weight of autoencoder reconstruction loss for target domain samples during feature learning as presented in Eq(6)). We evaluated the impact of γ with different values (0-1) for EADA and ADA-RoBERTa. As γ increases, the accuracy of EADA increases and becomes stable when $\gamma \geqslant 0.01$. The accuracy of ADA-RoBERTa fluctuates when γ is increased and decreased when $\gamma \geqslant 0.5$. Thus, EADA provides a more stable training procedure compared to conventional ADA methods, which makes it easier for generalization. We recommend using m=4 and γ=0.01 as the default setup for other tasks.

6 Conclusion

In this paper, we proposed EADA, a novel unsupervised energy-based adversarial domain adaptation method for cross-domain text classification tasks. First, a deep pre-trained language model is leveraged as a shared feature extractor to map the text sequences from both source and target domains to a feature space. The feature extractor and a label predictor are trained with labeled source data. Since the source feature representations are obtained under full supervision, they preserve great feature discriminability. To ensure that the label predictor also provides good label prediction in the target domain, the target feature representations should be encouraged to align with the source during adversarial training. Thus, we designed an autoencoder that focuses on reconstructing the source feature representations, while the feature extractor aims to generate source-like target feature embeddings to fool the autoencoder. Extensive experiments on public cross-domain TC benchmarks are conducted and demonstrate that EADA not only alleviates the domain discrepancy but also enhances the feature discriminability in the target domain, which leads to compelling cross-domain TC performance without requiring any labeled data in the target domain.

Survival text regression for time-to-event prediction in conversations

Christine De Kock

Abstract

Time-to-event prediction tasks are common in conversation modelling, for applications such as predicting the length of a conversation or when a user will stop contributing to a platform. Despite the fact that it is natural to frame such predictions as regression tasks, recent work has modelled them as classification tasks, determining whether the time-to-event is greater than a pre-determined cut-off point. While this allows for the application of classification models which are well studied in NLP, it imposes a formulation that is contrived, as well as less informative. In this paper, we explore how to handle time-to-event forecasting in conversations as regression tasks. We focus on a family of regression techniques known as survival regression, which are commonly used in the context of healthcare and reliability engineering. We adapt these models to time-to-event prediction in conversations, using linguistic markers as features. On three datasets, we demonstrate that they outperform commonly considered text regression methods and comparable classification models.

1 Introduction

The task of predicting when an event will occur in a conversation frequently arises in NLP research. For instance, Backstrom et al. (2013) and Zhang et al. (2018b) predict when a conversation thread will terminate. Danescu-Niculescu-Mizil et al. (2013) define the task of forecasting when users will cease to interact on a social network based on their language use. Although these questions naturally lend themselves to regression, this presents some difficulties: datasets may be highly skewed towards shorter durations (Zhang et al., 2018b) and samples with a longer duration can contribute inordinately to error terms during training. Furthermore, classical regression models do not explicitly consider the effect of time as distinct from other features.

The abovementioned studies instead frame the time-to-event prediction as a classification task, predicting whether the current state will continue for a set number of additional timesteps. For instance, Backstrom et al. (2013) predict whether the number of responses in a thread will exceed 8, after seeing 5 utterances. This presents obvious limitations; such a setup would assign the same error for mistakenly classifying conversations of respectively 9 and 30 utterances as "short". Additionally, its predictions are less informative: predicting that a conversation will be more than 8 utterances long is less telling than predicting whether it will be 9 or 30.

In this paper, we propose that *survival regression* is a more appropriate modelling framework for predicting when an event will occur in a conversation. Survival regression aims to predict the probability of an event of interest at different points in time, taking into account features of a subject as seen up to the prediction time. We apply survival models to two tasks: predicting conversation length, and predicting when conversations will get derail into personal attack. We report results for the conversation length prediction task on the datasets from Danescu-Niculescu-Mizil et al. (2012) and De Kock and Vlachos (2021), and evaluate the personal attack prediction task on the dataset of Zhang et al. (2018a). Our results illustrate that linear survival models outperform their linear regression counterparts, with an improvement in MAE of 1.22 utterances on the dataset of De Kock and Vlachos (2021). Further performance gains are made using neural network-based survival models. An analysis of the coefficients of our linear models indicates that survival models infer similar relationships as previous work on conversation length prediction, but that their predictions are more accurate than conventional regression and classification models due to their explicit accounting for the effect of time. On the personal attack prediction task,

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1219–1229
August 1–6, 2021.

the best survival model provides a 13% increase in ranking accuracy over linear regression models.

The remainder of this paper is structured as follows. In Section 2 we provide a description of key survival analysis concepts. In Section 3, we describe how we apply these concepts to conversations. Results are reported in Section 4.

2 Survival regression

Survival analysis is concerned with modelling time-to-event prediction, which often represents transitions between states throughout a subject's lifetime. In the general case, exactly one event of interest occurs per lifetime, after which the subject is permanently in the alternate state, often referred to as "death" in literature. In this section, we review some key concepts of survival analysis that are relevant to our work, however, we refer the interested reader to the exposition by Rodriquez (2007).

2.1 Definitions

Let T be a non-negative random variable representing the waiting time until the occurrence of an event. Given the cumulative distribution function $F(t)$ of the event time T, the *survival function* is defined as the probability of surviving beyond a certain point in time t:

$$\begin{aligned} S(t) &= P(T > t) \\ &= 1 - F(t). \end{aligned} \tag{1}$$

Per illustration, we consider the task of predicting conversation length using the dataset of disagreements of De Kock and Vlachos (2021). The event of interest is the end of a conversation, with time measured in utterances. We can estimate the survival function using Kaplan-Meier estimation (Jager et al., 2008) as follows:

$$S(t) = \prod_{t_i < t} \frac{R_i - d_i}{R_i}, \tag{2}$$

where d_i is the number of candidates who experience the event at time t_i, and R_i represents the so-called *risk set*, or candidates at risk of experiencing the event just prior to t_i. In Figure 1, the base function is the estimated survival probabilities over time for the full population. Only conversations of more than 5 utterances are considered; hence the survival probability is 1 for all curves up until $t = 5$. If we create subsets of the population by conditioning on the response time, the subset with a longer response time has a steeper decline, indicating that conversations where participants take longer to respond are more likely to end earlier. In survival regression, the aim is to learn survival regression functions based on such features, while the current time is modelled separately from them, unlike in standard regression models.

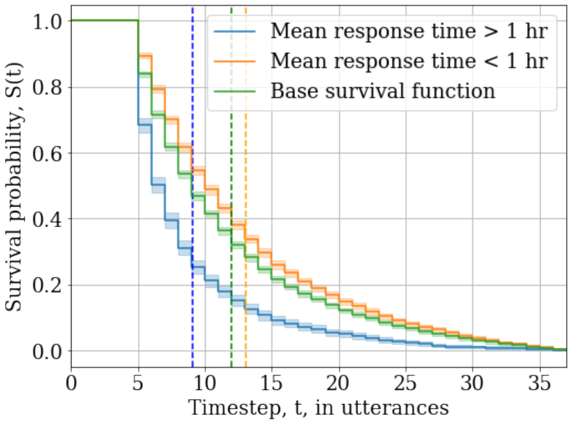

Figure 1: Survival functions for the conversation length prediction task, for the full population (orange) and subsets conditioning on the response time. Dashed lines indicate the expected event time per population.

To estimate the expected event time given a survival function, one can find the expected value of the survival function as follows:

$$\hat{T} = E[S] = \int_0^\infty S(t)dt. \tag{3}$$

These values are indicated with dashed lines in Figure 1, denoting the average conversation length on the full population and the two subsets based on the response time. The instantaneous risk of the event occurring at a point in time, i.e. the probability of the event time T being in a small interval around t, is defined by the *hazard function*:

$$h(t) = \lim_{dt \to 0} \frac{P(t \leq T < t + dt | T \geq t)}{dt}. \tag{4}$$

The cumulative hazard is given by $H(t) = \int_0^t h(t)dt$ and is related to the survival function according to $S(t) = e^{-H(t)}$.

Parameteric survival regression models (described in more detail in Section 2.3 and 2.4) are often optimised to predict either the survival or the hazard function, given that it is always possible to convert between them. Such models can include feature representations (such as the response time in Figure 1) to obtain individualised predictions.

2.2 Censoring

A common consideration in survival studies is the presence of censoring, where a participant leaves a study before the end of the observation period, or they do not experience the event of interest within this period. Under censoring, each subject i has an associated potential censoring time C_i and a potential lifetime T_i. We observe $Y_i = min\{T_i, C_i\}$, i.e. the minimum of the censoring and lifetimes, and an indicator variable δ_i for whether the observation ended with death or censoring.

Consider the task of predicting personal attacks (described in more detail in Section 3). Conversations that end without a personal attack occurring can be considered analogous to patients dropping out of a study before the end of the observation period. The duration of the observation can then be taken as the censoring time.

Different survival models account for censoring in different ways. For instance, for a survival curve estimated with the Kaplan-Meier method (Equation 2), censored individuals are removed from the set of candidates at risk (R_i) at the censoring time, without having experienced the event of interest.

2.3 Cox Proportional Hazards

The Cox Proportional Hazards (Cox-PH) model (Cox, 1972) is the most widely used model for survival analysis (Rodriquez, 2007; Kvamme et al., 2019). It has the following hazard function:

$$h(t|\mathbf{x};\theta) = h_0(t) \cdot exp(g(\mathbf{x};\theta)). \tag{5}$$

$h_0(t)$ represents the baseline hazard for the population at each timestep, such as the base survival function in Figure 1. The $g(\mathbf{x};\theta)$ term is often referred to as the *risk function* and specifies how the feature vector $\mathbf{x}$ of a sample is taken into account using parameters θ. In our experiments, we consider two variations of this approach:

Linear Cox The traditional Cox-PH model (Cox, 1972) uses a linear weighting of a feature vector to calculate the risk function as follows:

$$g(\mathbf{x};\theta) = \theta^T\mathbf{x}. \tag{6}$$

This model is still widely used in survival analysis research, e.g. Suchting et al. (2019); Zhang et al. (2018c).

DeepSurv DeepSurv (Katzman et al., 2018) uses a neural network to compute the risk function $g(\mathbf{x};\theta)$, where θ represents the weights of the network. The advantage of this is that the neural network can learn nonlinear features from the training data, which often improves predictive accuracy.

During training, the parameters θ are optimised with maximum likelihood estimation for both models. Given individuals i with event time T_i in dataset D, let R_i denote the risk set at T_i and δ_i the censoring indicator. Then, the likelihood of the data is given by:

$$\begin{aligned} L_{cox}(\theta, D) &= \prod_{i\in D}\left(\frac{h_0(t)\dot{e}xp(g(\mathbf{x_i};\theta))}{\sum_{j\in R_i} h_0(t)\dot{e}xp(g(\mathbf{x_j};\theta))}\right)^{\delta_i} \\ &= \prod_{i\in D}\left(\frac{exp(g(\mathbf{x_i};\theta))}{\sum_{j\in R_i} exp(g(\mathbf{x}_j;\theta))}\right)^{\delta_i}. \end{aligned} \tag{7}$$

Intuitively, we aim to maximise the risk of i experiencing an event, over all other candidates at risk at time T_i. In the context of predicting conversation lengths, this means that at time T_i, any conversation that has not yet ended could end, but we want to maximise the probability of the candidate that had indeed ended then over the rest. This is referred to as a *partial likelihood*, in reference to the fact that the effect of the features can be estimated without the need to model the change of the hazard over time. The indicator term δ expresses that only non-censored samples contribute terms that impact the likelihood (since the contribution of censored samples would be 1); however, the censored samples would be included in the risk set R_i up until their respective censoring times.

2.4 Survival regression as classification

A different approach to survival regression is to use classification to predict the timestep when an event will occur. DeepHit (Lee et al., 2018) is a neural network model that predicts a distribution over timesteps in this fashion. This provides more modelling flexibility compared to the Cox-PH models, where features are incorporated through the risk function and combined with a baseline hazard.

The model can incorporate multiple competing risks with distinct events of interest, and models censoring as a special type of risk. The output of the network is a vector representing the joint probability that the subject will experience each non-censoring event for every timestep t in the observation period. Censoring is assumed to take place at random and is therefore not included in the prediction. In the case of a single risk, it therefore predicts a vector: $\hat{y}_i = [\hat{y}_{t=0}, ..., \hat{y}_{t=t_{max}}]$, where each output element $\hat{y}_t$ represents the estimated probability $\hat{P}(t|\mathbf{x}, \theta)$ that a subject with feature vector $\mathbf{x}$ will experience the event at time t under the model parameters θ. Instead of a survival function, DeepHit defines a risk-specific *cumulative incidence function* (CIF) which expresses the probability that the event occurs before a time t^*, conditioned on features $\mathbf{x}^*$:

$$\begin{aligned} F(t^*|\mathbf{x}^*) &= \hat{P}(T \leq t^*|\mathbf{x}^*, \theta) \\ &= \sum_{t=0}^{t^*} \hat{P}(t|\mathbf{x}^*, \theta) = \sum_{t=0}^{t^*} \hat{y}_t^* \end{aligned} \tag{8}$$

The loss function for training DeepHit has two components: an event time likelihood and a ranking loss. The ranking loss ensures that earlier events are predicted to happen before later events based on their CIF, but does not penalise models for mispredicting the times in absolute terms. The event time likelihood maximises the probability of the event occurring at the right time ($y^{(i)}_{T^{(i)}}$), or, in the case of censoring, it maximises the probability of the event not happening before the censoring time $(1 - F(T^{(i)}|\mathbf{x}^{(i)}, \theta)$.

2.5 Previous applications in NLP

A small number of NLP studies have employed techniques from survival analysis for time-dependent tasks. Navaki Arefi et al. (2019) use survival regression to investigate factors that result in posts being censored on a Chinese social media platform, finding that negative sentiment is associated with shorter lifetimes. Stewart and Eisenstein (2018) use a linear Cox model to infer factors that are predictive of non-standard words falling out of use in online discourse, finding that words that appear in more linguistic contexts survive longer. Other applications include modelling fixation times in reading (Nilsson and Nivre, 2011) and evaluating dialogue systems (Deriu et al., 2020). However, none of these studies considered time-to-event prediction tasks based on conversations.

3 Survival regression in conversations

We evaluate survival models on two tasks, predicting conversation length and predicting when personal attacks will occur, where each conversation is a subject and the time is measured in utterances.[1]

Dataset	# Convs.	Median time to event	Task
Talk	16 896	6	**1**
Dispute	8 554	9	**1**
Attack	3 466	7	**2**

Table 1: Characteristics of datasets used in this paper. All three datasets originate from Wikipedia Talk pages.

Task 1: Predicting conversation length Having seen t utterances, predict the remaining conversation length in utterances. We use the dataset of Wikipedia Talk page discussions by Danescu-Niculescu-Mizil et al. (2012) (hereafter referred to as **Talk**) and the dataset of disagreements on Wikipedia Talk pages by De Kock and Vlachos (2021) (referred to as **Dispute**) for this task. The Talk dataset was also used to perform the thresholded classification version of this task in Backstrom et al. (2013), mentioned in Section 1.

Task 2: Predicting personal attacks Having seen t utterances, predict the number of utterances until a personal attack occurs. Conversations where no personal attack occurs are censored during training, and the conversation length is used as the observation time. Just less than half of the conversations contain personal attacks (1 569 out of 3 466). This is a novel task; previous work has only addressed predicting whether conversations will derail into personal attack, without attempting to predict when in a conversation this may occur (Zhang et al., 2018a; Chang and Danescu-Niculescu-Mizil, 2019). The motivation cited in both of the abovementioned studies is to prioritise conversations at risk of derailing for preemptive moderation. Survival models can give a more informative answer that takes into account the time until the attack, and therefore which conversations pose the most immediate risk. We use the dataset of Zhang et al. (2018a) for our experiments on this task.

Characteristics of the datasets we use are shown in Table 1. We use only conversations where the event of interest occurs after the fifth utterance, and we remove conversations longer than the 95th percentile as these are often flame wars which may have confounding impacts. Data is split into training, development and test sets with ratios 75:10:15.

3.1 Metrics

Two metrics are calculated to evaluate model performance: mean absolute error and concordance index. The mean absolute error (MAE) for a dataset

---

[1] The task of predicting when users would cease to use a platform would also have been an interesting case for this study; however, the datasets of Danescu-Niculescu-Mizil et al. (2013) are no longer available.

of n test samples is defined as

$$MAE = \frac{\sum_{i=1}^{n} |y_i - \hat{y}_i|}{n}. \quad (9)$$

This metric provides an easily interpretable score, and it is commonly used in evaluating regression models, e.g. Bitvai and Cohn (2015). However, MAE is not robust to outliers; large errors on a few values can outweigh many correct predictions.[2] MAE is also ill-defined in the presence of censoring as there is no event time to compare against, and it cannot be used to compare model performance between different datasets. For these reasons, we also include the concordance index (Harrell Jr et al., 1996), which is concerned with ordering rather than absolute values. A pair of observations i, j is considered concordant if the prediction and the ground truth have the same inequality relation, i.e. $(y_i > y_j, \hat{y}_i > \hat{y}_j)$ or $(y_i < y_j, \hat{y}_i < \hat{y}_j)$. The concordance index (**CI**) is the fraction of concordant pairs. A random model, or a model that predicts the same value for every sample, would yield a score of 0.5. A perfect score is 1. In the presence of censoring, censored samples are only compared with uncensored samples of a smaller event time, since it is known in that case that the uncensored sample should be assigned a later event time.

A disadvantage of the CI score is that it does not reflect how accurate the predictions are in absolute terms, meaning that good CI scores can be achieved with predictions in the wrong range. The two scores thus provide complementing views on model performance.

3.2 Features

The features we consider are based on previous work on conversation length prediction and predicting personal attacks. These are:

- Politeness (**POL**): The politeness strategies from Zhang et al. (2018a) as implemented in Convokit (Chang et al., 2020), which capture greetings, apologies, and saying “please”, etc.
- Arrival sequences (**ARR**): The order in which speakers partake in the first 5 utterances, defined by Backstrom et al. (2013).
- Hypergraph (**HYP**): Conversation structure features based on the reply tree, proposed by Zhang et al. (2018b) and implemented in Convokit (Chang et al., 2020). These features capture dynamics between participants, such as engagement and reciprocity.
- Sentiment (**SENT**): Positive and negative sentiment word counts, as per the lexicon of Liu et al. (2005), also implemented in Convokit.
- Time features (**TIME**): Log mean time between utterances and time between last two utterances, inspired by Backstrom et al. (2013).
- Utterance lengths (**LEN**): Log mean utterance length features, measured in tokens.
- Number of participants (**PART**): Also used in Backstrom et al. (2013) and Zhang et al. (2018b).
- Turn-taking features (**TURNS**): The fraction of turns and tokens contributed by the top user, inspired by Niculae et al. (2015).

For the POL, SENT, TIME and LEN features, we include both the mean value throughout the conversation and the gradient of a straight-line fit to capture how the feature changes throughout it. All features are calculated up to the point of prediction, and not for the full conversation.

4 Results

4.1 Experimental setup

We use partly conditional training (Zheng and Heagerty, 2005) to account for using features that change over time, such as politeness, in contrast with static features like the arrival sequence. Under partly conditional training, a feature measured at time t predicts the risk of the occurrence of an event at a future time T. In our case, each individual is a conversation and features are measured after every utterance. Each measurement t of a conversation i is recorded as an individual entry in the dataset, with event time $T_{i,t} = T_i - t$.

This construction is illustrated in Table 2 for the Talk dataset. There are 307 conversations that contain 12 utterances, but 0 samples of length 12 in the training data, since all conversations of this length have 0 utterances remaining and regression is therefore unnecessary. However, we include the first 11 utterances of the length-12 conversations in the training set at $t = 11$, since the remaining length here could be either 0 or 1. As such, there are (642+307=) 769 samples of length 11. We use

---

[2] This issue is even more pronounced in the root mean-squared-error, which is another popular metric for regression (Hyndman and Koehler, 2006).

t	# Convs. of length t	# Samples of length t
5	6 596	16 896
6	4 010	10 300
7	2 358	6 290
8	1 539	3 932
9	984	2 393
10	640	1 409
11	462	769
12	307	0
Total	16 896	41 989

a minimum value of $t = 5$ to ensure there is sufficient information from which to make a prediction. Details for the other datasets are in Appendix A.

Our **baseline** model is a univariate Kaplan-Meier estimator (Jager et al., 2008), which predicts the same event time for all samples without taking features into account. For this model and the linear Cox-PH model, we use the implementations in `lifelines`[3]. We use grid search on the validation set for each model to determine hyperparameter values, experimenting with regularisation values in $[0, 0.01, 0.1, 0.5]$, L1 ratios in $[0, 0.1, 0.5, 1]$ and learning rates in $[0.01, 0.1, 0.5, 1]$. We also compare to a **linear regression** model, implemented in `scikit-learn`[4] and using the same features. For the linear regression model, we truncate predictions at 0 since negative times are invalid. Finally, to compare to previous work on **threshold classification**, we implement a logistic regression classifier, using the median of each training set as the cut-off point. For these models, the upper and lower quartiles are used to compute the MAE. For instance, for the Dispute dataset, the threshold value is 9. To calculate MAE, we use an event time of 5 if the model predicts the shorter class and 12 for the longer class.

For the neural models (DeepSurv and DeepHit), we use the implementations in `PyCox`[5] by Kvamme et al. (2019). For both we use two hidden layers with $[128, 64]$ nodes, dropout ($p = 0.3$), batch normalisation, and the Adam optimiser (Kingma and Ba, 2014) with learning rate 0.01.

4.2 Task 1: Predicting conversation length

Results for the conversation length prediction task are shown in Table 3 for the Dispute and Talk datasets (left and middle columns respectively). MAE scores should not be compared between datasets since the datasets have different length distributions, with the Dispute dataset having conversations of up to 37 utterances, compared to a maximum of 12 in the Talk dataset.

For both datasets, all survival models outperform the linear regression and threshold classification models on the MAE metric. The survival baseline uses only population-level knowledge of the event time distribution, and predicts the same event time for all samples, whereas the other baselines take into account information from the features and can therefore tailor predictions per sample. While this results in the survival baseline having the worst CI (0.5), it is still better than linear reg and threshold in terms of MAE, illustrating the importance of separating the effect of time from the other features; time alone can be highly predictive.

The DeepHit model performs the best on the MAE metric on both datasets, with a statistically significant difference from the Linear Cox model at the P=0.01 level using the sign test. The latter performs better than DeepHit on the CI metric for the Dispute dataset, however, this difference is not statistically significant (P=0.869, using a randomised permutation test).

Coefficient analysis Since the linear Cox model performed well on the Dispute dataset and is more interpretable than its deep counterparts, we show its 10 largest coefficients in absolute value in Table 4. Positive weights are associated with larger risk function values, and therefore a shorter conversation. Time between utterances is the most predictive feature, with a longer time between utterances correlating positively with shorter conversations (also observed in Figure 1). This corroborates the findings of Backstrom et al. (2013) and Zhang et al. (2018b). Having more participants is also correlated with shorter conversations. This suggests that the conversations in the Dispute dataset are less prone to long expansionary-style threads (as defined by Backstrom et al. (2013)), where many participants each contribute one utterance. Given the dataset consists of disagreements, it is not surprising that there would rather be focused discussions between a small number of participants.

Features 4, 6, 7 and 8 are from the hypergraph

Figure 2: Example of a conversation in the Dispute dataset and the predictions of different models at $t = 5$. For this sample, the prediction from the linear Cox model matches the true value.

Feature	**Type**	**Coef.**
1. Time between last two utterances	TIME	0.161
2. Mean time between utterances	TIME	0.121
3. # participants	PART	0.045
4. Mean # replies received per post	HYP	0.042
5. # first person pronouns, mean	POL	0.037
6. Mean of non-zero # repliers per user	HYP	-0.035
7. Fraction of users with more than 1 replier	HYP	-0.035
8. Triadic replies to commenters in mid-thread	HYP	0.034
9. Length of last utterance	LEN	-0.031
10. Arrival sequence 00110	ARR	-0.026

Table 4: Coefficients of the linear Cox model for Task 1, using the Dispute dataset. Positive weights are associated with shorter time-to-event values.

feature set, which describes the structure of the reply-tree. Feature 4 indicates that a thread which forms a shallow tree, with posts receiving many direct responses, is likely to terminate soon. Features 6 and 7 indicate that interactions with multiple users is likely to extend the conversation. The length of the last utterance before the prediction is made (feature 9) is negatively associated with a short time-to-event, indicating that a long last utterance means that the conversation is still ongoing. Finally, the arrival sequence 00110 (feature 10) encodes the order in which two participants (indexes 0 and 1) contributed the first 5 utterances.

The only language-related feature in the 10 most predictive features is feature 5, the number of first person pronouns, which is positively correlated with a shorter time-to-event. Seven of the ten features on this list are from previous work on predicting conversation length (TIME, ARR and HYP), although this was for the thresholded classification version of the task. This indicates that the survival models are inferring similar relationships as the classification variant, while providing a more informative prediction and better performance on the MAE and CI metrics.

Results per timestep To gain an understanding for how our models perform at different timesteps in the conversation, we also evaluate the predictive accuracy at every utterance index. The intuition here is illustrated in Figure 2 for $t = 5$, with the task being: having seen 5 utterances, predict the conversation length. We can see that the actual conversation length is 8, as there are 3 more utterances after the prediction, which are not seen by the model. The linear Cox model predicts the right value in this case. We also show the survival functions predicted by DeepHit, the baseline and the linear Cox model. As explained in Section 2 (Equation 3), the predictions are the expected values of the survival function. We depict predictions in relation to the prediction time; for instance, the linear Cox model predicts a time-to-event of 3 utterances at timestep 5, meaning that the event time will be timestep 8.

Figure 3 shows the MAE and CI scores, aggregated per timestep, for the Talk dataset. Lower MAE scores are observed for later timesteps. However, this does not mean that these models are necessarily better; the possible range of error is smaller later in a conversation. An interesting deviation here is the linear regression model, which performs the best at the last timestep. Upon inspection, we note that this is because the model predicts small values (with median values in range 0.02-0.09) at every timestep. This strategy is likely the result of the dataset being biased towards shorter conversations. At smaller values of t, there is a portion of long conversations which would contribute large errors to drive up the MAE, but this is not present at larger t, hence the discrepancy.

CI allows for more direct comparison of models at different t, since it measures ranking accuracy. On this metric, DeepHit performs better than the linear regression model at all but the last timestep. Both models perform slightly worse at the last two timesteps. A reason for this may be that there are fewer training samples available at larger t, as illustrated in Table 2. Similar trends are observed in the Dispute dataset.

4.3 Task 2: Predicting personal attacks

Results for the personal attack prediction task are shown in the right column of Table 3. Compared to Task 1, higher values are observed on the CI. A reason for this may be that conversation length prediction has to rely on more subtle cues that indicate a conversation has run its course (e.g. users signing off) which are not captured by our features.

We observe again that the DeepHit model performs the best, and that the survival models outperform the three baselines. Due to censoring, the MAE score here is calculated using only uncensored samples; i.e. samples where a personal attack does occur. The censored samples are accounted for in the CI metric, as explained in Section 3.1.

A key question in this task is whether the survival models manage to prioritise samples where a personal attack occurs over censored examples. This means that when comparing a pair consisting of a censored and an uncensored example, we would like for the predicted time to event of the censored example to be higher. We can calculate how often this is true for the DeepHit model by calculating the concordance index of the predicted event times and the inverse of the censoring indicator. For instance, given a pair of samples $s = [censored, uncensored]$, the indicator function is [0,1] and the inverse therefore [1,0]. The ordering of the inverse ($s_0 > s_1$) should be concordant with the predictions. Using the DeepHit model, we find that the model ranks samples where an attack occurs over censored examples in 57.75% of cases, compared to 51.92% with the linear regression model, and 50% for a random baseline. The best model of Zhang et al. (2018a) has a predictive accuracy of 64.9% for classifying which conversations will derail into personal attacks, but does not predict when this will occur.

5 Conclusions

In this paper, we proposed that survival analysis is a useful but hitherto ignored framework for time-to-event prediction tasks in conversations, which are frequently framed as classification tasks. We provided evidence to this by showing that survival models outperform both linear regression and logistic regression models on two tasks and three datasets. The survival regression models explored can be useful in other tasks, for instance, predicting escalation in customer service conversations.

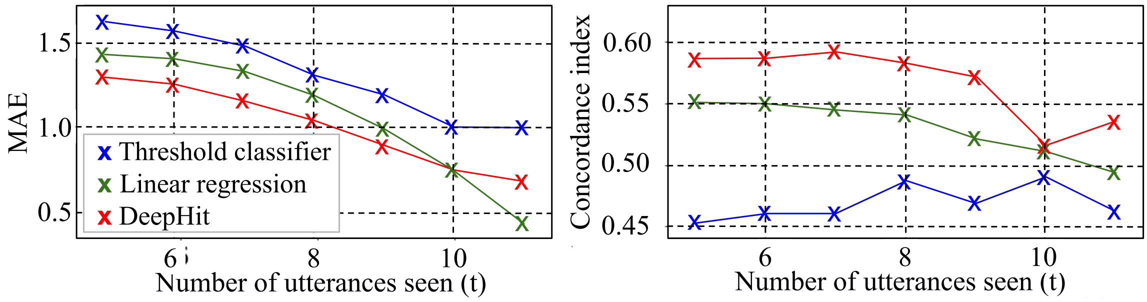

Figure 3: MAE and CI calculated per timestep, t, for the Talk dataset on Task 1. For MAE, lower values are preferred; for CI, higher.

Unsupervised Knowledge Selection for Dialogue Generation

Abstract

Knowledge selection is an important and challenging task which could provide the appropriate knowledge for informative dialogue generation. However, the needed gold knowledge label is difficult to collect in reality. In this paper, we study knowledge selection for dialogue generation in the unsupervised scenario and propose a novel Distilled Distant Supervision Loss (DDSL) to supervise knowledge selection when the gold knowledge label is unknown. Specifically, we first obtain an oracle knowledge label via distant supervision and then leverage knowledge distillation to alleviate the noisy labeling problem of distant supervision. Furthermore, we propose a pretraining-finetuning strategy to deal with the mismatch knowledge selection problem that models tend to select the mismatched knowledge for dialogue generation in the unsupervised setting and will cause the degeneration of knowledge-aware decoder. Experiments on two knowledge-grounded dialogue datasets show that our approach manages to select knowledge more accurately in the unsupervised setting and generates more informative responses, even outperforming many strong supervised baselines.[1]

1 Introduction

To avoid general and dull dialogue generation (Li et al., 2016), knowledge-grounded dialogue which equips dialogue systems with external knowledge has become a popular research topic. Thanks to the hand-collected knowledge-grounded dialogue datasets which align each dialogue (even each utterance) with a pre-identified document (Zhang et al., 2018; Zhou et al., 2018; Moghe et al., 2018; Zhou et al., 2020), many researchers focus on injecting the given knowledge to generate informative responses and achieve promising results (Yavuz et al., 2019; Tang and Hu, 2019; Qin et al., 2019a; Li et al., 2019b; Zheng and Zhou, 2019; Meng et al., 2019; Ren et al., 2019; Ye et al., 2020; Lin et al., 2020). However, they usually need the pre-identified knowledge and the knowledge access task is less studied (Kim et al., 2020b) which is the precursor to knowledge dialogue generation in reality (Zheng et al., 2020).

It is natural to extract the external knowledge via information retrieval technology. Several works regard the retrieved knowledge sentences as the pre-identified document (Ghazvininejad et al., 2018; Michel Galley, 2018; Yang et al., 2019b; Gopalakrishnan et al., 2019). However, the retrieved document contains redundant and irrelevant information which are harmful for dialogue generation (Zhao et al., 2020b). Hence, knowledge selection which chooses an appropriate sentence from the pre-retrieved knowledge pool gains much attention and it plays the role of knowledge access for generation. Dinan et al. (2019) first propose knowledge selection for dialogue generation which are two sequential subtasks and the generation is based on the selected knowledge. Several works follow their setting and achieve improvements with latent variable models (Kim et al., 2020a; Chen et al., 2020b) or more complex selection mechanism (Niu et al., 2019; Meng et al., 2020; Zheng et al., 2020; Meng et al., 2021). Although those works show promising performance with explicit use of knowledge in open-domain dialogue, they still need gold knowledge labels to train the selection module well (Kim et al., 2020a). And it is still less studied to make knowledge selection work well without gold knowledge label, which is valuable and challenging.

In this paper, we explore knowledge selection for dialogue generation in the unsupervised scenario and propose a novel Distilled Distant Supervision Loss (DDSL) to supervise knowledge selection when there is no gold knowledge label. Specifically, we first obtain an oracle knowledge

label via distant supervision (Mintz et al., 2009) to substitute the gold one in the unsupervised setting. However, distant supervision inevitably suffers from the noisy labeling problem due to literally matching (Yang et al., 2019a). Therefore, to train knowledge selection well without gold label, we leverage knowledge distillation to reduce the noise of the oracle label. Furthermore, we find that models tend to select the mismatched knowledge for dialogue generation in the unsupervised setting. And forcing the knowledge-aware decoder to leverage the selected knowledge at training will cause the decoder degenerating into the knowledge-independent decoder. To deal with this problem, we propose to pretrain the knowledge selection and response generation independently and then finetune the decoder with the selected knowledge using different sample weighting scores. We demonstrate the effectiveness of our unsupervised approach on two knowledge-grounded dialogue datasets, i.e., Wizard of Wikipedia (Dinan et al., 2019) and Holl-E (Moghe et al., 2018) in comparison with various supervised and unsupervised baselines.

Our contributions are summarized as follows:

- We propose Distilled Distant Supervision Loss to make knowledge selection work well in the unsupervised scenario where the gold knowledge label is not available.
- We propose a pretraining-finetuning strategy to alleviate the degeneration of knowledge-aware decoder caused by the mismatch knowledge selection problem.
- Results on two datasets show that our approach manages to select knowledge more accurately in the unsupervised setting and even generates more informative responses than many strong supervised baselines.

2 Approach

2.1 Task Formulation

Given the utterance x_t at each turn t and the associated knowledge pool $\mathcal{K}_t = \{k_t^i\} = \{k_t^1, \cdots, k_t^L\}$[2] containing L retrieved candidate sentences k_t^i, the final goal is to generate an informative response y_t. Following (Dinan et al., 2019), we first learn to select the appropriate knowledge k_t^s from the knowledge pool $\mathcal{K}_t$ and then generate the response y_t by incorporating the selected knowledge. In the conventional supervised setting, there exists gold knowledge label to supervise knowledge selection. However, the manually labeled knowledge is difficult to obtain in reality (Lian et al., 2019). As a result, we study the unsupervised knowledge selection for dialogue generation in this paper, which is very valuable and challenging.

2.2 Architecture Overview

In the following subsections, we first introduce the three major components (Section 2.3 $\sim$ 2.5): Encoder, Knowledge Selection (KS) and Decoder, which are trained jointly with the gold knowledge loss and response generation loss in the conventional supervised setting, as Figure 1 (a) shows. Then we introduce our Distilled Distant Supervision Loss (DDSL) in Section 2.6 to train knowledge selection well in the unsupervised setting, which consists of distant supervision and knowledge distillation, as Figure 1 (b) shows. Finally, we detail the mismatch knowledge selection problem and how to make the decoder leverage the selected knowledge k_t^s well in Section 2.7.

2.3 Encoder

For each sentence st, we obtain the context aware word representations $\mathbf{H}_{st}$ via BERT (Devlin et al., 2019) and the corresponding sentence representation $\mathbf{h}_{st}$ via Mean Pooling (Cer et al., 2018):

$$\begin{aligned} \mathbf{H}_{st} &= \mathrm{BERT}\left(st\right) \in \mathbb{R}^{N_{st} \times d} \\ \mathbf{h}_{st} &= \mathrm{Mean}\left(\mathbf{H}^{st}\right) \in \mathbb{R}^{d} \end{aligned} , \tag{1}$$

where N_{st} is the sentence length and d is the hidden size. Specifically, we represent the utterance x_t with $\mathbf{H}_{x_t}$ and $\mathbf{h}_{x_t}$, and represent each knowledge sentence $k_t^i \in \mathcal{K}_t$ with $\mathbf{H}_{k_t^i}$ and $\mathbf{h}_{k_t^i}$.

2.4 Knowledge Selection

In this paper, we mainly focus on knowledge selection in the unsupervised setting and adopt the standard dot-product attention over the knowledge candidates to select knowledge (Dinan et al., 2019).

Selection Query: The selection query consists of the current utterance, the dialogue history $dh_t = [x_1, y_1, \cdots, x_{t-1}, y_{t-1}]$ and the history of selected knowledge $kh_t = [k'_1, \cdots, k'_{t-1}]$ as they help the knowledge selection (Kim et al., 2020a). Formally, we use two GRUs (Cho et al., 2014) to summarize the dialogue and knowledge selection history as the

---

[2] k_t^i, k_t^s, k_t **and** k'_t indicate **any, selected, gold and oracle** knowledge sentences or labels, respectively.

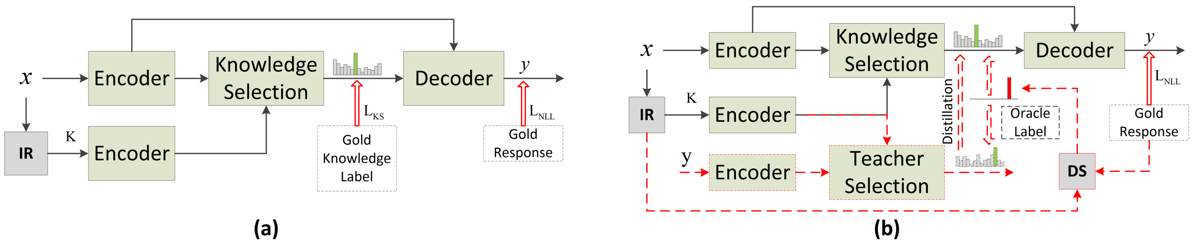

Figure 1: The framework of knowledge selection for dialogue generation. (a) In the supervised setting. (b) In the unsupervised setting. Specifically, we replace the gold knowledge loss with our Distilled Distant Supervision Loss (DDSL) which contains Distant Supervision (DS) and knowledge distillation (see the dotted red lines).

corresponding state vectors $\mathbf{s}_{dh_t}$ and $\mathbf{s}_{kh_t}$:

$$\begin{aligned} \mathbf{s}_{dh_t} &= \mathrm{GRU}_{\mathrm{dh}}\left(\left[\mathbf{h}_{x_t}; \mathbf{h}_{y_t}\right], \mathbf{s}_{dh_{t-1}}\right) \in \mathbb{R}^d \\ \mathbf{s}_{kh_t} &= \mathrm{GRU}_{\mathrm{kh}}\left(\mathbf{h}_{k'_t}, \mathbf{s}_{kh_{t-1}}\right) \in \mathbb{R}^d \end{aligned} , \quad (2)$$

where $\mathbf{s}_{dh_0}$ and $\mathbf{s}_{kh_0}$ are zero vectors, $\mathbf{h}_{x_t}$, $\mathbf{h}_{y_t}$ and $\mathbf{h}_{k'_t}$ are sentence vectors of utterance x_t, response y_t and the oracle knowledge k'_t (will be described in Equation 8) and $[\cdot;\cdot]$ denotes concatenation. Then, the selection query $\mathbf{q}_t$ is obtained:

$$\mathbf{q}_t = \mathbf{W}_q \left[\mathbf{s}_{kh_{t-1}}; \mathbf{s}_{dh_{t-1}}; \mathbf{h}_{x_t}\right] \in \mathbb{R}^d. \quad (3)$$

Knowledge Selection: The knowledge selection distribution $\mathcal{S} \in \mathbb{R}^L$ over the knowledge pool $\mathcal{K}_t \in \mathbb{R}^L$ is obtained by the dot-product attention:

$$\mathcal{S}_{k_t^i} = \frac{\exp\left(\mathbf{h}_{k_t^i} \cdot \mathbf{q}_t\right)}{\sum_{k_t^j \in \mathcal{K}_t} \exp\left(\mathbf{h}_{k_t^j} \cdot \mathbf{q}_t\right)}. \quad (4)$$

Finally, the knowledge k_t^{s} with the highest attention score is selected for further response generation. If the gold knowledge k_t exists, we could train this task via the Cross Entropy (CE) loss:

$$\mathcal{L}_{\mathrm{KS}} = \mathcal{L}_{\mathrm{CE}}\left(\mathcal{S}, k_t\right) = -\log \mathcal{S}_{k_t}, \quad (5)$$

2.5 Decoder

Following (Dinan et al., 2019; Kim et al., 2020a), our Transformer-based decoder takes the representation concatenation $\mathbf{H}_{rc} = \left[\mathbf{H}_{x_t}; \mathbf{H}_{k_t^s}\right] \in \mathcal{R}^{N_{rc},d}$ of current utterance x_t and the selected knowledge k_t^{s} as input, and uses the copy mechanism (Gu et al., 2016) to generate responses. The process of generating a word can be formulated as follows:

$$\begin{aligned} &\mathbf{s}_t^n = \mathrm{TD}\left(\mathbf{H}_{rc}, y_t^{<n}\right) \in \mathbb{R}^d \\ &\mathbf{p}_{\mathrm{v}} = \mathrm{softmax}\left(\mathbf{W}_o \mathbf{s}_t^n\right) \in \mathbb{R}^{|\mathcal{V}|} \\ &\mathbf{p}_{\mathrm{cp}}, \tilde{\mathbf{s}}_t^n = \mathrm{MultiHead}_{\mathrm{cp}}\left(\mathbf{s}_t^n, \mathbf{H}_{rc}, \mathbf{H}_{rc}\right) \\ &p_{\mathrm{gen}} = \mathrm{sigmoid}\left(\mathbf{W}_{\mathrm{gen}} \tilde{\mathbf{s}}_t^n\right) \in \mathbb{R}^1 \\ &\mathbf{p}\left(\mathcal{V}\right) = p_{\mathrm{gen}} \cdot \mathbf{p}_{\mathrm{v}} + \left(1 - p_{\mathrm{gen}}\right) \cdot \mathbf{p}_{\mathrm{cp}} \in \mathbb{R}^{|\mathcal{V}|} \end{aligned} , \quad (6)$$

where TD denotes the Transformer decoder, $\mathbf{s}_t^n$ is the hidden vector for the n-th word in the response y_t at t-th turn, $\mathbf{p}_{\mathrm{cp}}$ is the attention weight of the first head in the additional multi-head self-attention layer for the copy mechanism, which is short for $\mathrm{MultiHead}_{\mathrm{cp}}$ (Vaswani et al., 2017), $\mathcal{V}$ is the vocabulary, and $\mathbf{p}\left(\mathcal{V}\right)$ is the final generation distribution. Finally, we generate the word y_t^n with the highest probability, and we keep generating by feeding y_t^n to the decoder until the "$\langle$eos$\rangle$" token is generated. We train the generation task the Negative Log-Likelihood (NLL) loss:

$$\mathcal{L}_{\mathrm{G}} = \mathcal{L}_{\mathrm{NLL}} = -\log p\left(y_t | x_t, k_t^{\mathrm{s}}\right) \quad (7)$$

The model is trained with the loss $\mathcal{L} = \mathcal{L}_{\mathrm{KS}} + \mathcal{L}_{\mathrm{G}}$, where $\mathcal{L}_{\mathrm{KS}}$ is the knowledge selection loss, i.e., Equation 5 in the supervised setting.

2.6 Distilled Distant Supervision Loss

In this section, we will introduce our Distilled Distant Supervision Loss (DDSL) to train knowledge selection well in the unsupervised setting, which consists of distant supervision, label weighting and knowledge distillation. Actually, we first obtain a noisy oracle knowledge label via distant supervision. And then our DDSL tries to reduce the noise via label weighting and knowledge distillation.

Distant Supervision: Suppose that we have the utterance x_t, response y_t and the retrieved knowledge pool $\mathcal{K}_t$ without knowing the gold knowledge label, we first calculate the confidence score $\mathcal{W}_{k_t^i}$ whether each knowledge k_t^i is matched up with this dialogue flow by:

$$\begin{aligned} \mathrm{F1}\left(a, b\right) &= \frac{2 \cdot |\,\mathrm{set}(a) \cap \mathrm{set}(b)|}{|\,\mathrm{set}(a)| + |\,\mathrm{set}(b)| + \epsilon}, \\ \mathcal{W}_{k_t^i} &= \mathrm{softmax}_\tau\left(\mathrm{F1}\left(k_t^i, y_t\right)\right) \end{aligned} \quad (8)$$

where $\mathrm{set}(a)$ or $\mathrm{set}(b)$ indicates the tokens in the string a or b, $\mathrm{softmax}_\tau\left(z_i\right) = e^{(z_i/\tau)} / \sum_j e^{(z_j/\tau)}$

and τ is the temperature to reshape the confidence probability distribution $\mathcal{W} \in \mathbb{R}^L$ over the knowledge pool. Then, we obtain the oracle knowledge k'_t with the highest confidence score, assuming that the gold knowledge should contribute most tokens to the response generation. This is possible because that 1) the causal modeling specified conditions (Selltiz et al., 1976) hold between knowledge selection and response generation (Tuan et al., 2020), and 2) it is common for humans to (involuntarily) produce utterances which are copied or suitably modified from background knowledge sentences (Moghe et al., 2018).

Although we can directly replace the gold label k_t in Equation 5 with the alternative one k'_t, there are some noise. Therefore, we modify Equation 5 with label weighting via the confidence score:

$$\mathcal{L}_{\text{KS}} = \mathcal{L}_{\text{WCE}}(\mathcal{S}) = \mathcal{L}_{\text{CE}}\left(\mathcal{S}, k'_t\right) \cdot \mathcal{W}_{k'_t}. \tag{9}$$

Knowledge Distillation: We further alleviate the noisy labeling problem of distance supervision via Knowledge Distillation (KD) as shown in Figure 1 (b). Following (Tian et al., 2020; Chen et al., 2020b), the teacher takes the context and response as input and generates the distribution of knowledge selection as soft target. Compared with the student, i.e., the standard knowledge selection module described in Section 2.4, teacher has the gold response as an additional input.

Specifically, we make up the teacher query as $\mathbf{q}_t^{\text{tea}} = \mathbf{W}_{\text{tea}}\left[\mathbf{s}_{dh_t}; \mathbf{s}_{kh_{t-1}}\right] \in \mathbb{R}^d$, which contains more information (i.e., the response) than $\mathbf{q}_t$ in Equation 3. Then we use this query $\mathbf{q}_t^{\text{tea}}$ to obtain the teacher's knowledge selection distribution $\mathcal{T} \in \mathbb{R}^L$ by Equation 4. Finally, online response-base knowledge distillation[3] is formulated as:

$$\begin{aligned}\mathcal{L}_{\text{KD}} &= \mathcal{L}_{\text{WCE}}(\mathcal{T}) + D_{\text{KL}}(\mathcal{T} \,\|\, \mathcal{S}) \\ &= \mathcal{L}_{\text{CE}}(\mathcal{T}, k'_t) \cdot \mathcal{W}_{k'_t} + \sum_{k_t^i \in \mathcal{K}_t} \mathcal{T}_{k_t^i} \log \frac{\mathcal{T}_{k_t^i}}{\mathcal{S}_{k_t^i}},\end{aligned} \tag{10}$$

where the first term is used for teacher training and the second term transfers the knowledge from teacher to student based on the Kullback-Leibler (KL) divergence between the teacher and student distributions (i.e., $\mathcal{T} \in \mathbb{R}^L$ and $\mathcal{S} \in \mathbb{R}^L$).

Although the teacher is also trained with the noisy label, the teacher produces an independent source of variance that can be used to cancel out the variance introduced by the label noise (Li et al., 2017). Moreover, previous works have proved that the student can still be enhanced by the noisy teacher (Sau and Balasubramanian, 2016; Xie et al., 2020; Yuan et al., 2020). Therefore, we believe that the student trained by two supervision signals gets benefits from the regularization of the soft target (Yuan et al., 2020).

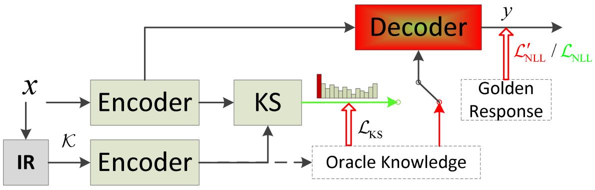

Figure 2: To deal with the mismatch problem, we first pretrain the Knowledge Selection (KS) and the decoder with the matched knowledge[4] in parallel along red lines. Then we finetune the decoder with the selected knowledge weightedly along the green line.

To sum up, our DDSL loss is as follows:

$$\mathcal{L}_{\text{KS}} = \mathcal{L}_{\text{DDSL}} = \mathcal{L}_{\text{WCE}}(\mathcal{S}) + \mathcal{L}_{\text{KD}}, \tag{11}$$

which consists of distant supervision, label weighting in Equation 9 and knowledge distillation in Equation 10 for unsupervised knowledge selection.

2.7 Training

The Mismatch Knowledge Selection Problem: As we know, there are chances that the selected knowledge is not the gold one due to 1) the diversity of knowledge selection in conversation (Kim et al., 2020a) and 2) the under-optimized knowledge selection at early training stage (Zhao et al., 2020b). And it is more serious in the unsupervised setting where it is hard to train knowledge selection well. The mismatch knowledge selection problem occurs due to the training paradigm in Figure 1 where the decoder is trained to generate the gold response with mismatched knowledge. This mismatch problem causes the knowledge-aware decoder to take the selected knowledge as noise and degenerate into the knowledge-independent decoder.

Our Pretraining-Finetuning Strategy: Although training the decoder with the matched knowledge[4] solves the mismatch problem. It can't deal with wrong knowledge selection at inference which is often the case, yet never seen at training.

---

[3] As surveyed in (Gou et al., 2020), response-based knowledge usually refers to the neural response of the last output layer of the teacher model, and online distillation means we train the teacher and student together.

[4] Note that the oracle knowledge is most literally matched with the gold response by the metric defined in Equation 8.

We take the plain idea as our pretraining stage, and then train the decoder to adapt to the selected knowledge using different weighting scores in the finetuning stage .

In the pretraining stage, we train knowledge selection and response generation in parallel as Figure 2 shows. The pretraining loss is as follows:

$$\begin{aligned}\mathcal{L}'_{\text{NLL}} &= -\log p\left(y_t | x_t, k'_t\right) \\ \mathcal{L} &= \mathcal{L}_{\text{KS}} + \mathcal{L}'_{\text{NLL}}\end{aligned}, \qquad (12)$$

where we use $\mathcal{L}_{\text{KS}} = \mathcal{L}_{\text{DDSL}}$ in the unsupervised setting and the decoder is trained to generate the gold response with the oracle knowledge k'_t instead of the selected one k^s_t. Therefore, the decoder learns how to incorporate the matched knowledge[4] k'_t into the response generation because k'_t is much more accurate than the selected one k^s_t as Table 4 shows. And we could alleviate the mismatch problem from the pretraining process because 1) we get a fully optimized knowledge selection module and 2) the pretrained decoder provides a good initialization for finetuning.

In the finetuning stage, we continuely train the pretrained decoder to adapt to the pretrained knowledge selection module with the sample weighting idea. And the finetuning loss is defined as follows:

$$\mathcal{L}_{\text{G}} = \mathcal{L}_{\text{NLL}} \cdot \left(1 + \mathcal{W}_{k^s_t}\right) \quad , \qquad (13)$$

where $\mathcal{L}_{\text{NLL}}$ is defined in Equation 7 and $\mathcal{W}_{k^s_t}$ is the confidence or weighting score of the selected knowledge k^s_t defined in Equation 8. As mentioned above, the mismatch knowledge selection problem is caused by the training paradigm that we may train the decoder to generate the gold response with the mismatched knowledge from the knowledge selection module. Here, we finetune the pretrained decoder with the selected knowledge k^s_t by giving higher importance weights if the selected knowledge is suitable for the gold response generation. In this way, we further alleviate the mismatch problem because we highlight the matched samples by assigning an importance weight to each instance (x_t, k^s_t, y_t) to reform the training data (Cai et al., 2020; Dong et al., 2020).

3 Experiments

3.1 Dataset

We evaluate our model on two public knowledge-grounded dialogue datasets: Wizard of Wikipedia (WoW) (Dinan et al., 2019) and Holl-E (Moghe et al., 2018), both of which provide the knowledge candidates with gold knowledge labels for knowledge selection. To test our approach in the unsupervised setting, we do not use the gold knowledge label provided in those datasets.

WoW contains the dialogues between two participants on some open-domain topics, where one is a curious learner while the other plays the role of a knowledgeable expert with access to the knowledge pool. Each knowledge pool contains about 61 sentences on average per turn, which are retrieved from Wikipedia based on the dialogue context via the IR system. There are 18430, 1948 and 1933 dialogues for training, validation and test, respectively. According to the topic overlapping, the test set is split into two subsets: 965 Test Seen and 968 Test Unseen dialogues, where Test Unseen consists of 58 topics never seen in train or validation.

Holl-E contains 7228, 930 and 913 dialogues for training, validation and test, respectively. Two test versions are provided: one with a single gold reference, the other with multiple gold references (more than one gold knowledge sentences and corresponding responses for each given conversation context). Each dialogue is assigned with a document of about 60 sentences on average as the knowledge pool. Here, we use the modified version (Kim et al., 2020a) which fits for knowledge selection.

3.2 Models for Comparison

We compare our method with a set of baselines:[5]

3.2.1 No Knowledge

S2S_{Transformer} is a Seq2Seq model based on Transformer (Vaswani et al., 2017) that does not leverage the external knowledge.

S2S_{BERT} replaces the Transformer Encoder with a pretrained BERT (Devlin et al., 2019).

3.2.2 Supervised Knowledge Selection

TMN is short for End-to-End Transformer MemNet (Dinan et al., 2019), which selects knowledge based on the Transformer memory network and generate responses via the Transformer decoder.

TMN_{BERT+PostKS+CP}, implemented by (Kim et al., 2020a), enhances the encoder with BERT, knowledge selection module with PostKS (Lian et al., 2019) and decoder with the copy mechanism (CP).

---

[5] See Appendix A.1 for more baselines, from knowledge-aware generation (Huang et al., 2020) to knowledge selection in the supervised, semi-supervised and unsupervised settings.

Table 1: Quantitative results on WoW. Our approach manages to select knowledge more accurately in the unsupervised setting and generate more informative responses than the strong baselines in the supervised setting. Note that models with "†" are implemented by ourselves and other models with citation are from the original paper.

SKT (Kim et al., 2020a), short for Sequential Knowledge Transformer, uses the posterior distribution by sequential latent modeling and achieves promising results in the supervised setting.

3.2.3 Unsupervised Knowledge Selection

TMN_0 is **TMN**, trained only via generation loss in Equation 7 without knowledge loss in Equation 5. **SKT_0** is SKT optimized without knowledge loss. **PostKS** (Lian et al., 2019) takes the benefits of latent variable models and leverages the posterior knowledge distribution as a pseudo label for knowledge selection without knowledge loss. Here, we use the results provided by (Kim et al., 2020a).

3.2.4 Our Unsupervised Methods

We implement our model in the unsupervised setting, namely Unsupervised Knowledge Selection for Dialogue Generation (**UKSDG**), which is optimized with our DDSL in Equation 11 for unsupervised knowledge selection and generation loss in Equation 7. **UKSDG_{PF}** indicates that we adopt our Pretraining-Finetuning strategy to alleviate the mismatch knowledge selection problem in Section 2.7. Furthermore, we remove several components for ablation study:

(1) **UKSDG w/o DDSL** is only optimized by the generation loss in Equation 7 without our DDSL.

(2) **$\text{UKSDG}_{\text{vec}}$ w/o DDSL** further replaces the decoder input $\mathbf{H}_{rc}$ (in Section 2.5) with the averaged knowledge vector enhanced context $\mathbf{H}_{vec} = \mathbf{H}_{x_t} + \sum_{k_t^i \in \mathcal{K}_t} \mathcal{S}_{k_t^i} \cdot \mathbf{h}_{k_t^i}$.

(3) **UKSDG_{PF} w/o SW** does not use the Sample Weighting in Equation 13.

3.3 Implementation Details

We use TensorFlow 2.0 to implement our approach base on SKT[6]. All sentences are encoded by the shared $\text{BERT}_{\text{BASE}}$ (Devlin et al., 2019), and the response is greedily generated via a 5-layer Transformer decoder with copy mechanism. The hidden size d is 768 and the vocabulary size $|V|$ is $30,522$. The knowledge selection module contains two separate one-layer GRUs and one projection layer. Our proposed DDSL contains no trainable parameters except one projection layer in the teacher selection module. And the temperature τ is 0.1.

We use the Adam optimizer (Kingma and Ba, 2014) with gradient clipping at 0.4 to train our models on a single GPU (TITAN Xp). The learning rate is $2e^{-5}$ and the batch[7] size is 1. Moreover, we apply label smoothing (Pereyra et al., 2017) and set 0.1 for knowledge selection and 0.05 for response generation. In the pretraining-finetuning strategy, we use 5 and 20 epochs in the pretraining and finetuning stage, respectively. The pretrained models are selected according to the accuracy score and other models are selected according to the R-1 score since knowledge selection aims to serve for high-quality generation.

It takes almost the same time for the convergence of UKSDG and KSDG as we only replace our DDSL with the gold knowledge selection loss. The convergence of SKT is a bit slower as it is hard

Table 2: Quantitative results on Holl-E. The method with "‡" is reported by rerunning the released code, and models with "†" are implemented by ourselves.

to optimize the latent variable model. It takes about 2.5 times as long for the convergence of UKSDG$_{\text{PF}}$ and KSDG$_{\text{PF}}$. The computation for confidence calculation during inference is the same for UKSDG, KSDG (w/ and w/o PF) and SKT because we adopt the same backbone. All of our models contain about $174M$ parameters.

3.4 Evaluation

Automatic Evaluation. We automatically evaluate knowledge selection with accuracy (Acc), response generation with perplexity (PPL), unigram F1 (R-1) and bigram F1 (R-2), which are commonly used in this task (Dinan et al., 2019; Kim et al., 2020a; Chen et al., 2020b). We also remove all the punctuation and (a, an, the) to compute the R-1 and R-2 scores as (Kim et al., 2020a) do. Note that lower PPL and higher R-1 and R-2 scores indicate better generation quality.

Human Evaluation. We firstly select 100 samples from each test set on WoW for human evaluation. Then we follow (Kim et al., 2020a; Li et al., 2019a) and ask three annotators to evaluate the generation quality according to Engagingness and Knowledgeability from 1 to 4, where 1 means not at all, 2 is a little, 3 is somewhat, and 4 is a lot. Engagingness measures how much do you like the response and Knowledgeability measures the informativeness in the responses.

4 Results and Analysis

4.1 Main Results

Quantitative Results. We report the automatic results on WoW and Holl-E in Table 1 and Table 2, respectively. And we have the following consistent observations:[8] (1) Comparing SKT and SKT$_0$, we see that the gold knowledge loss plays an important role to train knowledge selection well. (2) Comparing row 0 and 2, we see that our proposed DDSL is the key to train knowledge selection well in the unsupervised setting and can be the alternative of the gold knowledge loss. As a result, our approach significantly outperforms the other unsupervised methods on all metrics (significance tests (Koehn, 2004), p-value < 0.01). (3) Although UKSDG$_{\text{vec}}$ w/o DDSL could learn some patterns of knowledge selection from the gradient of generation loss, we see that compressing the knowledge into a vector will loss much information for dialogue generation. (4) Although our UKSDG$_{\text{PF}}$ usually makes knowledge selection worse than the supervised SKT in row 1_2, we achieve higher generation quality, which indicates that our pretraining-finetuning strategy could alleviate the mismatch knowledge selection problem and emphasizes the importance of leveraging the selected knowledge properly for future study on this task. (5) Comparing row 3 and 4, we see that the sample weighting also helps in the finetuning stage, though PPL score is slightly worse due to the difficulty of injecting the knowledge into responses. (6) Moreover, our approach demonstrates the stronger ability of generalization with smaller performance gap between Test Seen and Test Unseen in Table 1, which we attribute to our DDSL because it works in the unsupervised setting and is more suitable for Test Unseen. For example, compared with SKT in row 1_2, UKSDG$_{\text{PF}}$ in row

---

[8] More observations with other baselines can be found in Appendix A.2.

Method	Test Seen		Test Unseen	
	EGG	**KLD**	**EGG**	**KLD**
SKT	2.70±0.05	2.64±0.05	2.46±0.05	2.50±0.06
UKSDG (ours)	2.49±0.05	2.37±0.06	2.33±0.06	2.27±0.05
UKSDG$_{\mathrm{PF}}$ (ours)	2.72±0.05	2.71±0.05	2.49±0.06	2.60±0.05
Gold Response	3.25±0.04	3.37±0.05	3.16±0.05	3.24±0.05

Table 3: Results of human evaluations on WoW. **EGG** and **KLD** denote Engagingness and Knowledgeability, respectively.

Method	WoW		Holl E	
	Seen	Unseen	Single	Multi
Gold label (k_t)	100.0	100.0	100.0	100.0
Oracle Label (k'_t)	70.1	69.0	90.3	90.4
$\mathcal{L}_{\mathrm{DDSL}}$ in Eq. 11	26.4	20.8	25.1	35.0
w/o $\mathcal{L}_{\mathrm{KD}}$ in Eq. 10	25.8	19.1	24.1	33.5
w/o $\mathcal{L}_{\mathrm{KD}}$ & $\mathcal{W}_{k'_t}$ in Eq. 9	25.5	18.8	24.0	34.2

Table 4: Ablation study. Knowledge selection accuracy of UKSDG$_{\mathrm{PF}}$ trained with different losses.

4 achieves the highest selection accuracy in Test Unseen with a slightly lower accuracy in Test Seen.

Qualitative Results. We report human evaluation results of the generated responses according to Engagingness and Knowledgeability in Table 3. Comparing UKSDG and UKSDG$_{\mathrm{PF}}$, we see the effectiveness of our pretraining-finetuning strategy which could alleviate the mismatch problem described in Section 2.7. Our UKSDG$_{\mathrm{PF}}$ in the unsupervised setting generates responses slightly better than SKT in the supervised setting. Moreover, the improvement is much obvious according to Knowledgeability, which also indicates the importance of using the selected knowledge properly.

4.2 Ablation Study

We have introduced the components of our DDSL in Section 2.6 and shown its effectiveness in Section 4.1. Here, we analyse our DDSL via an ablation study in Table 4. Actually, we train UKSDG$_{\mathrm{PF}}$ on knowledge selection task, using our DDSL with components removed. We have the following observations: (1) We see that most of the oracle knowledge from distant supervision is the same as the gold knowledge label by human. Therefore, it is acceptable to directly use this oracle knowledge label to substitute the gold label as the supervision signal (see the last row of Table 4). (2) However, distant supervision inevitably suffers from the noisy labeling problem due to literally matching. For example, there are about 30% oracle knowledges different from the gold ones on WoW where the responses convey knowledge much more flexibly. (3) Loss weighting in Equation 9 helps on WoW where the noisy labeling problem is serious. (4) Knowledge distillation in Equation 10 could further alleviate the label noise, and our method manages to select knowledge accurately in the unsupervised setting.

4.3 Case Study

Table 5 presents several examples of generated responses on WoW and we have the following observations: (1) The oracle knowledge from distant supervision contains several informative tokens which could help dialogue generation since they appears in the gold response as defined by Equation 8. In particular, the oracle knowledge in the case 3 is also appropriate and the gold response contains much more information than the gold knowledge, which indicates the diversity of knowledge selection and selecting one sentence may be not enough for informative generation. (2) However, some oracle knowledge labels are different from the gold ones (i.e., the selected one by human). Our model still learns to select knowledge as human, which we attribute to our DDSL since knowledge distillation alleviates the noisy labeling problem of distant supervision. (3) SKT does not leverage the selected knowledge well and generates the dull response. For example, SKT repeats the context in case 1, generates the verbose and contradictory response in case 2 and does not provide new information in case 3. (4) Whereas, our UKSDG$_{\mathrm{PF}}$ firstly selects the appropriate knowledge as human does, and then generate fluent and informative responses by alleviate the mismatch knowledge selection problem with the help of the pretraining-finetuning strategy. This indicates the importance of leveraging the selected knowledge properly for future study.

5 Related Work

External knowledge has been wildly explored to enhance dialogue understanding and/or improve dialogue generation (Zhu et al., 2017; Liu et al., 2018; Chen et al., 2019; Wu et al., 2019; Chen et al., 2020a; Tuan et al., 2020; Sun et al., 2020; Zhang et al., 2020; Yu et al., 2020; Ni et al., 2021). To make use of knowledge, knowledge access is very important. Therefore, knowledge selection which selecting appropriate knowledge given the dialog context gains much attention (Zhang et al., 2019; Meng et al., 2019; Ren et al., 2019; Dinan

Table 5: Examples of generated responses on WoW. KS, DG and OK denote Knowledge Selection, Dialogue Generation and Oracle Knowledge, respectively.

et al., 2019; Kim et al., 2020a; Meng et al., 2020; Chen et al., 2020b; Zheng et al., 2020; Huang et al., 2020). In this paper, we focus on knowledge selection in the unsupervised setting where there is no gold knowledge label. Lian et al. (2019) and Kim et al. (2020a) attempt to deal with this problem via latent models, yet their performance is less than satisfactory. Differently, we design our DDSL to make knowledge selection work well in the unsupervised setting. There is a very recent work (Zhao et al., 2020b) that finetunes GPT-2 (Radford et al., 2019) with the unsupervised pretrained knowledge selection module on unlabeled dialogues. We are different in two aspects: (1) Our DDSL leverages knowledge distillation to alleviate the label noise at the pretraining stage; (2) We adopt the sample weighting idea at the finetuning stage. And we will leverage GPT-2 for future study.

Our work is inspired by Distant Supervision (DS), an effective method to generate labeled data with external knowledge base (KB) for information extraction (Mintz et al., 2009; Min et al., 2013; Zeng et al., 2015; Wang et al., 2018). Following this idea, Gopalakrishnan et al. (2019) use the oracle knowledge from DS to construct the Topical-Chat dataset. Similarly, Qin et al. (2019b) obtain the weakly labeled data to train a KB retriever in the task-oriented dialogue system. Ren et al. (2019) propose a distantly supervised learning schema at segment level to effectively learn the topic transition vector. Although inspired by the similar idea, we are devoted to knowledge selection in the unsupervised setting, which is a different application of DS. Moreover, rather than just using distant supervision, we design our DDSL with label weighting and knowledge distillation to deal with the noisy labeling problem from DS.

6 Conclusion

We study unsupervised knowledge selection for dialogue generation where the gold knowledge label is not available. Actually, we design the Distilled Distant Supervision Loss, a novel and effective solution to train knowledge selection well in the unsupervised setting. Furthermore, we propose the pretraining-finetuning strategy to deal with the mismatch knowledge selection problem that models tend to select the mismatched knowledge for dialogue generation in the unsupervised setting and will cause the degeneration of knowledge-aware decoder. Experiments show that our approach manages to select knowledge more accurately in the unsupervised setting and generates more informative responses than many strong supervised baselines.

A Additional Experiments

A.1 Models for Comparison

A.1.1 Our Unsupervised Methods

We implement our model in the unsupervised setting, namely Unsupervised Knowledge Selection for Dialogue Generation (**UKSDG**), which is optimized with our DDSL in Equation 11 for unsupervised knowledge selection and generation loss in Equation 7. **UKSDG$_{\textbf{PF}}$** indicates that we adopt our Pretraining-Finetuning strategy to alleviate the mismatch knowledge selection problem in Section 2.7. Furthermore, we remove several components for ablation study:

(1) **UKSDG w/o DDSL** does not use our DDSL.

(2) **UKSDG$_{\textbf{vec}}$ w/o DDSL** further replaces the decoder input $\mathbf{H}_{rc}$ (in Section 2.5) with the averaged knowledge vector enhanced context $\mathbf{H}_{vec} = \mathbf{H}_{x_t} + \sum_{k_t^i \in \mathcal{K}_t} \mathcal{S}_{k_t^i} \cdot \mathbf{h}_{k_t^i}$.

(3) **UKSDG$_{\textbf{PF}}$ w/o SW** does not use the Sample Weighting in Equation 13.

A.1.2 Our Supervised Methods

Here, we also report the Knowledge Selection for Dialogue Generation (**KSDG**) in the supervised setting as described in Section 2.3, 2.4 and 2.5. And **KSDG$_{\textbf{PF}}$** alleviates the mismatch problem using the pretrain-finetuning strategy in Section 2.7. We use the gold knowledge loss in Equation 5 to train KSDG and KSDG$_{\text{PF}}$ in the supervised setting while we train UKSDG and UKSDG$_{\text{PF}}$ with our DDSL when the gold knowledge is not available.

We compare our method with a set of baselines:

A.1.3 No Knowledge

S2S$_{\textbf{Transformer}}$ is a Seq2Seq model based on Transformer (Vaswani et al., 2017) that does not leverage the external knowledge.

S2S$_{\textbf{BERT}}$ replaces the Transformer Encoder with a pre-trained BERT (Devlin et al., 2019).

KnowExpert (Xu et al., 2021) avoids the knowledge retrieval process and attempts to inject prior knowledge into the pre-trained language models for knowledge-grounded dialogue generation task. Essentially, KnowExpert stores knowledge in its parameters with lightweight adapters. Therefore, KnowExpert does not use knowledge explicitly at inference.

A.1.4 Supervised Knowledge Selection

TMN is short for End-to-End Transformer MemNet (Dinan et al., 2019), which selects knowledge based on the Transformer memory network and generate responses via the Transformer decoder.

TMN$_{\textbf{BERT+PostKS+CP}}$, implemented by (Kim et al., 2020a), enhances the encoder with the pretrained BERT, knowledge selection module with PostKS (Lian et al., 2019) and decoder with the copy mechanism (CP).

SKT (Kim et al., 2020a), short for Sequential Knowledge Transformer, uses the posterior distribution by sequential latent modeling and achieves promising results in the supervised setting.

SKT+PIPM+KDBTS (Chen et al., 2020b) equips SKT with Posterior Information Prediction Module (PIPM) and Knowledge Distillation Based Training Strategy (KDBTS) to bridge the gap between prior and posterior knowledge selection for knowledge-grounded dialogue generation.

A.1.5 Unsupervised Knowledge Selection

TMN$_0$ is **TMN**, trained only via generation loss in Equation 7 without knowledge loss in Equation 5.

SKT$_0$ is **SKT** optimized without knowledge loss.

PostKS (Lian et al., 2019) takes the benefits of latent variable models and leverages the posterior knowledge distribution as a pseudo label for knowledge selection without knowledge loss. Here, we use the results provided by (Kim et al., 2020a).

A.1.6 Knowledge-Aware Generation

Different from ours on the knowledge selection setting, there are much work, named knowledge-aware generation (Huang et al., 2020), which regard the retrieved knowledge pool as the pseudo pre-identified document for dialogue generation with complex knowledge injection mechanism. Nevertheless, we provide the results to get a comprehensive understanding where this field is going.

MTASK-RF (Ghazvininejad et al., 2018) is an early model that realizes knowledge-grounded conversation without crowd-sourced knowledge-grounded dialogues. Here we use the results provided by (Li et al., 2020).

ITDD is short for Incremental Transformer with Deliberation Decoder (Li et al., 2019b) where the encoder incrementally represents multi-turn dialogues and knowledge, and the decoder conducts response decoding in two passes.

DRD is short for Disentangle Response Decoder (Zhao et al., 2020a), a model that exploits pre-training techniques to tackle the low-resource challenge in knowledge-grounded dialogue generation. We choose the one whose parameters are fine-tuned on the full training data.

KIC (Lin et al., 2020) integrates recurrent Knowledge-Interaction and knowledge Copy (KIC) to generate informative responses.

ZRKGC (Li et al., 2020) is a very recent and unpublished work, which learns their model under the zero-resource setting, where the dialogue corpus and the knowledge corpus that are independent with each other.

A.2 Quantitative Results

Table 6 shows the automatic results in various settings on the Wizard of Wikipedia dataset, from which we have the following observations[9]: (1) The models with retrieved document generally achieves much lower PPL, still the R-1 is worse than our UKSDG$_{\text{PF}}$. For the worse R-1 score, we think the retrieved document contains the redundant and irrelevant information which are harmful for dialogue generation (Zhao et al., 2020b). Meanwhile, we attribute the better PPL score to the complex knowledge injection mechanism. For example, ITDD leverages the deliberation decoder (Xia et al., 2017) to improve context coherence and knowledge correctness and DRD devises a disentangled response decoder with pretrained language model, context processor and knowledge processor. (2) Comparing KSDG with KSDG$_{\text{PF}}$, again we see the generation quality improvement via the pretrain-finetuning strategy. Hence, our method is general in both supervised and unsupervised setting. (3) Comparing UKSDG$_{\text{vec}}$ w/o DDSL with UKSDG w/o DDSL, we see that although selecting the knowledge vector softly allows the gradient from dialogue generation to update knowledge selection directly, compressing the knowledge into a vector will loss much information for dialogue generation. This observation, combined with observations (1) and (2), together indicates the importance of leveraging the selected knowledge well for future study.

---

[9] The observations in the main paper will not be discussed again here.

Abstract

Model-agnostic meta-learning (MAML) has been recently put forth as a strategy to learn resource-poor languages in a sample-efficient fashion. Nevertheless, the properties of these languages are often *not* well represented by those available during training. Hence, we argue that the *i.i.d.* assumption ingrained in MAML makes it ill-suited for cross-lingual NLP. In fact, under a decision-theoretic framework, MAML can be interpreted as minimising the expected risk across training languages (with a uniform prior), which is known as Bayes criterion. To increase its robustness to outlier languages, we create two variants of MAML based on alternative criteria: Minimax MAML reduces the *maximum* risk across languages, while Neyman–Pearson MAML *constrains* the risk in each language to a maximum threshold. Both criteria constitute fully differentiable two-player games. In light of this, we propose a new adaptive optimiser solving for a local approximation to their Nash equilibrium. We evaluate both model variants on two popular NLP tasks, part-of-speech tagging and question answering. We report gains for their average and minimum performance across low-resource languages in zero- and few-shot settings, compared to joint multi-source transfer and vanilla MAML. The code for our experiments is available at `https://github.com/rahular/robust-maml`.

1 Introduction

Knowledge transfer is ubiquitous in machine learning because of the general scarcity of annotated data (Pratt, 1993; Caruana, 1997; Ruder, 2019, *inter alia*). A prominent example thereof is transfer from resource-rich languages to resource-poor languages (Wu and Dredze, 2019; Ponti et al., 2019b; Ruder et al., 2019). Recently, Model-Agnostic Meta-Learning (MAML; Finn et al., 2017) has come to the fore as a promising paradigm: it explicitly trains neural models that adapt to new languages quickly by extrapolating from just a few annotated data points (Gu et al., 2018; Nooralahzadeh et al., 2020; Wu et al., 2020; Li et al., 2020).

MAML usually rests on the simplifying assumption that the source 'tasks' and the target 'tasks' are independent and identically distributed (henceforth, *i.i.d.*). However, in practice most scenarios of cross-lingual transfer violate this assumption: training languages documented in mainstream datasets do not reflect the cross-lingual variation, as they belong to a clique of few families, geographical areas, and typological features (Bender, 2009; Joshi et al., 2020). Therefore, the majority of the world's languages lies outside of such a clique. As training and evaluation languages differ in their joint distribution, they are not exchangeable (Ponti, 2021; Orbanz, 2012, ch. 6). Therefore, there is no formal guarantee that MAML generalises to the very languages whose need for transfer is most critical.

In this work, we interpret meta-learning within a decision-theoretic framework (Bickel and Doksum, 2015). MAML, we show, minimises the expected risk across languages found in the training distribution. Hence, it follows a so-called Bayes criterion. What if, instead, we formulated alternative criteria geared towards outlier languages? The first criterion we propose, Minimax MAML, is designed to be robust to worst-case-scenario out-of-distribution transfer: it minimises the *maximum* risk by learning an adversarial language distribution. The second criterion, Neyman–Pearson MAML, upper-bounds the risk for an arbitrary subset of languages via Lagrange multipliers, such that it does not exceed a predetermined threshold.

Crucially, both of these alternative criteria constitute competitive games between two players: one minimising the loss with respect to the neural pa-

rameters, the other maximising it with respect to the language distribution (Minimax MAML) or Lagrange multipliers (Neyman–Pearson MAML). Since an absolute Nash equilibrium may not exist for non-convex functions (Jin et al., 2020), such as neural networks, a common solution is to approximate local equilibria instead (Schäfer and Anandkumar, 2019). Therefore, we build on previously proposed optimisers (Balduzzi et al., 2018; Letcher et al., 2019; Gemp and Mahadevan, 2018) where players follow non-trivial strategies that take into account the opponent's predicted moves. In particular, we enhance them with first-order momentum and adaptive learning rate and apply them on our newly proposed criteria.

We run experiments on Universal Dependencies (Zeman et al., 2020) for part-of-speech (POS) tagging and TyDiQA (Clark et al., 2020) for question answering (QA). We perform knowledge transfer to 14 and 8 target languages, respectively, which belong to under-represented and often endangered families (such as Tupian from Southern America and Pama–Nyugan from Australia). We report modest but consistent gains for the average performance across languages in few-shot and zero-shot learning settings and mixed results for the minimum performance. In particular, Minimax and Neyman–Pearson MAML often surpass vanilla MAML and multi-source transfer baselines, which are currently considered state-of-the-art in these tasks (Wu and Dredze, 2019; Ponti et al., 2021; Clark et al., 2020).

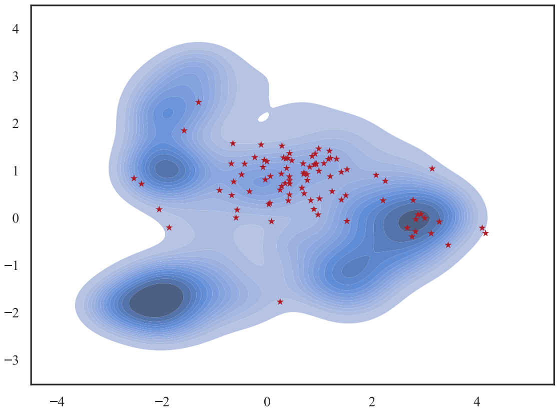

Figure 2: Density of WALS typological features of the world's languages reduced to 2 dimensions via PCA. Red dots are languages covered by UD. Darkness corresponds to more probable regions.

2 Skewed Language Distributions

Cross-lingual learning aims at transferring knowledge from resource-rich languages to resource-poor languages, to compensate for their deficiency of annotated data (Tiedemann, 2015; Ruder et al., 2019; Ponti et al., 2019a). The set of target languages ideally encompasses most of the world's languages. However, the source languages available for training are often concentrated around few families, geographic areas, and typological features (Cotterell and Eisner, 2017; Gerz et al., 2018b,a; Ponti et al., 2020; Clark et al., 2020). As a consequence of this discrepancy, a language drawn at random might have no related languages available for training. Even when this is not the case, they might provide a scarce amount of examples for supervision.

To illustrate this point, consider Universal Dependencies (UD; Zeman et al., 2020), hitherto the most comprehensive collection of manually curated multilingual data. First, out of 245 families attested in the world according to Glottolog (Hammarström et al., 2016), UD covers only 18.[1] In fact, some families are chronically over-represented (e.g. Indo-European and Uralic) and others are neglected (e.g. Pama-Nyugan and Uto-Aztecan). Second, as shown in Figure 1, the allocation of labelled examples across families is imbalanced (e.g. note the low counts for Niger–Congo or Dravidian languages). Third, one can measure how representative the linguistic traits of training languages are in comparison to those encountered around the globe. In

---

[1] For more details on family distributions, cf. Figure 5 in the Appendix.

Figure 2, we represent UD languages as dots in the space of possible typological features in WALS (Dryer and Haspelmath, 2013). These are plotted against the density of the distribution based on all languages in existence. Crucially, it emerges that UD languages mostly lie in a low-density region. Therefore, they hardly reflect the variety of possible combinations of typological features.

In general, this demonstrates that the distribution of training languages in existing NLP datasets is heavily skewed compared to the real-world distribution. Indeed, this very argument holds true *a fortiori* in smaller, less diverse datasets. While this fact is undisputed in the literature, its consequences for modelling, which we expound in the next section, are often under-estimated.

3 Robust MAML

Model-Agnostic Meta Learning (MAML; Finn et al., 2017) has recently emerged as an effective approach to cross-lingual transfer (Gu et al., 2018; Nooralahzadeh et al., 2020; Wu et al., 2020; Li et al., 2020). MAML seeks a good initialisation point for neural weights in order to adapt them to new languages with only a few examples. To this end, for each language $\mathcal{T}_i$ a neural model $f_{\boldsymbol{\vartheta}}$ is updated according to the loss on a batch of examples $\mathcal{L}_{\mathcal{T}_i}(f_{\boldsymbol{\vartheta}}, \mathcal{D}_{train})$. This inner loop is iterated for k steps. Afterwards, the loss incurred by the model on a held-out batch $\mathcal{D}_{val}$ is compounded with those of the other languages as part of an outer loop, as shown in Equation (1):

$$\begin{aligned} \boldsymbol{\vartheta}^\star &= \min_{\boldsymbol{\vartheta}} \sum_{\mathcal{T}_i} \mathcal{L}_{\mathcal{T}_i}(f_{\boldsymbol{\varphi}_i}, \mathcal{D}_{val})\, p(\mathcal{T}_i) \\ \text{where} \quad \boldsymbol{\varphi}_i &= \boldsymbol{\vartheta} - \eta \nabla_{\boldsymbol{\vartheta}} \mathcal{L}_{\mathcal{T}_i}(f_{\boldsymbol{\vartheta}}, \mathcal{D}_{train}) \end{aligned} \tag{1}$$

where $\eta \in \mathbb{R}_{>0}$ is the learning rate. Language probabilities are often taken to follow a discrete uniform distribution $p(\mathcal{T}_i) = \frac{1}{|\mathcal{T}|}$. In this case, Equation (1) becomes a simple average.

MAML can also be interpreted as point estimate inference in a hierarchical Bayesian graphical model (see Figure 4 in the Appendix). In this case, the adapted parameters $\boldsymbol{\varphi}_i$ are equivalent to an intermediate language-specific variable acting as a bridge between the language-agnostic parameters $\boldsymbol{\vartheta}$ and the data (Grant et al., 2018; Finn et al., 2018; Yoon et al., 2018). This allows us to reason about the conditions under which a model is expected to generalise to new languages. Crucially, generalisation rests on the assumption of independence and identical distribution among the examples (including both train and evaluation), which is known as exchangeability (Zabell, 2005). However, as seen in Section 2, most of the world's languages are outliers with respect to the training language distribution. Therefore, there is no solid guarantee that meta-learning may fulfil its purpose, i.e. generalise to *held-out* languages.

3.1 Decision-Theoretic Perspective

To remedy the mismatch between assumptions and realistic conditions, in this work we propose objectives which can serve as alternatives to Equation (1) of vanilla MAML. These are rooted in an interpretation of MAML within a decision-theoretic perspective (Bickel and Doksum, 2015, ch. 1.3), which we outline in what follows. The quantity of interest we aim at learning is the neural parameters $\boldsymbol{\vartheta}$. Therefore, the action space for a classification task assigning labels $y \in \mathcal{Y}$ to inputs $\mathbf{x} \in \mathcal{X}$ is $\mathcal{A} = \{f_{\boldsymbol{\vartheta}} : \mathcal{X} \to \mathcal{Y}\}$. The risk function is in turn a function $\mathcal{R} : \mathcal{F} \times \mathcal{A} \to \mathbb{R}^+$, which is the loss incurred by taking an action in $\mathcal{A}$ (making a prediction with a specific configuration of neural parameters) when the 'state of nature', the true function, is $f \in \mathcal{F}$. In the case of MAML, this is represented by the language-specific inner loop loss $\mathcal{L}_{\mathcal{T}_i}(\cdot)$ in Equation (1).

The decision for the optimal action given the sample space, the function $\delta : \mathcal{X} \times \mathcal{Y} \to \mathcal{A}$, is usually determined via gradient descent optimisation for a neural network. The optimal action, however, may vary depending on the language, which results in multiple possible 'states of nature'. Usually, there is no procedure δ whose loss is inferior to all others, such that:

$$\nexists \delta \;\; \mathcal{L}(\mathcal{T}_i, \delta) < \mathcal{L}(\mathcal{T}_i, \delta') \; \forall \mathcal{T}_i \in \mathcal{T}, \delta \neq \delta' \tag{2}$$

Therefore, decision functions have to be compared based on a global criterion rather than in a pairwise fashion between languages. As previously anticipated, Equation (1) minimizes the *expected* risk across languages, for an arbitrary choice of prior $p(\mathcal{T})$. In decision theory, a decision $\delta^\star$ with this property is called *Bayes criterion.*

3.2 Alternative Criteria

There exist alternative criteria to the Bayes criterion that are more justified in a setting that entails transfer between non-i.i.d. domains. Rather than minimising the Bayes risk, in this work, we propose to adjust MAML to either minimise the maximum risk (minimax criterion) or to enforce constraints on the risk for a subset of languages (Neyman–Pearson criterion). This is likely to yield more robust predictions for languages that are outliers to the training distribution. As demonstrated in Section 2, this definition encompasses most of the world's languages.

3.2.1 Minimax Criterion

Rather than the expected risk, the criterion could depend instead on the worst case scenario, i.e. the language for which the risk is *maximum*. This requires to select such a language with max. As an alternative to reinforcement learning (Zhang et al., 2020), to keep our model fully differentiable, we relax the operator by treating the choice of language as a categorical distribution $\mathcal{T}_i \sim \text{Cat}(\cdot \mid \boldsymbol{\tau})$. The parameters $\boldsymbol{\tau} \in [0,1]^{|\mathcal{T}|}, \sum_i \tau_i = 1$ consist of language probabilities and are learned in an adversarial fashion:

$$\min_{\boldsymbol{\vartheta}} \max_{\mathcal{T}_i \sim \text{Cat}(\cdot \mid \boldsymbol{\tau})} \mathcal{L}_{\mathcal{T}_i}(f_{\boldsymbol{\vartheta} - \eta \nabla_{\boldsymbol{\vartheta}} \mathcal{L}_{\mathcal{T}_i}(f_{\boldsymbol{\vartheta}}, \mathcal{D}_{train})}, \mathcal{D}_{val}) \tag{3}$$

Equation (3) can be interpreted as a two-player game between us (the scientists) and nature. We pick an action $\boldsymbol{\vartheta}$. Then nature picks a language $\mathcal{T}_i \in p(\mathcal{T})$ for which the risk is maximum given our chosen action. Therefore, our goal becomes to minimise such risk.

3.2.2 Neyman–Pearson Criterion

As an alternative, we might consider minimising the expected risk, but subject to a guarantee that the risk does not exceed a certain threshold for a subset of languages. In practice, we may want to enforce a set of inequality constrains, so that we minimise Equation (1) subject to $\{\mathcal{L}_{\mathcal{T}_i} \leq r \; \forall \mathcal{T}_i \in \mathcal{C}\}$, where $r \in \mathbb{R}_+$ is a hyper-parameter. In general, $\mathcal{C} \subseteq \mathcal{T}$ can be any subset of the training languages; in practice, here we take $\mathcal{C} = \mathcal{T}$. Constrained optimisation is usually implemented through Lagrange multipliers, where we add as many new terms to the objective as we have constraints (Bishop, 2006, ch. 7):

$$\begin{aligned} &\min_{\boldsymbol{\vartheta}} \max_{\boldsymbol{\lambda}} \sum_{\mathcal{T}_i} \frac{1}{|\mathcal{T}|} \mathcal{L}_{\mathcal{T}_i} + \sum_{\mathcal{T}_i} \lambda_i (\mathcal{L}_{\mathcal{T}_i} - r) \\ &= \min_{\boldsymbol{\vartheta}} \max_{\boldsymbol{\lambda}} \sum_{\mathcal{T}_i} \left(\frac{1}{|\mathcal{T}|} + \lambda_i \right) \mathcal{L}_{\mathcal{T}_i} - \lambda_i r \end{aligned} \tag{4}$$

where $\boldsymbol{\lambda}$ is a vector of non-negative Lagrange multipliers $\{\lambda_i \geq 0 \quad \forall \lambda_i \in \boldsymbol{\lambda}\}$ to be learned together with the parameters $\boldsymbol{\vartheta}$, but adversarially.

Intuitively, if the risk for the estimated parameters $\boldsymbol{\vartheta}$ lies in the permissible range, the constraints should become inactive $\{\lambda_i = 0 \quad \forall \lambda_i \in \boldsymbol{\lambda}\}$, i.e. each Lagrange multiplier should go towards 0. Otherwise, the solution should be affected by the constraints, which should keep $\boldsymbol{\vartheta}$ from trespassing the boundary $\{\mathcal{L}(\boldsymbol{\vartheta})_{\mathcal{T}_i} = r \quad \forall \mathcal{T}_i \in \mathcal{T}\}$. In gradient-based optimisation, this unfolds as follows: the gradient of each λ_i depends uniquely on $(\mathcal{L}_{\mathcal{T}_i} - r)$. Due to being maximised, the value of each λ_i increases when the corresponding risk is above the threshold, and shrinks otherwise. Incidentally, note that the Lagrangian multipliers at the critical point $\boldsymbol{\vartheta}^\star$ are equal to the negative rate of change of r, as $\frac{\partial \mathcal{R}(\boldsymbol{\vartheta}^\star)}{\partial r} = -\boldsymbol{\lambda}$. In other words, upon convergence λ_i expresses how much we can decrease the risk in $\mathcal{T}_i$ as we increase the threshold.

Constrained Parameters The additional variables $\boldsymbol{\tau}$ and $\boldsymbol{\lambda}$, contrary to the neural parameters, are constrained in the values they can take. In neural networks, there are two widespread approaches to coerce variables within a certain range, viz. reparametrisation and gradient projection (Beck and Teboulle, 2003).[2] For simplicity's sake, we opt for the former, which just requires us to learn unconstrained variables and scale them with the appropriate functions. Thus, we redefine the abovementioned variables as $\boldsymbol{\tau} \triangleq \text{softmax}(\boldsymbol{\tau}_u)$ and $\boldsymbol{\lambda} \triangleq \text{softplus}(\boldsymbol{\lambda}_u)$.

4 Optimisation in 2-Player Games

Based on the formulation of Minimax MAML and Neyman–Pearson MAML in Section 3.2, both are evidently instances of two-player games. On one hand, the first agent minimises the risk with respect to $\boldsymbol{\vartheta}$; on the other, the second agent maximises the risk with respect to $\boldsymbol{\tau}$ (for minimax) or $\boldsymbol{\lambda}$ (for Neyman–Pearson). In other words, both optimise the same (empirical risk) function in Equation (3) or Equation (4), respectively, but with opposite signs. However, the first term of Equation (4) does not depend on $\boldsymbol{\lambda}$. Therefore, Minimax MAML is a zero-sum game, but not Neyman–Pearson MAML.

If the risk function were convex, the solution would be well-defined as the Nash equilibrium. But

---

[2] `https://vene.ro/blog/mirror-descent.html`

this is not the case for a non-linear function such as a deep neural network. Therefore, we resort to an approximate solution through optimisation. The simplest approach in this scenario is Gradient Descent Ascent (GDA), where the set of parameters of both players are optimised simultaneously through gradient descent for the first player and gradient ascent for the second player. With a slight abuse of notation, let us define $\mathcal{R} \triangleq \mathcal{R}(\boldsymbol{\vartheta}_t, \boldsymbol{\alpha}_t)$, where $\boldsymbol{\alpha}_t$ stands for the adversarial parameters ($\boldsymbol{\tau}_t$ for Minimax and $\boldsymbol{\lambda}_t$ for Neyman–Pearson) at time t. Then the update rule is:

$$\boldsymbol{\vartheta}_{t+1} = \boldsymbol{\vartheta}_t - \eta \nabla_{\boldsymbol{\vartheta}} \mathcal{R} \tag{5}$$

$$\boldsymbol{\alpha}_{t+1} = \boldsymbol{\alpha}_t + \eta \nabla_{\boldsymbol{\alpha}} \mathcal{R} \tag{6}$$

for a learning rate $\eta \in \mathbb{R}$. Equations (5) and (6) are equivalent to allowing each player to ignore the other's move and act as if it will remain stationary. This naïve assumption often leads to divergence or sub-par solutions during optimisation (Schäfer and Anandkumar, 2019).

4.1 Symplectic Gradient Adjustment

To overcome the limitations of GDA, several independent works (Balduzzi et al., 2018; Letcher et al., 2019; Gemp and Mahadevan, 2018) proposed to correct Equations (5) and (6) with an additional term. This consists of a matrix-vector product between the mixed second-order derivatives ($\mathrm{D}^2_{\boldsymbol{\vartheta}\boldsymbol{\alpha}}\mathcal{R}$ and $\mathrm{D}^2_{\boldsymbol{\alpha}\boldsymbol{\vartheta}}\mathcal{R}$, respectively)[3] and the gradient of the risk with respect to the adversarial parameters ($\nabla_{\boldsymbol{\alpha}}\mathcal{R}$ and $\nabla_{\boldsymbol{\vartheta}}\mathcal{R}$, respectively). The resulting optimisation algorithm, Symplectic Gradient Adjustment (SGA), updates parameters as follows:

$$\boldsymbol{\vartheta}_{t+1} = \boldsymbol{\vartheta}_t - \eta \nabla_{\boldsymbol{\vartheta}} \mathcal{R} - \eta^2 \mathrm{D}^2_{\boldsymbol{\vartheta}\boldsymbol{\alpha}} \mathcal{R}\ \nabla_{\boldsymbol{\alpha}} \mathcal{R} \tag{7}$$

$$\boldsymbol{\alpha}_{t+1} = \boldsymbol{\alpha}_t + \eta \nabla_{\boldsymbol{\alpha}} \mathcal{R} - \eta^2 \mathrm{D}^2_{\boldsymbol{\alpha}\boldsymbol{\vartheta}} \mathcal{R}\ \nabla_{\boldsymbol{\vartheta}} \mathcal{R} \tag{8}$$

Intuitively, the mixed second-order derivative represents the interaction between the players, and the adversarial gradient represents the opponent's move if they follow the simple GDA strategy. Schäfer and Anandkumar (2019) cogently demonstrate how Equations (7) and (8) correspond to an approximation of the Nash equilibrium[4] of a local bi-linear approximation (with quadratic regulariser) of the underlying game dynamics.

Algorithm 1 Adaptive Symplectic Gradient Adjustment (ASGA)

```
Require: $\eta \in \mathbb{R}_+$: Learning rate
Require: $\beta_1, \beta_2 \in [0, 1)$: Decay rates
Require: $\boldsymbol{\vartheta}_0, \boldsymbol{\alpha}_0$: Initial parameter values
Require: $\mathcal{R} \triangleq \mathcal{R}(\boldsymbol{\vartheta}_{t-1}, \boldsymbol{\alpha}_{t-1}) : \mathbb{R}^{|\boldsymbol{\vartheta}|+|\boldsymbol{\alpha}|} \to \mathbb{R}$
 1: $\boldsymbol{m}_0 \leftarrow \mathbf{0}$ Initialise first moments
 2: $\boldsymbol{v}_0 \leftarrow \mathbf{0}$ Initialise second moments
 3: $t \leftarrow 0$ Initialise time step
 4: while $\boldsymbol{\vartheta}_t, \boldsymbol{\alpha}_t$ not converged
 5:     $t \leftarrow t + 1$
 6:     $\boldsymbol{g}_{\boldsymbol{\vartheta},t} \leftarrow \nabla_{\boldsymbol{\vartheta}}\mathcal{R} + \eta D_{\boldsymbol{\vartheta}\boldsymbol{\alpha}}\mathcal{R}\ \nabla_{\boldsymbol{\alpha}}\mathcal{R}$
 7:     $\boldsymbol{g}_{\boldsymbol{\alpha},t} \leftarrow \nabla_{\boldsymbol{\alpha}}\mathcal{R} - \eta D_{\boldsymbol{\alpha}\boldsymbol{\vartheta}}\mathcal{R}\ \nabla_{\boldsymbol{\vartheta}}\mathcal{R}$
 8:     $\boldsymbol{g}_t \leftarrow \boldsymbol{g}_{\boldsymbol{\vartheta},t} \oplus \boldsymbol{g}_{\boldsymbol{\alpha},t}$
 9:     $\boldsymbol{m}_t \leftarrow \beta_1\, \boldsymbol{m}_{t-1} + (1 - \beta_1)\, \boldsymbol{g}_t$
10:     $\boldsymbol{v}_t \leftarrow \beta_2\, \boldsymbol{v}_{t-1} + (1 - \beta_2)\, \boldsymbol{g}_t^2$
11:     $\hat{\boldsymbol{m}}_t \leftarrow \boldsymbol{m}_t \,/\, (1 - \beta_1^t)$
12:     $\hat{\boldsymbol{v}}_t \leftarrow \boldsymbol{v}_t \,/\, (1 - \beta_2^t)$
13:     $\boldsymbol{\vartheta}_t \leftarrow \boldsymbol{\vartheta}_{t-1} - \eta \cdot \hat{\boldsymbol{m}}_{\boldsymbol{\vartheta},t} \,/\, (\sqrt{\hat{\boldsymbol{v}}_{\boldsymbol{\vartheta},t}} + \epsilon)$
14:     $\boldsymbol{\alpha}_t \leftarrow \boldsymbol{\alpha}_{t-1} + \eta \cdot \hat{\boldsymbol{m}}_{\boldsymbol{\alpha},t} \,/\, (\sqrt{\hat{\boldsymbol{v}}_{\boldsymbol{\alpha},t}} + \epsilon)$
15: return $\boldsymbol{\vartheta}_t, \boldsymbol{\alpha}_t$
```

In practice, estimating the above-mentioned products is tedious because of their space and time complexity. Therefore, we resort to an approximation known as *Hessian-vector product* (Pearlmutter, 1994). For the third term of Equation (7):

$$\mathrm{D}^2_{\boldsymbol{\vartheta}\boldsymbol{\alpha}}\mathcal{R}(\boldsymbol{\vartheta}, \boldsymbol{\alpha})\nabla_{\boldsymbol{\alpha}}\mathcal{R}(\boldsymbol{\vartheta}, \boldsymbol{\alpha}) = \frac{\partial}{\partial h}\nabla_{\boldsymbol{\vartheta}}\mathcal{R}(\boldsymbol{\vartheta}, \boldsymbol{\alpha} + h\nabla_{\boldsymbol{\alpha}}\mathcal{R}(\boldsymbol{\vartheta}, \boldsymbol{\alpha}))\bigg|_{h=0} \tag{9}$$

And similarly for the matrix product term in Equation (8), by swapping $\boldsymbol{\vartheta}$ and $\boldsymbol{\alpha}$ in Equation (9).

4.2 Adaptive Learning Rate and Momentum

While SGA may provide a more appropriate optimisation framework for competitive games, it still lacks several defining features of optimisers that accelerate convergence, such as first-order momentum and adaptive learning rate (second-order momentum). Therefore, we modify the update rule in Equations (7) and (8) to include both of these. Our starting point is Adam (Kingma and Ba, 2015). The changes we apply are the following (also illustrated in Algorithm 1):

① The current difference (lines 6–7) is adjusted with the terms introduced in Equations (7) and (8) by Schäfer and Anandkumar (2019).

---

[3] Here $\mathrm{D}^2_{\boldsymbol{wz}}\mathcal{R}$ stands for the sub-matrix of the Hessian containing the derivative of the risk taken first with respect to $\boldsymbol{w}$ and then with respect to $\boldsymbol{z}$.

[4] A Nash equilibrium is a pair of strategies whose unilateral modification cannot result in loss reductions.

② The exponentially decayed, unbiased estimates of the expectations over mean and standard deviation are computed similarly to Adam. However, note that, in line 14, the update of the adversarial parameters corresponds to an ascent (rather than a descent).

This results in a novel optimiser, Adaptive Symplectic Gradient Adjustment (ASGA). We employ ASGA in our experiments to optimise the objectives of Minimax MAML and Neyman–Pearson MAML, as it enables a fair comparison with Adam-optimised Bayes MAML.

5 Experiments

We now outline the main experiments of our work on multilingual NLP. We evaluate our methods on part-of-speech (POS) tagging, a sequence labelling tasks, and question answering (QA), a natural language understanding task.

We focus on POS given its ample coverage of languages and its frequent use as a benchmark for resource-poor NLP (Das and Petrov, 2011; Ponti et al., 2021). In fact, cross-lingual transfer in sequence labelling tasks was demonstrated to be the most challenging, as knowledge of linguistic structure is more language-dependent than semantics (Hu et al., 2020). However, we also include QA to illustrate the generality of our methods for cross-lingual NLP. In this task, given the gold passage and a question, the system has to predict the beginning and end positions of a single contiguous span containing the answer.

Data. POS data are sourced from the Universal Dependencies (UD) treebanks[5] (Zeman et al., 2020) and QA data from the 'gold passage' variant of TyDiQA (Clark et al., 2020).[6] We retain the original training, development, and evaluation sets of UD. In TyDiQA, we use the original development set for evaluation.[7] For meta-learning, $\mathcal{D}_{train}$ and $\mathcal{D}_{val}$ examples are both obtained from disjoint parts of the training set.

We aim to create a partition of languages between training and evaluation that corresponds to the most realistic scenario in deploying NLP technology on resource-poor languages spoken around the world. Therefore, we reserve for evaluation all language isolates and languages with at most 2 family members in each dataset. We use all the remaining languages in the dataset for training. Therefore, for POS, the evaluation set spans 16 treebanks (14 languages, 11 families) and the training set 99 treebanks; QA comprises 9 languages (7 families). We hold out 4 of them in turn for evaluation (except English) and use the rest for training. We provide the full list of languages in Appendix A.

Training. In all tasks, we train a neural network consisting of two stacked modules: an encoder and a classifier. The encoder is a 12-layer, 768-hidden unit, 12-head Transformer initialised with multilingual BERT Base (mBERT), which was pre-trained on cased text from 104 languages.[8] The classifier is a single affine layer for TyDiQA and a 2-layer Perceptron (with 1024 hidden units) for POS tagging. The combined parameters of the encoder and classifier correspond to $\boldsymbol{\vartheta}$ from Section 3.

These are meta-learned via Meta-SGD (Li et al., 2017), a first-order MAML variant where each parameter is assigned a separate inner-loop learning rate η. Moreover, each η is trained end-to-end based on the outer-loop loss (such as Equation (1) for the Bayes criterion).[9] Similar to Bansal et al. (2020), to avoid an explosion in the number of parameters, we assign a per-layer learning rate (rather than per-parameter). To avoid overfitting, we employ both dropout (with a probability of 0.2) and early stopping (with a patience of 10). For the Neyman-Pearson formulation, we set $r = 0.1$ as a threshold for all language-specific losses.[10] The parameters $\boldsymbol{\tau}$ and $\boldsymbol{\lambda}$ were initialized uniformly as $\frac{1}{|\mathcal{T}|}$. Complete details of the hyper-parameters for all settings are given in Appendix B.

Methods. To assess the effectiveness of the proposed criteria and optimisers, we compare them with two competitive baselines, while maintaining the same underlying neural architecture: (i) **J**: a joint multi-source transfer method where a model is trained on the concatenation of the datasets for all languages; (ii) **B:** the original MAML (Finn et al., 2017) with Bayes criterion and uniform prior. Our choice of baselines is justified by the fact that these methods (or variations thereof) are currently

state of the art for the tasks of POS and QA, as well as other innumerable NLP applications (Wu and Dredze, 2019; Nooralahzadeh et al., 2020; Ponti et al., 2021). In addition, we evaluate the following combinations: (iii) **MM:** MAML with a minimax criterion, optimised with GDA; (iv) **NP:** MAML with a Neyman–Pearson (constrained) criterion, optimised with GDA; (v) **MM+:** MAML with a minimax criterion, optimised with ASGA; and (vi) **NP+:** MAML with a Neyman–Pearson criterion, optimised with ASGA.

Evaluation. For each evaluation language in a given task, we randomly sample $k \in \{0, 5, 10, 20\}$ examples from the evaluation data as the support set (for adaptation) and the rest of the examples as the query set (for testing). When $k > 0$, we repeat the evaluation 100 times and report the following average metrics: (i) F_1 score for POS tagging, and (ii) exact-match (EM) and F_1 scores for QA.[11] Due to lack of space, we only report the average mean and standard deviation across languages for each model described above.

6 Results and Discussion

We report the results for POS tagging in Table 1 and for QA in Table 2. These include mean and standard deviation across languages. Note that, in this case, the standard deviation is by no means an interval for statistical significance, but rather reflects the heterogeneity among the evaluation languages. In what follows, we address a series of questions in the light of these figures.

Baselines. MAML and joint multi-source transfer are both strong contenders as state-of-the-art methods for cross-lingual transfer, but which one is better? By comparing J and B rows, no definite response emerges in our experiments. While MAML outperforms its competitor in POS tagging, it lags behind in QA. We speculate that the larger pool of training languages available in POS tagging (22 times more than QA) endows meta-learning with better generalisation capabilities. Both methods, however, surpass single-source transfer from English SQuAD (Rajpurkar et al., 2016) in the zero-shot setting by a large margin: Clark et al. (2020) report 56.4 F_1 score in average for TyDiQA, which is 6.66 points below our best model.

Criteria. The minimax and Neyman-Pearson criteria both improve over the Bayes criterion baseline, although the latter more sporadically. Compared to the B rows, MM+ achieves gains for every k in POS tagging, with 0.94 points of margin at $k = 0$ and 0.79 at $k = 20$. The same holds for MM in QA, with margins that span from 1.73 at $k = 0$ to 1.47 at $k = 20$ in the Exact Match metric, and from 0.55 at $k = 0$ to 1.14 at $k = 20$ in F_1 score. Therefore, Minimax MAML is remarkably consistent in outperforming the baselines, although the gains are sometimes significant, sometimes only marginal. This is also reflected in language-specific performances, available in Table 5 and Table 6 in the Appendix. For POS tagging, the F_1 scores of only 2 languages (Indonesian and Naija) moderately decrease, whereas the rest of the 14 languages show improvements.

Incidentally, it may be worth noting that we did not perform any large-scale search over hyperparameters like $\boldsymbol{\tau}$ and $\boldsymbol{\lambda}$ initialisations, the threshold r, or differential learning rates for maximised and minimised parameters. Therefore, these early

---

[11] We refer the reader to Rajpurkar et al. (2016) for a precise definition of these metrics.

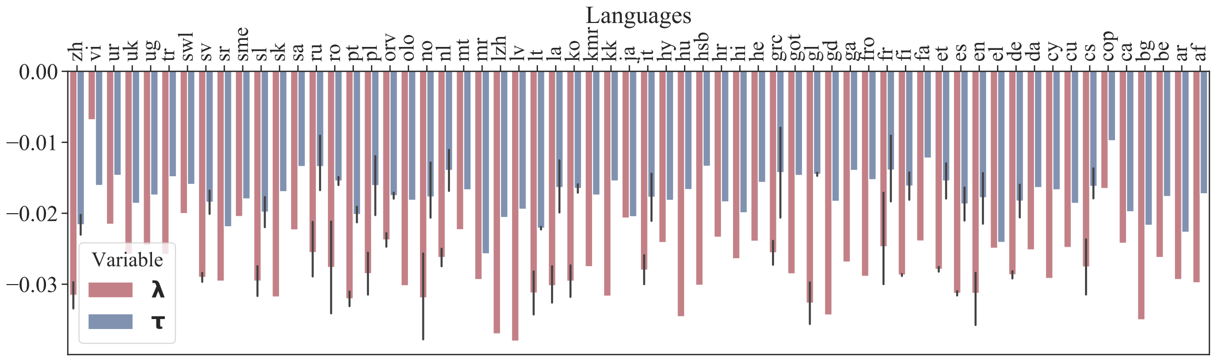

Figure 3: Unconstrained values of $\boldsymbol{\tau}_u$ and $\boldsymbol{\lambda}_u$ upon convergence in MM+ and NP+ models for POS tagging.

k ▷	0	5	10	20
		F_1 Score		
J	14.34	33.32	37.52	40.83
B	24.11	35.03	40.38	44.92
MM	20.41	37.61	43.00	45.83
NP	**26.81**	39.23	42.70	45.25
MM+	16.42	37.41	43.57	45.21
NP+	22.55	**39.95**	**45.41**	**48.12**

Table 3: The minimum F_1 scores of our models across languages, for POS tagging.

k ▷	0	5	10	20
		Exact Match		
J	42.33	**45.97**	47.22	**49.47**
B	**42.75**	44.58	46.44	48.24
MM	41.01	45.33	**47.59**	49.21
NP	40.39	44.89	46.40	48.80
MM+	41.01	41.87	45.32	47.11
NP+	37.44	42.92	46.30	48.88
		F_1 Score		
J	52.43	59.27	59.88	62.11
B	51.10	**59.60**	60.64	62.10
MM	53.10	59.21	**61.86**	63.43
NP	52.83	59.31	60.03	61.84
MM+	51.93	57.91	59.86	61.52
NP+	**53.96**	57.21	61.74	**63.55**

Table 4: The minimum Exact Match and F_1 scores of our models across languages, for QA.

results are amenable to improve even further in the future. This lends credence to our proposition that minimax and Neyman–Pearson criteria are more suited for out-of-distribution transfer to outlier languages.

Optimiser. The results for the proposed optimiser ASGA (Algorithm 1) are favourable in comparison to Gradient Descent Ascent via Adam (Kingma and Ba, 2015) for POS tagging; on the other hand, the opposite trend is observed for QA. Therefore, future investigations are required to shed further light on modifications such as the Symplectic Gradient Adjustment. A tentative explanation of such discrepancy could be the disproportionate number of training languages available in either task.

To get insights into the game dynamics of the adversarial criteria, we plot the unconstrained values for $\boldsymbol{\tau}_u$ and $\boldsymbol{\lambda}_u$ upon convergence in Figure 3. Interestingly, both variables appear to follow the same profile of peaks and troughs; therefore, as expected, languages chosen adversarially in MM have also higher Laplace multipliers in NP. To this group belong for instance languages with rare scripts (e.g. Coptic) or with no relatives in the training languages (e.g. Vietnamese). As a final note, we remark that the proposed criteria and optimiser are in principle more general than NLP and could facilitate transfer in other fields. While this thread of research transcends the scope of our work, we illustrate an example for regression in Appendix C.

Minimum Scores across Languages. In addition to the *average* cross-lingual performance, we also report the *minimum* cross-lingual performance for POS tagging in Table 3 and for QA in Table 4. This corresponds to the lowest score achieved across all evaluation languages. For POS tagging, we observe that NP and NP+ outperform J and B by 7-12 and 2-5 F1 points, respectively. This reveals that worst-case and constrained risk minimisation drastically uplifts the scores for the most disadvantaged language. Nevertheless, the opposite trend is observed for QA: MM(+) and NP(+) do not alter the minimum score with respect to the F_1 metric, and even degrade it with respect to the exact-match metric. Again, we conjecture that these mixed findings may depend on the different amount and distribution of the training languages in the corresponding datasets: UD offers greater language coverage than TyDiQA, which gives better guidance.

7 Related Work

MAML is a cutting-edge method for cross-lingual transfer in several NLP tasks (Gu et al., 2018; Nooralahzadeh et al., 2020; Wu et al., 2020; Li et al., 2020, *inter alia*). However, in all these experiments, the model is adopted in its standard formulation, minimising the expected risk. Therefore, its performance is prone to suffer in outlier languages. Moreover, the assumptions underlying our proposed variants are different from other instances of robust optimisation in NLP (Globerson and Roweis, 2006; Oren et al., 2019). In particular, the target language distributions are not explicitly treated as subspaces or covariate shifts of source languages. In separate fields such as vision, previous attempts at worst-case-aware meta-learning include Collins et al. (2020), who use a Euclidean version of the robust stochastic mirror-prox algorithm, and Wang et al. (2020), who rely on reinforcement learning. Our formulation is both fully differentiable and broader, as the decision-theoretic interpretation admits alternative criteria for MAML. What is more, to our knowledge we are the first to successfully augment MAML with minimax criteria in cross-lingual NLP and with Neyman–Pearson criteria in general.

8 Conclusions

To perform cross-lingual transfer to low-resource languages, under a decision-theoretic interpretation Model-Agnostic Meta-Learning (MAML) minimises the expected risk across training languages. Generalisation then relies on the evaluation languages being identically distributed. However, this assumption is incongruous for cross-lingual transfer in realistic scenarios. Therefore, we propose more appropriate training objectives that are robust to out-of-distribution transfer: Minimax MAML, where worst-case risk is minimised by learning an adversarial distribution over languages; and Neyman–Pearson MAML, where constraints are imposed on language-specific losses, so that they remain below a certain threshold. From a game-theoretic perspective, both of these variants consist of 2-player competitive games. Therefore, we also explore adaptive optimisers that take into account the underlying game dynamics. The experimental results on zero-shot and few-shot learning for part-of-speech tagging and question answering, whose datasets span tens of typologically diverse languages, confirm that in several settings the proposed criteria are superior to both vanilla MAML and transfer from multiple source languages.

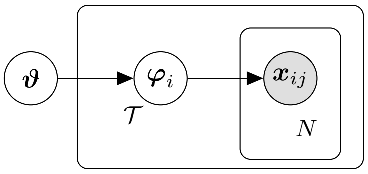

Figure 4: Bayesian graphical model of MAML, where the variable φ_i is parameterised as $\vartheta - \eta\nabla_{\vartheta}\mathcal{L}_{\mathcal{T}_i}(f_{\vartheta}, \mathcal{D}_{train})$.

A Language Partitions

The languages from the following families in UD are held out for evaluation (16 treebanks, 14 languages in total): Northwest Caucasian (Abaza), Mande (Bambara), Mongolic (Buryat), Basque, Tupian (Mbya Guarani), Creole (Naija), Tai–Kadai (Thai), Pama–Nyungan (Warlpiri), Austronesian (Indonesian, Tagalog), Dravidian (Tamil, Telugu), Niger-Congo (Wolof, Yoruba). As all 8 languages in TiDiQA belong to families with at most 2 members in the dataset, we randomly create two partitions: in the former, Finnish, Korean, Bengali, and Arabic are used for evaluation, and the others for training; in the latter, Russian, Indonesian, Telugu, and Swahili are used for evaluation, and the others for training.

B Hyperparameter Setting

POS Tagging. For POS tagging: (i) the batch size was 32, (ii) the maximum sequence length was 128, (iii) the number of epochs was 20, with a patience limit of 10, (iv) both outer and inner learning rates were 5×10^{-5}, (v) the number of episodes per iteration was 32, (vi) the number of inner loops per outer update was 4, (vii) the number of shots (k) during training was 30, and (viii) the hidden layer dropout probability for the classifier was 0.2.

QA. (i) the batch size and k were reduced to 12 due to memory constraints, (ii) the maximum context length was 336, and the document stride was 128, (iii) the maximum question length was 64, (iv) the inner and outer learning rates were 3×10^{-5}.

For all J baselines, we used a uniform language sampler, since proportional sampling performed worse. As an optimiser, we chose Adam with a learning rate of 5×10^{-5}, a weight decay of 0.1;

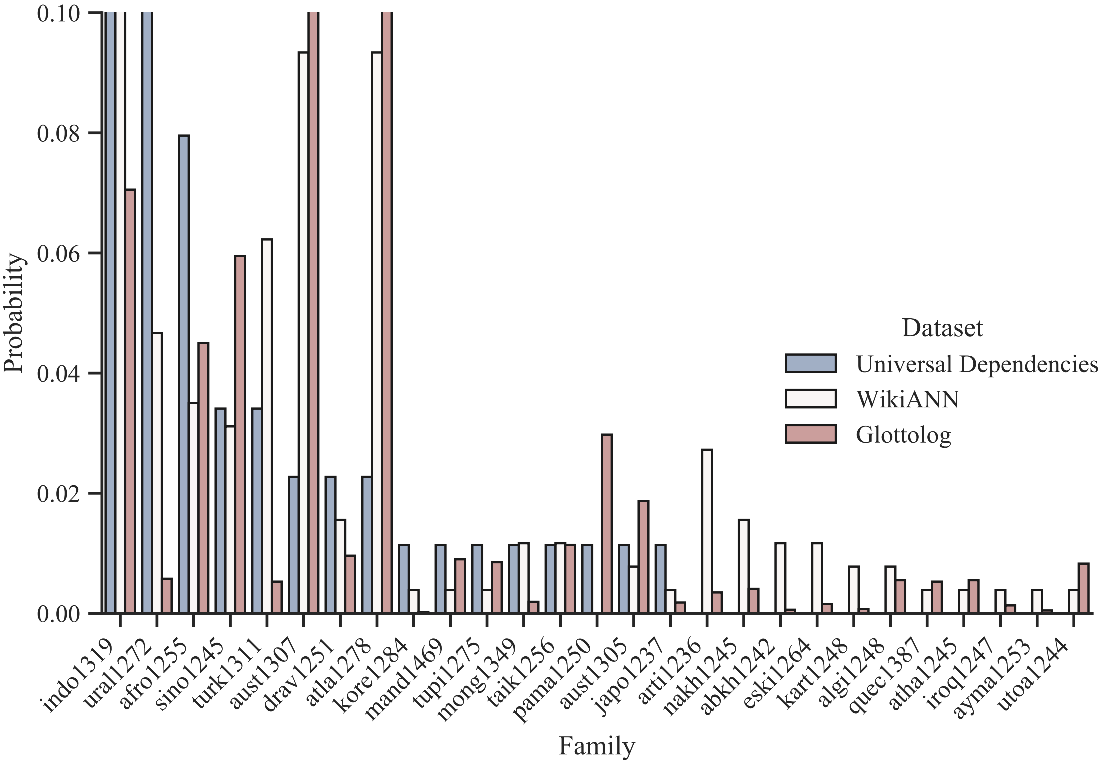

Figure 5: Empirical distribution of languages across families in 2 datasets (WikiANN and UD) and in the world, according to Glottolog. The families shown are a subset {(WikiANN ∪ Universal Dependencies) ∩ Glottolog}. The y-axis is truncated for the sake of clarity.

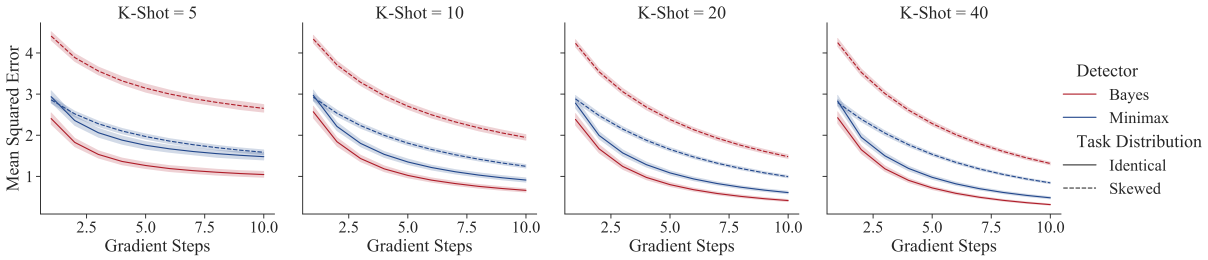

Figure 6: Mean Squared Error of MAML across gradient steps (from 1 to 10) of different criteria (B and MM) under identical and skewed task distributions. Each frame represents a separate run of fast adaptation with different amounts of target examples available (k-shot).

we clipped the gradient to a maximum norm of 5.0. For all MAML models, we performed 4 updates in the inner loop, both during training and fast adaptation (few-shot learning). We ran our experiments on a 48GB NVIDIA Quadro RTX 8000 GPU with Turing micro-architecture. Each run took approximately 2 hours for training and 3 hours for few-shot learning and evaluation.

C Additional Experiments & Results

Additional Results. Table 5 contains POS tagging F_1 scores of all languages, for all models, in both zero and few-shot settings. Table 6 shows the exact match and F_1 scores for QA.

Sinusoidal Regression. After delving into real-world, large-scale NLP applications, we additionally illustrate the effect of the alternative criteria on other ML domains. We run a proof-of-concept experiment on a toy task where we can fully control the distribution of the training and evaluation data, viz. regression of a sinusoidal function.

For this task, we follow the same experimental setting and hyper-parameters of Finn et al. (2017): combinations of amplitudes $a \in [0.1, 5]$ and phases $p \in [0, \pi]$ determine a set of tasks characterised by the function $y = \sin(x - p) \cdot a$. The inputs are sampled at random from the interval $x \in [-5, 5]$.

While both train and evaluation tasks in the original version were sampled uniformly from *identical* ranges, we also construct an alternative setting with *skewed* distributions sampled from disjoint ranges: during training, $a \in [2.5, 5]$ and $p \in [\frac{\pi}{2}, \pi]$; during evaluation, $a \in [0.1, 2.5]$ and $p \in [0, \frac{\pi}{2}]$.

For Minimax MAML, we aim at learning the distribution over tasks adversarially. In particular, we consider two separate discrete categorical distributions for amplitudes $\mathrm{softmax}(\boldsymbol{\tau}_u^{(a)})$ and phases $\mathrm{softmax}(\boldsymbol{\tau}_u^{(p)})$ over their respective ranges discretised into 1,000 atoms. Hence, the probability of a task with the i-th amplitude value and the j-th phase value is simply $\tau_i^{(a)} \times \tau_j^{(p)}$.

The results for sinusoidal regression are shown in Figure 6. Vanilla MAML (Bayes criterion) consistently outperforms the minimax criterion when the task distribution is identical; on the other hand, the reverse occurs when the task distribution is skewed. MM performs much better in this case, with the gap in performance increasing as the shots k decrease. This verifies our hypothesis that the minimax criterion should benefit out-of-distribution regression tasks.

Abstract

Despite considerable advancements with deep neural language models (LMs), neural text generation still suffers from *de*generation: the generated text is repetitive, generic, self-contradictory, and often lacks commonsense. Our analyses on sentence-level attention patterns in LMs reveal that neural degeneration may be associated with insufficient learning of task-specific characteristics by the attention mechanism. This finding motivates on-the-fly attention modulation[1]– a simple but effective method that enables the injection of priors into attention computation during inference. Automatic and human evaluation results on three text generation benchmarks demonstrate that attention modulation helps LMs generate text with enhanced fluency, creativity, and commonsense reasoning, in addition to significantly reduce sentence-level repetition.

1 Introduction

Neural text generation is critical for a wide range of downstream natural language applications. However, the standard approach – using a Transformer-based (Vaswani et al., 2017) language model (*e.g.*, Radford et al., 2019) with maximum likelihood fine-tuning and non-stochastic decoding – is known to exhibit *de*generation (Welleck et al., 2019). Despite being pre-trained on large amounts of data, text generated by neural models is observed to be repetitive, generic, self-contradictory, and lacking commonsense (Holtzman et al., 2020).

Many explanations have been proposed for neural text degeneration, including inappropriate training objectives (Welleck et al., 2019) and decoding discrepancies relative to human language (Holtzman et al., 2018, 2020). While the aforementioned may be factors for neural degeneration, we show that insufficient learning of *task-specific* characteristics – reflected in the self-attention mechanism in transformer blocks – is associated with neural text degeneration. We demonstrate that degeneration is alleviated if we inject priors through attention modulation (AttnM) during inference.

Figure 1: Example of fine-tuned GPT2-L outputs without (top) and with (bottom) attention modulation on αNLG. The task is to generate a plausible explanatory hypothesis H for observations O_1 and O_2. Our proposed attention modulation injects the task-specific prior – LMs should consider both observations relative equally – through balancing the sentence-level attention weights (Eqn. 5) in Transformer blocks during inference. Applying attention modulation with the aforementioned prior make sentence-level attentions from generation to observation pairs (O_1,O_2) more balanced[2], which are reflected in the sentence-level attention heatmaps of GPT2-L (darker = lower attention) across layers (y-axis) and heads (x-axis).

Self-attention – the ubiquitous component of Transformers – is task-agnostic with a large learning capacity for many NLP tasks (Vaswani et al., 2017; Devlin et al., 2019; Brown et al., 2020). It

learns the general characteristics of language processing through pre-training on large amounts of unlabeled data. For example, multiple analyses have suggested that attention patterns in pre-trained Transformers implicitly encode syntactic information (Raganato and Tiedemann, 2018; Michel et al., 2019; Vig and Belinkov, 2019). In sequence transduction tasks, these learned characteristics, embedded in attention, make pre-trained Transformers a powerful language model (Radford et al., 2019).

A final task-specific step is typically required for adapting a task-agnostic language model to perform the desired task[3]. However, these task-specific characteristics might not sufficiently coincide with general characteristics even after fine-tuning. For example, task-specific characteristics embedded in attention patterns – such as word alignments for machine translation – are often noisy and imperfect for generalization (Kobayashi et al., 2020).

We show that insufficient learning of task-specific characteristics, reflected in sentence-level attention patterns[4] often being out of focus, may be associated with neural text degeneration (§3). Based on this observation, we propose a simple attention modulation framework that can dynamically redistribute sentence-level attention weights by injecting task-specific priors in Transformer blocks for different downstream tasks (§4). Remarkably, in long-range narrative story generation, abductive reasoning generation and constrained commonsense text generation, both automatic and human evaluation have shown improved quality in fluency, dullness, repetition, and commonsense reasoning with attention modulation (§6).

2 Background

We briefly discuss how vanilla attention works, as well as Transformer architecture used in this paper.

Single-headed attention Given a sequence of d-dimensional input vectors $\boldsymbol{x} = \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\}$, attention mechanism computes a set of weights based on a query vector $\boldsymbol{y}_i \in \mathbb{R}^d$:

$$\mathrm{Attn}(\boldsymbol{x}, \boldsymbol{y}_i) = (\alpha_{i,1}(\boldsymbol{x}, \boldsymbol{y}_i), \ldots, \alpha_{i,n}(\boldsymbol{x}, \boldsymbol{y}_i)) \quad (1)$$

where $\alpha_{i,j}$ is the attention weight that $\boldsymbol{y}_i$ pays to $\boldsymbol{x}_j$. One formulation of attention — scaled dot product attention — is computed as:

$$\alpha_{i,j} := \operatorname*{softmax}_{\boldsymbol{x}_j \in \boldsymbol{x}}\Big(\frac{\boldsymbol{q}(\boldsymbol{y}_i)\boldsymbol{k}(\boldsymbol{x}_j)^\top}{\sqrt{d}}\Big) \in \mathbb{R} \quad (2)$$

where query $\boldsymbol{q}(\cdot)$ and key $\boldsymbol{k}(\cdot)$ functions are linear transformations. In self attention, every $\boldsymbol{x}_i$ is used as the query vector ($\boldsymbol{y}_i$). An updated representation $\tilde{\boldsymbol{x}}_i$ is computed as a weighted sum of value vectors that are linearly transformed by $\boldsymbol{v}(\cdot)$:

$$\tilde{\boldsymbol{x}}_i = \sum_{\boldsymbol{x}_j \in \boldsymbol{x}} \alpha_{i,j} \boldsymbol{v}(\boldsymbol{x}_j). \quad (3)$$

Multi-head attention In *multi-headed* attention (MHA), N_h attention heads are computed independently to obtain the updated $\tilde{\boldsymbol{x}}_i$:

$$\tilde{\boldsymbol{x}}_i = W_o \mathop{\Big\Vert}_{h=1}^{N_h} \Big(\sum_{\boldsymbol{x}_j \in \boldsymbol{x}} \alpha_{i,j}^h \boldsymbol{v}^{\boldsymbol{h}}(\boldsymbol{x}_j) \Big). \quad (4)$$

$\alpha_{i,j}^h$ follows Eqn. 2 except the model dimension in each head h is often reduced to $d_h = \frac{d}{N_h}$. $\tilde{\boldsymbol{x}}_i$ is obtained by the concatenation of lower-rank representations from all heads and $W_o \in \mathbb{R}^{d \times h \cdot d_h}$.

GPT2-L GPT2 (Radford et al., 2019) is a family of Transformer-based language models (LMs) that follows the architecture of stacked decoder. As GPT2 follows a multi-layer and multi-headed setting, $\alpha_{i,j}$ is specific to a layer l and head h, noted as $\alpha_{i,j}^{l,h}$. We use the GPT2-L model that has 36 layers with 20 heads per layer (762M total parameters).

3 Neural text degeneration vs. attention

As researchers have sought to understand the internal mechanisms of Transformers, the attention patterns exhibited by these heads have drawn considerable study (Vig and Belinkov, 2019; Jain and Wallace, 2019; Wiegreffe and Pinter, 2019). We perform sentence-level attention analysis to explore whether aggregated attention patterns are associated with neural text degeneration.

3.1 Sentence-level attention

We first define the sentence-to-sentence attention of a language model $\mathcal{M}$ with L layers and H heads. Given two sentences p and g such that p precedes g,

---

[3] Brown et al. (2020) have shown that GPT3 greatly improves task-agnostic, few-shot performance, but still struggles on tasks with strong task-specific characteristics.

[4] We study the global context in the multi-sentence prompts and choose sentence-level attention (Eqn. 7) as the experiment unit, since sentences are linguistic units of complete meaning.

the mean $\bar{\alpha}_{g,p}^{l,h}$ and max $\hat{\alpha}_{g,p}^{l,h}$ sentence-to-sentence attentions from g to p for layer l and head h are:

$$\bar{\alpha}_{g,p}^{l,h} = \frac{\sum_{i=1}^{|g|}\sum_{j=1}^{|p|}\alpha_{i,j}^{l,h}(g_i,p_j)}{|g|\cdot|p|} \tag{5}$$

$$\hat{\alpha}_{g,p}^{l,h} = \max_{\substack{i\in\{1,\dots,|g|\}\\ j\in\{1,\dots,|p|\}}} \alpha_{i,j}^{l,h}(g_i,p_j). \tag{6}$$

The aggregated sentence-to-sentence attention over the Transformer architecture $\mathcal{M}$ is defined as:

$$\alpha_{g,p}^{\mathcal{M}} = \frac{\sum_{l=1}^{L}\sum_{h=1}^{H}\alpha_{g,p}^{l,h}}{L\cdot H} \tag{7}$$

where $\alpha \in \{\bar{\alpha},\hat{\alpha}\}$ computes either the mean or the max sentence-level attention over $\mathcal{M}$.

3.2 Is neural text degeneration related to attention patterns?

We conduct experiments to evaluate whether neural text degeneration is associated with sentence-level attention patterns. Empirical results on two types of neural degeneration that are easy to detect – repetition and lacking commonsense reasoning under constraints – reveal their association.

Repetition vs. attention One common form of neural text degeneration is sentence-level repetition (Welleck et al., 2019). This type of degeneration happens frequently in our experiment on ROCStories test set (§6.1): given a five-sentence prompt, 35.4% of the consecutive sentences from the next five greedily generated sentences by the fine-tuned GPT2-L are exact repetitions. We check whether sentence-level attention patterns behave differently when generating repeated or different consecutive sentences.

We inspect the attention behavior by measuring the change of sentence-level attention when generating two consecutive sentences. The generations of fine-tuned GPT2-L on ROCStories test set are separated into two subsets $\{\mathcal{D}_{\text{repeated}},\mathcal{D}_{\text{different}}\}$: in which consecutive sentences that are either repeated (*i.e.*, degenerate) or different. Given the fine-tuned GPT2-L language model $\mathcal{M}$, we measure the sentence-level attention change Δ on the prompt sentence $p_{j\in\{1,\dots,5\}}$ while generating the consecutive sentence pair $(g_i, g_{i+1}), i \in \{1,\dots,4\}$, aggregated over the subset $\mathcal{D} \in \{\mathcal{D}_{\text{different}},\mathcal{D}_{\text{repeated}}\}$:

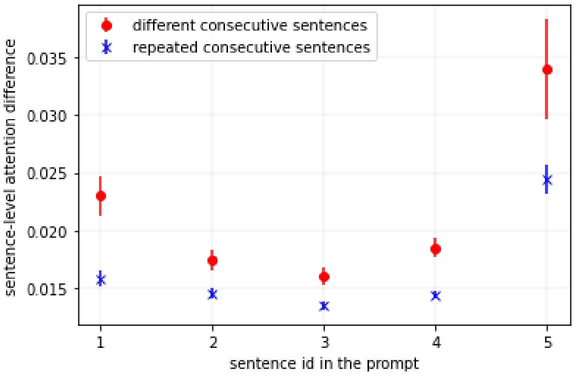

Figure 2: Mean sentence-level attention change of GPT2-L on ROCStories test set, while generating different (red) or repeated (blue) consecutive sentences.

$$\Delta(j,\mathcal{D}) = \sum_{d\in\mathcal{D}} |\bar{\alpha}^{\mathcal{M}}_{g^d_{i+1},p^d_j} - \bar{\alpha}^{\mathcal{M}}_{g^d_i,p^d_j}|/|\mathcal{D}| \tag{8}$$

where $\bar{\alpha}^{\mathcal{M}}_{g_i,p_j}$ is the mean sentence-level attention from sentence g_i to sentence p_j defined in Eqn. 7.

Figure 2 plots the aggregated mean sentence-level attention change over prompt sentences when GPT2-L generates repeated (red) or different (blue) consecutive sentences. The sentence-level attention changes are vastly lower on all prompt sentences when generating repeated consecutive sentences. Thus, sentence-level repetition may be correlated with the insufficient change of sentence-level attention. In §4 and §6, we show that generation quality can be vastly improved by injecting the prior – attention should look at the prompt differently when generating different sentences – through our proposed attention modulation.

Lack of commonsense reasoning vs. attention Text generated by neural language models is also observed to be lacking commonsense reasoning (Mao et al., 2019). We check whether this type of neural degeneration is associated with attention patterns. A benchmark dataset for generative commonsense reasoning – CommonGen (Lin et al., 2020) – is used as our test bed. CommonGen is designed for constrained commonsense reasoning: given a set of common concepts (e.g., use, tool, piece, metal); the task is to generate a coherent and plausible sentence covering all these concepts (e.g., "a piece of metal is used for making tools"). Covering the concepts in generation requires relational reasoning with background commonsense knowledge.

	agg. max attn.	SD	#
covered	0.434	0.0040	4515
uncovered	0.376	0.0068	1473

Table 1: Aggregated max sentence-level attention of the fine-tuned GPT2-L; the results are aggregated from the generation to covered or uncovered concepts on the CommonGen test set. agg. max attn., SD, # refer to aggregated max sentence-level attention, standard deviation, and the number of instances.

Each concept is represented as a prompt sentence in our experiments.[5] During generation, a concept (*e.g.*swim) is covered if its reflected form (*e.g.*{swim, swimming, swam, swum}) is generated in the CommonGen test set. We use a fine-tuned GPT2-L for the generation. Among the 5988 concepts in the prompt, about 75% of them are covered in the generation of GPT2-L. We can then easily separate sentence-level attention from the generation to the concept into two subsets: concept in the prompt that is covered or uncovered by the generated sentence.

Table 1 shows the results of max sentence-level attention (Eqn. 7) of the finetuned GPT2-L on the CommonGen test set[6]. We can observe that sentence-level attention from the generation to the concept is vastly higher when the concept is covered. Compared to that of uncovered concepts, the aggregated max sentence-level attention is 15.4% higher. Therefore, failing to generate a common concept through reasoning may be associated with insufficient attention to the concept.

In both cases, neural text degeneration is associated with insufficient attention to elements that are important for downstream generations. This motivates us to explore whether we can inject these priors in the language model by altering the attention mechanism to alleviate degeneration.

4 Method

This section describes our method – attention modulation – that can alleviate neural text degeneration. In §4.1, we describe the general attention modulation framework. In §4.2, §4.3, and §4.4, we discuss the priors injected through attention modulation for three different tasks: narrative story generation, abductive reasoning generation, and constrained commonsense reasoning.

4.1 Attention Modulation

Attention modulation aims to change the attention weights of a Transformer-based language model during inference, so that the generation can reflect priors that alleviate neural text degeneration. This additional signal is added to the self-attention computation in the Transformer blocks.

We reformulate the attention computation of Eqn. 2 by adding an attention reweighting function f, where priors can be injected. Given a sequence of input tokens $\boldsymbol{x}$, the self-attention from $\boldsymbol{x}_i$ to $\boldsymbol{x}_j$ ($i \geq j$) while generating the t-token is reformulated to:

$$\alpha_{i,j}^t := \underset{\boldsymbol{x}_j \in \boldsymbol{x}}{\operatorname{softmax}}\Big(\frac{\boldsymbol{q}(\boldsymbol{x}_i)\boldsymbol{k}(\boldsymbol{x}_j)^\top}{\sqrt{d}} + f_{i,j}(\boldsymbol{x}, \boldsymbol{\alpha}^{t-1})\Big) \tag{9}$$

where $f(\boldsymbol{x}, \boldsymbol{\alpha}^{t-1})$ is the attention reweighting function and $\boldsymbol{\alpha}^{t-1}$ is the attention weight matrix for all layers and heads in the Transformer architecture at time step $t-1$. The attention reweighting function f can be either pre-defined or learned. In our experiments, we inject pre-defined sentence-level priors (heuristics) through f and show that this injection alleviates neural text degeneration. We leave the learning of better reweighting functions automatically to future work.

In the following sections, we describe sentence-level attention reweighting functions that are used for three different text generation tasks.

4.2 ROCStories: narrative generation

As shown in §3, sentence repetition in long-form generation may be associated with insufficient attention change while generating consecutive sentences. To amplify the attention changes, we can redistribute sentence-level attention with some priors while generating consecutive sentences.

We choose the prior that language model should consider long-range context during generation, as we observed that attention mostly focuses on the near history in many cases (Appendix A.1). Note this prior also increases the sentence-level attention change while generating consecutive sentences: the sentence-level attention for all previous sentences is always re-balanced based on the newly-generated sentence. To balance the attention of tokens in

---

[5] We can obtain a clear boundary for each concept with this design choice of adding a period as the separator, as concepts can be tokenized into multiple subwords by GPT2 tokenizers.

[6] We measure the max sentence-level attention rather than the mean sentence-level attention on CommonGen, as the attention to a concept is usually reduced once it is generated.

each sentence received while generating the next sentence, we define the attention reweight function in Eqn. 9 with the aforementioned prior for ROCStories as:

$$f_{i,j}(\boldsymbol{x}, \boldsymbol{\alpha}_{i,j}^{t-1}) = \frac{1}{\alpha_{g_i,p_j}^{t-1}}. \tag{10}$$

As later sentences in the prompt usually receive larger sentence-level attention weights (Appendix A.1), attention reweighting function defined in Eqn. 10 will add a large weight to tokens in the early sentences and a small weight to tokens in the late context sentences. The simple heuristic of balancing context sentences to be considered relatively equal, namely more weights on early context sentences, might not be optimal prior. However, it improves the long-form story generation in multiple measures, including fluency, interesting, newness, and repetition (§6.1).

4.3 αNLG: abductive reasoning generation

The second benchmark dataset we tested with attention modulation is αNLG (Bhagavatula et al., 2020). This dataset is proposed for abductive reasoning generation: given two observations O_1 and O_2, the model needs to generate a valid hypothesis h that explains what happened between the two observations. For example, given O_1: "Today was the first day of school." and O_2: "I hate school.", the task is to generate h such as "The teacher made fun of me." as a plausible explanation.

Bhagavatula et al. (2020) has shown that the fine-tuned GPT2 performs far below human performance on the αNLG task. We hypothesis that this may be associated with insufficient learning of sentence-level attention to both observations; for example, the model might over-fit to one of the observations for generation. Thus, we inject the prior – the language model should consider both observations relative equally – while generating a plausible explanation. This prior can be injected with attention reweighting function defined in Eqn. 10.

4.4 CommonGen: constrained commonsense generation

The third benchmark is CommonGen – a constrained text generation challenge for generative commonsense reasoning. CommonGen requires machines to generate a realistic sentence using *all* concepts from a given concept set by conducting commonsense reasoning over the relations among the given concepts. To successfully generate a plausible and grammatical sentence that follows the commonsense, models need to conduct commonsense reasoning over the relations among the given concepts. Our experiment in §3.2 shows that the fine-tuned GPT2-L can only cover about 75% of concepts during generation. We infer from Table 1 that this may be associated with GPT2-L giving insufficient sentence-level attention to uncovered concepts. Thus, we propose a simple heuristic – model should pay more attention to concepts that are not covered yet – to be injected with attention modulation.

Consider the prompt with m concepts $\boldsymbol{c} = \{c_1, \dots, c_m\}$ and a partially generated sentence $y_1, \dots, y_{t-1}$. While generating the t-th token, the sentence-level reweighting function from the i-th token to the j-th token in c_k is defined as:

$$f_{i,j}(\boldsymbol{x}) = \begin{cases} 1/m & \text{if} \quad c_k \subset y_{1:t-1} \\ 1 & \text{else} \end{cases} \tag{11}$$

Intuitively, if a concept c_k is covered in the partial generation, attention modulation with Eqn. 11 will reduce the attention weights of the tokens in concept c_k.

5 Experimental Setups

This section describes the experiment setups, including the baselines, decoding algorithms, datasets, and evaluation metrics.

Model architecture & baseline Attention modulation is architecture-agnostic and can be applied to any Transformer-based models that contain self-attention computation. We choose GPT2-L (Radford et al., 2019) for our experiments, which has achieved state-of-the-art performance on a variety of generation tasks (Vig and Belinkov, 2019). Attention modulation can be applied to any range of layers in the Transformer. To compare models with and without attention modulation on each of the three generation tasks, we use the best fine-tuned GPT2-L based on the validation set after fine-tuning for 4 epochs with the default settings.

Decoding Attention modulation directly changes the attention weights of the context tokens during inference. It is orthogonal to different decoding algorithms that change the searching strategies based on the softmax distribution emitted by Transform-

Table 2: Test results of the fine-tuned GPT2-L w/ and w/o attention modulation on ROCstories with the greedy decoding algorithm. uniq. represent the unique number of tokens generated in the whole test corpus, which measures the number of new unique tokens generated. rel. represent relevancy, which measures the percentage of tokens generated appears in the prompt. rep. measures the sentence-level repetition – whether two sentences generated are identical.

ers.[7] We present the results with non-stochastic decoding algorithms (*i.e.* greedy decoding and beam search), as generations based on them truly reflect the token-level probabilities predicted by the model (Holtzman et al., 2018).

Datasets We use three different generation datasets – ROCStories (Mostafazadeh et al., 2016), αNLG (Bhagavatula et al., 2020), and CommonGen (Lin et al., 2020). For ROCStories, we used the 2017 version and split the data into 75/10/15 for train/val/test.

Evaluation On ROCStories, we measure dullness, relevancy and repetition similar to Welleck et al. (2019). We report the number of unique tokens generated, where the generation is less dull if more unique tokens are generated. For repetition, we directly measure sentence-level repetition: two generated sentences are repeated if their strings are the same. For relevancy, we measure the percentage of generated tokens that appear in the prompt. Besides, we perform a human evaluation, where three annotators are asked to rate the generations based on fluency, interestingness, newness, relevancy, and repetition.

On αNLG, we score the generated explanation with respect to the reference using the following automatic metrics: BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Banerjee and Lavie, 2005), and CIDEr (Vedantam et al., 2015). In addition, we ask annotators to compare the generated explanations without and with attention modulation. Human judges are asked to decide which system provides a more plausible explanation of the observations.

On CommonGen, we report SPICE (Anderson et al., 2016) – a measure that evaluates semantic propositional content, in addtion to BLEU, ROUGE, METEOR, CIDEr. We also report Coverage (Lin et al., 2020), which computes the average percentage of input concepts that appear in the lemmatized outputs. We conduct a human evaluation following the protocol of Lu et al. (2020). Human judges are asked to compare two systems in terms of fluency, coverage (covers the concept), and overall quality (covers the concepts and follows commonsense).

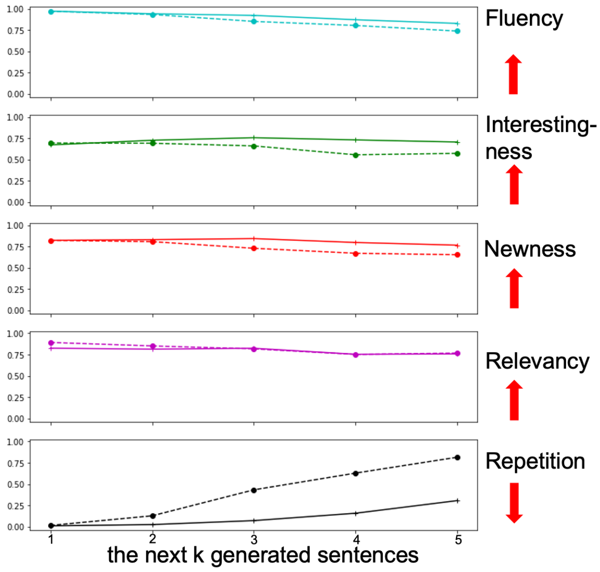

Figure 3: Human evaluation results on the next 1 to 5 sentences generated without (dashed lines) and with (solid lines) attention modulation (1000 samples).

6 Result

In this section, we present the vast improvements of the fine-tuned GPT2-L with attention modulation on three narrative generation and generative reasoning tasks: ROCStories, αNLG, and CommonGen.

6.1 ROCstories

Table 2 indicates that attention modulation significantly reduces repetition in narrative generation,

while increasing the relevancy of generated sentences to the original story. We can observe a vast improvement in the number of unique generated tokens using attention modulation, indicating a reduced repetition rate (confirmed by the % number of repeated sentences in the next five sentence generated – 35.43 vs. 17.49 for our approach). This intuition is confirmed by our human evaluation in Figure 3, where the GPT2-L with attention modulation produces sentences that are more fluent, more interesting, more novel, and less repetitive than the original decoder. Furthermore, we note that the difference in performance across these evaluation categories generally increases as the number of generated sentences increases, indicating less sensitivity to long-form degeneration.

6.2 αNLG

Table 4 presents the automatic and human evaluation results on αNLG. We can see that our model performs similarly with and without attention modulation in terms of automatic evaluation. However, our human evaluation results in the last column show that overall, the human judges prefer the explanations produced using attention modulation significantly more than those of the original model. With 100 samples generated, 33% of the time, human judges select explanations generated with attention modulation as more plausible. In contrast, explanations from the original model are only preferred 14% of the time.

6.3 CommonGen

Table 3 shows the automatic evaluation results on the CommonGen dataset. We separate different settings of decoding algorithms in blocks. By injecting the prior – the model should put more attention on uncovered concepts – into the GPT2-L with attention modulation, we can improve the text generated in every automatic measure significantly. Interestingly, despite our attention-reweighted decoder only encouraging coverage, we see all the other measures such as ROUGE, BLEU, METEOR, CIDEr, SPICE improve, as well.

These improvements also hold when we use a different base decoding algorithm, such as beam search. Again, the performance improvement for using attention modulation is significant over all measures. Thus, unlike decoding algorithms that improve downstream tasks through truncation of the sampling distribution, we directly re-calibrate the token-level probabilities predicted by the model by altering attention patterns in the Transformer blocks during inference.

We also conduct a human evaluation to check whether this improvement in the automatic metrics transfers to human judgments. In Table 6, we see that our attention modulation algorithm significantly outperforms the original inference model on every measure – from fluency, quality, and overall performance.

6.4 Vast improvements on few-shot learning

Table 5 presents the results of attention modulation on GPT2-L that are fine-tuned on different numbers of training examples from CommonGen. We observe the improvements on all measures are

Training size	Method	R-2	R-L	B-3	B-4	Meteor	CIDEr	SPICE	Coverage

Table 5: CommonGen test results of the fine-tuned GPT2-L w/ or w/o attention modulation trained on different size of training examples (greedy decoding).

	Fluency	Quality	Overall
w/o AttnM	85.07	39.30	44.77
w/ AttnM (ours)	**89.55**	**48.76**	**52.73**

Table 6: Human evaluations of the fine-tuned GP2-L w/o or w/ attention modulation on CommonGen.

more prominent when the fine-tuning data size is small. For example, adding attention modulation can improve coverage by 9.43% on the GPT2-L fine-tuned with only 10 examples. This not only validates that priors we injected into the model are suitable for improving the downstream task performance, but also shed lights to use attention modulation on different few-shot learning scenarios where the number of training examples is limited.

7 Related Work

We propose to use attention modulation to heuristically re-balance sentence-level attention for neural text degeneration. At least three domains of work are closely related to our proposal, namely, attention pattern analysis, work that focuses on changing or approximating learned attention patterns, and work for countering neural text degeneration.

Attention analysis: Previous work has investigated the attention patterns within the local context of a sentence. These works highlighted that attention patterns in Transformers implicitly encode syntactic information such as dependency relations (Htut et al., 2019), and part-of-speech tags (Vig and Belinkov, 2019; Raganato and Tiedemann, 2018). Other works observed that attention patterns can provide explanations (Wiegreffe and Pinter, 2019) or coarse word alignments in machine translation (Zenkel et al., 2019; Kobayashi et al., 2020). In contrast to these works, we analyze sentence-level attention patterns for neural text degeneration, and propose to directly modify the attention computation to reduce it.

Alternative attention: Many works have been proposed to change attention mechanisms to optimize their O(n^2) complexity. Some promising directions in this space include sparse attention mechanisms (Beltagy et al., 2020; Zaheer et al., 2020) and linearized attention (Choromanski et al., 2021). These alternative attention mechanisms require training the model and are used as replacements to the original attention mechanism for fast training or reduced computation. Our work is fundamentally different as we seek to inject priors into the standard attention mechanism during inference (without re-training the model).

Neural text degeneration: Previous works seek to solve neural text degeneration by changing the training objective to reduce the likelihood of common tokens (Welleck et al., 2019), or modifying the decoding algorithm by truncating the sampling distribution (Holtzman et al., 2018, 2020). Specifically, Welleck et al. (2019) introduce an additional training loss that reduces the likelihood of common tokens. Holtzman et al. (2018, 2020) propose stochastic decoding algorithms with truncation of the sampling distribution. Our work is orthogonal to these methods by injecting priors into the model's attention computation during inference.

8 Conclusions and future work

Neural language models often exhibit degeneration: the output texts are repeated, bland, and inconsistent. Our empirical analyses show that neural text degeneration may be associated with insufficient learning of task-specific characteristics by the attention mechanism. We propose a simple but effective module – attention modulation – that can inject priors for better generation through re-balancing the attention weights during inference. Results on three different narrative and commonsense generation tasks indicate that attention modulation can reduce repetition and enhance commonsense reasoning while maintaining fluency and coherence.

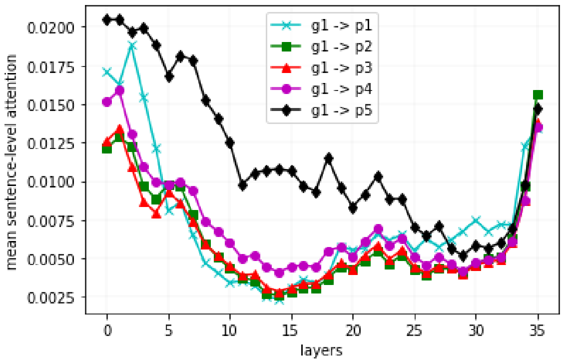

Figure 4: Sentence-level attention distribution across different layers in GPT2-L. The result is aggregated by computing the mean sentence-level attention from the next generated sentence to the five sentences in the prompt of ROCStories development set. Lower number represents lower layers in the Transformer.

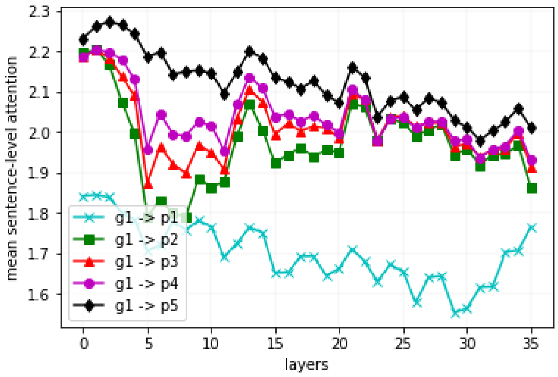

Figure 5: Attention entropy of each sentence in the prompt aggregated over the ROCStories dev. set. In the first sentences, there are particularly high-entropy attention heads that produce bag-of-vector-like representations.

A Appendices

A.1 How does a language model use attention to model a multi-sentence prompt?

Sentence-level attention portion To reveal which part of context – near or distant history – are important for context representation, we compute aggregated mean sentence-level attention (Eqn.5 in the main text) each prompt sentence p_i received, while generating the sentence g_1 after the prompt. We observe from Figure 4 that GPT2-L mostly attends to the nearest sentence (p_5) during the generation. This effect is especially prominent in the early and middle layers. In the late layers, the attention from different sentences evens out. This observation is consistent with previous analysis of attention patterns within sentences such that deeper layers focus on longer-range context (Vig and Belinkov, 2019).

	train	dev.	test
ROCStories	39498	5269	7899
αNLG	169,654	1,532	3,059
CommonGen	67,389	4,018	7,644

Table 7: Dataset Statistics

Sentence-level attention entropy Khandelwal et al. (2018) observed that LSTM represent distant context as topics; only a few token in the distant context are used to compute the context representation. We check whether this observation also holds on Transformer-based models by computing attention entropy. This sentence-level attention entropy of p_i based on the attention from g_1 to p_i at layer l_m over a corpus X is defined as:

$$E_A(g_1, p_i, l_m) = -\frac{\sum\limits_{x\in X}\sum\limits_{h\in l_m}\sum\limits_{j=1}^{|p_i|}\sum\limits_{k=1}^{|g_1|}\alpha^h_{j,k}\log(\alpha^h_{j,k})}{|X|\cdot|H|\cdot|p_i|\cdot|g_1|} \tag{12}$$

where h is a head in layer l_m and $\alpha^h_{j,k}$ is the attention weight from $x_j \in p_i$ to $x_k \in g_1$ for h. Figure 5 shows a clear separation of entropy over different sentences in the prompt, where more distant sentences have lower entropy values. This suggests that LMs only modelling distant sentences as topics – attention over key words being a proxy.

A.2 Hyperparameters

Attention modulation can be applied to any layer and any head in the Transformer based on our implementation. However, the weights learned by different heads in a particular layer have a large variance (Vig and Belinkov, 2019) and are subject to change from different training sessions. Therefore, we only reweight attention on all heads in different layers, where what layers are re-weighted are hyperparameters. We choose to reweight the consecutive layers from a starting layer l_s to an end layer l_e and performed a grid search on different layer ranges. For the start layer, we experimented with $l_s \in \{0, 4, 8, 12, 16, 20, 24, 28, 32\}$; for the end layer, we experimented with $l_e \in \{4, 8, 12, 16, 20, 24, 28, 32, 36\}$. The reweighting layers are chosen based on the validation set performance. On ROCstories, the GPT2-L are re-weighted with $l_s = 8$ and $l_e = 32$; On αNLG, the

propmt	attention reweight	Generated sentence with attention-decoding
field. stand. look. =	(1,3,2)	A man stands looking at a sign in a field.
field. stand. look. =	(1,2,3)	He looks up and sees a group of people standing in the field.
field. stand. look. =	(2,3,1)	He stands in the middle of the field, looking down at the stands.

Table 8: An example of attention modulation with different attention reweighting functions on CommonGen dev set. Only by redistributing the sentence-level attention during inference, we can generate sentences following the desired order specified in the attention reweighting function.

		R-2	R-L	B-3	B-4	Meteor	CIDEr	SPICE	Coverage
beam=20	w/o AttnM	17.98	38.07	35.14	25.61	27.63	12.90	23.28	79.62
	w/ AttnM	18.11	39.32	36.69	26.80	28.02	13.71	23.94	81.85
	w/ AttnM$_{pm}$	**19.78**	**41.17**	**38.28**	**28.36**	**30.97**	**15.38**	**28.24**	**91.89**

Table 9: Results on CommonGen test set with beam search and permutations defined in A.3.

GPT2-L are re-weighted with $l_s = 12$ and $l_e = 32$; On CommonGen, the GPT2-L are re-weighted with $l_s = 24$ and $l_e = 32$.

A.3 Attention modulation and generation order

CommonGen provides the concept set in a random order, where models need to perform a relational commonsense reasoning to find the optimal order of them for generating a plausible sentence. We found that attention modulation provide signals for generation order given different reweighting functions (examples in Table 8). In this experiment, we guide the generation order by providing different initialization weights in the reweighting functions. We enforce different attention modulation weights based on the order we want the concepts to be generated. For examples, row 1 in table 8 means the concepts of (FIELD, STAND, LOOK) are initialized to be re-weighted by scales of (1,3,2).

This interesting finding motivates us to conduct a permutation experiment on CommonGen. For a k concept set, we initialize the attention modulation weights based on the permutations of 1 to k ($k!$ permutations in total) and generate $k!$ sentences with attention modulation. We then select the generation that covers the most concepts[8] from these $k!$ generations as output. We call this method "attention modulation with permutation". Table 9 presents the results of attention modulation with permutation. We see that just by enforcing the order in attention modulation, the coverage can be improved by another 10%.

A.4 Human evaluation details

Figure 6 and 7 show the evaluation templates for tuckers for Rocstories and CommonGen[9], respectively. On ROCstories, the inter-annotator agreements is 0.743 and fleiss kappa is 0.229 averaged over the five dimensions on 200 × 5 samples. The inter-annotator agreements are 84.6%, 72.2%, 76.1%, 78.5%, and 59.9% for fluency, interestingness, newness, relevance, and repetition. On αNLG, the human evaluation results are 33%, 14%, 10%, 32%, 11% for preferring outputs with attention modulation, without attention modulation, both, neither and no agreement. The inter-annotator agreements is 0.835 and kappa is 0.439 over 100 samples. On CommonGen, the inter-annotator agreements are 77.94%, 71.64%, and 67.50% for fluency, quality, and overall on 200 samples.

---

[8] If there is a tie, we choose the shorter generation.

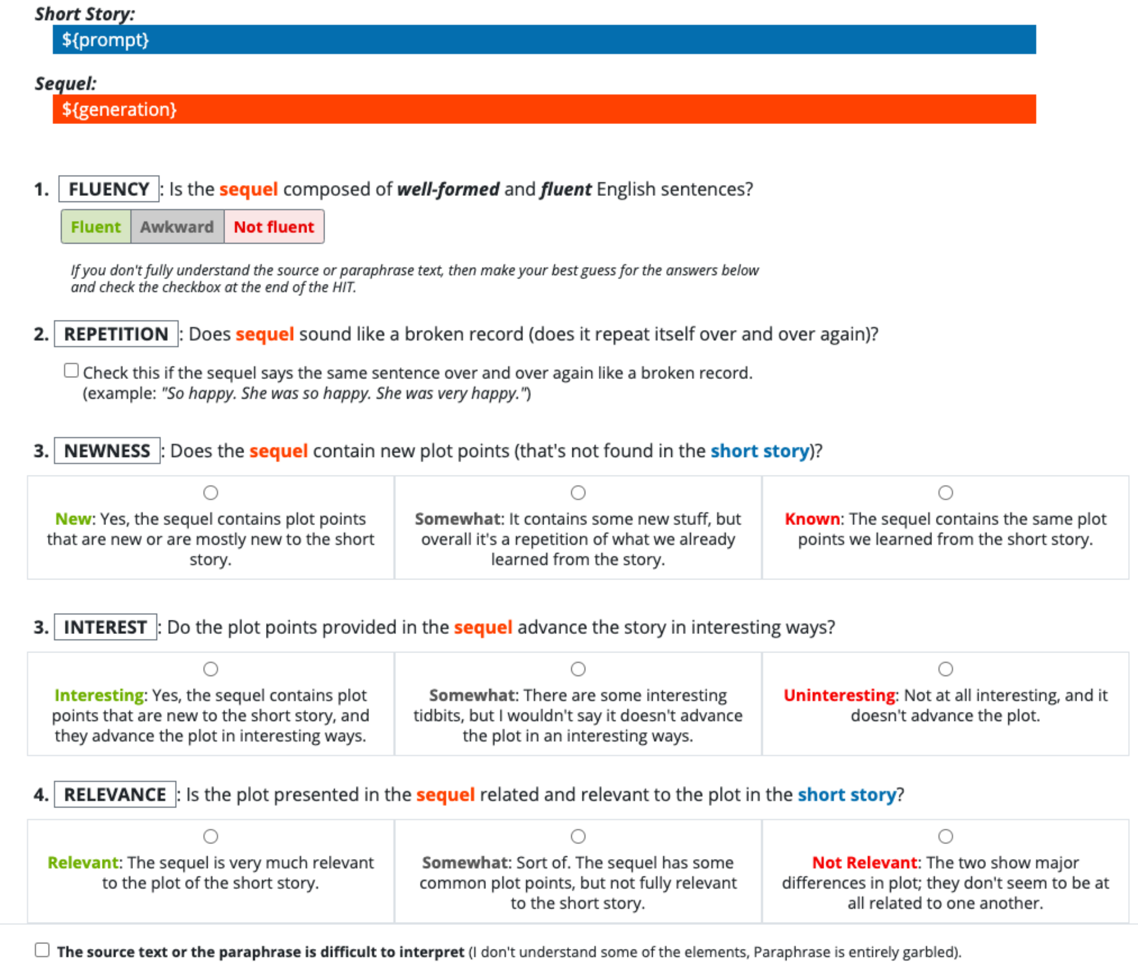
[9] omitted αNLG template due to space limitation.

prompt	Jen was always afraid of flying. She needed to fly to Japan for an important meeting. Jen took some Dramamine and boarded her plane. Jen dozed off shortly after the plane took off.
w/o AttnM	Jen woke up to a huge headache. She had to cancel her trip to Japan. Jen was glad she had taken Dramamine. She was able to fly safely. Jen was glad she had taken Dramamine.
w/ AttnM	She woke up to a loud bang and felt sick. She had to sit in the back of the plane. She was so scared she couldn't even get out of her seat. Jen was so embarrassed she never flew again. She was so scared she never flew again.

Table 10: A generation example (greedy decoding) without and with attention modulation on ROCStories. Adding attention modulation during inference **improves the commonsense reasoning and consistency of the generation**.

prompt	Neil had been journeying through Asia. But he contracted malaria on a Thai island, and had to be flown home for treatment.
w/o AttnM	He was so sick that he couldn't go to the hospital. He was so sick that he couldn't go to the hospital. He was so sick that he couldn't go to the hospital. He was so sick that he couldn't go to the hospital. He was so sick that he couldn't go to the hospital.
w/ AttnM	He was very sick and had to be hospitalized. He was in the hospital for a week. He recovered and was released. Neil was very happy to be home. He was able to get better and was able to go back to his home country.

Table 11: Example (greedy decoding) of the fine-tuned GPT2-L without and with attention modulation on story completion. Adding attention modulation during inference significantly **reduces the sentence-level repetition**.



Short Story:

${prompt}

Sequel:

${generation}

1. **FLUENCY**: Is the **sequel** composed of ***well-formed*** and ***fluent*** English sentences?

Fluent | Awkward | Not fluent

If you don't fully understand the source or paraphrase text, then make your best guess for the answers below and check the checkbox at the end of the HIT.

2. **REPETITION**: Does **sequel** sound like a broken record (does it repeat itself over and over again)?

☐ Check this if the sequel says the same sentence over and over again like a broken record. (example: *"So happy. She was so happy. She was very happy."*)

3. **NEWNESS**: Does the **sequel** contain new plot points (that's not found in the **short story**)?

○ **New**: Yes, the sequel contains plot points that are new or are mostly new to the short story.	○ **Somewhat**: It contains some new stuff, but overall it's a repetition of what we already learned from the story.	○ **Known**: The sequel contains the same plot points we learned from the short story.

3. **INTEREST**: Do the plot points provided in the **sequel** advance the story in interesting ways?

○ **Interesting**: Yes, the sequel contains plot points that are new to the short story, and they advance the plot in interesting ways.	○ **Somewhat**: There are some interesting tidbits, but I wouldn't say it doesn't advance the plot in an interesting ways.	○ **Uninteresting**: Not at all interesting, and it doesn't advance the plot.

4. **RELEVANCE**: Is the plot presented in the **sequel** related and relevant to the plot in the **short story**?

○ **Relevant**: The sequel is very much relevant to the plot of the short story.	○ **Somewhat**: Sort of. The sequel has some common plot points, but not fully relevant to the short story.	○ **Not Relevant**: The two show major differences in plot; they don't seem to be at all related to one another.

☐ **The source text or the paraphrase is difficult to interpret** (I don't understand some of the elements, Paraphrase is entirely garbled).

Figure 6: Mechanical Turk template used to evaluate ROCstories generations.

	propmt	Generated sentence with attention-decoding

w/ AttnM.	run. team. field. drill. =	person runs a drill during a training session with his team.
w/o AttnM	use. tool. piece. metal. =	tool or piece of metal used in manufacturing.
w/ AttnM	use. tool. piece. metal. =	piece of metal used to make tools.

Table 12: Examples produced by GPT2-L without and with attention modulation. Use attention modulation would have higher concept coverage (details in Table 3 in the main text with 5% coverage improvements on all decoding algorithms we tested);

Instructions (click to expand/collapse)

Thanks for participating in this HIT! Please read the instructions carefully.

In this HIT, you will be shown a **sentence** that tries to describe a plausible scenario by combining as many given **concepts** as possible.
Your task is to ***evaluate*** the **sentence** along two dimensions:

1. Is the **sentence** ***understandable*** and describes a ***plausible*** scenario?
   - **Yes**: The sentence is understandable and describes a realistic or possible scenario.
   - **No**: The sentence is either not understandable, or describes a completely impossible scenario.
2. Does the **sentence** include the given **concepts**?
   - **Yes**: The sentence meaningfully includes all of the concepts.
   - **Somewhat**: The sentence meaningfully includes some, but not all of the concepts. It may include all, but with many not properly incorporated.
   - **No**: The sentence includes few or none of the concepts in a meaningful way.
3. Considering your answers to 1. and 2., Does the **sentence** combine all of the **concepts** into a reasonably well-formed and plausible scenario?
   - **Yes**: The sentence is reasonably well-formed/understandable, and combines all the concepts into a plausible scenario.
   - **No**: The sentence is not well-formed/understandable, or fails to properly combine the concepts into a scenario.

Please take care to not submit responses that are uninformed by the instructions.

Concepts:
${source}

Sentence:
${generation}

1. **SENTENCE QUALITY**: Is the **sentence** ***well-formed*** and describes a ***plausible*** scenario?

○ **Yes**: The sentence is understandable and describes a realistic or possible scenario.
○ **No**: The sentence is either not understandable, or describes a completely impossible scenario.

2. **CONCEPTS**: Does the **sentence** include the given **concepts**?

○ **Yes**: The sentence meaningfully includes all of the concepts.
○ **Somewhat**: The sentence meaningfully includes some, but not all of the concepts. It may include all, but with many not properly incorporated.
○ **No**: The sentence includes few or none of the concepts in a meaningful way.

3. **OVERALL**: Considering your answers to 1. and 2., Does the **sentence** combine all of the **concepts** into a well-formed and plausible scenario?

○ **Yes**: The sentence is reasonably well-formed/understandable, and combines the concepts into a plausible scenario.
○ **No**: The sentence is not well-formed/understandable, or fails to properly combine the concepts into a scenario.

Abstract

Target meaning representations for semantic parsing tasks are often based on programming or query languages, such as SQL, and can be formalized by a context-free grammar. Assuming a priori knowledge of the target domain, such grammars can be exploited to enforce syntactical constraints when predicting logical forms. To that end, we assess how syntactical parsers can be integrated into modern encoder-decoder frameworks. Specifically, we implement an attentional SEQ2SEQ model that uses an LR parser to maintain syntactically valid sequences throughout the decoding procedure. Compared to other approaches to grammar-guided decoding that modify the underlying neural network architecture or attempt to derive full parse trees, our approach is conceptually simpler, adds less computational overhead during inference and integrates seamlessly with current SEQ2SEQ frameworks. We present preliminary evaluation results against a recurrent SEQ2SEQ baseline on GEOQUERY and ATIS and demonstrate improved performance while enforcing grammatical constraints.

1 Introduction

Semantic parsing aims at delivering granular, structured representations of natural language utterances, referred to as *meaning representations* or *logical forms*. Thus, it goes beyond shallow semantic analysis involving argument identification and role labeling (Collobert et al., 2011; Roth and Lapata, 2016). Meaning representations based on programming or query languages (PYTHON, SQL) are describable by (deterministic) context-free grammars and used for general purpose code generation (Xiao et al., 2016; Yin and Neubig, 2017). Our work targets this particular subset of logical forms. A context-free grammar may be exploited to constrain a semantic parser to only produce token sequences derivable from the grammar. Specifically, we investigate how syntax constraints can be enforced in semantic parsers based on modern encoder-decoder frameworks in a non-intrusive, computationally inexpensive way at inference time. We show that enforcing grammatical constraints with LR parsers is particularly well suited for modern autoregressive neural network architectures used in neural machine translation (Sutskever et al., 2014; Vaswani et al., 2017). We do not require any modifications to standard SEQ2SEQ neural network architectures and make very little assumptions about the inputs and outputs of such models. In contrast, most grammar-constrained decoders attempt to model the grammar explicitly within the neural network, complicating the architecture. Moreover, they predict complete syntax trees or derivation sequences. Our approach predicts source code token streams, preserving syntactic validity throughout the decoding procedure. Enforcing syntactical constraints relieves neural networks models from having to learn the syntactic structure of the target language, which is particularly beneficial for ensuring balanced expressions over long ranges (Bahdanau et al., 2014; Ling et al., 2016). Also, when integrating our models into larger application environments, we may want to preclude specific failure modes (i.e., syntax errors) when executing the generated program snippets to increase robustness. Preliminary evaluation results on the GEOQUERY and ATIS data sets demonstrate that simply enforcing syntactical constraints on the pre-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1275–1279

dicted lexical tokens at inference time improves the performance of the semantic parser against a recurrent SEQ2SEQ baseline.

2 Related Work

Enforcing grammatical constraints within neural network models has sparked a fair amount of research interest. (Xiao et al., 2016) take a derivational viewpoint when decoding derivation trees, demonstrating improved performance when accounting for grammatical constraints. They predict leftmost derivation sequences, each uniquely associated with a corresponding derivation tree. Employing a constrained loss over probabilities $p'(\hat{\mathbf{y}}_t)$, where $\hat{\mathbf{y}}_t$ are the permissible continuations of a derivation sequence, constraints are enforced at training time. We take inspiration from (Xiao et al., 2016), however, enforce grammatical constraints at inference time and on lexical token streams in a bottom-up fashion, eliminating the need to derive entire syntax trees and effectively reducing the sequence length. Similarly, (Yin and Neubig, 2017) predict entire syntax trees sequentially using a SEQ2SEQ model, starting from the root node and generating tree nodes in depth-first, left-to-right order, deterministically converting them to the corresponding surface code. They define a dedicated grammar model that predicts action sequences that either apply a production rule or generate a lexical token. (Krishnamurthy et al., 2017) additionally ensure that decoder predictions satisfy type constraints by providing a type-constrained grammar. (Rabinovich et al., 2017) propose a decoder that employs a separate neural network module for each construct in the grammar. The decoder generates an abstract syntax tree (AST) through mutual recursion between modules. At each decoding step, the decoder either generates a symbol or propagates the decoder state to the next module. (Yin and Neubig, 2018) developed a transition-based abstract syntax parser (TRANX) guided by a grammar specified under ASDL (Wang et al., 1997). TRANX uses ASTs as general-purpose intermediate meaning representations, decoupling the semantic parsing procedure from domain-specific grammars. A user-defined grammar converts ASTs to domain-specific meaning representations. Similar to (Yin and Neubig, 2017) an AST is generated using a sequence of tree-constructing actions. All approaches enforce syntactical constraints by first predicting the tree-structured syntax tree top-down. Instead, we propose to directly generate lexical tokens (the values of syntax tree leaves) and constrain the decoding process by means of an bottom-up LR parser.

3 Problem Statement

Informally, we aim at translating a set of natural language utterances X to a structured representation of their meaning. We assume the syntax of target meaning representations is describable by a deterministic context-free grammar and that it is known at training time. Given a grammar G, our goal is to enforce the constraints imposed by G during decoding. That is, the image of our model f shall be the language generated by G.

$$f\colon\ X \rightarrow L(G) \tag{1}$$

We achieve this by means of a recurrent encoder-decoder model as proposed by (Sutskever et al., 2014) and an LR parser. We briefly introduce recurrent encoder-decoder NMT models and the specifics of our model.

3.1 SEQ2SEQ Model

All modern encoder-decoder frameworks define a probability distribution $P(\mathbf{y}|\mathbf{x})$ (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014), where in our case, $\mathbf{x}$ represents a natural language input. For a target source code string, $\mathbf{y}$ represents the token stream generated by a lexical analyzer and a corresponding lexical grammar (see section 3.2). $P(\mathbf{y}|\mathbf{x})$ is factorized as:

$$p(y_1, ..., y_\kappa|\mathbf{x}) = \prod_{t=1}^{\kappa} p(y_t|\mathbf{x}, y_1, ..., y_{t-1}) \tag{2}$$

The encoder portion of the neural network encodes $\mathbf{x}$ into a vector-valued, so-called *context*. Conditioned on the context and all previous decoder hidden states, the decoder generates the output tokens $y = (y_1, ..., y_\kappa)$. Both encoder and decoder are distinct recurrent neural networks (LSTM's in our case). The decoder generates a sequence of hidden states and outputs a hidden state $\mathbf{h}_t^L$ at the topmost, L-th layer at timestep t. The individual factors in Eq. 2 are finally obtained using a feedforward neural network with a softmax layer that maps each hidden state to a probability distribution over the token vocabulary V_D of the decoder. We optimize standard cross-entropy loss.

3.2 Grammar-Constrained Decoder

LR parsers are used to verify that a given token stream is derivable from a deterministic context-free grammar G. The parsing stage is usually preceded by lexical analysis. During lexical analysis, a source code string is converted into a sequence of tokens, ready to be consumed by the parser. LR parsers employ ACTION and GOTO tables associated with the grammar, governing the applicable shift-reduce decisions the parser can make on each token input and determining the error states of the parser. The decoder stage in the SEQ2SEQ model can be viewed as taking the role of the lexical analyzer in the parsing process (see Figure 1).

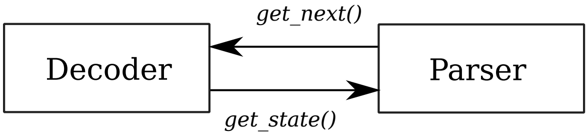

Figure 1: The parser requests the next token from the decoder. The decoder queries the current parser state to determine the set of applicable tokens, generates a token and returns it to the parser.

Algorithm 1 : LR(1) Assisted Decoder

```
let $s$ ← top of stack state;
let $h$ ← encoder context vector;
let $a$ ← Token(SOS, '<SOS>');

while ACTION($s$, $a$) $\neq$ acc do
    let $e_t$ ← EXPECTED($s$);
    if $|e_t| > 1$: $h$, $a$ ← DECODE($h$, $e_t$, $a$);
    else: $a$ ← $e_t$;

    if ACTION($s$, $a$) = shift $i$:
        push state $i$ onto stack;
    elif ACTION($s$, $a$) = reduce [$i$, $A \to \beta$]:
        pop $|\beta|$ symbols off stack;
        push GOTO($i$, $A$) onto stack;

    $s$ ← top of stack state;
```

The decoder determines the set of applicable tokens in its vocabulary by consulting the parser's ACTION table. We generate a probability distribution as described in section 3.1 over the actions (identified by lexical tokens) in the current parser state and return the most likely token to the parser. The parser consumes the token, updates its state, and requests the next token. This process continues until the parser encounters a token that indicates acceptance (an EOF token "\$"). The neural network model is implemented using PYTORCH [1]. The parser implementation relies on the parsing toolkit LARK [2]. The output vocabulary V_D consists of all source code tokens defined by the given grammar. Literals, such as string or integer values, are usually tokenized by matching them with a regular expression. We explicitly include all occurrences of literal values in the data sets as distinct tokens in the vocabulary. Algorithm 1 describes our modified LR parsing procedure relying on the decoder module providing the token stream. The procedure is initialized with the context vector obtained from the encoder and the parser start state. Given the state s, we determine the set of possible tokens e_t by looking in the parser's ACTION table. Conditioned on the previous hidden state, we invoke the DECODE function and generate an output distribution $\hat{\mathbf{y}}$ over *all* output vocabulary tokens. We finally choose $a = \max(\hat{\mathbf{y}}_{e_t})$ as our prediction, where $\hat{\mathbf{y}}_{e_t}$ are the elements of $\hat{\mathbf{y}}$ indexed by e_t. The next hidden state h_t is returned, and the parser updates its state by parsing a. On shift actions, we push the associated state i onto the stack and request the next token. On reduce actions, we pop the recognized handle off the stack and push the left-hand side of the production onto the stack. The decoding procedure concludes when the parser encounters a token that indicates acceptance (corresponding to action "acc"). Note, that the decoder is invoked only if $|e_t| > 1$, i.e., when there is more than one applicable token. Otherwise, we simply set $a = e_t$. The additional computational overhead of running a single parsing step is constant at each decoding step. Although most programming languages are close to deterministic, generalizing our approach to GLR parsers (and thus to context-free grammars) may incur an additional computational cost proportional to the non-determinism in the grammar (Tomita, 1985).

3.3 Model Training

Algorithm 1 is only used during inference. Thus, during model training, the decoder may generate sequences $s \notin L(G)$. Furthermore, since the decoder is only invoked when $|e_t| > 1$, there is a mismatch between sequences seen during training and during test time. To account for this mismatch, each target sample is parsed prior to training, and

---

[2] https://github.com/lark-parser/lark

for each state s for which $\text{EXPECTED}(s) = 1$, we filter the corresponding target sequence element from the target sample.

4 Experimental Evaluation

We present preliminary evaluation results and compare our approach to a recurrent SEQ2SEQ baseline (see section 3.1) and an attentional SEQ2SEQ model as reported in (Finegan-Dollak et al., 2018). Our attentional model extends the recurrent baseline with an attention layer as proposed by (Bahdanau et al., 2014).

4.1 Datasets

For our trials we use the canonicalized and annotated semantic parsing data sets for text-to-SQL tasks provided by (Finegan-Dollak et al., 2018). Compared to data sets like WIKISQL, GEOQUERY and ATIS feature complex queries with low levels of redundancy. We hypothesize that the benefits of a grammar-constrained decoder will be particularly pronounced in data sets with high complexity and variability. To ensure comparability, we use identical training, validation and test splits as (Finegan-Dollak et al., 2018).

4.2 Setup

We run trials without entity anonymization and with anonymized entities. We refer to trials with the standard dataset, i.e., the trials without anonymized entities, as *standard* trials. Trials with entity anonymization are referred to as *oracle* trials. Greedy-search was used for generating output sequences. We measured the exact match classification accuracy. A predicted token sequence that is identical to the token sequence in the corresponding test set example constitutes an exact match. Stochastic gradient descent with momentum (0.9) and a learning rate of 0.1 was used for each trial. The batch sizes ($\{16, 32, 64\}$ for GEOQUERY and $\{128, 256\}$ for ATIS), hidden and embedding dimensions ($\{64, 96, 128, 256\}$), the dropout rate for embeddings and hidden units ($\{0.05, 0.1, 0.2, 0.4\}$), the number of layers ($\{1, 2\}$) and the teacher-forcing ratio ($\{1.0, 0.9, 0.8, 0.7\}$) were determined using grid search. We tested the models with best validation set performance during training and set an early stopping criterion.

4.3 Results

In Table 1 and Table 2 we present the results of the evaluation. We see the greatest improvements in the oracle trials without an attention layer. This verifies that the main utility of enforcing syntactical constraints lies with resolving the complex syntactical structures of target logical forms. Correctly recognizing entities and inserting the appropriate literals into the query is more akin to a *slot-filling* task than a semantic parsing task, and we observe no added value in enforcing grammatical constraints to resolve such literals in the standard trials. Applying an attention mechanism to both our approach and the basic recurrent model of (Finegan-Dollak et al., 2018) further puts the results into perspective. An attention layer in recurrent SEQ2SEQ models helps with resolving long range dependencies that may occur when expanding non-terminals, for example, involving long sub-queries (Bahdanau et al., 2014). Similarly, long range dependencies are resolved by virtue of the LR parser, ensuring that any non-terminal node is fully expanded, even if it involves sub-expressions that are expanded to long token sequences. Thus, using an attention mechanism, syntactic relationships between tokens can be learned much better, although syntax errors cannot be completely precluded as with an LR parser.

5 Conclusion and Future Work

We showed that grammatical constraints can be enforced with LR parsers, imposing no assumptions on the neural machine translation model used and adding little computational overhead. We intend to expand the trials to include other logical forms than SQL and comparable approaches to enforcing grammatical constraints (Xiao et al., 2016; Yin and Neubig, 2017). Moreover, we intend to generalize our approach to context-free grammars using GLR parsers and enforce grammatical constrains at training time.

Enhanced Metaphor Detection via Incorporation of External Knowledge Based on Linguistic Theories

Chang Su, Kechun Wu, Yijiang Chen*
School of Informatics, Xiamen University, Xiamen, China
`{suchang,cyj}@xmu.edu.cn`, `wukechun@stu.xmu.edu.cn`

Abstract

Use of external knowledge is an important and effective method applied widely in metaphor detection. Although existing knowledge-based methods perform well, when leveraging external knowledge, they take little consideration on linguistic theories of metaphor detection. Based on Metaphor Identification Procedure (MIP) and Select Preference Violation (SPV), directly using examples and definitions of words from the Oxford Dictionary[1], we propose two BERT-based models for metaphor detection: ExampleBERT and DefinitionBERT. Experimental results show that our methods achieve state-of-the-art performance on two established metaphor datasets. Furthermore, we show that our DefinitionBERT is highly interpretable.

1 Introduction

Metaphor Detection (MD) is a high-level natural language processing (NLP) task, which aims to identify the metaphorical expressions/words in the text. Identifying metaphors, a cognitive activity in which humans use their experience in one field to explain or understand another field (Shutova et al., 2016), is a challenging task that requires rich prior knowledge and a high level of semantic understanding.

In earlier studies, many resources were exploited to develop rule-based and machine learning systems, such as domain types,word abstractness/concreteness(Turney et al., 2011; Tsvetkov et al., 2014). Recently, many deep learning based methods have been applied to metaphor detection (Kehat and Pustejovsky, 2020; Le et al., 2020; Rohanian et al., 2020), which achieve the current state-of-the-art performance. They also make use of external knowledge. Hence, we can infer that incorporating external knowledge is indeed important. In this paper, we show that some level of lexical semantic information, even if its just dictionary entries, can improve performance in identifying verbal metaphor.

A recent study (Mao et al., 2019) shows the effectiveness of taking advantage of linguistic theories when identifying metaphors. According to one of the linguistic theories, Metaphor Identification Procedure(**MIP**) (Semino et al., 2007; Steen et al., 2010), a metaphor is identified if the literal meaning of a word contrasts with the means that word takes in this context. For example, in the metaphorical sentence, *the deep learning model is flying during training*, the context meaning of 'flying' is 'the loss of the model is getting bigger and even become indefinite', which contrasts with its literal meaning of 'move through the air using wings' according to **Oxford** Dictionary. An alternative approach is Select preference Violation(**SPV**) (Wilks, 1975, 1978), wherein a metaphor is identified by noticing a semantic contrast between a target word and its context. For example, in *the deep learning model is flying during training*, 'fly' is unusual in the context of 'model' and 'training': a model cannot fly.

To incorporate external knowledge, we take advantage of the linguistic theories of metaphor detection. Following SPV, we use examples of the word from Oxford Dictionary, where the literal meanings of the word are expressed in the contextual examples for the most of time. Hence, some common contextual information of the word can be inferred from examples. In accordance with MIP, we use the definitions of a word from the Oxford dictionary, which directly express the literal meanings of the word. To better use this knowledge and conform the idea of linguistic theories, we propose (1) ExampleBERT, which, before it identifies metaphor, learns the common contextual information of the

target word and (2) DefinitionBERT, which, while identifying a metaphor, directly takes advantage of the literal meanings of the target word. In particular, our contribution is two-fold as follows:

1. We directly use the examples and definitions of the word from the Oxford Dictionary. To the best of our knowledge, it is the first time this knowledge is incorporated into metaphor detection.

2. We propose ExampleBERT and DefinitionBERT. Experimental results show that both of our models can outperform the state-of-the-art models on two verb metaphor detection datasets. Also, experimental analysis proves that our DefinitionBERT is indeed effective and has a strong interpretability.

2 Related Work

Metaphor identification is a linguistic metaphor processing task that identifies metaphors in textual data. Most of the earlier works on metaphor identification were based on feature-engineering. Unigrams, imageability, concreteness, abstractness, word embedding and semantic classes are features commonly employed by supervised machine learning (Turney et al., 2011; Assaf et al., 2013; Tsvetkov et al., 2014; Klebanov et al., 2016). Recently, many deep learning based methods have been proposed, which treat metaphor identification as a sequence tagging task. Considering whether to use external knowledge directly, we divide these methods into the following two categories:

Use of pre-trained word embeddings. The first methods use only pre-trained word embeddings, which are commonly used in NLP tasks. (Wu et al., 2018) proposed a model based on word2vec (Mikolov et al., 2013) and PoS tags and word clusters, which are encoded by a Convolutional Neural Network (CNN) and Bi-LSTM. The encoded information is directly fed into a softmax classifier. (Gao et al., 2018) and (Mao et al., 2019) concatenated Glove (Le et al., 2020) and ELMO (Peters et al., 2018) as the inputs of Bi-LSTM, the difference is (Mao et al., 2019), inspired by linguistic theories, uses attention mechanism to improve performance.

External knowledge. The second methods use different kinds of external knowledge to boost performance. (Kehat and Pustejovsky, 2020) use Vision-Language datasets to derive the concreteness scores of words and then convert them to Visibility Embeddings, which, like with (Gao et al., 2018) , finally feed to Bi-LSTM. (Le et al., 2020) propose a multi-mask learning method, which transfer knowledge from Word Sense Disambiguation (WSD); to improve performance, they also employe Graph Convolution Neural networks (GCN) with dependency trees. Like (Le et al., 2020), (Rohanian et al., 2020) also use GCN, but they incorporate annotations for verbal multiword expressions. Obviously, our methods belong to this second category.

3 Method

3.1 BERT

BERT (Devlin et al., 2019) is a powerful language representation model, whose architecture is a multi-layer bidirectional transformer encoder. The BERT model is pre-trained on a large corpus and two novel unsupervised prediction tasks, i.e., masked language model and next sentence prediction tasks are used in pre-training. Here, it must note that BERT is chosen as our base model, not only because of its excellent performance on many other NLP tasks, but also BERT is a bidirectional language model. More specifically, during training, BERT randomly mask some words in the sentence and then use all the unmasked words to predict them based on a self-attention mechanism. Hence, this procedure allow BERT to learn the common context of the target word, which is very useful for our task because if a target word appears in uncommon contexts, then BERT is more likely to predict it to be a metaphorical word.

3.2 BERT(Token-CLS)

To incorporate BERT to our metaphor detection task, we take the final hidden state of the token corresponding to the target word, and then add a classification layer to predict whether or not the target word is metaphorical. We compare this model as our baseline with ExampleBERT and DefinitionBERT mentioned below.

3.3 ExampleBERT

The intuition behind SPV is that metaphoricity is identified by detecting the incongruity between a target word and its context. Hence, we assume that, if a model has learned the common context information of a target word, then the model works more effectively. As described in Section 3.1 above, a bidirectional pre-training model satisfies our requirement. Therefore, our proposed ExampleBERT

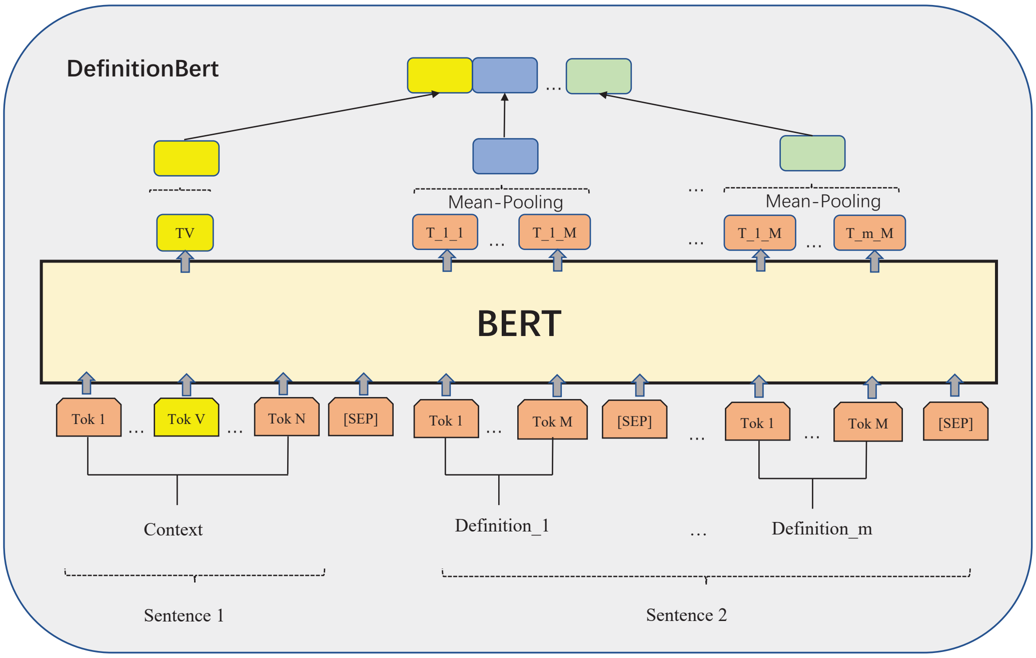

Figure 1: The overall of DefinitionBERT architecture and its context-definitions input pair.

model is built based on the standard BERT architecture (Devlin et al., 2019) which is based on the two-stage '*Pre-training*'-then-'*Fine-tuning*' pre-training language model approach, that recently become enormously popular in NLP. During the pre-training phase, we collect examples of the target word under its definitions from the Oxford dictionary and use only MaskLM as our pre-training objective. Here, we continue pre-training based on the pre-trained uncased BERT$_{BASE}$ model from (Wolf et al., 2020). The train strategy is the same as (Devlin et al., 2019). The training data generator chooses fifteen percent of the token positions at random for prediction. If the i-th token is chosen, we replace the i-th token with (1) the [MASK] token eighty percent of the time, (2) a random token ten percent of the time, and (3) the unchanged i-th token ten percent of the time. Here, our hypothesis is that most of the examples of a target word are expressing its literal meanings. Thus, whether or not a target word is selected, the model can also learn some common context information of a target word. During fine-tuning phase, we directly use the pre-trained ExampleBERT to fine-tune on the metaphor detection datasets as described in Section 3.2 above.

3.4 DefinitionBERT

Based on MIP, we assume that if we tell the model directly the literal meanings of the target word, then the model will work more effectively. Fortunately, BERT can explicitly model the relationship of a pair of texts, and this has been proved to be beneficial to many pair-wise natural language understanding tasks. Therefore, to fully leverage the definitions of words, we construct *context-definition* pair based on all possible definition of the target word from the Oxford dictionary, thereby treating MD task as a sentence pair classification problem seemingly. But, different from (Huang et al., 2019), here we cannot and don't need to match multiple definition and sentence directly one by one, because the contextual meaning of a metaphorical word is different from all its definitions. Also, we don't know which definition the contextual meaning of a non-metaphorical word corresponds to. Moreover, although there are word definition collections in WordNet (Miller, 1995), we find they cannot express accurately the literal meaning of words, and some of them are exactly the metaphorical meanings. For example, in WordNet, one of the definition for 'drink' is 'take in liquids'. On one hand, in the sentence, *car drinks gasoline*, that definition does not help us, or a model, identify that 'drink' is metaphorical. On the other hand, the Oxford Dictionary definition – 'take (a liquid) into the mouth and swallow' – can be of help. A car, which has no mouth and cannot swallow, is obviously unsuitable here. Hence, the latter is helpful to us.

As shown in Figure 1, we directly concatenate the multiple definitions of the target word, and use "[SEP]" to separate them. Finally we use the *context-definitions* pair as the inputs for BERT. After encoding by BERT, we take the final hidden state of the target word as its context meaning. To obtain the literal meaning of its definition, we also take the final hidden states of the tokens of each definition, and use Mean-Pooling to average the hidden states of each definition, which represents literal meaning expressed by the definition. This is formulated as follows :

$$h_{di} = f_m(f_b(\boldsymbol{x_{di}})) \quad (1)$$

where f_b represents the BERT encoder, and $f_m : \mathbb{R}^{n\times d} \rightarrow \mathbb{R}^d$ is a mean pooling function that maps from output vectors of n tokens to the definition vector. Then, we concatenate the vectors of the target word and definitions into one vector and apply a Feed-Forward Neural Network (FFNN) over the concatenated representations. This is formulated as:

$$h_f = FFNN([h_{tt}; h_{di}; ...h_{dn}]) \quad (2)$$

where h_{tt} indicates the hidden state of the target word from BERT. Then h_f is taken as input for a logistic regression classifier to make the prediction.

4 Experiments

4.1 Dataset

To be compatible with previous work (Gao et al., 2018; Mao et al., 2019; Le et al., 2020; Rohanian et al., 2020), we evaluate the proposed models using three widely used datasets for metaphor detection.

VUA (Steen and Gerard) It represents the largest public evaluation dataset for metaphor detection that is used by the NAACL-2018 Metaphor Shared Task(Klebanov et al., 2016). It contains 10,567 sentences and the average length of sentences is 19.4. Annotation for this dataset is based on MIP, for which every word in a sentence is labeled for metaphor identification. There are two versions of this dataset: (1) VUA ALL POS, where words of all types (e.g., nouns, verbs, adjectives) are labeled, and (2) VUA VERB, which focuses only on the verbs for metaphor detection. In this paper, we consider only the VUA VERB version.

MOH-X (Mohammad et al., 2016) Here, the sentences are shorter and simpler than those in the other datasets, as they are sampled from WordNet. It contains 647 sentences and the average length of sentences is 8.0. Only one single verb is labeled in each sentence in this dataset.

TroFi (Birke and Sarkar, 2006) This dataset consists of sentences from the 1987-89 Wall Street Journal Corpus Release 1 (Charniak et al., 2000). It contains 3737 sentences and the average length of sentences is 28.3. Each sentence has a single annotated target verb. There are only fifty unique target verbs in this dataset, which means, that for one target verb, there are many training samples.

4.2 Baselines

RNN-ELMo (Gao et al., 2018) This very representative model uses Glove and ELMo as features for sequential metaphor identification. The ELMO word vectors they trained has been adopted in many subsequent works.

RNN-HG & RNN-MHCA (Mao et al., 2019) These are BiLSTM-based systems grounded in linguistic theories of SPV and MIP, which are the first to explore using linguistic theories to directly inform the design of Deep Neural Networks (DNN) for metaphor identification. They use the Glove and ELMO word embeddings as the literal meaning of a word.

MUL-GCN (Le et al., 2020) This is a multi-task learning model for metaphor detection that, to improve performance, features graph convolutional neural networks to appropriately capture the following; important context words, the control mechanism to emphasize the target words, and the transference of knowledge from WSD.

BERT+MWE-Aware GCN (Rohanian et al., 2020) This is a neural model to classify metaphorical verbs in their sentential context using information from the dependency parse tree and annotations for verbal multiword expressions. It evaluates on the MOH-X and TroFi datasets.

4.3 Setup

For pre-training ExampleBERT, we collect about 40,000 examples of the verb words in all three datasets (See Section 4.1). The batch size is 128; the learning rate is 5e-5, and we train over ten epochs. For DefinitionBERT, because different words have a different number of definitions and to achieve batch computing, we choose the most common three definitions[2] for each word. If a word don't have three definitions, we simply use *"no*

---

[2] Although the dictionary doesn't state that definitions listed in the page are sorted by frequency, it is basically indeed this case according to our observation.

Models	VUA VERB				MOH-X				TroFi			
	Acc	P	R	F1	Acc	P	R	F1	Acc	P	R	F1
RNN-ELMo (Gao et al., 2018)	69.1	53.4	65.6	58.9	78.5	75.3	84.3	79.1	73.7	68.7	74.6	72.0

Table 1: Performance on three metaphor detection datasets

definition ." to replace the remaining insufficient definitions. We believe that three definitions cover most of the context of words; adding more uncommon definitions could become noise for the model. Following the settings in the prior work, we perform 10-fold cross validation on MOH-X and TroFi and use the same splits of training, validation and test sets for VUA VERB datasets. For VUA VERB datasets, we select the best checkpoint on validation data as the final model to evaluate test data performance. For the MOH-X and TroFi datasets, we train 10 epoch and select the last epoch model to evaluate the test data for every fold. Finally we take the 10 fold average for the performance of our final model.

To pre-train ExampleBERT and fine-tune DefinitionBERT, we all use the pre-trained uncased BERT$_{base}$ model from (Wolf et al., 2020). The number of its transformer blocks is 12, the number of self-attention heads is 12, and the number of the hidden layer is 768. For the FFNN in Eq. 2 of DefinitionBERT, we simply use a 256 hidden units of fully connected layer, followed by a classification layer. The two models are all fine-tuned with shuffled minibatches of size 32. The Adam optimizer is used to update the parameters, and the initial learning rate is set at 5e-5.

4.4 Results

Results in terms of accuracy (Acc), precision (P), recall (R) and F1-score are given in Table 1. Scores with the best performances across all models are indicated in bold. Results not reported are indicated by (-). As shown in Table 1, our ExampleBERT and DefinitionBERT achieve state-of-the-art performance on VUA VERB and MOH-X datasets.

VUA VERB dataset. For the VUA VERB datasets, even our proposed BERT-Baseline model achieves excellent performance, gaining improvement over the best of the other methods (MUL-GCN) by a large margin: 2.28% and 3.37% on accuracy (Acc) and F1, respectively. Compared with our BERTBaseline, regarding F1, our ExampleBERT and DefinitionBERT show improvement of 0.36% and 1.02%, respectively.

MOH-X dataset. For the MOH-X dataset, our DefinitionBERT, compared with BERTBaseline and the best of the other models, achieves significant improvement across all results.

TroFi dataset. However,for the TroFi dataset, the performance of our ExampleBERT and DefinitionBERT is somewhat bad than other state-of-the-art results. Compared with our BERTBaseline, for F1, ExampleBERT and DefinitionBERT still show a gain of 0.54% and 1.10%, respectively, indicating that our method is effective also. The TroFi dataset, contains fewer samples than the VUA dataset, but with longer average sequence length (28.3). Thus, on one hand, it is more difficult for DefinitionBERT to capture the relationship between the target and its definitions. On the other hand, because the dataset contains only fifty unique verbs, there are many samples for a target verb, and most express the literal meanings of the word, e.g., the dataset contains 71 literal sentences and 25 metaphor sentences of the target word 'absorb'. Thus, the models can learn sufficient common contextual information and literal meanings of a target word from the dataset. That is to say, the prior knowledge we add provides only limited help. However, taking a step back, compared with the performances of other well-designed models, the performance of our model does not lag too far behind; therefore, we believe our method is still acceptable. Moreover, the results of MOH-X and TroFi dataset suggest that our two models are more useful when there exists only a small amount of training corpus.

We note that the DefinitionBERT always perform expect on precision, the possible reason is , when the model cannot obtain the context meaning of the target world accurately(i.e.,when the sentence is complex) , or the definitions we get from the dictionary are highly summarized, there would exist a gap between the context meaning and literal meaning, although they express the same meaning actually. So the model could predict the literal one to metaphorical more likely, then the precision could be lower(precision=TP/(TP+FP), FP increased). Finally, this could be a inspiration that how to improve our methods in the future work.

4.5 Analysis

As described in Section 3.4, if DefinitionBERT works correctly, it should learn the differences and relationships between the contextual and literal meanings expressed by the definitions of the target word during identifying. Therefore, to understand how DefinitionBERT uses the definitions we provide, we compute the cosine similarity between h_{tt} and each h_{di} described in Eq. 2. If a word is predicted as metaphorical, then the cosine similarity between its definitions will be very small, and the definition which expresses the literal sense of its contextual meaning would always have the smallest cosine similarity. Inversely, if a word is predicted as non-metaphorical, the value will be larger, and the meaning with the greatest cosine similarity will always be the definition that expresses its contextual meaning.

A specific example is given in Table 2. For example, in the sentence, *Her husband often abuses alcohol*, 'abuses' is a metaphorical word; its context meaning is 'a man drinks too much resulting in a bad effect'. Thus, we infer this metaphorical meaning is based on the first definition that has the smallest similarity. In the sentence, *This boss abuses his workers*, 'abuse' is a non-metaphorical word; its context meaning is 'speaking in a insulting and offensive way', which obviously is the third definition that has the greatest similarity. That is to say, our DefinitionBERT takes advantage of the definitions during training. The definitions directly help the model distinguish the contextual and literal meanings of the target word, which exactly is our purpose.

4.6 Disscussion

The main reason for the improvements in our experimental results is that we use external knowledge based on linguistic theories, which is very suitable and effective for detecting metaphors. The ways we incorporate the examples and definitions of a word correspond exactly to the two pre-training objectives of BERT, which are also its advantages. However, it seems possible to combine ExampleBERT and DefinitionBERT to attain better performance, we can use pre-trained ExampleBERT to fine-tune DefinitionBERT. But, our experimental results show that, although its performance can surpass that of ExampleBERT, but cannot surpass DefinitionBERT. The possible reason is may due to the only MaskLM pre-training objective, the ability of pre-trained ExampleBERT to model the relationship of a pair-wise is weakened.

RNN-HG and RNN-MHCA proposed by (Mao et al., 2019), which are inspired also by linguistic theories, focus more on the model architecture suitable for SPV or MIP; whereas, we focus on external knowledge suited for SPV or MIP. Moreover, we believe our ExampleBERT and DefinitionBERT are just base models that can be further improved by other technology, such as GCN applied in (Rohanian et al., 2020).

Moreover, compared to previous state-of-the-art models, especially knowledge-based methods like (Le et al., 2020; Rohanian et al., 2020), our DefinitionBERT is highly interpretable while achieving excellent performance. As described in Section 4.5, because our DefinitionBERT locates the intended meaning of the metaphor in context, it helps us further interpret metaphors. One approache for metaphor interpretation is *Definition Generation* proposed in (Zayed et al., 2020), which aims to find the most probable definition/interpretation (if exists) of the highlighted expression among the given definitions. Obviously, our DefinitionBERT is very suitable for this task(dataset). Another approach is *Lexical Substitution* explored in (Mao et al., 2018), where the metaphoric word/phrase is replaced with its literal counterpart to clarify its semantic meaning. We also believe our DefinitionBERT can be an alternative method for (Mao et al., 2018).

5 Conclusion

We proposed two simple, but effective, methods for metaphor detection, which achieve state-of-the-art performance on two verb metaphor detection datasets. More importantly, we showed that our DefinitionBERT is highly interpretable and can be further applied to metaphor interpretation. For future work, we will explore how to use the external knowledge of words for a sequential task, such as the VUA ALL POS dataset, which is not evaluated

Abuse (definitions according to the Oxford Dictionary)
d-1 : use (something) to bad effect or for a bad purpose;misuse.
d-2 : treat with cruelty or violence, especially regularly or repeatedly.
d-3 : speak to (someone) in an insulting and offensive way.

Abuse (samples and cosine similarity between the three definitions)					
samples	**label**	**predict**	**d-1-s**	**d-2-s**	**d-3-s**
1.Her husband often abuses alcohol .	1	1	0.1632	0.1948	0.1800
2.This boss abuses his workers .	0	0	0.6448	0.6457	0.6478
3.The actress abused the policeman who gave her a parking ticket .	0	0	0.7344	0.7312	0.7403
4. Do n't abuse the system .	1	1	0.0274	0.0267	0.0330

Table 2: Examples for the word 'abuse' from the MOH-X dataset. **'d-1-s'** indicates the cosine similarity between the feature vector of the first definition and the feature vector of the target word extracted from DefinitionBERT.

in this paper. A simple, crude way is to collect all the examples of words in the datasets and then continue to use ExampleBERT according to SPV. If based on MIP, combining the definitions of all words into one sentence like this paper do seems to be a terrible implementation. Moreover, there are several dictionaries (Zayed et al., 2020) giving examples and definitions of the word, and the examples or definitions from different dictionaries are somewhat different in types and contents, which may cause a different result when combined with our methods. Therefore, to obtain better performance, we will try resources from different dictionaries, where the premise is the definitions of the words must be non-metaphorical.

Acknowledgments

We thank Mr.Michael McAllister for his valuable assistance in proofreading this paper. We also appreciate the anonymous reviewers for providing valuable suggestions.

Controlling Text Edition by Changing Answers of Specific Questions

Lei Sha, Patrick Hohenecker, Thomas Lukasiewicz
Department of Computer Science
University of Oxford, United Kingdom

`patrick@serein.ai`

Abstract

In this paper, we introduce the new task of *controllable text edition*, in which we take as input a long text, a question, and a target answer, and the output is a minimally modified text, so that it fits the target answer. This task is very important in many situations, such as changing some conditions, consequences, or properties in a legal document, or changing some key information of an event in a news text. This is very challenging, as it is hard to obtain a parallel corpus for training, and we need to first find all text positions that should be changed and then decide how to change them. We constructed the new dataset WIKIBIOCTE for this task based on the existing dataset WIKIBIO (originally created for table-to-text generation). We use WIKIBIOCTE for training, and manually labeled a test set for testing. We also propose novel evaluation metrics and a novel method for solving the new task. Experimental results on the test set show that our proposed method is a good fit for this novel NLP task.

1 Introduction

In many cases, we need to change some specific content in a document. For example, in the legal domain, the items and conditions in contract documents often need to be revised many times. We would like to use artificial intelligence to conduct this process for human editors. A major difficulty of this process is that the machine learning model should decide where to edit and how to edit.

Usually, the place of specific content ("where to edit") can be located by a question, and the content updating ("how to edit") can be determined by the answer of the question. Therefore, in this paper, we propose the new task of *controllable text edition (CTE)*. In this task, we would like to achieve the following goal: *adjust some content of a document D, to make the answer A of a document-related question Q changed to a new answer A'*. For example, in Fig. 1, when we change the red part of the original text to the blue part, the answer of the question turned to the new answer as a consequence.

Origin document (D):

Lang Ping (born 10 December 1960) is a former Chinese volleyball player and the current head coach of China women's national volleyball team. She was the former head coach of the United States women's national volleyball team, herself being the MVP of women volleyball in 1984 Olympics.

Question (Q): What is Lang Ping's current job?

*Original Answer (A): **the head coach of China women's national volleyball team***

New Answer (A'): the director of the National Sports Administration

Modified document (D'):

Lang Ping (born 10 December 1960) is a former Chinese volleyball player and the current director of the National Sports Administration. She was the former head coach of the United States women's national volleyball team, herself being the MVP of women volleyball in 1984 Olympics.

Figure 1: The original text D is in the upper box. The question Q to D has an answer A (in red; its rationale in D also in red). If we would like to change the answer to the new answer A' (in blue), then we have to change some content in D, yielding the modified text D' (with the new content in blue) in the lower box.

There are three main challenges in this task:

(1) The machine learning model should decide the positions that need to be changed in the document. Usually, finding the answer positions for a given document-related question is similar to extractive machine reading comprehension tasks (Zeng et al., 2020), which requires to fully understand both the question and the document. Nearly all extractive machine reading tasks, such as SQuAD (Rajpurkar et al., 2016, 2018) and CNN/Daily Mail (Hermann et al., 2015), focus on extracting one span from the document as answer. Differently from extractive machine reading, in our task, the answer A is not necessarily a substring of the document, and there may exist multiple positions that have to be changed. Therefore, our task is much more challenging than extractive machine reading.

(2) The model should generate a new document that supports the new answer A' for question Q. Note that this cannot be solved by directly replacing the original words in the edit positions with the new answer A', because the new answer may not fit

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1288–1299
August 1–6, 2021. ©2021 Association for Computational Linguistics

perfectly with the document, which would make the document disfluent.

(3) There are nearly no parallel data for model training, because obtaining a large annotation set for this task is very hard.[1] However, the model may be trained by lists of triples $\langle Q, D, A\rangle$ that can be obtained from datasets in machine reading and/or structured data extraction (as described below).

In this paper, we introduce and define the task of controllable text edition (CTE). We propose to transform the WIKIBIO dataset (Lebret et al., 2016) into a list of triples $\langle Q, D, A\rangle$ for training. WIKIBIO was originally designed for table-to-text generation, in which each case is composed of a Wikipedia passage D and an infobox (which is a list of $\langle$field, content$\rangle$[2] pairs). In detail, we take each "field" in the infobox as the question Q, and each "content" in the infobox as the answer A. Therefore, for each $\langle$field, content$\rangle$ pair, we can create a $\langle Q, D, A\rangle$ triple. After some pruning, we finally selected 26 different Q's and $141k$ $\langle Q, D, A\rangle$ triples for the training set, as well as $17.7k$ triples for the development set. We also annotated a small test set of about $1k$ data for evaluation in the form of $\langle Q, D, A, A', D'\rangle$ (A' represents the new answer, and D' represents the ground-truth modified text). The resulting new dataset is called WIKIBIOCTE.

In addition, we propose a novel method, called *Select-Mask-Generate (SMG)*, to solve the proposed CTE task. In this method, we use the selector-predictor architecture by Sha et al. (2021) to select the answer-related tokens, and we then use complementary masks to split the text into an answer-related part and an answer-unrelated part. Then, we reconstruct the original text based on the answer-unrelated part and the original answer. The reconstruction process is a partial generation method, which only generates the masked-out part without any length limit. In our experiments, the SMG model has achieved the state-of-the-art performance, compared to baseline models in the generation of modified documents. The code and the test set WIKIBIOCTE are available at: `https://sites.google.com/view/control-text-edition/home`.

2 Related Work

The proposed task of *controllable text edition* is related to the following existing tasks.

2.1 Attribute Disentanglement

Attribute disentanglement tends to control the attributes of a given text or image (such as sentiment, tense, syntax, or face pose) by disentangling different attributes into different subspaces. When transferring attributes, the content of the text/image needs to be preserved. Usually, disentanglement works can be divided into implicit and explicit disentanglement. Implicit disentanglement (Higgins et al., 2017; Chen et al., 2018; Moyer et al., 2018; Mathieu et al., 2018; Kim and Mnih, 2018) separates the latent space into several components in a purely unsupervised way, expecting that each component corresponds to an attribute. However, the number of components cannot be decided in advance, neither does the correspondence between attributes and components. Also, the training process may prune some of the components (Stühmer et al., 2019), which will hurt the interpretability of the latent space. Explicit disentanglement (Chen et al., 2016; John et al., 2019; Romanov et al., 2019; Sha and Lukasiewicz, 2021) tends to separate the latent space into more interpretable components with explicit correspondence to specific attributes. Hence, it usually requires gold labels of attributes in the training set.

In comparison, our task tends to control the content of the text by tuning answers to text-related questions. Attribute disentanglement is difficult to be applied to our task, because the modification of the content should be decided by both the question and the answer simultaneously, which is much sparser than attributes.

2.2 Lexically Constrained Decoding

Lexically constrained decoding (Hokamp and Liu, 2017; Miao et al., 2019; Sha, 2020) directly controls the output of the generation model by adding constraints. Usually, the constraints include hard constraints (requiring the generated sequence to contain some keywords) and soft constraints (requiring the generated sentence to have the same meaning to a given text). The basic methods of lexically constrained decoding can be divided into enhanced beam search (Hokamp and Liu, 2017; Post and Vilar, 2018) and stochastic search (Miao et al., 2019; Liu et al., 2020; Sha, 2020). Enhanced

---

[1] To annotate a large parallel dataset, we need to prepare a document, a document-related question, and its expected answer. Then, the data grader should provide an adjusted version of the document that satisfies the expected answer, which requires the data grader to have a high education level.

[2] In the Wikipedia Infobox, "field" represents the type of information (such as *Name*, *BirthDate*, and *Known for*), while "content" represents the value of "field".

Table:

ID	Field	Content
1	Name	*Frank Fenner*
2	Born	*21 December 1914, Ballarat*
3	Died	*22 November 2010 (aged 95) Canberra*
4	Occupation	*Virology*
5	Nationality	*Australian*
6	Known for	*Eradication of smallpox, Control of Australia's rabbit plague*

Text: Frank John Fenner (21 December 1914 – 22 November 2010) was an Australian scientist with a distinguished career in the field of virology. His two greatest achievements are cited as overseeing the eradication of smallpox, and the control of Australia's rabbit plague by introducing the Myxoma virus.

Table 1: An example of a Wikipedia infobox and a reference text.

beam search (Hokamp and Liu, 2017; Hasler et al., 2018; Hu et al., 2019) changes some strategies in beam search to make the process of searching for a constraint-satisfying sentence easier. However, for some tasks with an extremely large search space, beam-search-based methods may be computationally too costly or even fail (Miao et al., 2019). Stochastic search tends to edit an initial sentence step-by-step, where the editing position and action can be decided by Metropolis-Hastings sampling (Miao et al., 2019), a discrete scoring function (Liu et al., 2020), or gradient-based methods (Sha, 2020). However, lexically constrained decoding is hard to be applied to our task, because adjusting the text to fit a text-related question's new answer is much more complicated than simply satisfying a hard or soft constraint.

2.3 Text Editing and Infilling

In some tasks, to simplify the text generation problem, researchers tend to edit existing text or prototypes to obtain a refined text that satisfies some specific requirements. Examples are the generation of summaries by template-based rewriting (Cao et al., 2018; Hashimoto et al., 2018) and the generation of text or a response by editing a prototype sentence (Guu et al., 2018; Pandey et al., 2018; Wu et al., 2019). In (Yin et al., 2018), the distributed representations of edit actions are learned and applied to editing Wikipedia records (Faruqui et al., 2018) and Github code (Yin et al., 2018). Panthaplackel et al. (2020) further integrate a copy mechanism into text editing.

Text infilling (Fedus et al., 2018) means to use machine learning models to fill the blanks of a cloze test. Zhu et al. (2019) propose a more general text infilling task, which allows an arbitrary number of tokens (instead of a single token) in each blank.

In the above text editing tasks, the goal of editing is always consistent among all the datasets: for a better summarization, a better response, or a better informative sentence. Differently from them, our proposed task requires the editing to be guided by the document-related answer of the question. So, each above case has a different editing goal. Thus, our task requires deciding where to edit according to the given question in the first step, and then deciding how to edit, which makes our task more complicated than all the above text editing tasks.

3 Dataset

We now formally define the task of controllable text edition and propose a dataset for this task.

3.1 Task Definition

The task of *controllable text edition (CTE)* is defined as follows. The input is a triple $\langle D, Q, A' \rangle$, where D is a document, Q is a document-related question, and A' is an expected answer for Q to D. The output is D', which is a minimal modification of D such that the answer for Q to D' is now A'. Note that the original answer of Q to D is A, but A is not an input to the task, and usually $A \neq A'$.

3.2 WIKIBIO as Controllable Text Editing Dataset

We propose to modify the WIKIBIO dataset (Lebret et al., 2016) to make it fit for our task. WIKIBIO was originally designed for table-to-text generation (Lebret et al., 2016; Sha et al., 2018; Liu et al., 2018), which generates a celebrity's biography according to his/her basic information. Each example in the dataset is composed of a Wikipedia infobox and a text (the first paragraph in the Wiki page) describing the infobox as shown in Table 1.

In an inverse way, the WIKIBIO dataset can be taken as a question-answering dataset: each *field* can be taken as a question, and each *content* can be taken as an answer. For example, in Fig. 1, the *field* "Occupation" can be interpreted as question "What is the person's occupation?", and the corresponding *content* "Virology" is the answer.

Therefore, we take the *text* in WIKIBIO as the document (D) in our task, the *field* as the question (Q), and the *content* as the answer (A). Due to the huge cost of data annotation, the model needs to be trained without the changed answer (A') and the referenced document (D').

For the creation of the training and development sets, we count the frequency of *fields* and select the *fields* that occurred more than 5k times in WIKIBIO's training set as candidate questions (Q's). Then, we filter out some Q's that do not have corresponding answers in D[3]. We then get a list of 26 different Q's as shown in Table 2. After filtering the Q's according to Table 2, we get $141k$ $\langle Q, D, A\rangle$ triples for the training set and $17.7k$ triples for the development set.

Then, we manually labeled a small test set in which each example contains (D, Q, A) as well as the changed answer (A') and the referenced document (D'). The annotation process can be illustrated as follows:

1. We randomly sampled an equal number of examples for all the *fields* in Table 2. For each *field*, we sample $\lceil \frac{1000}{\#F} \rceil$ cases ($\#F$ is the number of selected *fields*), to make sure that the size of the test set is around 1k.
2. We assigned a changed answer (A') to each example by randomly picking a similar phrase to the original answer (A). The similar phrase may occur in different examples, but it shares the same Q with the original answer (A).
3. We asked human data graders to give a modified text (D') for each example according to the original text (D), question (Q), and the changed answer (A'). We asked two talented linguistics to annotate the 1k test set.

Note that there are also other datasets that are potentially able to be modified as controllable text editing dataset, such as SQuAD (Rajpurkar et al., 2016), RACE (Lai et al., 2017), and MCTest (Richardson et al., 2013). We did not choose them for the following reasons: (1) For extractive machine reading tasks like SQuAD (Rajpurkar et al., 2016), the answers are simple substrings of the document, so that in most cases, the text modification in our task can be solved by a simple string replacement, which violates the goal of our task. (2) Multiple-choice machine reading tasks like RACE (Lai et al., 2017) usually require full and deep reasoning of the whole document to get the answer, which would make the text modification in our task unable to be solved by partial modification. Differently from them, most *contents* (A) in WIKIBIO usually cannot be directly extracted as substrings from the document (D). Besides, the *contents* usually has some related information that should be modified at the same time. For example, if somebody is a pianist, then he/she may have received a piano award instead of a guitar award. Therefore, WIKIBIO satisfies the goal of our proposed task: making minimal changes to the original document to make it fit the changed answer (A').

4 Select-Mask-Generate (SMG) Method for Controllable Text Edition

We introduce the training and testing method of our proposed method. In the training phase, the model is trained to learn to recognize answer-related (A-related) tokens and learn to fill new-answer-related (A'-related) tokens into the blanks after deleting answer-related tokens.

4.1 Training Phase

In the training phase, we only have Q, D, and A. So, we teach the model to (1) identify answer-related information, and (2) be able to reconstruct D from A and $(D - A_p)$ (the original text with all answer-related information masked out, where A_p means the predicted answer-related tokens).

The model architecture is shown in Fig. 2. Inspired by InfoCal (Sha et al., 2021), we use a *Selector-Predictor* architecture to identify the least-but-enough answer-related words in the original document (D). The main architecture of the *Selector* network is a BiLSTM model, which samples[4] a binary-valued mask (M) for each input token (called answer mask), denoting whether to select

---

[3] Since D is the first paragraph in the Wikipedia page, it usually does not contain everything mentioned in the infobox, such as *death cause* and *high school*.

[4] The sampling process is implemented by Gumbel Softmax (Jang et al., 2016), which is differentiable.

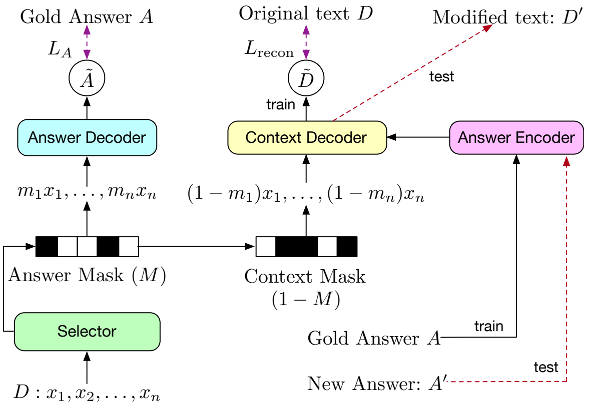

Figure 2: The architecture of our SME model. In the testing phase, we need to replace the input to the answer encoder from the gold answer A to the new answer A', then the output of the context decoder will become the modified text $\tilde{D}'$.

this token as answer-related token (1) or not (0). Given an input document $D = \{x_1, \ldots, x_n\}$ and a question Q, the *Selector* samples an answer-related mask $M = \{m_1, \ldots, m_n\}$ as follows:

$$M \sim \text{Sel}(M|D, Q), \tag{1}$$

where "Sel" represents the selector network. Then, we call the complement of the answer mask ($\overline{M} = 1 - M$) as the context mask, and we denote *context template* as the token sequence after masking out the answer-related tokens.

4.1.1 Answer Reconstruction

We require that the answer-related information contains everything about the answer A, so we use an answer decoder to reconstruct an answer sequence $\tilde{A}$. Then, we calculate the reconstruction loss L_A as follows:

$$p_a(\tilde{A}|M, D) = \text{Dec}_A\Big(\frac{1}{\sum_j m_j}\sum_i m_i x_i\Big), \tag{2}$$

$$L_A = \mathbb{E}_{M \sim \text{Sel}(M|D,Q)} p_a(A|M, D), \tag{3}$$

where Dec_A is the answer decoder, and p_a is the sentence distribution generated by Dec_A. Note that the input to Dec_A is the average vector of the selected token vectors: the answer-related tokens are usually very few, so it is not necessary to use heavier encoders like LSTMs (Hochreiter and Schmidhuber, 1997) or transformers (Vaswani et al., 2017).

4.1.2 Document Reconstruction

On the other hand, D should be reconstructed by the *context template* and the gold answer A. We use an LSTM encoder Enc_D to encode the *context tokens* as shown in Eqs. 4 and 5:

$$h'_1, \ldots, h'_n = \text{Enc}_D([\overline{m}_1 x_1, \ldots, \overline{m}_n x_n]), \tag{4}$$

$$H_m = \text{Maxpooling}(h'_1, \ldots, h'_n), \tag{5}$$

where $h'_1, \ldots, h'_n$ are the encoding vectors corresponding to each input token. We then take the averaged word vector of the input gold answer A, denoted V_A, as an external condition of the decoder.

Differently from conventional decoders, our decoder only partially generates tokens to fill in the blanks of the *context templates*, as shown in Fig. 3. This brings two changes in the training phase: (1) we only need to calculate the loss caused by the tokens filled in the blank, and (2) the model needs to learn an external end-of-answer (EOA) token S_{eoa} for each token filled in the blanks. The EOA token is very important because it is an indicator about when to stop filling the current blank.

Learning to generate the words. In each time step t of the decoder, we use an LSTM (Hochreiter and Schmidhuber, 1997) unit to predict the next word y_t and the EOA token S_{eoa} as follows:

$$h_t = \mathcal{F}_{\text{LSTM}}([y_{t-1}, V_A], h_{t-1}), \tag{6}$$

$$\begin{bmatrix} h_w \\ h_{\text{eoa}} \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \end{bmatrix} \mathcal{F}_m(h_t), \tag{7}$$

$$s_t^{\text{lstm}}(w) = \mathcal{F}_w(h_w), \tag{8}$$

$$p(\tilde{S}_{eoa}(t)) = \text{Softmax}\big(\mathcal{F}_{eoa}(h_{\text{eoa}})\big), \tag{9}$$

where h_w and h_{eoa} are hidden layers (the time step index t is omitted), $\mathcal{F}_{\text{LSTM}}$ is an LSTM cell, $\mathcal{F}_m$, $\mathcal{F}_w$, and $\mathcal{F}_{eoa}$ are linear layers, and $s_t^{\text{lstm}}(w)$ is a scoring function that suggests the next word to generate. $p(\tilde{S}_{eoa}(t))$ is the probability distribution of the EOA token.

Note that in the decoder, we use the copy mechanism (Gu et al., 2016), which encourages the decoder to generate words by directly copying from the input context sequence D and answer sequence A. The copy mechanism computes a copy score $s_t^{\text{copy}}(w)$ for each word in D and A. Then, the generated probability of each word is computed as:

$$s_t(w) = s_t^{\text{lstm}}(w) + s_t^{\text{copy}}(w), \tag{10}$$

$$p_t(w) = \text{Softmax}(s_t(w)). \tag{11}$$

Thus, the document D's reconstruction loss is as follows:

$$L_{\text{recon}} = -\mathbb{E}_M\Big[\sum_t m_t \log p_t(y_t|\overline{M}, A)\Big], \tag{12}$$

where $M \sim \mathrm{Sel}(M|D,Q)$, the mask m_t is multiplied in each time step, because we only need the losses of blank-filling tokens.

Learning the end-of-answer (EOA) tags. We have an EOA tag for each blank-filling token. The EOA tag is 1 if the corresponding token is the last token in the blank. For the other blank-filling tokens, the EOA tag is 0. The gold EOA tag in each time step g_t^{eoa} can be computed by the difference between the previous answer mask m_{t-1} and the current answer mask m_t. There are three possible values (-1, 0, and 1): $g_t^{\text{eoa}} = 0$ when the difference is -1 or 0, and $g_t^{\text{eoa}} = 1$ when the difference is 1. Then, we have the cross-entropy loss as Eq. 13:

$$\begin{aligned} g_t^{\text{eoa}} &= \max(m_{t-1} - m_t, 0) \\ L_{\text{eoa}} &= -\mathbb{E}_M\Big[\sum_t \Big(g_t^{\text{eoa}} m_t \log p(S_{eoa}(t) = 1) \\ &\quad + (1 - g_t^{\text{eoa}}) m_t \log p(S_{eoa}(t) = 0)\Big)\Big]. \end{aligned} \tag{13}$$

Therefore, the final optimization objective is shown in Eq. 14:

$$L = L_A + \lambda_r L_{\text{recon}} + \lambda_{\text{eoa}} L_{\text{eoa}}, \tag{14}$$

where λ_r and λ_{eoa} are hyperparameters.

4.2 Inference Phase

In the inference phase, we take the new answer A' as the input to the context decoder instead of the gold answer A. Then, the output of the context decoder will become the modified text $\tilde{D}'$.

We choose an autoregressive partial generation method for inference. Our partial generation method can fill the blanks with any-length phrases and can directly replace any decoder, which cannot be done by any existing alternative methods. For example, in the method using global context (Donahue et al., 2020), it is an pretrained language model by itself. However, in our architecture, the masks are decided by the selector module. Therefore, even the number and length of the blanks cannot be decided before training. So, the ground-truth target sequence for the finetuning of the pretrained language model would also be hard to decide. Therefore, the partial generation method is the best choice for our task.

4.2.1 Partial Generation

Since we already have a *context template* when we are generating the modified document, we only need to generate tokens to fill the blanks in the *context template*. The partial decoding process is shown in Fig. 3. We use an indicator *state*= 0 to denote the *reading* mode (reading the *context template* words), and *state*= 1 to denote the *writing* mode (generating the blank-filling words). The basic generating process is described as follows: when the model is *reading* the *context template*, if it meets a masked token, the mode turns to *writing* mode, and it starts to generate words to fill the current blank. When the EOA tag turns to 1, or the decoding length l_g surpassed a limit $l_{\max}$, the mode turns back to *reading* mode. Note that this decoding process can generate an arbitrary number of words for each blank, and we can fill all blanks in a *context template* in a single decoding pass, which is much more efficient than MaskGAN (Fedus et al., 2018) and text filler (Zhu et al., 2019). The detailed algorithm is shown in Algorithm 1.

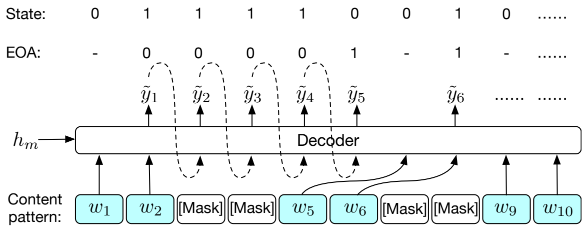

Figure 3: The partial decoding process. This process requires two tags (state and EOA tag) for indicating when to start generation and when to stop generation.

5 Experiments

In the experiment part, we proposed some specific evaluation metric for our *controllable text edition* task and then compare and analysis the performance of our proposed method (SMG) on the WIKIBIOCTE dataset.

5.1 Evaluation Metrics

For the evaluation of the modified document $\tilde{D}'$, we use the following two automatic evaluation metrics:

(1) BLEU ($\tilde{D}'$ vs. D'): This metric measures the BLEU score (Papineni et al., 2002) between the generated modified document $\tilde{D}'$ and the reference document D'.

(2) iBLEU (Sun and Zhou, 2012): This metric is previously widely used in evaluating paraphrase generation tasks (Liu et al., 2020; Sha, 2020). iBLEU is defined as: iBLEU $= \mathrm{BLEU}(\tilde{D}', D') - \alpha\mathrm{BLEU}(\tilde{D}', D)$[5], which penalizes the similarity

---

[5] α is set to 0.9, which is consistent with previous

Algorithm 1: The decoding process.

```
Input: Context template: $C$
Output: Generated Sequence: $\tilde{D}'$
Data: Read-write state: $S$, End-of-answer label:
      $S_{eoa}$, Context template index: $I_c$, Local
      generate length: $l_g$, current input token $x_{in}$
$S \leftarrow 0, I_c \leftarrow 0, l_g \leftarrow 0, \tilde{D}' \leftarrow []$;
Set the first input token $x_{in} \leftarrow C[0]$;
for each time step $t \leftarrow 1, 2, \dots$ do
    Calculate $\tilde{y}_t$ by Eqn. 11;
    Calculate $S_{eoa}$ by Eqn. 9;
    if $S = 0$ then
        $\tilde{D}' \leftarrow \tilde{D}' + [C[I_c]]$;
        if $C[I_c] \neq$ '[M]' and $C[I_c + 1] =$ '[M]'
         then
            $I_c \leftarrow I_c + 1$;
            while $C[I_c] =$ '[M]' do
                $I_c \leftarrow I_c + 1$;
            end
            if $S_{eoa} \neq 1$ then
                $S \leftarrow 1$;
            end
        end
        else if $C[I_c] \neq$ '[M]' and $C[I_c + 1] \neq$ '[M]'
         then
            $I_c \leftarrow I_c + 1$;
        end
    end
    else if $S = 1$ then
        $\tilde{D}' \leftarrow \tilde{D}' + [\tilde{y}_t], l_g \leftarrow l_g + 1$;
        if $S_{eoa} = 1$ or $l_g \geq l_{max}$ then
            $S \leftarrow 0, l_g \leftarrow 0$;
        end
    end
    if $S = 0$ then
        $x_{in} \leftarrow C[I_c]$;
    end
    else if $S = 1$ then
        $x_{in} \leftarrow \tilde{y}_t$;
    end
end
return $\tilde{D}'$;
```

	Seq2Seq	SMG (g)	SMG (p)
BLEU ($\tilde{D}$ vs. D)	82.21	**89.29**	87.53
iBLEU	5.63	**10.05**	8.94
diff-BLEU ratio	21.3%	**62.5%**	59.8%
Perplexity	**198**	235	373
Human (Correctness)	73.5%	**80.2%**	76.9%
Human (Fluency)	**4.56**	4.54	4.32

Table 3: The overall performance of all competing methods. SMG (g) denotes that the method SMG is using the gold templates for partial generation, and SMG (p) denotes that the method SMG is using the predicted templates for partial generation.

	Random	Seq2Seq	SMG
BLEU (predicted template)	21.5	59.5	**89.1**
Answer F_1	0.14	0.55	**0.68**

Table 4: Performance of answer-related words selection.

between the modified document $\tilde{D}'$ and the original document D. The goal of this metric is to measure the extent to which the model directly copies words from the original document D without taking any content from A'.

(3) diff-BLEU ratio: diff-BLEU is a BLEU score computed between $\tilde{D}'$ and a *difference sequence* between the gold modified document D' and the original document D. The *difference sequence* is obtained by masking out the longest common sequence between D and D' from D'. Since this maximum value of this BLEU score is the BLEU value between the gold modified document D' and the *difference sequence*, we use their quotient as the diff-BLEU ratio score as shown in Eq. 15:

$$\text{diff-BLEU ratio} = \frac{\text{BLEU}(\tilde{D}', D' - D)}{\text{BLEU}(D', D' - D)}. \quad (15)$$

(4) Perplexity: This metric measures the fluency of the generated content-modified document $\tilde{D}'$. We applied a third-party language model (Kneser-Ney language model (1995)) as the perplexity evaluator. We trained the language model on the whole training set of WIKIBIO, and use the trained model as the evaluation of fluency, where a lower perplexity value is better.

Besides, we used human effort to evaluate two aspects of the content-modified document $\tilde{D}'$. *Correctness* is an accuracy score from $0.0\% \sim 100.0\%$, which evaluates whether $\tilde{D}'$ has successfully turned the answer of question Q from A to A'. *Fluency* is from $0.0 \sim 5.0$, which evaluates whether $\tilde{D}'$ is fluent from a human being's view. The scoring details are in the supplemental materials.

Also, in our method, the selection of answer-related words is very important, so we have two evaluations for the selection part:

(1) BLEU (predicted template) is the BLEU score between the predicted template (the token sequence after we masked out the answer-related words from the text D) and the gold template (the common sequence of D and D').

(2) Answer F_1 measures the Bag-of-words (BOW) F_1 value of the generated answer $\tilde{A}$ compared to the gold answer A. This metric is difficult to

Table 5: The example generated cases of competing methods. The underlined tokens are gold answer-related tokens. The bold tokens in the “Input” row are predicted answer-related tokens. In the other three rows, the bold tokens are the modified tokens that are related to the given new answer A'.

achieve, because it requires both to select the correct answer-related tokens and to generate the correct words for the answer A.

5.2 Overall Performance

We compare our method (SMG) with a baseline method (Seq2Seq). In Seq2Seq, the difference with SMG is that the decoder part is a conventional decoder that completely generates the modified document $\tilde{D}'$ ignoring the *context template*. The overall performance is shown in Table 3.

In Table 3, we see that our SMG method has outperformed the Seq2Seq baseline in nearly all evaluation metrics, no matter whether the *context template* applied to the decoding phase is gold or predicted. Especially, in the two most important metrics for the performance of controllable text edition: iBLEU and diff-BLEU ratio, our model has achieved a significantly higher score than competing methods. These results show that our method is effective in controllable text edition.

The human evaluation results are also listed in Table 3. The inter-rater agreements are all acceptable (> 0.85) due to Krippendorff's principle (2004). According to the human evaluation, when we are using the gold template for partially generating, both the correctness and the fluency of the partially generated text $\tilde{D}'$ are better than using the predicted template, which is also consistent with our intuition. Note that the perplexity score and the fluency score of Seq2Seq are the best of all the three methods; this is because in the partially generated text, the end position of each blank may not fit very well with the next word sometimes, although we have trained an EOA tag.

Table 4 shows the experiments evaluating the selection of answer-related words. We can see that our SMG model has a higher BLEU (predicted template) score than the Seq2Seq model. This fact shows that partially training the blank-filling tokens helps for the selection of answer-related tokens. Also, our model SMG has achieved a higher *answer* F_1 score (0.68) than competing methods.

5.3 Case Study

We have listed some examples of the modified document $\tilde{D}'$ generated by the three competing methods (Seq2Seq, SMG(g), and SMG(p)) in Table 5. We can see that although the answer-related words are already masked out, Seq2Seq still always generates the words in the original answer A and tends to mix up the words in A and the changed answer A' (like in the second example, Seq2Seq mixed “gymnastic” and “basketball” together.) Also, Seq2Seq cannot precisely change everywhere what should be modified, for example, in the second example, Seq2Seq failed to change “gymnastic coach” to “basketball coach”. In the SMG methods, when we are using the gold template for partial generation, the model is able to generate the correct words aiming to change Q's answer to A'. Although there is still some risk to have some answer-related tokens left unchanged due to the error in the predicted template, the *context tokens* in the predicted template are ensured to be generated. Therefore, our model with predicted template is more fit for NLP products than Seq2Seq.

6 Conclusion

In this paper, we proposed a novel task, the goal of which is to modify some content of a given text to make the answer of a text-related question change to a given new answer. This task is very useful in many real-world tasks, like contract editing. We constructed a test set for evaluation and released this test set. We also proposed a novel model SMG to solve this task. In SMG, we first use a selector-predictor structure to select the answer-related tokens in the input document, then we use a novel partial generation technique to generate the modified document without changing answer-unrelated tokens in the original document. The experiments proved the effectiveness of our model.

Appendices

A Human Evaluation Question Marks

Our annotators were asked the following questions, in order to assess the correctness and fluency of the modified document provided by our model.

A.1 Correctness of modified document

Q: Do you think the modification of the document is correct so that it can make the question answer pair $\langle Q, A' \rangle$ true? (For partially correct cases: Partially correct means some places are changed to the new answer, and some places keep the old answer. In this case, only all places (that need to be changed) have been changed can be taken as correct.)

Please choose “Yes” or “No”.

After all human annotators finished their work, the correctness score is calculated by dividing the number of “Yes” by the total number of examples.

A.2 Fluency

Q: How fluent do you think the modified document is?

Please choose a score according to the following description. Note that the score is not necessarily an integer, you can give scores like 3.2 or 4.9 , if you deem appropriate.

- 5: Very fluent.
- 4: Highly fluent.
- 3: Partial fluent.
- 2: Very unfluent.
- 1: Nonsense.

B Experiment Details

The word embedding size is 300. The BiLSTM in the selector model has the following hyperparameters: hidden size = 200. The hidden size of decoder’s LSTM cell is 200. The rest hyperparameters has the following values: $\lambda_r = 1.0$, $\lambda_{\text{eoa}} = 10$. The hyperparameters are obtained by grid search, the search scopes are $\lambda_r \in [0.0, 2.0]$ with step size

0.2, $\lambda_{\text{eoa}} \in [1, 20]$ with step size 1, the hidden size are searched in $[100, 500]$ with step size 50. The best hyperparameters are selected when the model achieves the highest answer's F_1 in the development set. The total parameter size is $72M$. Each training epoch costs about 1.5 hours on V100 GPU.

Grammar-Based Patches Generation for Automated Program Repair

Abstract

Automated program repair (APR) aims to find an automatic solution to program language bugs without human intervention, and it can potentially reduce debugging costs and improve software quality. Conventional approaches adopt learning-based methods such as sequence-to-sequence models for the patches generation. However, they tend to ignore the code structure information and suffer from grammar and syntax errors. To consider the grammar and syntax information, in this paper, we propose a grammar-based rule-to-rule model, which regards the repair process as the transformation of grammar rules, and leverages two encoders modeling both the original token sequence and the grammar rules, enhanced with a new tree-based self-attention. Besides, to guarantee grammar correctness, we employ a grammatically restricted inference method to generate each grammar rule in a legally constrained sub-search-space considering the generated previous rules. Experimental evaluations on a Java dataset demonstrate that the proposed approach significantly outperforms the state-of-the-art baselines in terms of generated code accuracy.

1 Introduction

Advances in machine learning and the availability of large corpora of source code have led to growing developments of software engineers. Researchers have exploited machine learning to automate several development and maintenance tasks, such as code completion (Svyatkovskiy et al., 2020), comment generation (Hu et al., 2018), code search (Gu et al., 2018), bug localization (Zheng et al., 2016) and fixing (Tufano et al., 2018). It's worth noting that localizing and fixing bugs is known to be an effort-prone and time-consuming task for software developers (Weiss et al., 2007). Hence, several works recently focused on automatically repairing programs without human intervention, which can improve programmer productivity and software quality (Tufano et al., 2018; Chen et al., 2019; Vasic et al., 2019; Yasunaga and Liang, 2020).

Figure 1: Schematic diagram of our model. Source code is parsed into AST (Abstract Syntax Tree) and then into a sequence of rules. Each rule consists of one head token (parent node) and several tail tokens (children nodes).

Automated program repair (APR) research is very active and dominated by techniques based on static analysis (Mechtaev et al., 2016) and dynamic analysis (Wen et al., 2018). Meanwhile, APR is also challenging because fixing bugs is a difficult task. Previous approaches mainly are based on a relatively limited and manually-crafted set of fixing patterns, which need substantial effort and expertise (Saha et al., 2017; Jin et al., 2011; Nguyen et al., 2013). Moreover, these techniques can only fix bugs in a given language or a specific application domain and lack scalability and maintainability.

Very recently, deep learning based approaches, such as sequence-to-sequence learning (Sutskever et al., 2014), are proposed to automatically repair program by learning from massive open-source projects with numerous bug fixes (Tufano et al.,

---

*Contribution during internship at Microsoft Research

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1300–1305
August 1–6, 2021.

2018; Chen et al., 2019). However, these sequence-to-sequence methods ignore codes' structure information because they are designed for natural language which is significantly different from program language with strict syntactic and grammatical requirements. Hence, the generated patches of these methods suffer from grammar and syntax errors.

To address the problem, in this paper, we propose a novel grammar-based approach to automatically generate fixed patches for automated program repair. More specifically, instead of using a sequence-to-sequence model with code sequence, we first introduce a grammar-based rule-to-rule model, which regards the repair process as the transformation of code grammar rules, as shown in Figure 1. Second, to guarantee the grammatical and syntactic correctness, we not only introduce a rule encoder (together with a token encoder) to directly extract grammatical features but also employ a grammatically restricted inference method to generate the fixed code. Experimental results conducted on BFPs dataset (Tufano et al., 2018) of CodeXGLUE (Lu et al., 2021) demonstrate that the proposed grammar-based approach significantly outperforms the state-of-the-art baselines.

2 Related Work

Automatic program repair, consisting of automatically finding a solution to software bugs without human intervention, has recently received significant attention (Tufano et al., 2018; Chen et al., 2019; Yasunaga and Liang, 2020). Traditional approaches generate patch candidates by first applying a predefined set of mutation operators on the fault space. They then deploy some heuristics (Qi et al., 2014) to search among these candidates for a correct patch that passes all given test cases (Weimer et al., 2009; Qi et al., 2014). Although these methods have shown to be able to fix a wide range of bugs, they can only fix bugs in a given language or a specific application domain (Saha et al., 2017; Jin et al., 2011; Nguyen et al., 2013).

Inspired by the development of deep learning in a variety of problems, researchers attempt to employ deep learning based approaches to automatically repair code by learning from massive buggy-fixes pairs (Tufano et al., 2018; Chen et al., 2019; Vasic et al., 2019; Guo et al., 2020). Tufano et al. (2018) first presented an end-to-end approach to fix program language based on sequence-to-sequence learning. They released datasets of APR and evaluated the performance of neural machine translation. SequenceR (Chen et al., 2019) employed copy mechanism based on line level. DeepFix (Gupta et al., 2017) and SynFix (Bhatia et al., 2018) repair syntax errors in programs using neural program representations. Despite their effectiveness, the generated patches of these methods suffer from grammar and syntax errors.

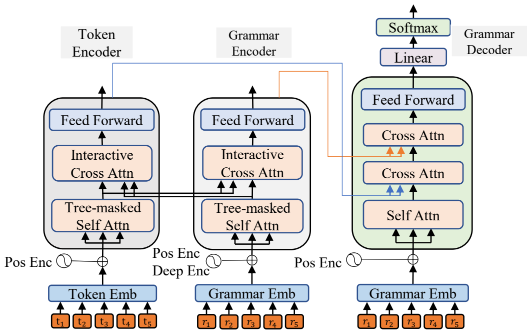

Figure 2: The framework of our proposed model.

Compared to previous works, our proposed approach has three advantages: (1) we employ the state-of-the-art Transformer model as the skeleton of code repair model; (2) we incorporate the grammar information of fixing ingredients into our model by using token and grammar encoders; (3) we propose a grammar-guided inference method to guarantee the grammar correctness.

3 Our Approach

In this section, we will first introduce a grammar-guided rule-to-rule model (Section 3.1), and then present a grammar-constrained inference method (Section 3.2).

3.1 Grammar-Driven Model

Our grammar-guided model, which is based on the state-of-the-art Transformer model (Vaswani et al., 2017), has a token encoder, a grammar encoder, and a grammar decoder, as shown in Figure 2.

3.1.1 Token and Grammar Encoder

To model token representations and grammar structures, we employ token encoder and grammar encoder to model code unit and code grammar, respectively. The two encoders have similar model architecture and different inputs, which are token sequence $\{t_1, t_2, ..., t_m\}$ and rule sequence $\{r_1, r_2, ..., r_n\}$. Considering the difference of sequence and tree structure, besides conventional sinusoidal positional embedding (Vaswani et al., 2017), we also introduce a **depth embedding** to enhance of capacity of modeling tree structure for the grammar encoder. As for the model structure, the first sub-layer of encoders is **tree-masked self-attention**, the second sub-layer is **interactive cross-attention**, and the last sub-layer is a feed-forward layer.

Depth Embedding We extract the depth information of each rule in the corresponding abstract syntax tree (AST). For the example in Figure 1, the depth of rule *modifiers* $\rightarrow$ *private* is depending on the depth of its head token *modifiers*, which counts 1 in this example. The final position embedding is the sum of the sinusoidal position encoding and the depth embedding.

Tree-Masked Self-Attention To focus on the local information from directly contacted tokens or rules, we propose tree-based attention applied to one head of multi-head self-attention. Formally, we first build a distance-based mask M_{tree}, where $M_{tree}[i,j] = 0$ if node i is the parent or one of the children of j, else $M_{tree}[i,j] = -e^9$. Then, we employ the proposed M_{tree} to one dot-product attention:

$$\mathrm{ATT}(Q,K,V) = \mathrm{softmax}(\frac{QK^T}{\sqrt{d_k}} + M_{tree})V \tag{1}$$

Interactive Cross-Attention The goal of interactive cross-attention is to make full use of token information and syntax information interactively. Specifically, given the outputs of tree-masked self-attention in token encoder and grammar encoder, e.g., H_{tok} and H_{gra}, the output of interactive cross-attention can be expressed as:

$$\begin{aligned} O_{tok} &= \mathrm{Attention}(H_{tok}, H_{gra}, H_{gra}) \\ O_{gra} &= \mathrm{Attention}(H_{gra}, H_{tok}, H_{tok}) \end{aligned} \tag{2}$$

where $\mathrm{Attention}(\cdot)$ is the same as standard self-attention in Transformer.

3.1.2 Grammar Decoder

For each layer in the grammar decoder, the lowest sub-layer is the masked multi-head self-attention network, and the top layer is a feed-forward layer, as shown in Figure 2. Moreover, we design three attention strategies to integrates source token and grammar information.

(1) The **standard strategy** is the same as the traditional cross-attention in Transformer. Specifically, the query Q comes from the output of decoder self-attention, and the key-value pair $\{K, V\}$ is transformed only from the output of the grammar encoder. (2) Figure 2 shows the **cascade strategy**, in which we first compute the cross-attention with token encoder, then use the output as the query to calculate the cross-attention with grammar encoder. (3) The **parallel strategy** attends to each encoder independently and then sums up the context vectors. We will compare the three strategies in Section 4.4.

3.2 Grammar-Constrained Inference

Considering the sensitivity and strictness of program language, we further propose a grammar-constrained inference method to guarantee the grammatical correctness of the output. More specifically, we first build an AST in the inference process according to the currently generated rule sequence and maintain an indicator to locate the AST node where the extension is happening. Then, we filter out the unsatisfactory rules whose head token is not the current extending node, by using mask operation in softmax function. Finally, our AST and indicator can be updated for the next prediction. It is worth noting that the node pointed by the indicator is the one that should be expanded as a parent (head token) in the next inference.

Take figure 1 as an example, when R9 has been predicted, the indicator is pointing the node *parameters*. We limit the search space of the next rules, which have to satisfy its head node is *parameters* (marked by a brown border). Then applicable rule with the highest probability (R10 in this case) is chosen and tail tokens *type* and *identifier* of R10 are added into AST. Finally indicator is transferred from *parameters* to *type*, denoting that *type* is the next expanded node.

4 Experiments

4.1 Datasets and Metrics

Datasets We evaluate our approach on BFPs dataset (Tufano et al., 2018), a collection of Java functions on Github Archive. BFPs consists of 58K bug-fixes data and is divided into training, validation and test sets by 8:1:1. We extracted 4.5K grammar constraints from the dataset in total, among which 0.5K are related to vocab and others related to grammar rules.

Metrics Following Tufano et al. (2018), we employ **XMatch**, a metric indicating the percentage of model's outputs that exactly match the reference, including Top XMatch and All XMatch. Top Match only utilizes top 1 of the beams as output, and All Match uses all beams as outputs to match the refer-

Method	Beam	XMatch (Top)	XMatch (All)	XBug
NMT (Tufano et al., 2018)	1	9.22%*	9.22%*	-
	5	-	27.33%*	-
Token-Trans	1	10.03%	10.03%	56
	5	10.32%	24.02%	44
Rule-Trans	1	10.87%	10.87%	31
	5	11.95%	24.94%	14
Our Model	1	11.47%	11.47%	0
	5	13.42%	28.03%	0

Table 1: Main results of our model on BFPs. Results marked with * are from Tufano et al. (2018).

ence. The correlation coefficient analysis of (Ren et al., 2020) also shows that human evaluation is more correlated with **XMatch** than n-gram matching for code repair task. Besides, we employ **XBug** as the auxiliary metric to evaluate the grammatical correctness of output, which examines basic grammar structure of output, like symbol usage and context matching.

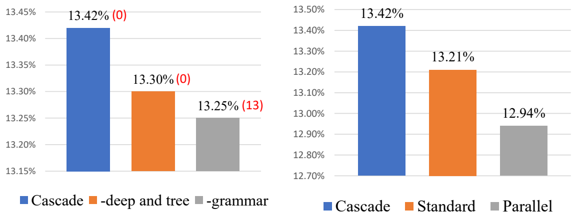
4.2 Experimental Setting

Our model is built on PyTorch and trained on 4 GPUs of TITAN XP for 7 hours. We parse source code into AST with *tree sitter*[1], and use the same Transformer setting as Vaswani et al. (2017). The hidden size is 512. The layer of both two encoders and decoder is 6. The dropout probability is 0.5. The number of trainable parameters in our best model is 49M. We test system performance with beam size = 1 and 5, and the latter is used as default.

4.3 Main Results

Table 1 shows the results of all models. The first line is the performance of the previous RNN-based NMT model (Tufano et al., 2018) on BFPs. Token-Trans is built on the Transformer model using sequences of source code as input, while Rule-Trans employs grammar sequences as input and output.

Top Match Token-Trans and Rule-Trans models get the performance of 10.32% and 11.95% with beam search respectively, which first demonstrates the model superiority by using grammar rules. Furthermore, our proposed model outperforms Token-Trans and Rule-Trans by 3.1% and 1.5% respectively, indicating the effectiveness of our proposed grammar-aware modules and inference method in the APR task.



(a) Ablation (b) Strategies

Figure 3: Comparison on different modules (a) and strategies (b). "deep and tree" means the depth embedding and tree-based attention, and "grammar" demotes the grammar-constrained inference method.

All Match We verify All Match metric to compare with previous work (Tufano et al., 2018), which judges correct model predictions if any one of the beams can fix the buggy code. Results show that our proposed model suggests 28.03% correct patches with beam search, and our model performs better with 2.2% and 0.7% improvements than (Tufano et al., 2018) when beam is 1 and 5 respectively.

XBug We further analyze the grammatical quality of different models. Token-Trans model suffers from grammatical errors with 56 samples in the test set, while in Rule-Trans model, the number decreases to 31. Due to the ability to model grammar rules and guide rule generation of our approach, our proposed model can effectively avoid grammatical errors, guaranteeing the grammar correctness of generated patches.

4.4 Effect of Modules and Strategies

In this section, we will evaluate the contribution of different modules and compare the three combination strategies described in Section 3.1.2.

Figure 3 shows the XMatch results of different models, and we also list the XBug number in brackets. The results in Figure 3 (a) show that all of the proposed methods have positive effects. It's worth noting that the performance significantly drops in terms of XBug if we remove the grammar-constrained inference method. Compare different combination strategies in Figure 3 (b), parallel strategy performs worse than other strategies, and the underlying reason is that concatenating token and grammar sequences results in too long sentences. Besides, the cascade strategy behaves best because it can make full use of the token information and the grammar information provided by encoders.

5 Conclusion

In this paper, we propose a grammar-guided end-to-end approach for automated program repair. Particularly, we introduce three structure-aware modules and three combination strategies, and present a grammar-based inference algorithm to guarantee grammar correctness of generated patches. Experiments on BFPs dataset demonstrate that Grammar-based system performs better than Token-based system for both model learning and grammar correctness. Moreover, system that simultaneously modeling grammar and its inside token information showed great potentiality in our works. Besides, the advantage of grammar-constrained inference inspires us to explore more about the possibility of combining grammar constraints with NLP model.

Abstract

Distantly supervised (DS) relation extraction (RE) has attracted much attention in the past few years as it can utilize large-scale auto-labeled data. However, its evaluation has long been a problem: previous works either take costly and inconsistent methods to manually examine a small sample of model predictions, or directly test models on auto-labeled data—which, by our check, produce as much as 53% wrong labels at the entity pair level in the popular NYT10 dataset. This problem has not only led to inaccurate evaluation, but also made it hard to understand where we are and what's left to improve in the research of DS-RE. To evaluate DS-RE models more credibly, we build manually-annotated test sets for two DS-RE datasets, NYT10 and Wiki20, and thoroughly evaluate several competitive models, especially the latest pre-trained ones. The experimental results show that the manual evaluation can indicate very different conclusions from automatic ones, especially some unexpected observations, e.g., pre-trained models can achieve dominating performance while being more susceptible to false-positives compared with previous methods. We hope that both our manual test sets and observations can help advance future DS-RE research.[1]

1 Introduction

Relation extraction (RE) aims at extracting relational facts between entities from the text. One crucial challenge for building an effective RE system is how to obtain sufficient annotated data. To tackle this problem, Mintz et al. (2009) propose distant supervision (DS) to generate large-scale auto-labeled data by aligning relational facts in knowledge graphs (KGs) to text corpora, with the core assumption that one sentence mentioning two entities is likely to express the relational facts between the two entities from KGs.

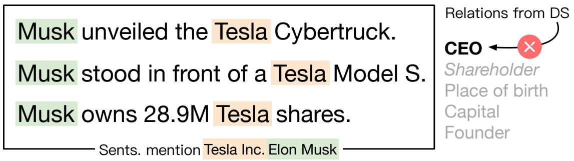

Figure 1: Typical errors made by DS evaluation. In the figure, DS labels the bag with only the relation `CEO`, while none of the sentences express the relation. Also, it misses a correct relation `shareholder` due to the incompleteness of the knowledge graphs.

As DS can bring hundreds of thousands of auto-labeled training instances for RE without any human labor, DS-RE has been widely explored in the past few years (Riedel et al., 2010; Hoffmann et al., 2011; Zeng et al., 2015; Lin et al., 2016; Feng et al., 2018; Vashishth et al., 2018) and has also been widely extended to other related domains, such as biomedical information extraction (Peng et al., 2017; Quirk and Poon, 2017) and question answering (Bordes et al., 2015; Chen et al., 2017).

Although DS-RE has achieved great success, we identify one severe problem for the current DS-RE research—its evaluation. Existing works usually take two kinds of evaluation methods following Mintz et al. (2009): *held-out evaluation*, which directly uses DS-generated test data to approximate the trend of model performance, and *human evaluation*, which manually checks the most confident relational facts predicted by DS-RE models. Since manually checking is costly, most works with human evaluation only examine a small proportion of the predictions. Moreover, different works may sample different splits of data, making human evaluation inconsistent across the literature. Most recent studies even skip the human evaluation for the above factors and only take the held-out one.

However, the held-out evaluation can be quite noisy: there are many false-positive cases, where the sentences do not express the auto-labeled relations at all; besides, due to the incompleteness of KGs, DS may miss some relations, just as shown in Figure 1. After checking $9,744$ sentences in the held-out set of NYT10 (Riedel et al., 2010), the most popular DS-RE dataset, we found that about 53% of the entity pairs are wrongly labeled, emphasizing the need for a more accurate evaluation.

To make DS-RE evaluation more credible and alleviate the trouble of manual checking for later work, we build human-labeled test sets for two DS-RE datasets: NYT10 (Riedel et al., 2010) and Wiki20 (Han et al., 2020). For NYT10, we manually annotate sentences with positive DS relations in its held-out test set. We also use a fine-tuned BERT-based (Devlin et al., 2019) RE model to predict all “N/A” (not applicable) sentences, and manually label the top $5,000$ sentences scored as having a relation. Additionally, we merge some unreasonably split relations and reduce the number of relation types from 53 to 25. For Wiki20 dataset, we utilize both the relation ontology and human-labeled instances of an existing supervised dataset Wiki80 (Han et al., 2019) for the test, and then re-organize the DS training data accordingly.

Based on the newly-constructed benchmarks, we carry out a thorough evaluation of existing DS-RE methods, as well as incorporating recently advanced pre-trained models like BERT (Devlin et al., 2019). We found that our manually-annotated test sets can indicate very different conclusions from the held-out one, especially with some surprising observations: (1) although pre-trained models lead to large improvements, they also suffer from false-positives more severely, probably due to the pre-encoded knowledge they have (Petroni et al., 2019); (2) existing DS-RE denoising strategies that have been proved to be effective generally do not work for pre-trained models, suggesting more efforts needed for DS-RE in the era of pre-training. To conclude, our main contributions in this work are:

- We provide large human-labeled test sets for two DS-RE benchmarks, making it possible for later work to evaluate in an accurate and efficient way.
- We thoroughly study previous DS-RE methods using both held-out and human-labeled test sets, and find that human-labeled data can reveal inconsistent results compared to the held-out ones.
- We discuss some novel and important observations revealed by manual evaluation, especially with respect to pre-trained models, which calls for more research in these directions.

2 Related Work

Relation extraction is an important NLP task and has gone through significant development in the past decades. In the early days, RE models mainly take statistical approaches, such as pattern-based methods (Huffman, 1995; Califf and Mooney, 1997), feature-based methods (Kambhatla, 2004; Zhou et al., 2005), graphical methods (Roth and Yih, 2002), etc. With the increasing computing power and the development of deep learning, neural RE methods have shown a great success (Liu et al., 2013; Zeng et al., 2014; Zhang and Wang, 2015; Zhang et al., 2017). Recently, pre-trained models like BERT (Devlin et al., 2019) have dominated various NLP benchmarks, including those in RE (Baldini Soares et al., 2019; Zhang et al., 2019b). All these RE methods focus on training models in a supervised setting and require large-scale sufficient human-annotated data.

To generate large-scale auto-labeled data without human effort, Mintz et al. (2009) first use DS to label sentences mentioning two entities with their relations in KGs, which inevitably brings wrongly labeled instances. To handle the noise problem, Riedel et al. (2010); Hoffmann et al. (2011); Surdeanu et al. (2012) apply multi-instance multi-label training in DS-RE. Following their settings, later research mainly takes on two paths: one aims at selecting informative sentences from the noisy dataset, using heuristics (Zeng et al., 2015), attention mechanisms (Lin et al., 2016; Han et al., 2018c; Zhu et al., 2019), adversarial training (Wu et al., 2017; Wang et al., 2018; Han et al., 2018a), and reinforcement learning (Feng et al., 2018; Qin et al., 2018); the other incorporates external information like KGs (Ji et al., 2017; Han et al., 2018b; Zhang et al., 2019a; Hu et al., 2019), multilingual corpora (Verga et al., 2016; Lin et al., 2017; Wang et al., 2018), as well as relation ontology and aliases (Vashishth et al., 2018). Recently, pre-trained DS-RE models have also been explored, including both domain-general (Alt et al., 2019; Xiao et al., 2020) and domain-specific (Amin et al., 2020) models. Some other latest works (Peng et al., 2020) utilize DS data for intermediate pre-training in order to boost supervised RE tasks.

As mentioned in our introduction, the evalua-

Dataset	#rel	Train			Validation			Test		
		#facts	#sents	N/A	#facts	#sents	N/A	#facts	#sents	N/A
NYT10†	53	18,409	522,611	74%	-	-	-	1,950	172,448	96%
NYT10	25	17,137	417,893	80%	4,062	46,422	80%	3,899 (1,940)	9,744 (157,859)	32% (96%)
Wiki20†	454	203,176	1,050,246	48%	4,333	29,145	48%	4,333	28,897	48%
Wiki20	81	157,740	698,721	59%	17,485	64,607	73%	56,000	137,986	25%

Table 1: The statistics of the datasets used for our benchmarks, including both the original (†) and our modified versions. We list the numbers of relations (#rel), relational facts (#facts) and sentences (#sents), and N/A rate (N/A) for these datasets. For NYT10, numbers in brackets are for the held-out test, otherwise for bag-level manual test.

tion of DS-RE has long been a problem, especially since many existing methods solely rely on auto-labeled test data. Some preliminaries have noticed this problem: Jiang et al. (2018); Zhu et al. (2020) also annotate the test set of NYT10, yet Jiang et al. (2018) only sample $2,040$ sentences from it, and Zhu et al. (2020) discard all N/A data from DS, which are an important part of DS evaluation, and assume that the original held-out data have either the DS relations or no relation at all, while we find that a large proportion of held-out data actually express some other relations; Li et al. (2020) propose active testing, an iterative method to correct the bias of DS evaluation. However, it still requires consistent human efforts during each evaluation phase. To the best of our knowledge, our work, building benchmarks with large-scale manually-labeled test data, conducts the most comprehensive human evaluations of DS-RE methods so far.

3 DS-RE Datasets

In this section, we introduce the way we build the manually-annotated test sets for NYT10 (Riedel et al., 2013) and Wiki20 (Han et al., 2020). We show the statistics of these datasets in Table 1.

3.1 NYT10 Dataset

NYT10 is constructed by aligning facts from the FreeBase (Bollacker et al., 2008) with the New York Times (NYT) corpus (Sandhaus, 2008). The original NYT10 dataset contains 53 relations (including N/A). After thoroughly examining the dataset, we found that (1) there are many duplicate instances in the dataset, (2) there is no public validation set, and some previous works directly take the test set to tune the model, and (3) the relation ontology is not reasonable for an RE task. Therefore, we first clean the dataset by removing duplicate sentences, split a validation set, and then merge some of the relations as described below.

A New Relation Ontology One example of NYT10's improper relation ontology is the relations related to state/province capitals. There are 12 such relations in the original dataset, representing region capitals of different countries, while some of these relations even do not have instances in the test set. We merge these 12 relations as one unified relation `/location/region/capital`, and we also merge 3 relations related to organization locations as `/business/location`. Besides, we delete relations that only show up in either the training set or the test set (most of which have very few sentences). In the end, we get 25 relations in the new dataset. We provide the detailed relation list of the new dataset in Appendix A.

Interestingly, we found that training models with the new dataset leads to a slight performance degeneration, as shown in Table 2, which is counter-intuitive (since merging classes usually makes the task easier). We suspect that the original relation ontology provides heuristics for the model. For example, models can learn from the original ontology that every sentence with a "US state" as the head entity expresses the fine-grained relation `/location/us_state/capital`, which is a shortcut that cannot be acquired with the merged relation `/location/region/capital`. This shows the bias of the original NYT10 dataset being inappropriately exploited by models.

Annotated Test Set The original NYT10 dataset only provides an auto-labeled test set for the held-out evaluation. Based on the original test set, we manually annotate all sentences that have a positive DS label. In addition to that, we also fine-tune a BERT model (as described in §4.2) to predict the relations of all sentences originally labeled as N/A, and annotate the $5,000$ sentences with the highest predicted scores of non-N/A relations. For each sentence, we ask 4 annotators to decide whether it expresses one or more relations among 25 rela-

Model	Original AUC	Original F1	New AUC	New F1
PCNN+bag+AVG	31.8	38.6	28.4	35.8
PCNN+bag+ATT	33.6	40.2	32.2	39.1

Table 2: AUC and micro F1 (%) of model predictions on the original NYT10 relation ontology and our new NYT10 relation ontology (using held-out test).

tions. Note that one sentence may have multiple relations. Specially, we do not provide any relation suggestions using DS labels or model predictions to annotators, in order to avoid the annotators being biased by the external information.

When aggregating the final annotation results, we consider each relation for each sentence independently. The sentence is regarded to express one relation if more than half of the annotators labeled it with this relation. If one sentence gets no votes for any positive relations in the above process, then it is labeled as N/A. For annotation conflicts (i.e., no candidate relation gets more than half votes), the authors manually annotate these sentences.

Finally, we obtain the human-labeled test set with $9,744$ sentences, 32% of which are N/A instances. It contains $5,174$ entity pairs and $3,899$ manually-verified relational facts in total. After comparing it with the corresponding original DS-generated labels, we found that at the fact level, the DS annotations only have a precision of 69.1% and a recall of 33.9%. At the entity pair level, the accuracy of DS labels is only 47.1%. This emphasizes the need to take the human-annotated test set for more accurate evaluation in DS-RE.

3.2 Wiki20 Dataset

Han et al. (2020) construct the Wiki20 dataset by aligning the English Wikipedia corpus with Wikidata (Vrandečić and Krötzsch, 2014). To provide an annotated test set for it, we utilize Wiki80 (Han et al., 2019), a supervised RE dataset with 80 relations from Wikidata. We re-organize Wiki20 by adopting the same relation ontology as Wiki80 and re-splitting the train/validation/test sets, while taking sentences in Wiki80 as the test set. We make sure that there is no overlap of entity pairs among the three splits, to avoid any information leakage.

Note that Wiki20 is quite different from NYT10: NYT10 labels a sentence as "N/A" if the entity pair in the sentence does not have a relation in the KG. On the contrary, Wiki20 labels entity pairs with a relation outside its relation ontology as "N/A". In other words, "N/A" instances in Wiki20 express *unknown* relations instead of *no* relation.

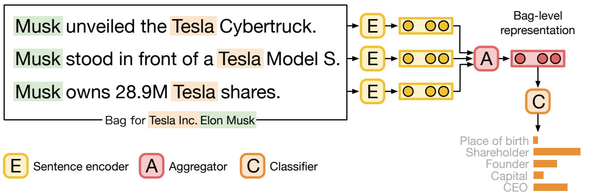

Figure 2: An illustration for a typical multi-instance multi-label (bag-level) model. The model aims to predict relation probabilities for entity pairs, instead of sentences, which is usually accomplished by aggregating a bag representation and doing classification over it.

4 DS-RE Models

In this section, we elaborate the multi-instance multi-label framework for DS-RE, and introduce models we evaluate, including both previous methods and the latest pre-trained ones.

4.1 Multi-instance Multi-label Evaluation

Unlike the supervised RE tasks which usually evaluate models at the sentence level, DS-RE evaluates *how well models can extract relational facts* from the corpus, i.e. measuring the precision and recall of extracted relational facts (a *fact* is an entity pair and a relation between them). It is named as **multi-instance multi-label**, since each entity pair might be mentioned in multiple sentences, and one entity pair can have more than one relation. Under the framework, models are required to predict the potential relations for each entity pair—according to all sentences mentioning the pair—during the evaluation, as shown in Figure 2. Sentences correlated with the same entity pair are also named as a *bag*, and thus we interchangeably refer to multi-instance multi-label framework as **bag-level** framework.

The most popular way to compare DS-RE models is to plot precision-recall (P-R) curve and calculate the area-under-the-curve (AUC). We also report micro F1 and macro F1 in our experiments. Since the numbers of instances for different relations are extremely imbalanced, macro F1 can better demonstrate model performance while avoiding the bias brought by those major relations.

4.2 Model Details

Sentence-level Training Models are trained in a sentence-level fashion (as in supervised RE), but used as a bag-level model during evaluation. As shown in Figure 2, a typical bag-level model takes

Model	AUC	Micro	Macro
PCNN+bag+AVG (full)	28.4	35.8	13.3
PCNN+bag+ATT (full)	32.2	39.1	9.5
PCNN+bag+ATT (sample)	31.8	39.6	11.8

Table 3: Comparison between full and sampled bag training with NYT10 held-out test. For PCNN+bag+ATT, the sampled bag performs similarly to the full bag, and it still outperforms PCNN+bag+AVG (full). "Micro" and "Macro" represent micro and macro F1 (%).

an *aggregator* to fuse embeddings of all sentences in the bag, and then feeds the bag-level representation to the classifier. Here we take two aggregation strategies: average (**AVG**), which averages the representations of all the sentences in the bag; and at-least-one (**ONE**) (Zeng et al., 2015), which first predicts relation scores for each sentence in the bag, and then takes the highest score for each relation.

Bag-level Training Directly deploying sentence-level training for DS-RE suffers from the wrong labeling problem: one sentence mentioning two entities may not express its auto-labeled relation. To alleviate this problem, models can also take bag-level framework in the training, based on the *expressed-at-least-one* assumption (Riedel et al., 2010): at least one sentence in the bag expresses the auto-labeled relation. Besides the AVG and ONE[2] strategies mentioned above that can be directly deployed for bag-level training, Lin et al. (2016) also propose to use sentence-level attention (**ATT**) for aggregation: It produces bag-level representation as a weighted average over embeddings of sentences, and determines weights by attention scores between sentences and relations.

For our experiments, we take CNN (Liu et al., 2013), PCNN (Zeng et al., 2015) and BERT (Devlin et al., 2019) as options of sentence encoders, which are all common choices for neural RE models. We evaluate combinations of different sentence encoders, training policies, and aggregation strategies, e.g., bag-level trained PCNN with ATT aggregator (PCNN+bag+ATT) or sentence-level trained BERT with ONE aggregator (BERT+sent+ONE). Besides, we evaluate several representative DS-RE models from literature, namely RL-DSRE (Qin et al., 2018), which takes deep reinforcement learning for denoising training instances, BGWA (Jat et al., 2017), which takes both word-level and sentence-level attention, and RESIDE (Vashishth et al., 2018), which introduces side information like relation aliases to put soft constraints on prediction.

For BERT-based sentence encoder, there are some practical challenges when adopting bag-level training: in the worst cases, one bag can contain thousands of sentences, which are beyond the capacity of most computing devices due to the large size of pre-trained models. To address this issue, we take a random sampling strategy during training: for each bag, we randomly sample b sentences, instead of taking all of them. For evaluation, we use the same routine as other non-pre-trained encoders, taking all of the sentences into account (because back propagation is not needed here so the bag can be split into several batches). Since this is different from the original bag-level training, we carry out a pilot experiment to examine the effect of the sampled training. From Table 3, we can see that our sampling strategy does not significantly hurt the performance of the bag-level training.

We also add another variant, BERT-M, in our evaluation. We observe from the top predictions of BERT models (Figure 3) that BERT tends to make false-positive errors for entity pairs that express a relation in the KG but do not have any sentence truly expressing the relation in the data, probably due to that model learns shallow cues solely from entities. Thus, following Peng et al. (2020), we mask entity mentions during training and inference to avoid learning biased heuristics from entities.

5 Experiment

5.1 Implementation Details

We use the OpenNRE toolkit (Han et al., 2019) for most of our experiments, including both sentence-level and bag-level training. For CNN and PCNN, we follow the hyper-parameters of Han et al. (2019). For BERT, we use pre-trained checkpoint `bert-base-uncased` for initialization, take a batch size of 64, a bag size of 4 and a learning rate of 2×10^{-5},[3] and train the model for 3 epochs. For RL-DSRE, RESIDE and BGWA, we directly use their original implementation.

5.2 Evaluation Settings

We take three different settings in our experiments:

---

[2] During training, since we have DS label r for the bag, we directly take the sentence embedding that has the highest score for r as the bag-level representation.

[3] This is determined by a grid search over batch sizes in $\{16, 32, 64\}$ and learning rates in $\{1e\text{-}5, 2e\text{-}5, 5e\text{-}5\}$.

Model	Bag	Strategy	Held-out			Bag-level Manual			Sentence-level Manual		
			AUC	Micro	Macro	AUC	Micro	Macro	AUC	Micro	Macro
CNN	-	AVG	20.0	30.3	6.5	48.7	50.4	21.3	52.0	53.3	22.1
	-	ONE	21.2	31.8	7.2	50.5	51.6	19.8	52.0	53.3	22.1

Table 4: Results (%) on NYT10, including the held-out evaluation, bag-level manual evaluation, and sentence-level manual evaluation. The "bag" column indicates whether the model uses bag-level training, and the "strategy" column shows the bag aggregation policy. We report the AUC, micro F1 (Micro) and macro F1 (Macro) scores.

Held-out evaluation: We take the test data of the original DS datasets for evaluation. The trend of this evaluation should be consistent with the reported results in most DS-RE literature.

Bag-level manual evaluation: We take our human-labeled test data for bag-level evaluation. Since annotated data are at the sentence-level, we construct bag-level annotations in the following way: For each bag, if one sentence in the bag has a human-labeled relation, this bag is labeled with this relation; if no sentence in the bag is annotated with any relation, this bag is labeled as N/A.

Sentence-level manual evaluation: As we wonder how well bag-level-trained models can handle sentence-level predictions, our human-labeled test set is also used for a sentence-level evaluation.

We report AUC, micro F1 and macro F1 for all above evaluation settings. We take the best micro F1 on the P-R curves and use the corresponding threshold for calculating macro F1. Considering the difference between NYT10 and Wiki20, we evaluate models on the two datasets respectively.

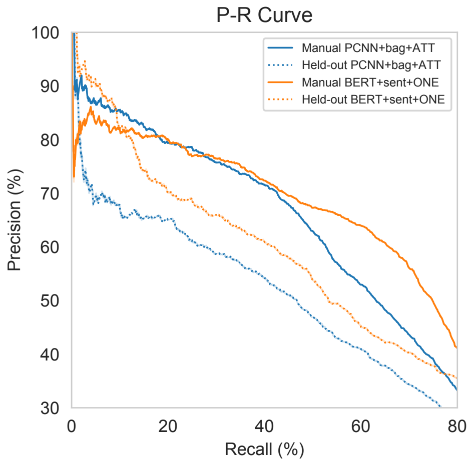

Figure 3: Comparisons of using bag-level manual test (solid lines) and corresponding held-out test (dotted lines). Both absolute and relative scores of models significantly change when taking on human-labeled data.

5.3 The Results on NYT10

Table 4 shows the main results on NYT10. We also plot P-R curves of selected models in Appendix B. Overall, for all three settings, training pre-trained models in a sentence-level style always perform the best, while applying bag-level training strategies can significantly boost the performance when taking other non-pre-trained encoders. Feng et al. (2018) observe that bag-level training is not helpful in the sentence-level evaluation, which contradicts our observation. We suspect that it is because Feng et al. (2018) only manually check a small proportion of test data, leading to a biased result.

More importantly, by comparing the held-out test results to the manual ones, we come to the conclusion that **manual evaluation matters**: auto-labeled and human-labeled test data lead to very different observations. For example, the comparisons between PCNN and RL-DSRE, and BGWA and RESIDE are reversed when taking different evaluations. Also, the performance gaps between different models become much smaller when it

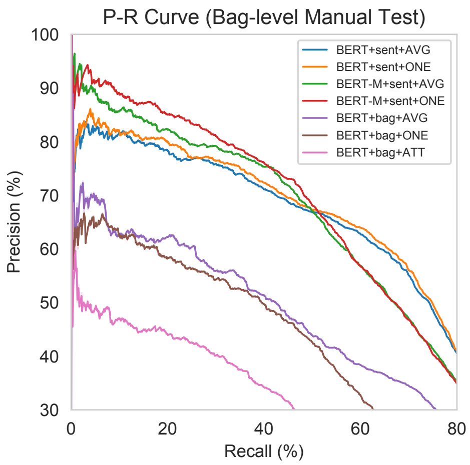

Figure 4: Comparisons of different DS-RE models with BERT on NYT10 bag-level manual test set.

comes to the manual test. Since our manual test set is smaller than the original held-out one (because we did not annotate all N/A sentences), to make a clearer comparison, we evaluate two selected models on the bag-level manual test set and on the corresponding instances in the held-out test set, respectively, and we plot the P-R curves in Figure 3. It shows that not only the absolute values of the two measurements differ a lot, but it also affects the relative performances between the models. For instance, BERT+sent+ONE shows a considerable advantage over PCNN+bag+ATT at the top predictions on the held-out test set, but it is completely the opposite case at the manual test, where BERT+sent+ONE is even significantly worse than PCNN+bag+ATT. It clearly suggests that using the held-out test set cannot well demonstrate the real pros and cons of the models.

Compared to others, BGWA and RESIDE suffer an extreme change in performance between the held-out and manual evaluations, and we suspect that it is due to the fact that they use entity types as extra information, which leads to overfitting biased heuristics of entities. This further emphasizes the need of using manually-labeled test data in DS-RE.

After checking the manual results, we further identify some interesting observations that have not been clearly demonstrated with the DS evaluation:

Pre-trained Models First of all, BERT-based models have achieved supreme performance across all three metrics. To thoroughly examine BERT and its variants in the DS-RE scenario, we further plot their P-R curves with the bag-level manual test in Figure 4. It is surprising to see that all bag-level training strategies, especially the ATT strategy which brings significant improvements for PCNN-based models, do not help or even degenerate the performance with pre-trained ones. This observation is also consistent with that in Amin et al. (2020), though they only compare BERT+bag+AVG and BERT+bag+ATT. We hypothesize the reasons are that solely using pre-trained models already makes a strong baseline, since they exploit more parameters and they have gained pre-encoded knowledge from pre-training (Petroni et al., 2019), all of which make them easier to directly capture relational patterns from noisy data; and bag-level training, which essentially increases the batch size, may raise the optimization difficulty for these large models.

Another unexpected observation is that, though the P-R curve of BERT is far above other models in the held-out test, we identify a significant drop of that in the manual test, as shown in Figure 3 and Appendix B. By manually checking those errors, we find that most of them are models predicting facts that exist in the KG but are not supported by the text (i.e., false-positive). For example, *Arthur Schnitzler* was indeed born in *Vienna*, but it is wrong for the model to infer the relation *place of birth* from sentence "*Authur Schnitzler wrote a story set in Vienna.*" We assume that it is not only because of the prior knowledge of pre-trained models, but is also due to that BERT can better learn heuristics from entity themselves, as shown in the study of Peng et al. (2020) with supervised RE. Considering the data of DS-RE are noisy and in many cases the text does not support the labeled facts, this overfitting-to-heuristic phenomenon can only be more severe.

To verify the assumption and try out a simple solution to alleviate the problem, we take a BERT-M variant (as described in §4.2) and show its results in Figure 4. We can see that the P-R curves of BERT-M are above those of BERT at the beginning, demonstrating that BERT-M models have higher precisions at those top predictions. Later on, since BERT can extract more facts than BERT-M by fully utilizing information from entity names, BERT-M reduces below BERT. From these results, we highlight that **how to handle the false-positives and denoise DS-RE data for pre-trained models** still remains an open and challenging problem.

Imbalanced Classes Previous works of DS-RE usually take AUC, micro F1, or P-R curves to measure the abilities of models, which show the over-

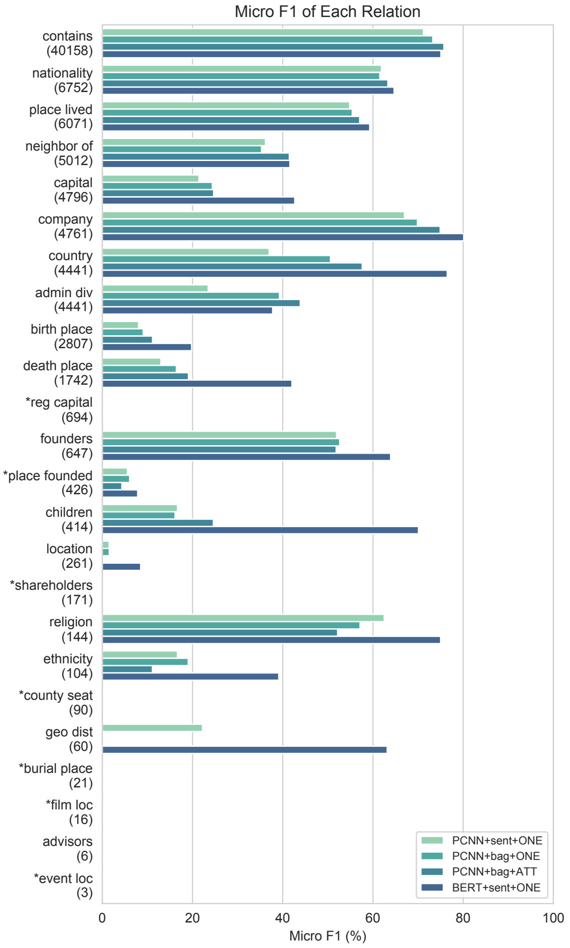

Figure 5: Micro F1 (%) of different relations on the bag-level manual test of NYT10. * represents the relation has less than 20 sentences in the test sets. Numbers in brackets are numbers of training sentences.

all performance trend averaged on relational facts. However, the distribution of training instances across relations is extremely uneven. For example, in NYT10 , almost half of the positive instances are `/location/location/contains`. On the contrary, half of the relations have fewer than $1,000$ sentences. In this case, macro F1 can better show the averaged performance across different relations, without being biased by the majority class. Table 4 demonstrates that even though in most times conclusions of different metrics are consistent, there are cases when models improve micro F1 but degenerate macro F1.

To further study how models perform on each relation, we plot several representative models and their micro F1 scores for each relation in Figure 5. We can see that: (1) The top-4 relations, which account for 80% test instances, do not vary much in performance with different models, while the difference of performance takes place mostly outside the top-4; (2) Some relations even have zero F1 scores, mostly because they have very few training or test sentences. These results further underscore the importance to look into per-relation scores for DS-RE, and we advocate that later works should **include macro F1** for more comprehensive comparisons.

Model	Bag	Strategy	AUC	Micro	Macro

Table 5: Results (%) on Wiki20 of representative models. "Bag" indicates bag-level training and "Micro" and "Macro" represent micro and macro F1 respectively.

5.4 The Results on Wiki20

We choose several representative models and further evaluate them on Wiki20, as shown in Table 5. The main observation of results on Wiki20 is consistent with that of NYT10—sentence-level pre-trained models perform the best, and using bag-level training helps with non-pre-trained ones—though the overall performance is much higher. Another difference is that, in Wiki20, AVG performs better than ONE and ATT. We think that it is due to the inherent difference in how the two datasets are constructed, especially the difference in the aspect of determining N/A sentences. Compared to NYT10, part of the N/A instances in Wiki20, instead of indicating no relation between the entities, may correspond to a specific relation that is outside of the dataset ontology. It suggests that when dealing with N/A instances, **considering their latent semantics, rather than simply treating them as one abstract class**, may further benefit RE models.

6 Conclusion

In this paper, we study the problem of test protocols in DS-RE and build large manually-annotated test sets for two DS-RE datasets, to enable a more accurate and efficient evaluation. We not only demonstrate that our manual test sets show different observations from previous held-out ones, but also capture some interesting reflections by using the manual test, e.g., pre-trained models suffer false-positives more and bag-level training strategies generally do not help with pre-trained models.

We hope that our manual test sets can mark a new starting line for DS-RE, while these observations can motivate novel research directions towards better DS-RE models, e.g., studying denoising methods for pre-trained models or processing N/A relations in a more fine-grained way.

Ethical Considerations

Our work mainly focuses on two parts: the construction of two manually-labeled test sets and the analyses of models based on the manual test. Regarding the annotation, we first approximate the workload by annotating a few examples on our own, and then determine the wages for annotators according to local standards. The two datasets are based on NYT and Wikipedia, and we did not identify any unethical content during annotation.

Concerning the analyses, we find that models tend to utilize some shallow clues for classification, such as learning heuristics from entities. This behavior can potentially create biased extraction results based on the distributions of entities in the training set and is worth further investigating.

Abstract

Recently, driven by numerous publicly available machine reading comprehension (MRC) datasets, MRC systems have made some progress. These datasets, however, have two major limitations: 1) the defined tasks are relatively simple, and 2) they do not provide explainable evaluation which is critical to objectively and comprehensively review the reasoning capabilities of current MRC systems. In this paper, we propose GCRC, a new dataset with challenging and high-quality multi-choice questions, collected from Gaokao Chinese (Chinese subject from the National College Entrance Examination of China). We have manually labelled three types of evidence to evaluate MRC systems' reasoning process: 1) sentence-level relevant supporting facts in an article required for answering a given question, 2) error reason of a distractor (i.e., an incorrect option) for explaining why a distractor should be eliminated, which is an important reasoning step for multi-choice questions, and 3) types of reasoning skills required for answering questions. Extensive experiments show that our proposed dataset is more challenging and very useful for identifying the limitations of existing MRC systems in an explainable way, facilitating researchers to develop novel machine learning and reasoning approaches to tackle this challenging research problem.[1]

1 Introduction

Machine Reading Comprehension (MRC) is a critical task in many real-world applications, which requires machines to understand a text passage, and answer relevant questions. It evaluates machines' understanding and reasoning capabilities on the underlying natural language text. Numerous MRC datasets have been proposed and facilitate the progress of MRC systems, which have achieved near-human performance on some datasets. However, this does not indicate the MRC systems have owned human-like language understanding and reasoning capabilities.

One reason is that questions in current data are not challenging enough, leading to most of them get "solved" very soon. (Sugawara et al., 2018) demonstrate that in many MRC datasets, a considerable number of easy questions can be answered based on the first few tokens of the questions or word matching, without complex reasoning capabilities. The other reason is that most datasets only provide a black-box and overall evaluation on the accuracy of predicted answers, which does not provide **explainable evaluation** on a system's internal reasoning capabilities. In other words, it is unable to explain whether a system gets a correct answer via the right reasoning process, and not enough to identify the specific limitations of a system.

Recently, in order to address the problems mentioned, some datasets, focusing on reasonings and providing additional information to evaluate the internal reasoning steps of a system, have been proposed. For example, MultiRC (Khashabi et al., 2018) and HotpotQA (Yang et al., 2018) include the questions requiring multi-sentence reasoning

Article	随着全球人口的不断增长和科学技术的飞速发展，人类在创造文明的同时也缔造了一个深受人类影响的全球生态系统。长期以来对生物资源及土地的过度利用，导致了动植物栖息地丧失、环境污染等一系列问题的出现，生态环境及生物系统遭受了严重破坏。据专家估计，由于人类活动和气候变化，地球上的生物种类目前正在以相当于正常水平1000倍的速度消失，全球已有约3.4万种植物和5200多种动物濒临灭绝，物种分布发生了大范围的变化，这些形成了全球性的生物多样性危机。... 生物多样性为人类发展带来了巨大财富，目前它却面临着来自城市化等方面的威胁。城市化对生物多样性的影响成为生态学研究者关注的焦点问题。	With the continuous growth of global population and rapid development of science and technology, human beings has created a global ecosystem which is deeply influenced by mankind while creating civilization. The long-term over-utilization of biological resources and land has led to the emergence of problems such as the loss of wildlife habitats and environmental pollution, and meanwhile, the ecological environment and biological systems have been severely damaged. According to experts, the species on the earth are disappearing at a rate of 1,000 times the normal level due to human activities and climate change. Currently, about 34,000 species of plants and more than 5,200 species of animals are on the verge of extinction, and the species distribution has been changed significantly, which has resulted in a global biodiversity crisis. ... Biodiversity has brought huge wealth to human development, but it is facing the threat from urbanization and other aspects. The impact of urbanization on biodiversity has become the focus of ecological researchers.
Question stem	根据材料一，下列理解和分析，符合文意的一项是?	Which of the following statements agrees with the information given in the article?
Options	A：深受人类影响的全球生态系统利于缓解生物多样性危机。 （所需推理能力：归纳推理） （错误原因：主谓宾关系错误） *B：第一段通过列举数据来凸显生物多样性危机的严重程度。 （所需推理能力：鉴赏分析） C：生态学者关注的焦点是生物多样性危机给人类带来哪些损失。 （所需推理能力：细节推理） （错误原因：细节错误） D：这则材料反映了对生物多样性危机的担忧并提出了应对策略。 （所需推理能力：归纳推理） （错误原因：无中生有）	A: The global ecosystem, which is deeply influenced by human beings, helps alleviate the biodiversity crisis. (Reasoning skill: Inductive reasoning) (Error reason: Wrong subject-predicate-object relationship) *B: *The first paragraph* highlights the severity of the biodiversity crisis by giving some statistics. (Reasoning skill: Appreciative analysis) C: The focus of ecological researchers is what loss the biodiversity crisis has brought to human beings. (Reasoning skill: Detail understanding) (Error reason: Wrong details) D: *This article* reflects the concerns about biodiversity crisis and proposes countermeasures. (Reasoning skill: Inductive reasoning） (Error reason: Irrelevant to the article.）

Figure 1: An annotated instance in GCRC, which is from the real Gaokao Chinese in 2019 (* indicates the correct option). The sentences marked in yellow/green are respectively the SFs for Option A and C. As mentioned in Option B, the SFs of Option B are the first paragraph. Similarly, the SFs of Option D are the whole article. The contents marked in blue are the required reasoning skills for the options and the ERs of distractors.

or multi-hop reasoning. Moreover, MultiRC and HotpotQA both provide *sentence-level supporting facts (SFs)*, which can be used as a kind of internal explanation for the answers, although locating SFs is just the first step for question answering (QA), as many questions need to integrate the SF information with reasoning. R4C (Inoue et al., 2020) and 2WikiMultiHopQA (Ho et al., 2020) introduce *a chain of facts* (reflecting entity relationships) as the derivation steps to evaluate the internal reasoning step of systems.

However, these kinds of reasonings are quite limited and not enough to answer those complex and comprehensive questions. For example, Figure1 shows a multi-choice question, where the option D "***This article reflects** the concerns about biodiversity crisis and proposes countermeasures*" is a summarization of the whole given article, and its judgement cannot be made by simply reasoning over some entity relationships. Instead, the reasoning over the full information across the article will be needed.

To address the above real challenges, we propose GCRC, a new challenging dataset with 8,719 multi-choice questions, collected from reading comprehension (RC) tasks of Gaokao Chinese (short for Chinese subject from the National College Entrance Examination of China). GCRC is of high quality and high difficulty level, because Gaokao Chinese examinations are designed by educational experts, with high-level comprehensive questions and complicated articles, aiming to test the language comprehension of adult examinees.

In order to provide **explainable evaluation**, instances (e.g. Figure 1) in the dev. and test sets (including 1725 questions and 6900 options, as presented in Table 2 and Section 4) of GCRC are annotated with three kinds of information: (1) ***sentence-***

level supporting facts **(SFs)**, serves as the basic evaluation for a system's internal reasoning; and (2) ***error reasons*** **(ERs)** ***of a distractor*** (i.e. an incorrect option) for explaining why a distractor should be eliminated. In Gaokao Chinese, distractors are often designed in a very confusing way and look like a correct option, although they are incorrect. Identifying the semantic difference between a distractor and the given article, and knowing exactly why a distractor is wrong could help systems or examinees to choose the correct answers. Therefore, we spend considerable effort to thoroughly understand articles and manually label seven types of ERs of a distractor as a form of internal reasoning step for multi-choice questions; and (3) ***types of reasoning skills*** required for answering questions in Gaokao Chinese. We introduce eight typical reasoning skills in GCRC, which enable us to evaluate whether a system has corresponding reasoning capability at individual question level.

Our main contributions can be summarized as:

- We construct a new challenging dataset GCRC that is collected from Gaokao Chinese, consisting of 8,719 multiple-choice questions, which will be released on Github in future.
- Three kinds of critical information are manually annotated for explainable evaluation. To the best of our knowledge, GCRC is the first Chinese MRC dataset to provide most comprehensive, challenging, high-quality articles and questions for more deep explainable evaluation on different MRC system performance. In particular, error reasons of a distractor are the first introduced in this area as an important reasoning step for complex multi-choice questions.
- Extensive experiments show that GCRC is not only a more challenging benchmark to facilitate researchers to develop novel models, but also help us identify the limitations of existing MRC systems in an explainable way.

2 Related Work

2.1 Datasets from standard tests

There exist some datasets, collected from standard exams/tests, including English datasets RACE (Lai et al., 2017), DREAM (Sun et al., 2019), ARC (Clark et al., 2018), ReClor (Yu et al., 2020), etc., and Chinese datasets C3 (Sun et al., 2020), MCQA (Guo et al., 2017), GeoSQA (Huang et al., 2019) and MedQA (Zhang et al., 2018) etc.

Some of these datasets are of specific domains. For example, ARC is of the science domain and the questions are from the American science exams from 3rd to 9th grade. ReClor targets logical reasoning and the questions are collected from the Law School Admission Council. MCQA and GeoSQA are extracted from Gaokao History and Gaokao Geography respectively. Other datasets cover generic topics. For example, RACE and DREAM are both collected from the English exams for Chinese students, while C3 is collected from the Chinese exams for Chinese-as-a-second-language learners.

GCRC is more similar to C3, RACE and DREAM, as their questions are all generic ones. However, their question difficulty level is different, because questions in GCRC target for adult native speakers, while questions in other datasets target for second-language learners. As such, the GCRC is much more challenging than other datasets. Additionally, GCRC provides three kinds of rich information for more deep explainable evaluation.

2.2 Datasets with explanations

Some datasets provide explanation information. (Wiegreffe and Marasovic, 2021) identified three types of explanations: highlights, free-text and structured explanations. Highlights are subsets of the input elements (words, phrases, snippets or full sentences) to explain the prediction. Free-text explanations are textual or natural language explanations containing the information beyond the given input. Structured explanations have various forms for specific datasets. One of the most common form is a chain of facts as the derivation of multi-hop reasoning for an answer.

(Inoue et al., 2020) classified explanations into two types: justification explanation (collections of SFs for a decision) and introspective explanation (a derivation for a decision), which are respectively corresponding to highlights and structured explanations.

For the MRC task, a few datasets are with explanation information. For example, MultiRC (Khashabi et al., 2018) and HotpotQA (Yang et al., 2018) provides sentence-level SFs, belonging to justification explanations, to evaluate a system's ability to identify SFs from articles that related to a question/option. R4C (Inoue et al., 2020) and 2WikiMultiHopQA (Ho et al., 2020) provide both justification and introspective explanations. In both datasets, introspective explanations are a set of factual entity relationships. Their difference is that the explanation of R4C is of semi-structured form, while the explanation of 2WikiMultiHopQA is of structured data form.

The dataset C3 provides the types of required prior knowledge for 600 questions, and its goal is to study how to leverage various knowledge to improve the system's ability for text comprehension.

Inspired by these datasets, we provide more rich explanations in GCRC. Different from the existing work, besides SFs, we provide two additional information. Specifically, we propose innovative ERs of a distractor as a reasoning step for multi-choice questions. In addition, we annotate the required reasoning skills for each instance, which enable us to clearly identify the limitations of existing MRC systems. Note that prior knowledge annotated in C3 is different from reasoning skills in GCRC, as prior knowledge in C3 mainly include linguistic, domain specific, and general world knowledge, while reasoning skills in GCRC focus on the abilities of making an inference. Generally, reasoning needs to integrate prior knowledge and the information in the given text. As far as we know, *GCRC is the first Chinese MRC dataset with rich explainable information* for evaluation purpose.

3 Dataset Overview

Questions in GCRC are of multi-choice style. Specifically, given an article D, a question Q and its options O, the evaluation based on GCRC will measure a system from the following aspects:

- *QA accuracy*. It is a common evaluation metric, also provided by the other QA datasets.
- *The performance of locating the SFs in D*, which is a basic evaluation metric to assess whether MRC system can collect all necessary sentences from articles before reasoning.
- *The performance of identifying ERs of a distractor*, which evaluates whether a system is able to exclude incorrect options by deep reasoning for multi-choice questions.
- *The performance of different reasoning skills required by questions*. This evaluation shows the limitations of reasoning skills for a MRC system.

Next, we clearly define the ERs of a distractor and the reasoning skills required for choosing a correct option in Section 3.1 and Section 3.2 respectively. The ERs of a distractor are concrete and focus on the forms of the errors, while reasoning skills are more abstract, referring to the abilities of making an inference.

3.1 Error reasons of a distractor

As mentioned in Section 1, knowing exactly why a distractor is wrong will help MRC systems or an examinee select correct answers. Therefore, we introduce error reasons of a distractor as an important internal reasoning step, and present seven typical ERs of a distractor after investigating the instances in GCRC.

Wrong details. The distractor is *lexically similar to the original text, but has a different meaning caused by alterations of some words*, such as modifiers or qualifier Words.

Wrong temporal properties. The distractor describes an events with *wrong temporal properties*. Generally, we consider five temporal properties defined in (Zhou et al., 2019): duration, temporal ordering, typical time, frequency, and stationary.

Wrong subject-predicate-object triple relationship. The distractor has a triple relationship of subject-predicate-object (sub-pred-obj) , but *the relationship conflicts with the ground truth triple in the given article*, caused by substituting one of the components in the triple. For example, in Figure 1, Option A "*The global ecosystem, which is deeply influenced by human beings, helps alleviate the biodiversity crisis.*" has a sub-pred-obj triple "*the global ecosystem—**alleviate**—the biodiversity crisis*. However, from the given article, the correct triple is "*the global ecosystem—**result in** —the biodiversity crisis*", leading to the wrong distractor.

Wrong necessary and sufficient conditions. The distractor *intentionally misinterprets the necessary and sufficient conditions* expressed in the original article. A necessary condition is a condition that must be present for an event to occur, while a sufficient condition is a condition or set of conditions that will produce the event. For example, the statement "*Plants will grow as long as* *with air*" is wrong, as air is the necessary condition for plant growing, but besides air, plants also need water and sunshine to grow.

Wrong causality. The distractor reverses/confuses the causes and effects mentioned in an original article or add non-existent causality. Generally, the cause-effect relationship is explicitly expressed with causal connectives in distractors.

Irrelevant to *the question*. The distractor's contents are indeed mentioned in the given article, but are irrelevant to the current question.

Irrelevant to *the article*. The distractor's contents are not mentioned in the original article. For example, in Figure 1, "*proposes countermeasures*" expressed in Option D "*This article reflects the concerns about biodiversity crisis and proposes countermeasures*." is not mentioned in the given article. Thus, Option D should be excluded.

3.2 Required reasoning skills

In Gaokao Chinese, RC tasks measure an examinee's text understanding and logical reasoning abilities from different perspectives. We investigate the skills required for answering questions in GCRC, and introduce eight typical skills, which are organized into the following three levels according to the amount of information needed and the complexity of reasoning for QA. Some of the reasoning skills (marked with *) are similar to those proposed by Sugawara et al. (2017).

3.2.1 Level 1: Basic information capturing

This level covers the ability to capture relevant detailed information distributed across the article, and combine them to match with options.

Detail understanding. It focuses on distinguishing the semantic differences between the given article and an option. The option, most of the time, preserves the most lexical surface form of the original article, but has some minor differences in details by using different modifiers or qualifying words.

3.2.2 Level 2: Local information integration

This level covers how to identify different types of relationships linked between sentences in an article. In Gaokao Chinese, the relationship's expressions are often implicit in a given article.

Temporal/spatial reasoning*. It aims to understand various temporal or spatial properties of events, entities and states.

Coreference resolution*. It aims to understand the coreference and anaphoric chains by recognizing the expressions referring to the same entity in the given article.

Deductive reasoning. It focus on taking a general rule or key idea described in an article, and applying it to make inferences about a specific example or phenomenon expressed in the option. For example[2], the statement of "*we rely on mobile navigation to travel and lose the ability to identify routes.*" is a specific phenomenon of the statement of "*while we are training artificial intelligence systems, we may also be trained by artificial intelligence systems*".

Mathematical reasoning*. It performs some mathematical operations, such as numerical sorting and comparison, to obtain a correct option.

Cause-effect comprehension*. It aims to understand the causal relationships explicitly or implicitly expressed in a given article.

3.2.3 Level 3: Global information integration

This level involves information integration of multiple sentences or the whole articles to comprehend the main ideas, article organization structures and the authors' emotion and sentiment.

Inductive reasoning. It integrates information from separate words and sentences, and makes inferences about an option, which is often a summarization of several sentences, a paragraph or the whole article.

Appreciative analysis. It aims to understand the article organization method, the authors' writing style and method, attitude, opinion and emotional state. For example, in Figure 1, Option B "*The first paragraph highlights the severity of the biodiversity crisis by giving some statistics*" is the analysis result of authors' writing style and method.

4 Construction and Annotation of GCRC

We have spent tremendous effort to construct the important GCRC dataset. Firstly, we search and download about 10,000 latest (year 2015 to 2020)

---

[2] This example is translated from real Gaokao Chinese in 2018.

multiple-choice questions of real and mock Gaokao Chinese from five websites. Then, for preprocessing, we remove those duplicated questions and questions with figures and tables, and keep those questions with four options (only one of them is correct). Next, we identify and rectify some mistakes, such as typos, in articles or corresponding questions/options. Finally, the total number of questions in GCRC is 8,719. Moreover, we adjust the labels of the correct answers, making them evenly distributed over the four different options, i.e., A, B, C, D.

Next, we will annotate the questions according to the following three steps. We would emphasize that the annotation process is extremely challenging, as it requires human annotators to fully understand both syntactic structure and semantic information of the articles and corresponding questions and options, as well as identify the error reasons of distractors, and reasoning skills required.

- **Step 1: Annotation preparation.** We first prepare an annotation guideline, including task definition and annotated examples. Then, we invite 12 graduate students of our team to participate in the annotation work. To maintain high quality and consistent annotations, our annotators first annotate these questions individually, and subsequently discuss and reach agreements if there is any discrepancy between two annotators. The process further improves the annotation guideline and better trains our annotators.
- **Step 2: Initial annotations.** Firstly, each question is annotated by an annotator independently, where we show an article, question, all candidate options and the label of the answer. Annotators have completed the following three tasks: (1) select the sentences in the article, which are needed for reasoning, as the sentence-level SFs; (2) provide ERs of a distractor from the types discussed in Section 3.1; (3) provide the reasoning skills required for each option based on the skills described in Section 3.2.
- **Step 3: Annotation consistency.** When two annotators disagree with their own annotations, we invite the third annotator to discuss with them, and reach the final annotations. In the rare cases where they cannot agree with each other, we will keep the annotations with at least two supports.

The annotators' consistency is evaluated by the Inter Annotator Agreement IAA) value and the IAA value is 83.8%.

As mentioned before, manual annotations of GCRC is expensive and complicated, because questions in Gaokao Chinese are designed for adult native speakers and thus are challenging. It requires deep language comprehension to solve these questions. As a result, making explainable annotations in GCRC across multiple levels implies *GCRC is a very precious dataset with valuable annotations*. Although the size of the dataset is not too big, it is big enough to be used for providing diagnosis of existing MRC systems. It also provides an ideal testbed for researchers to propose novel transfer learning or few-shot learning methods to solve the tasks.

Statistics. We partition our data into training (80%), development (dev, 10%) and test set (10%), mainly according to the number of questions. We have annotated three types of information for a subset of GCRC. Specifically, we annotate the sentence-level SFs for 8,084 options (of 2,021 questions) sampled from the training set, and 6,900 options (of 1725 questions) in the dev and test sets.

In addition, we annotate ERs of 6,159 distractors in the training, dev and test sets, and reasoning skills for 6,900 options in the dev and test sets. We believe our dataset with relatively big annotation sizes can ensure us to identify the limitations of existing RC systems in an explainable way. Table 1 shows the the details of GCRC data splitting and corresponding annotation size.

Table 2 shows the detailed comparisons for GCRC and other three RC datasets collected from standard exams, including C3 (Sun et al., 2020), RACE (Lai et al., 2017), DREAM (Sun et al., 2019). As shown in Table 2, we observe that GCRC is the longest in terms of the average length of articles, questions and options.

Table 3 shows the distribution of types of reasoning skills based on the dev and test sets. We observe that 48.77% questions need detail understanding, and 33.10% questions require inductive reasoning. In addition, Figure 2 presents the ERs types distribution of distrators based on the dev and test sets, in which 33.2% of distractors are with wrong details and 26.4% of distractors include information irrelevant to the corresponding articles.

Splitting	**Train**	**Dev**	**Test**	**Total**
# of articles	3790	683	620	5093
# of questions	6994	863	862	8719
# of questions/options with SFs	2021/8084	863/3452	862/3448	3746/14984
# of questions/distractors with ERs	2000/3261	863/1428	862/1470	3725/6159
# of questions/options with rea. ski.	-	863/3452	862/3448	1725/6900

5 Experiments

With our newly constructed GCRC dataset, it is interesting to evaluate the performance of existing models, and better understand GCRC's characteristics comparing with other existing data sets.

5.1 QA accuracy and GCRC difficulty level

We evaluate the QA performance of several popular MRC systems on GCRC, which will reflect the difficulty level of GCRC. Specifically, for comprehensive evaluation, we employ four models, including one *rule-based model* and three recent *state-of-the-art models based on neural networks*.

- **Sliding window** (Richardson et al., 2013). It is a rule-based baseline and chooses the answer with the highest matching score. In particular, it has TFIDF style representation and calculates the lexical similarity between a sentence (via concatenating a question and one of its candidate options) and each span in the given article with a fixed window size.

- **Co-Matching** (Wang et al., 2018). It is a Bi-LSTM-based model and consists of a co-matching component and a hierarchical aggregation component. The model not only matches the article with a question and each candidate option at the word-level, but also captures sentence structures of the article. It has achieved promising results on RACE.

  Note that we have used 300-dimensional word embeddings based on GloVe (Global Vectors for Word Representation).[3]

- **BERT** (Devlin et al., 2019). It is a pre-trained language model, which adopts multiple bidirectional transformer layers and self-attention mechanisms to learn contextual relations between words in a text. BERT has achieved very good performance on numerous NLP tasks, including the RC task defined by SQuAD. We employ Chinese BERT-base and English BERT-base released on the website.[4]

- **XLNet** (Yang et al., 2019). It is a generalized autoregressive pretraining model, which uses a permutation language modeling objective to combine the advantages of autoregressive and autoencoding methods. XLNet outperforms BERT on 20 tasks. For experiments on Chinese datasets, we use XLNet-large and its Chinese version released on the website.[5]

[5] https://github.com/brightmart/xlnet$_{z}h$

In addition to evaluate the performance of different models on GCRC, we also want to see how these models perform on other datasets, namely C3, RACE, and DREAM. In order to fairly and objectively compare with them, we randomly sample from these datasets, and create three new datasets with the same sizes of the splits (train, dev, test) as GCRC (shown in Table 1). The hyper-parameters of these neural baselines can be seen in Appendix.

Human Performance. We obtain the human performance on 200 questions, which are randomly sampled from the GCRC test set. We invite 20 high school students to answer these questions, where they are provided with the questions, options and articles. The average accuracy of human is 83.18%.

We first use the training sets from four datasets to train four models, which are subsequently used to evaluate their accuracies on respective test data. Dev sets are used to tune the values of the parameters of different models. Table 4 shows the comparison results. We observe that the neural network based models outperform the rule based sliding window model. In addition, pretrained models perform better than the non-pretrained models in most cases. Moreover, it is interesting to observe that all four existing models generally perform worse on GCRC than other three datasets, and the human performance on GCRC is also the lowest among the four datasets. This clearly indicates that GCRC is more challenging. Meanwhile, it can be seen that the performance gap between human and the best system on GCRC is 46.45%, suggesting that there is sufficient room for improvement, which contradicts with some overly optimistic claims that machines have exceeded humans on QA. As there is a significant performance gap between machines and humans, GCRC dataset facilitates researchers to develop novel learning approaches to better understand its questions and bridge the huge gap.

	GCRC	C3	RACE	DREAM
Sliding window	27.70%	36.70%	30.85%	40.08%
Co-Matching	35.73%	45.01%	35.38%	48.91%
BERT	30.74%	64.96%	46.13%	53.36%
XLNet	35.15%	60.90%	50.00%	59.63%
Human	83.18%	96%*	95.5%*	94.5%*

Table 4: Accuracy comparison between four computational models and human on four benchmark datasets (* indicates the performance is based on the annotated test set and copied from the corresponding paper).

In the next few subsections, we will study whether a representative model, i.e. BERT, can perform well in the explainable evaluation related subtasks, namely locating sentence-level SFs, identifying ERs, and the performance of different reasoning skills required by questions.

5.2 Performance of locating sentence-level SFs using BERT

We investigate whether BERT benefits from sentence-level SFs. We conduct an experiment, in which we input the ground-truth SFs, instead of the given article, to BERT for question answering. We observe that the accuracy of QA on the test set of GCRC is 37.47%. Comparing with the result shown in Table 4, the accuracy is increased by 6.73%, indicating that locating SFs is helpful for QA. On the other hand, we can see that the improvement is still far from closing the gap to human performance because the questions are difficult and need further reasoning to solve.

Due to the usefulness of SFs, we train a BERT model to identify whether a sentence belongs to SFs. We regard this task as a sentence pair (i.e., an original sentence in the given article and an option) classification task. We use the GCRC subset (2,021/863/862 questions as shown in Table 1) annotated with SFs for training and testing, where the training, dev and test sets include 200,798/85,024/83,656 sentence-option pairs respectively. The experimental results are shown in Table 5. We can see that performance of locating the SFs is still low (in terms of precision P, recall R and F1 measure), indicating that accurately obtaining the SFs in GCRC is challenging and directly applying BERT will not work well.

	P	R	F1
Dev	78.07%	50.18%	61.10%
Test	70.20%	51.46%	59.39%

Table 5: Results of BERT locating SFs.

5.3 Performance of identifying ERs of a distractor using BERT.

In order to evaluate whether BERT model understands why a distractor is excluded, we modify BERT model and add a new component to perform the identification of distractors' ERs. The component is a multi-label (i.e., 8 labels including 1

ERs	#of options	R	P
Wrong details	484	1.65%	9.09%
Wrong temporal properties	29	13.79%	0.55%
Wrong subject-predicate-object triple	190	2.11%	5.88%
Wrong causality	218	24.77%	7.62%
Wrong necessary and sufficient conditions	106	1.89%	2.22%
Irrelevant to the question	85	17.65%	2.21%
Irrelevant to the article	352	4.83%	17.35%
Correct options	1984	28.18%	56.69%

Table 6: Results of BERT identifying ERs of distractors.

correct type and 7 types of ERs) classifier to predict the probability distribution of the types of ERs, and is jointly optimized with normal QA, and it shares the low-level representations. The classifier's objective is to minimize a cross entropy loss, which is jointly optimized with normal QA, and they share the low-level representations. For this task, the contextual input of BERT is ground-truth SFs, instead of the given article. The results are shown in Table 6. We observe that the performance of identification of ERs is quite low, indicating the significance and value of our dataset, which is to identify the limitations of existing systems on explainability and facilitates researchers to develop novel learning models.

5.4 Performance of different reasoning skills required by questions using BERT

We also investigate BERT's performance on the questions requiring different reasoning skills. We categorize the performance for each type of reasoning skills on the test set of GCRC. Table 7 shows the results. Note that the reasoning skills are annotated for options of questions. We observe BERT obtains the lowest score on the options requiring deductive reasoning. Overall, the system generally performs worse on each type of options, indicating the reasoning power of the system is not strong enough and needs to be significantly improved.

Reasoning	Detail understanding	Temporal/spatial	Coreference	Deductive
#of options	1683	42	179	143
Accuracy	31.97%	61.90%	39.66%	35.66%
	Mathematical	Cause-effect	Inductive	Appreciative
#of options	40	175	1056	130

Table 7: Results of BERT on GCRC by reasoning skills required for QA.

From the above, it can be seen that no baseline is realized to output answers, sentence-level SFs and ERs of a distractors together, but it doesn't affect our dataset to diagnose the limitations of existing RC models. For each task, we modify the existing model of BERT, output the corresponding explanations, and report their performance. Thus, the limitations of the model can be clearly identified. In the future, we will realize such a baseline that can do all the tasks together, and we will design a new joint metric for evaluating the whole question-answering process.

6 Conclusions

In this paper, we present a new challenging machine reading comprehension dataset (GCRC), collected from Gaokao Chinese, consisting of 8,719 high-level comprehensive multiple-choice questions. To the best of our knowledge, this is currently the most comprehensive, challenging, and high-quality dataset in MRC domain. In addition, we spend considerable effort to label three types of information, including sentence-level SFs, ERs of a distractor, and reasoning skills required for QA, aiming to comprehensively evaluate systems in an explainable way. Through experiments, we observe GCRC is very challenging data set for existing models, and we hope it can inspire innovative machine learning and reasoning approach to tackle the challenging problem and make MRC as an enabling technology for many real-world applications.

Abstract

Identifying events and mapping them to a pre-defined taxonomy of event types has long been an important NLP problem. Most previous work has relied heavily on labor-intensive, domain-specific, annotation, ignoring the *semantic meaning* of the event types' labels. Consequently, the learned models cannot effectively generalize to new label taxonomies and domains. We propose a zero-shot event extraction approach, which first identifies events with existing tools (e.g., SRL) and then maps them to a given taxonomy of event types in a zero-shot manner. Specifically, we leverage label representations induced by pre-trained language models, and map identified events to the target types via representation similarity. To semantically type the events' arguments, we further use the definition of the events (e.g., argument of type "Victim" appears as the argument of event of type "Attack") as global constraints to regularize the prediction. The proposed approach is shown to be very effective on the ACE-2005 dataset, which has 33 trigger and 22 argument types. Without using any annotation, we successfully map 83% of the triggers and 54% of the arguments to the semantic correct types, almost doubling the performance of previous zero-shot approaches[1].

1 Introduction

Event extraction, the process of identifying events triggers and arguments and classifying them into a set of pre-defined types is an important part of natural language understanding, and a commonly studied NLP task (Grishman et al., 2005). Consider the example shown in Figure 1, where two events (i.e., "war" and "protesting") are identified. By mapping them to [Conflict:Attack] and [Conflict:Demonstrate] and using the knowledge of "Attack" might result in "Demonstrate", we can infer that the war in Iraq is probably the cause of the protesting in Pakistan.

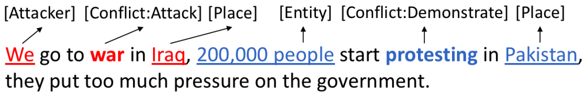

Figure 1: Event classification examples. Two events are highlighted with red and blue colors. Triggers and arguments are in bold and underline fonts, respectively.

Most existing event extraction work (Wadden et al., 2019; Lin et al., 2020) treats event identification as a supervised sequence labeling task and event classification as a supervised classification problem, and relies on large amounts of event-specific annotated text. Take ACE-2005 (Grishman et al., 2005) as an example; the training set of ACE consists of 4,419 events, annotated and typed into 33 event types. Such large-scale and high-quality annotation requires significant expertise, and it facilitates the success of supervised learning models. However, scaling these efforts to new domains and more event types is very costly and unrealistic.

Indeed, there has already been some effort to address the limitation of supervised models on new event types via a transfer-learning based zero-shot event classification approach (Huang et al., 2018). By jointly encoding the event structures (i.e., the relations between event triggers and their arguments) of event mentions and of pre-defined event types, their model learns to map event mentions to the most similar event types. As a result, at inference time, the model can be extended to new types as long as the structures of new types are provided. Nonetheless, the success of this transfer learning approach also heavily relies on the similarity between observed event types and new ones. When

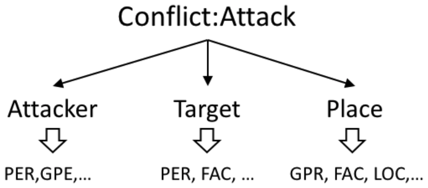

Figure 2: Pre-defined event type demonstration. Event type "Conflict:Attack" is associated with three argument types ("Attacker", "Target", "Place") and each of them is associated with a list of potential entity types.

new event types are different enough from those the model was trained on, the model will struggle.

This paper shows that the whole event extraction pipeline (i.e., identification and classification) can be done without any event-specific annotation. Since the event identification task can also be viewed as a classification task that determines whether the event triggers provided by the SRL models belong to the pre-defined event ontology or not, in this paper, we focus on the classification task. Specifically, we explore a reliable zero-shot solution to mapping observed events to any given set of event types. Unlike previous approaches, we do not use any annotation and only rely on the given event type *definitions*. We classify events by matching the semantics of the identified triggers and arguments to the type names, and then regularize the predictions with the constraints in the pre-defined event ontology.

A pre-defined event type example is shown in Figure 2, where domain experts choose to use "attack" to describe the whole event type and the labels "attacker", "target", and "place" for its roles, since the semantics of these words reflect ones' understanding of this event type. To fully utilize the semantics of these labels, we propose to represent the labels with a cluster of contextualized embeddings rather than just words. In the aforementioned example, we first select several sentences that contain the word "attack" from an external corpus (e.g., New York Times (NYT) (Sandhaus, 2008)). For each selected sentence, we use a pre-trained language model (e.g., BERT (Devlin et al., 2019)) to encode it and then use the resulting embedding of "attack" as a data point in the "attack" cluster. At the inference time, we can then acquire the contextualized representation of identified triggers and arguments, and map them to their corresponding types based on their similarities to those clusters in the embedding space. Beyond the labels, event definitions also provide constraints between types and roles. For example, the role "Attacker" can only appear as an argument of "Conflict:Attack" rather than "Life:Marry," and only a person or a nation can take the role of an "Attacker". In our system, we propose to use these constraints to regularize the zero-shot model. Specifically, we formulate the final inference step as an integer linear programming (ILP) (Roth and tau Yih, 2004) and only produce decisions that satisfy all the constraints.

Our experiments show that the proposed model is very effective on the standard evaluation dataset ACE-2005, which has 33 event trigger types and 22 argument role types. Without using any annotation, we map 83% of the triggers and 54% of the arguments to correct types, almost doubling the performance of the previous best zero-shot event classification approach. When pipelined with our improved zero-shot identification step, we exhibit an zero-shot event extraction pipeline that rivals a SOTA supervised system (Lin et al., 2020) trained on over 6,000 sentences.

2 Task Definition and Notations

We denote the overall sets of predefined event trigger types, argument role types, and entity types as $\mathcal{E}$, $\mathcal{R}$, and $\mathcal{T}$ respectively. Each pre-defined event type (e.g., "Conflict:Attack") $E \in \mathcal{E}$ is associated with several role types $R \in \mathcal{R}_E$ and for each $R \in \mathcal{R}$, the event definition also links it with several possible entity types $T \in \mathcal{T}_R$. Given a sentence S, which has a predicate v, several arguments a, and associated entity types t, the task of zero-shot event classification is mapping v and a to the correct types without any annotation.

3 Model Overview

As shown in Figure 3, the whole framework can be divided into two phases: preparation and prediction. In the preparation phase, we generate the representations for all pre-defined event types and argument roles, which are indicated by blue and orange, respectively. For each type, we select the label word and its synonyms[2] as the anchor words, and then for each of them, we retrieve a list of anchor sentences that use these words from an external corpus. After applying the pre-trained language models to encode all anchor sentences, we can then obtain the contextualized representations of selected anchor words and treat the cluster of these embeddings to

---

[2] For labels that have multiple words, we select words that can best represent the label semantics.

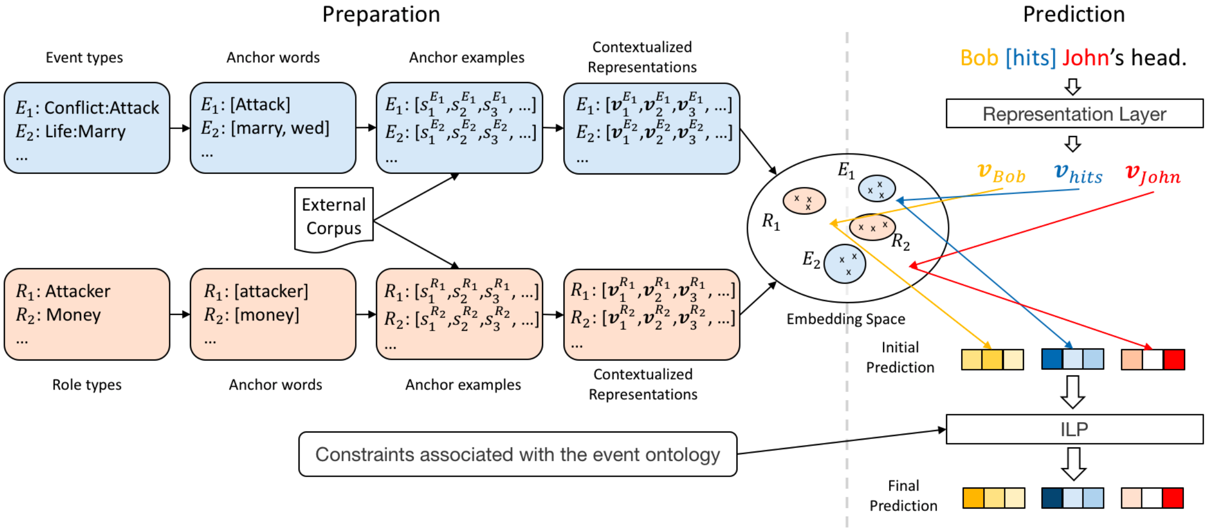

Figure 3: Architecture Overview. Pre-defined types, anchor words, anchor sentences, and contextualized representations for event trigger types and argument role types are indicated with blue and orange, respectively.

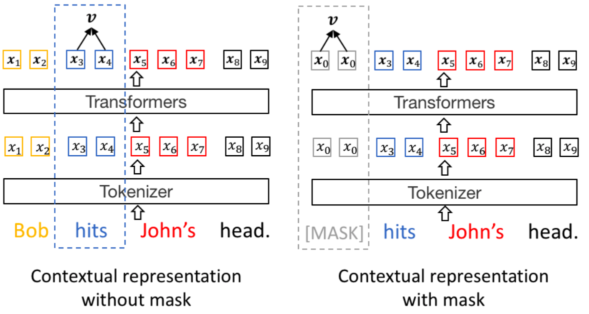

Contextual representation without mask

Contextual representation with mask

Figure 4: Demonstration of the proposed two contextualized representation acquisition methods.

as the type representation. In the prediction phase, given S, v, and a, we first acquire the contextualized representation for the triggers and arguments. After that, in the embedding space, we can easily map them to the most similar types based on the cosine distance to each cluster. Based on these initial predictions, we then leverage constraints provided by the event definitions to regularize the prediction by modeling it as an ILP problem.

4 Preparation

In this section, we introduce the preparation details.

4.1 Anchor Words and Sentences Selection

Since the most frequently-occurred POS of triggers is verb and they typically have multiple senses, we also include their synonyms of the same meaning as anchor words to improve the overall representation quality. In total, we got 107 anchor words for 33 event trigger types and 22 anchor words for 22 event argument types. After that, we then go to an external corpus (NYT corpus (Sandhaus, 2008) in our experiment) for finding anchor sentences that contain the corresponding anchor words.

4.2 Contextualized Representation Generation

As shown in Figure 4, we propose two different representation acquisition methods for triggers and arguments. For triggers, we use all words in S as the input, while for arguments, we mask the target anchor words. The motivation is that most triggers contribute the most important semantic meaning while the semantics of arguments are often inferred from their context rather than the anchor words themselves. For example, many arguments are pronouns or names, which only have weak semantics by themselves and we need to understand them by understanding their context.

For each sentence S and a target anchor word $w^\star$, we first tokenize S based on the type of the target word:

$$X, p_s, p_e = \begin{cases} Tokenize\_Full(S, w^\star) \text{ for } w^\star \in \mathcal{W}^T \\ Tokenize\_Mask(S, w^\star) \text{ for } w^\star \in \mathcal{W}^A, \end{cases} \tag{1}$$

where $\mathcal{W}^T$ and $\mathcal{W}^A$ are sets of anchor words for triggers and arguments, respectively. $X = x_1, x_2, \cdots, x_n$ is the list of tokens. As the tokenizer tool may tokenize words into sub-word pieces, we use p_s and p_e to record the start and end token positions for the anchor word. We then input X into a multi-head transformer module to get the

Explanation	Constraint
One type per trigger.	$\sum_{i\in\lvert\mathcal{E}\rvert} I_t(i) = 1$
One type per argument.	$\forall j\ \sum_{k\in\lvert\mathcal{R}\rvert} I_r(j,k) = 1$
Different arguments in one event must have different types.	$\forall k\ \sum_{j\in\lvert\mathcal{A}\rvert} I_r(j,k) \leq 1$
Predicted trigger and argument type must appear in the ontology .	$\forall i,j,k\ I_t(i) + I_r(j,k) \leq 1$ if E_i and R_k cannot be paired in the ontology.
Entity types of arguments match the requirements.	$\forall i,j,k\ I_t(i) = 0, I_r(j,k) = 0$ if a_i does not match the requirement of E_k or R_k.

Table 1: Selected constraints for the ILP regularization.

	Train	Dev	Test	Overall
# Sentences	19,244	902	676	20,822
# Event triggers	4,419	468	424	5,311
# Event arguments	6,604	759	689	8,052

Table 2: ACE-2005 statistics.

contextualized representations of all tokens.

$$\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_n = Transformer(x_1, x_2, \cdots, x_n). \tag{2}$$

We omit the technical details of transformers for the clear representation, but the details are available in the original paper (Vaswani et al., 2017). In the end, we took the mean pooling of embeddings for tokens belonging to the target anchor word as one of its contextualized representation:

$$\mathbf{v} = \frac{\sum_{p_e \leq i \leq p_s} \mathbf{x}_i}{p_e - p_s}. \tag{3}$$

By grouping the acquired representations from all anchor sentences together, we get a cluster of embeddings for each pre-defined type, which can be used for the prediction. For trigger type E_i and argument type R_i, we denote the corresponding vector cluster as $\mathcal{V}^{E_i}$ and $\mathcal{V}^{R_i}$, respectively.

5 Prediction

We then introduce the prediction part. For each identified event, whose trigger and m arguments are denoted as t and $\mathcal{A} = a_1, a_2, \cdots, a_m$, we first acquire the contextualized representations for trigger and arguments following the same way as what we did for anchor words. Similar to the label representations, we acquire the event trigger representation without using masks and the argument embeddings with masks. We denote the resulting embeddings as $\mathbf{t}$ and $\mathbf{a}_1, \mathbf{a}_2, \cdots, \mathbf{a}_m$. After that, we compute the prediction score from t to a predefined event trigger type E as:

$$f(t, E) = Cos\_Dist(\mathbf{t}, \frac{\sum_{\mathbf{v}\in\mathcal{V}^E} \mathbf{v}}{|\mathcal{V}^E|}), \tag{4}$$

where Cos_Dist represents the cosine distance and $|\mathcal{V}^E|$ means the number of vectors in the cluster of E's label representations. Similarly, for any argument a and pre-defined argument type R, we compute the prediction score via:

$$f(a, R) = Cos\_Dist(\mathbf{a}, \frac{\sum_{\mathbf{v}\in\mathcal{V}^R} \mathbf{v}}{|\mathcal{V}^R|}). \tag{5}$$

After getting the initial predictions with cosine similarities, the next step would be leveraging the constraints to regularize the prediction results. Specifically, we model this problem as an integer linear programming (ILP) problem (Roth and tau Yih, 2004), which maximizes the following objective while satisfying the constraints in Table 1:

$$\operatorname*{argmax}_{I_t, I_a} \sum_{j\in|\mathcal{A}|} (\sum_{i\in|\mathcal{E}|} f(t, E_i) \cdot I_t(i) \cdot \lambda + \sum_{k\in|\mathcal{R}|} f(a_j, R_k) \cdot I_a(j,k)). \tag{6}$$

Here, λ is the hyper-parameter we use to balance the weight of trigger and argument predictions, and I_t and I_a record the final prediction for the trigger and arguments, respectively. I_t is a vector of integer variables with length $|\mathcal{E}|$, and I_a is a matrix of integer variables with the size $|\mathcal{A}| \times |\mathcal{R}|$.

6 Experiment Details

We follow (Lin et al., 2020) and use ACE-2005 (E^+) as the dataset. In total, ACE-2005 contains 33 event types and 22 role types. The original dataset provides the official training, development, and test splits. However, as the proposed model is zero-shot and we do not need any training data, we merge all of them together to be the test set, which is consistent with the setting in (Huang et al., 2018). Detailed statistics about ACE-2005 are presented in Table 2. Considering that (Huang et al., 2018) trains the model with the most frequent ten event types and tests on the other 23 types, we provide two evaluation settings: (A) Evaluation on the least 23 frequent event types and associated role types, which is consistent with the previous work; (B) Evaluation on all 33 event types, which is used to demonstrate the overall performance of our model on the whole dataset. We treat the trigger and argument classification as two separate ranking problems, and follow the previous work (Huang et al., 2018) to report Hit@1, Hit@3, and Hit@5.

Model	# Types		Event Triggers			Event Arguments		
	Train	Test	Hit@1	Hit@3	Hit@5	Hit@1	Hit@3	Hit@5

Table 3: Event trigger and argument classification results on ACE-2005. Best performing models are annotated with the bold font. Standard deviations are shown in brackets.

6.1 Baseline Methods

To the best of our knowledge, only two previous methods were used to solve event typing in a zero-shot manner, thus we compare with both of them:

1. **WSD-embedding** (Huang et al., 2018): The WSD baseline first obtains the sense of event mentions with a word sense disambiguation module (Zhong and Ng, 2010) and then acquires the sense embedding with the skip-gram model (Mikolov et al., 2013). During the inference, it can then map triggers and arguments to the candidate types with the pre-trained word sense embeddings.

2. **Transfer Learning** (Huang et al., 2018): The transfer-learning based zero-shot approach first learns to map the AMR parsing (Wang et al., 2015) result of events to a few observed event types and then apply the learned model to unseen event types. In the original paper, four experiment settings are provided, which are distinguished by the number of seen event types, and we consider all of them to be the baselines.

Besides them, we also present the performance of the "Frequency" baseline, which predicts all triggers and arguments with the most frequent types.

6.2 Implementation Details

We implement our model with Huggingface (Wolf et al., 2019) and use BERT-large (Devlin et al., 2019) as the pre-trained language model. For each anchor word, we randomly select ten anchor sentences from the NYT corpus (Sandhaus, 2008). λ is set to be 100. We implemented the ILP optimization with gurobi[3]. All other hyper-parameters are inherited from BERT. We repeat the experiments five times and report the average performance as well as the standard deviations. The effect of all hyper-parameters is carefully evaluated.

7 Result Analysis

From the results in Table 3, we can observe that:

1. Despite the difficulty of this task (we have 33 and 22 candidates types for triggers and arguments), our model can map 83% of the triggers and 54% of the arguments to the correct types, which shows that when the class labels are carefully designed, their semantics can serve as an excellent signal for the classification task.

2. Compared with the baseline method, our model doubles the performance on the selected 23 event type subset. The main improvement we made is that we do not only use the labels but also put them back into some real usage and then use the contextualized representations to represent them. By doing so, we can best represent the label semantics and leverage them for the classification task.

3. The dataset distribution is imbalanced. For example, 28.9% of the event triggers are "attack," which is relatively simple. This also explains why our model achieves higher performance for triggers on the whole dataset, where we need to map them to 33 types that include "attack", than

Table 5: Effect of different representation strategies.

the selected subset, where we only need to map them to 23 types but without “attack”.

7.1 Ablation Study

We present the following ablation studies to show the contribution of different modules:

1. **No Context**: One of the largest contributions of the proposed model is using contextualized representations to represent each label. To demonstrate the importance of the context, we try to remove them and acquire the label representation only with selected anchor words[4].

2. **BERT-base**: To demonstrate the contribution of a good representation model, we replace BERT-large with its weaker version (i.e., BERT-base (Devlin et al., 2019)).

From the results in Table 4, we can see that the context information is crucial to our success. Without the context, the anchor word embeddings can no longer effectively represent the label semantics. Besides that, a good language model also helps better merge the contextual information into the anchor words, which also shows that leveraging the context well is the key to our success.

7.2 Hyper-parameter Analysis

The effect of anchor sentence quantity n and trigger weight λ are shown in Figure 5(a) and 5(b), respectively. First of all, we can observe that ten anchor sentences are enough to achieve a good performance, which helps verify the motivation of this paper that with the careful usage, labels can serve as a crucial semantic signal for zero-shot classification tasks. For λ, as shown in Table 3, before the ILP regularization, the model performs much better on triggers than arguments, that is why we need to give more weights to the trigger (i.e., the model should not change the trigger prediction unless it is very certain about the argument prediction). On the other hand, λ cannot be infinitely large, otherwise, the ILP may simply ignore the argument prediction, which may also hurt the performance. To achieve the balance, we select $\lambda = 10$.

7.3 Representation Acquisition Strategy

As aforementioned, we adopt two different label representation strategies for triggers and arguments. Specifically, we kept the anchor words in the sentence for triggers while masking them for arguments. To clearly show the effectiveness of different strategies, we show the performance of different strategy combinations in Table 5. From the results, we can see that if we apply masks to the

---

[4] Context are also removed for candidate triggers and arguments. For arguments, as there is no context, we also remove the masks.

	P	R	F1
Trigger (I)	58.9	57.8	58.3
Trigger (I + C)	54.1	53.1	53.6
Trigger + Argument (I)	12.0	26.0	16.4
Trigger + Argument (I + C)	4.6	10.0	6.3

Table 6: Zero-shot event extraction performance. "I" and "C" mean the identification and classification.

trigger representations or remove the mask from the argument representation pine, the performance decreases. This observation verifies the assumption that event triggers are often textually similar to the trigger labels and thus keeping these words in the sentence can help to map them. On the other hand, event arguments are often named entities, which are often very different from the labels (e.g., "victim") textually, and what helps determine their roles is the context surrounding them. As a result, we achieve better performance when we mask these arguments and only leverage the context to generate the representations.

8 Zero-shot Event Extraction

Previous experiments have demonstrated that with the help of the label representations and the post-regularization, our zero-shot system can effectively map detected triggers and arguments to the correct types. However, if the goal is to automatically extract events from the raw documents, we still need the support from other NLP modules to identify the event triggers and arguments first. In this section, we present the performance of a zero-shot event extraction pipeline, which combines our classification model with other NLP tools.

8.1 Identification

The first step is identifying event triggers and arguments from the raw sentences. In our pipeline, we use a BERT-based SRL model (Shi and Lin, 2019) and a nominal SRL model[5] to detect verbal and nominal events. A limitation of these models is that they adopt a different event ontology (i.e., FrameNet (Baker et al., 1998)) from ACE-2005. As a result, they could miss some events or detect irrelevant events, which are not annotated as events under the ACE definition. To include more ACE-specified events, we include all nominal anchor words[6] in the sentences as triggers. To filter out events that are not covered by the ACE ontology, we introduce an additional filtering step, whose details are introduced in the next sub-section. Last but not least, considering that the definition of arguments in SRL systems varies from ACE, we include a mention detection module from CogCompNLP (Khashabi et al., 2018) to further detect mentions as argument candidates.

8.2 Filtering and Classification

For triggers, following the previous work (Huang et al., 2018), we first combine the 1,161 event types from FrameNet and 33 event types from the ACE ontology together. Duplicated event types are manually removed. As a result, we got 1,147 event types. For each detected event trigger, we try to map it to all 1,147 event types with the proposed zero-shot classification approach. Considering that 1,147 event types may still be not enough for covering all event types, we need to leave room for other events in the embedding space. To do so, for each event type, we automatically acquire a cluster radius by optimizing the F1 score over all anchor sentences (i.e., the distance from representations of anchor sentences for that type to the mean representation should be smaller than the radius while others should be larger than the radius). If a trigger is mapped to one of the 33 types in ACE and its cosine distance to the mean embedding of that type is smaller than the corresponding cluster radius, it will be categorized into that type. For arguments, we select all mentions that overlap with the ARG0 and ARG1 of selected triggers given by SRL systems to be candidate arguments. All selected triggers and arguments are jointly classified with the proposed classification model.

8.3 Result Analysis

The performance of our zero-shot event extraction pipeline is shown in Table 6. "Identification" requires the model to detect the correct spans of triggers and arguments. "Classification" requires the model to correctly classify the detected triggers and arguments. As the identification task is often viewed as the sequence labeling problem, where

---

[5] As no previous work has applied BERT to the nominal SRL task, we trained one BERT-based nominal SRL model by ourselves.

[6] Some event type labels are nominal (e.g., "bankruptcy") and some are verbal (e.g., "execute"). For nominal labels, we directly use them; for verbal labels, we use their nominal form (e.g., "execution") if available. As the used verb SRL system has already detected almost all verbal triggers, there is no need to add verbal keywords.

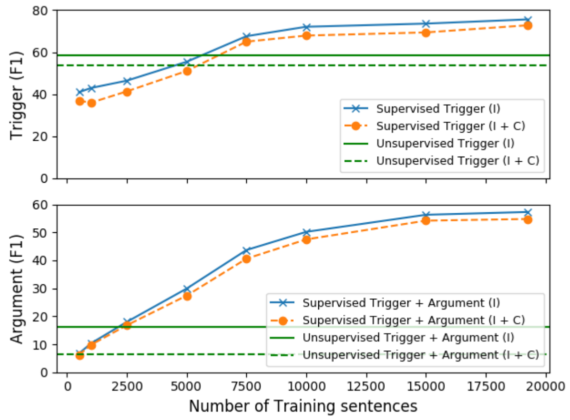

Figure 6: Comparison to the best supervised model.

the Recall@K metric is no longer suitable, we follow the previous work (Lin et al., 2020) to report Precision, Recall, and F1. For the "Argument" evaluation, we provide gold triggers. But for the "Trigger+Argument" evaluation, the model has to detect and classify the correct trigger and associated arguments. We also show the comparison of our system to the current best supervised model OneIE (Lin et al., 2020) in Figure 6. For triggers, our system achieves the comparable performance of the supervised model that is trained with about 6,000 training sentences, which is equivalent to approximately 75% of OneIE's full performance. Considering that our system does not use any annotation and can be easily applied to new datasets and new event definitions, such performance is quite encouraging. In the meantime, compared with triggers, our system cannot detect arguments very well, which is mainly due to poor identification performance. As demonstrated in Figure 7, this is mainly because SRL and ACE adopt different definitions of arguments. SRL requires the arguments to cover all the details, whereas arguments in ACE are often just the key entities. To solve this problem, we propose to use a mention detection module to detect mentions inside the arguments given by SRL systems. Consequently, we cover more gold arguments but also introduce noise. How to automatically identify arguments that fit the ACE definition is a problem worth exploring in the future.

9 Related Works

In this section, we introduce related works about the event extraction and NLP without annotation.

Figure 7: Case study for event extraction. Gold triggers and arguments are indicated with red and blue. Arguments detected by SRL and mention detection module are indicated with underlines and brackets.

9.1 Event Extraction

Previous event extraction works often aim at learning supervised models, employing either symbolic features (Ji and Grishman, 2008; Liao and Grishman, 2010; Liu et al., 2016) or distributed features (Chen et al., 2015b; Lin et al., 2020). To address the problem that supervised models cannot be easily applied to new types, (Huang et al., 2018) separates the event extraction task into two parts (i.e., identification and classification) and proposes a zero-shot transfer-learning classification framework to apply the model trained with seen event types to unseen ones. However, the prerequisite of their high performance is the similarity between seen and unseen event types. Unlike previous works, we do not use any annotation and only leverage the label semantics to classify event triggers and arguments. By combining our classification model and other NLP modules (i.e., SRL and mention detection), we achieve a decent zero-shot event extraction pipeline that can be easily applied to any new documents and event types.

9.2 NLP without Annotation

Solving NLP problems without using annotations has been explored in many NLP tasks including text classification (Chang et al., 2008; Yin et al., 2019), entity typing (Zhou et al., 2018), sequence classification (Rei and Sogaard, 2018), and intent detection (Xia et al., 2018). The idea of leveraging the label semantics was first proposed in the dataless classification framework (Chang et al., 2008), a predecessor name to what is now called zero-shot classification. The idea was to first map the text and labels into a common space using Explicit Semantic Analysis (ESA) (Gabrilovich and Markovitch, 2007) and then pick the label with the highest matching score. This direction was later extended in (Song and Roth, 2014; Chen et al., 2015a; Li et al., 2016a,b; Song et al., 2016). The most significant difference between our work and previous approaches is that, rather than using a fixed representation for each label, we use a group of contextualized embeddings as the representation.

10 Conclusion

In this paper, we present a novel zero-shot classification model for event triggers and arguments. By leveraging the rich semantics contained in labels and other constraints provided by the event definitions, we successfully classify 83% of event triggers and 54% of arguments to their correct types on the ACE-2005 dataset. The ablation study demonstrates that the contextualized usage of the labels and correct way of using the context is key to our success. Further experiments demonstrate that after combining the proposed zero-shot classification model with other available NLP tools, we can effectively extract and classify events without using any annotation. All the codes are submitted.

Abstract

Graph Attention Networks (GATs) have proven a promising model that takes advantage of localized attention mechanism to perform knowledge representation learning (KRL) on graph-structure data, e.g., Knowledge Graphs (KGs). While such approaches model entities' local pairwise importance, they lack the capability to model global importance relative to other entities of KGs. This causes such models to miss critical information in tasks where global information is also a significant component for the task, such as in knowledge representation learning. To address the issue, we allow the proper incorporation of global information into the GAT family of models through the use of scaled entity importance, which is calculated by an attention-based global random walk algorithm. In the context of KRL, incorporating global information boosts performance significantly. Experimental results on KG entity prediction against the state-of-the-arts sufficiently demonstrate the effectiveness of our proposed model.

1 Introduction

Graph Attention Networks (GATs) have been successfully applied to various tasks over graphs (Velickovic et al., 2018; Lee et al., 2018b), such as graph classification (Wu et al., 2019b; Lee et al., 2018a), link prediction (Abu-El-Haija et al., 2018), and node classification (Lee et al., 2019; Zhang et al., 2020a). GATs learn from the underlying graph structure by making use of localized attention mechanism (Wu et al., 2019a; Xu et al., 2019; Vashishth et al., 2020b), where the hidden representation of each node is computed by recursively aggregating and attending over its corresponding local neighbors' features, and the weighting coefficients are calculated inductively with self-attention strategy (Thekumparampil et al., 2018; Qian et al., 2018; Zhang et al., 2018). The original GATs perform only on single-relational homogeneous graphs (Velickovic et al., 2018; Wang et al., 2019b). Recent advancements were proposed to operate on more general and prevalent multi-relational graphs (Wang et al., 2019b; Hong et al., 2020; Nathani et al., 2019; Zhang et al., 2020c), such as the representative Knowledge Graphs (KGs) which contain multiple types of entities (nodes) and relationships (edges) (Zhou et al., 2018; Han et al., 2018; Wang et al., 2019a; Zhao et al., 2020). However, these approaches can only exploit localized features within the neighborhood of individual entities (Nathani et al., 2019; Busbridge et al., 2019; Zhang et al., 2020c). For some tasks, such simplified localized feature aggregation may be sufficient, but insufficient for knowledge representation learning (KRL) tasks that also need exploring global information (Xie et al., 2020).

In this paper, we concentrate on how to incorporate **global information** in **local attention** for knowledge representation learning. Specifically, we allow the proper incorporation of global information into the GAT family of models through the use of scaled entity importance, which is estimated by a global random walk algorithm upon the whole graph structural information. In KGs, entity importance[1] indicates the global significance or authority of an entity. Intuitively, it can be quite beneficial if an entity attends more to its "authoritative" neighbors that have high scores of global entity importance. For instance, a movie *"Titanic"* links to different actors, among which a superstar

---

[1] The notions of its counterparts, e.g., global node importance or object authority, have been widely studied in graphs (Li et al., 2012; Liu et al., 2017; Park et al., 2019), which enable a number of applications such as Web search (Brin and Page, 1998; Kleinberg, 1999), social network analysis (Weng et al., 2010), RecSys (Jing et al., 2014), query disambiguation (Makris et al., 2012; Saxena et al., 2020).

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1341–1351

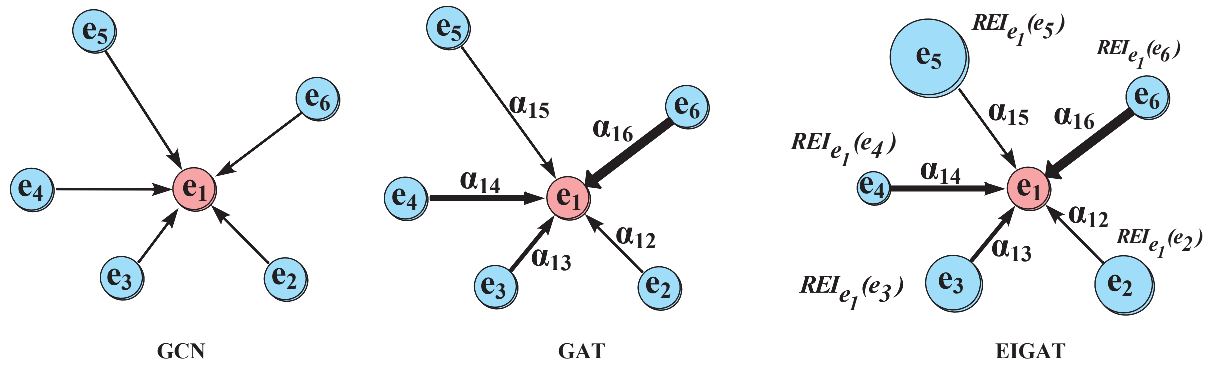

Figure 1: An illustration of Graph Neural Network architectures that model on a graph which is centered on node e_1 with its one-hop neighbors. Left: Graph Convolution Network (GCN); Center: Graph Attention Network (GAT); **Right: our proposed model (EIGAT) that incorporate global information in local attention through the use of relative entity importance (REI)**. $REI_{e_1}(e_i)$ is calculated by an attention-based global random walk algorithm upon the whole graph. GAT parameterizes the edge weights based on local attention score (α_{1i}, also represented by the distinct edge widths). Our EIGAT adds the relative importance score (represented by different scaling of nodes), which is derived from global structural information. Note that although relationship should be drawn in the knowledge graph, for clarity, we intentionally ignore it here, which does not hurt the presentation of the basic idea of our model in this paper.

(e.g. *"Leonardo Dicaprio"*) may be more indicative than other actors.

In this paper, we propose a novel **E**ntity **I**mportance-aware **G**raph **AT**tention Networks, EIGAT, which incorporates global entity importance in local attention mechanism for learning effective knowledge representations. As shown in Figure 1, we give a brief illustration of our proposed EIGAT, which is compared to early proposed GCN (Kipf and Welling, 2017) and GAT (Velickovic et al., 2018). In EIGAT, the importance scores of all entities are expected to be estimated upon global information and to be incorporated in local entity aggregation (Equation 5) for building better entity embeddings. In particular, we provide an attention-based random walk approach to estimate entity importance upon global structural information for serving EIGAT. We conduct extensive experiments on several different types of KGs by entity prediction against state-of-the-art methods, which sufficiently demonstrate our proposed EIGAT can successfully incorporating global information in local attention to improve knowledge representation learning.

The contributions of this paper are threefold:

- We propose to incorporate global information in local attention for knowledge representation learning.
- We propose EIGAT, a novel entity importance-aware graph attention networks which incorporate global entity importance into local entity aggregation.
- The extensive experimental results demonstrate the efficacy of our proposed model in link prediction.

2 Related Work

To make this paper self-contained, we introduce some related topics here on Knowledge Representation Learning and Graph Neural Networks (GNNs).

2.1 Knowledge Representation Learning (KRL)

In recent years, knowledge representation learning on KGs has been a hot research topic (Xiao et al., 2017; Shi and Weninger, 2017; Ebisu and Ichise, 2019; Balazevic et al., 2019; Zhang et al., 2020b). These methods roughly fall into four categories: (i) Translational-based models, which view relations as translations from a head entity to a tail entity, such as Trans(E, H, R, D and G) (Bordes et al., 2013; Wang et al., 2014; Lin et al., 2015; Ji et al., 2015; Xiao et al., 2016), ComplEx (Trouillon et al., 2016), JoBi ComplEx (Balkır et al., 2019). (ii) Tensor factorization based models, which assume the score of a triple can be factorized into several tensors, such as RESCAL (Nickel et al., 2011), NTN (Socher et al., 2013), DistMult (Yang et al., 2015), HOLE (Nickel et al., 2016). (iii) CNN-based models, which use convolution over embed-

Table 1: Different variants of Graph Neural Networks: GNN (Scarselli et al., 2008), GCN (Kipf and Welling, 2017), GAT (Velickovic et al., 2018), and our proposed model EIGAT that incorporates global information in local attention.

GNN-based Models	Node Aggregation	Operation	Key Concepts
GNN (Scarselli et al., 2008)	$x_j = f\left(l_j, l_{co[j]}, x_{ne[j]}, l_{ne[j]}\right)$	$f(\cdot)$	Transduction function
GCN (Kipf and Welling, 2017)	$\mathbf{E}^\ell = \sigma\left(\tilde{D}^{-\frac{1}{2}}\tilde{A}\tilde{D}^{-\frac{1}{2}}\mathbf{E}^{\ell-1}W^{\ell-1}\right)$	$\tilde{D}^{-\frac{1}{2}}\tilde{A}\tilde{D}^{-\frac{1}{2}}$	Convolutional operation
GAT (Velickovic et al., 2018)	$\vec{\mathbf{e}_j}^\ell = \sigma\left(\sum_{e_i \in In(e_j)} \alpha_{ij}^\ell \cdot W^{\ell-1}\vec{\mathbf{e}_i}^{\ell-1}\right)$	α_{ij}	Local attention
EIGAT (our proposed)	$\vec{\mathbf{e}_j}^\ell = \sigma\left(\sum_{e_i \in In(e_j)} REI_{e_j}(e_i)^\ell \sum_{k \in \mathcal{R}_{ij}} \alpha_{ikj}^\ell \cdot \vec{\mathbf{v}_{ikj}}^\ell\right)$	$REI_{e_j}(e_i),\ \alpha_{ikj}$	Global information + Local attention

dings to predict links, such as ConvE (Dettmers et al., 2018), ConvKB (Nguyen et al., 2018), InteractE (Vashishth et al., 2020a), ReInceptionE (Xie et al., 2020), and ParamE (Che et al., 2020). (iv) Graph neural network-based models, such as R-GCN (Schlichtkrull et al., 2018), A2N (Bansal et al., 2019), Nathani's (Nathani et al., 2019), RGHAT (Zhang et al., 2020c), ATTH (Chami et al., 2020), which yielded state-of-the-art performance for KRL. Along this line, we focuses on a GNN-based approach to deal with knowledge representation learning task.

2.2 Graph Attention Networks (GATs)

Graph Neural Networks (GNNs) develop a deep neural network to deal with arbitrary graphs for representation learning (Scarselli et al., 2008; Zhou et al., 2019; Hou et al., 2020). Graph Convolutional Networks (GCNs) are one of their most prominent progress (Schlichtkrull et al., 2018; Wu et al., 2019a; Xu et al., 2019; Vashishth et al., 2020b), which generalize local convolutional operation on the graph-structured data, i.e. gather information from one-hop neighbors and all neighbors contribute equally in the message passing. Inspired by the successful development of the attention mechanism in NLP and CV, Velickovic et al. (2018) proposed Graph Attention Networks (GATs) by incorporating local attention mechanism (Vaswani et al., 2017; Qian et al., 2018; Lu and Li, 2020) into GCNs, which calculate the hidden states of each node by attending over its neighbors (Thekumparampil et al., 2018; Lee et al., 2018b; Yang et al., 2019).

Recently, several advanced extensions of GATs were proposed for operating on knowledge graphs. Han et al. (2018) proposed to jointly apply attention to KGs and external text data. Busbridge et al. (2019) proposed RGAT by extending non-relational GATs to incorporate relational information, but with poor performance. Nathani et al. (2019) proposed a triple-level attention model that captures the integrated features of both entity and relation in a given entity's neighborhood, and Zhang et al. (2020c) proposed a two-level hierarchical attention mechanism. These studies are related to our work in the sense that we all use GNNs to capture more structural information in KGs. However, all of them ignore global information in local attention computation.

Most recently, (Xu et al., 2020) proposed a Transformer-based model to enhance the copy mechanism for abstractive summarization by considering the global importance of each source word based on the degree centrality in the Transformer, which inspires our idea of incorporating global information in local attention for KRL. Table 1 summarizes the key concepts and other different settings of GNNs.

3 Methodology

In this section, we introduce the details of the proposed EIGAT model that incorporates global information in local attention for knowledge representation learning on KGs. We start by describing a single entity importance-aware graph attention layer, which is the building block of our model's overall architecture. Before that, we briefly introduce the notations of this paper.

Notations. In a graph attention networks with L layers, the input to ℓ-th layer ($\ell = 1, \ldots, L$) are two embedding sets: **(1)** the *output entity embeddings* from (ℓ-1)-th layer which is represented by a matrix $\mathbf{E}^{\ell-1} \in \mathbb{R}^{\eta^{\ell-1} \times N_e}$, $\mathbf{E}^{\ell-1} = \{\vec{\mathbf{e}_1}^{\ell-1}, \vec{\mathbf{e}_2}^{\ell-1}, \ldots, \vec{\mathbf{e}_{N_e}}^{\ell-1}\}$, where N_e is the number of entities, and $\eta^{\ell-1}$ is the dimension of output entity embedding in (ℓ-1)-th layer. **(2)** the *output relationship embeddings* from (ℓ-1)-th layer, denoted by a matrix $\mathbf{R}^{\ell-1} \in \mathbb{R}^{\zeta^{\ell-1} \times N_r}$, $\mathbf{R}^{\ell-1} = \{\vec{\mathbf{r}_1}^{\ell-1}, \vec{\mathbf{r}_2}^{\ell-1}, \ldots, \vec{\mathbf{r}_{N_r}}^{\ell-1}\}$, where N_r and $\zeta^{\ell-1}$ represent the number of relationships and the output relationship's feature dimension in (ℓ-1)-th layer, respectively. The ℓ-th layer then produces the corresponding new output embedding matrices (of potentially different cardinality), $\mathbf{E}^{\ell} \in \mathbb{R}^{\eta^{\ell} \times N_e}$ and $\mathbf{R}^{\ell} \in \mathbb{R}^{\zeta^{\ell} \times N_r}$. Specifically, we describe the ℓ-th graph attention layer.

3.1 Local Attention Evaluation

A triple relation $t_{ij}^{k} = (e_i \xrightarrow{r_k} e_j)$ indicates a relationship r_k between head entity e_i and tail entity e_j. Following (Nathani et al., 2019), the representation $\vec{\mathbf{v}_{ikj}}^{\ell}$ of the triple t_{ij}^{k} is built as follows:

$$\vec{\mathbf{v}_{ikj}}^{\ell} = \mathbf{W}_1^{\ell} \cdot \left[\vec{\mathbf{e}_i}^{\ell-1} \| \vec{\mathbf{r}_k}^{\ell-1} \| \vec{\mathbf{e}_j}^{\ell-1}\right], \tag{1}$$

where $\mathbf{W}_1^{\ell}$ denotes a linear transformation matrix in ℓ-th layer, $\vec{\mathbf{e}_i}^{\ell-1}$, $\vec{\mathbf{r}_k}^{\ell-1}$ and $\vec{\mathbf{e}_j}^{\ell-1}$ denote the output embeddings of e_i, r_k and e_j in (ℓ-1)-th layer, respectively. $\|$ represents concatenation. We then calculate the absolute relation attention value b_{ikj}^{ℓ} of the triple t_{ij}^{k}.

$$b_{ikj}^{\ell} = \text{LeakyReLU}\left(\mathbf{W}_2^{\ell} \cdot \vec{\mathbf{v}_{ikj}}^{\ell}\right), \tag{2}$$

where $\mathbf{W}_2^{\ell}$ and LeakyReLU are a linear weight vector in ℓ-th layer and a non-linearity active function respectively that act upon the embedding $\vec{\mathbf{v}_{ikj}}^{\ell}$ in turn. We then utilize *softmax* to evaluate the relative relation attention value α_{ikj}^{ℓ} of the triple t_{ij}^{k} in ℓ-th layer.

$$\alpha_{ikj}^{\ell} = \text{softmax}_{ik}(b_{ikj}^{\ell}) = \frac{\exp\{b_{ikj}^{\ell}\}}{\sum\limits_{e_n \in In(e_j)} \sum\limits_{r \in \mathcal{R}_{nj}} \exp\{b_{nrj}^{\ell}\}}. \tag{3}$$

$In(e_j)$ denotes the neighbors pointing to targeted tail entity e_j, $\mathcal{R}_{nj}$ denotes the set of relationships between e_n and e_j.

3.2 Global Entity Importance Estimation

To obtain global entity importance $EI(e_i)$ of an entity e_i, we formally introduce a relation attention-based global random walk method, as follows:

$$EI(e_i)^t = (1-d) + d \times \sum_{e_m \in In(e_i)} \sum_{r \in \mathcal{R}_{mi}} \frac{b_{mri}}{\sum\limits_{e_n \in Out(e_m)} \sum\limits_{\bar{r} \in \mathcal{R}_{mn}} b_{m\bar{r}n}} EI(e_m)^{t-1}, \tag{4}$$

where d is a hyperparameter denoting the probability that an imaginary surfer randomly moves to a neighboring entity. $(1-d)$ denotes the probability of teleporting to any other entities randomly, which is able to alleviate the *information island problem* caused by the isolated entities that lack of any in-degree or out-degree neighbors (e.g. #median in-degree=0 in NELL-995 in Table 2). $Out(e_m)$ denotes the neighborhoods that an entity e_m points to. $EI(e_m)^{t-1}$ denotes the EI score of the entity e_m in (t-1)-th iteration. The random walk distance[2] t depends on both the number of attention layers L and training epochs C, $t \in (1, L \times C]$. The relation weights (e.g. b_{mri}) are calculated by Equation (2). Unlike conventional fixed weights-based random walk methods (Mihalcea and Tarau, 2004; Florescu and Caragea, 2017), a novelty is that the dynamic relation weights (e.g. b_{mri}) are iteratively and automatically optimized during training by the graph attention mechanism. In line with the theoretical desiderata for modeling node importance in MRGs, this method develops the following essential characteristics: **(i)** *Neighborhood-awareness*, i.e. neighboring EI scores can be taken into account when a given entity's importance score is modeled. **(ii)** *Relationship-awareness*, i.e. different relationships could play a different role in propagating EI score. **(iii)** *Centrality-awareness*, i.e. more central nodes inherently and reasonably would be more important than less central nodes. **(iv)** *Universal and flexible*, i.e. it utilizes only graph global structural information.

3.3 Incorporate Global Information in Local Attention

Though attention mechanism can assign different importance to nodes via learned weights, it is still a local computation. The attention value, e.g., α_{ikj} in Equation (3), is the function of pairwise feature interaction within local neighborhood and do not take account of entity importance from global graph structure. To this end, we incorporate global information in local attention computation, as shown in Figure 1 (EIGAT).

Specifically, to generate the output embedding $\vec{\mathbf{e}_j}^{\ell}$ of tail entity e_j in ℓ-th layer, we incorporate global relative head entity importance $REI_{e_j}(e_i)^{\ell}$ in local attention to conduct entity aggregation with its associated triple representations $\vec{\mathbf{v}_{ikj}}^{\ell}$ weighted

---

[2] To denote EI score of e_i in ℓ-th layer explicitly, we omit the training epoch symbol and denote it as $EI(e_i)^{\ell}$ in the following.

by their relative attention values α_{ikj}^{ℓ} , as follows:

$$\vec{\mathbf{e}}_j^{\,\ell} = \sigma\left(\sum_{e_i \in In(e_j)} REI_{e_j}(e_i)^{\ell} \sum_{k \in \mathcal{R}_{ij}} \alpha_{ikj}^{\ell} \cdot \vec{\mathbf{v}_{ikj}}^{\ell}\right), \quad (5)$$

and

$$\begin{aligned} REI_{e_j}(e_i)^{\ell} &= \mathrm{softmax}_{In(e_j)}(EI(e_i)^{\ell}) \\ &= \frac{\exp\{EI(e_i)^{\ell}\}}{\sum\limits_{e_i' \in In(e_j)} \exp\{EI(e_i')^{\ell}\}}, \forall e_i \in In(e_j)\,. \end{aligned} \quad (6)$$

In Eq. (5), we bring in global relative entity importance $REI_{e_j}(e_i)^{\ell}$ of different head entities in $In(e_j)$ for learning more about those significant neighboring entities, and thus could get better knowledge representations for the targeted tail entity e_j.

To stabilize the learning process of self-attention, as suggested by (Velickovic et al., 2018), we employ multi-head attention. Specifically, M independent attention mechanisms execute the transformation of Eq. (5), and then their features are concatenated as:

$$\vec{\mathbf{e}}_j^{\,\ell} = \Big\Vert_{m=1}^{M} \sigma\left(\sum_{e_i \in In(e_j)} REI_{e_j}(e_i)^{\ell,m} \sum_{k \in \mathcal{R}_{ij}} \alpha_{ikj}^{\ell,m} \cdot \vec{\mathbf{v}_{ikj}}^{\ell,m}\right) \quad (7)$$

We conduct a linear transformation on input relationship embedding $\vec{\mathbf{r}_k}^{\ell-1} \in \mathbb{R}^{\zeta^{\ell-1}}$ in ℓ-th layer as:

$$\vec{\mathbf{r}_k}^{\ell} = \mathbf{W}^{\ell,\mathcal{R}} \cdot \vec{\mathbf{r}_k}^{\ell-1}, \quad (8)$$

where $\mathbf{W}^{\ell,\mathcal{R}} \in \mathbb{R}^{\zeta^{\ell} \times \zeta^{\ell-1}}$ is a weight matrix, $\zeta^{\ell-1}$ and ζ^{ℓ} are dimensions of input and output relationship embeddings, respectively. $\vec{\mathbf{r}_k}^{\ell} \in \mathbb{R}^{\zeta^{\ell}}$ represents the output relationship embedding in the ℓ-th layer.

4 Model Architecture

Our model follows an encoder-decoder framework: **(i)** the encoder model includes L attention layers, **(ii)** the decoder model provides a scoring function (Eq. 11) to calculate the likelihood of given triples being valid. Based on it, the KG incompleteness issue is expected to be alleviated by link prediction (Section 5), i.e., inferring possible missing relations, e.g. $(e_i, r_k, ?)$ or $(?, r_k, e_j)$.

4.1 Encoder

Based on a single attention layer introduced above, we build the overall architecture of our encoder model with L layers. In practice, we set L=2 for our encoder model. In the final L-th layer, instead of concatenation (Equation 7), we employ averaging and delay applying the final non-linearity activation:

$$\vec{\mathbf{e}}_j^{\,L} = \sigma\left(\frac{1}{M}\sum_{m=1}^{M} \sum_{e_i \in In(e_j)} REI_{e_j}(e_i)^{L,m} \sum_{k \in \mathcal{R}_{ij}} \alpha_{ikj}^{m} \vec{\mathbf{v}_{ikj}}^{L,m}\right) \quad (9)$$

To keep initial entity information in the final embedding, we obtain the final entity embedding $\vec{\mathbf{e}}^{\star} \in \mathbb{R}^{\eta^L}$ by combining the transformed initial embeddings $\vec{\mathbf{e}}^0 \in \mathbb{R}^{\eta^0}$ and the output entity embedding $\vec{\mathbf{e}}^L \in \mathbb{R}^{\eta^L}$ of the L-th layer, as follows:

$$\vec{\mathbf{e}}^{\star} = \mathbf{W}^{\star} \cdot \vec{\mathbf{e}}^0 + \vec{\mathbf{e}}^L, \quad \forall e \in \mathcal{E}\,. \quad (10)$$

$\mathbf{W}^{\star} \in \mathbb{R}^{\eta^L \times \eta^0}$ is a projecting matrix. The initial entity embeddings (i.e. $\vec{\mathbf{e}}^0, \forall e \in \mathcal{E}$) and relationship embeddings (i.e. $\vec{\mathbf{r}}^0, \forall r \in \mathcal{R}$) are pre-trained by Bordes et al. (2013).

4.2 Decoder

Among the existing KG completion (KGC) models, we utilize the most recent model ConvKB (Nguyen et al., 2018) as decoder model[3]. Given a triple t_{ij}^k, the scoring function is formally defined as:

$$f(t_{ij}^k) = \Big(\Big\Vert_{m=1}^{|\Omega|} g([\vec{\mathbf{e}_i}^{\star}, \vec{\mathbf{r}_k}^{L}, \vec{\mathbf{e}_j}^{\star}] * \omega^m)\Big) \cdot \mathbf{W}\,, \quad (11)$$

where Ω denotes the set of filters, τ=$|\Omega|$ and $\omega \in \Omega$. Ω and $\mathbf{W}$ are shared parameters and independent of e_i, r_k and e_j. $g(\cdot)$ is an activation function such as ReLU. $*$ denotes a convolution operator. These τ feature maps are concatenated into a single vector $\in \mathbb{R}^{\tau\phi}$ which is then computed with a weight vector $\mathbf{W} \in \mathbb{R}^{\tau\phi}$ via a dot product to give a likelihood score for the triple t_{ij}^{κ}. ϕ denotes the dimension of entity and relation embeddings. In practice, we set ϕ=η^L=ζ^L for ConvKB.

4.3 Optimization

We utilize a two-step training procedure for the encoder-decoder framework, which is a routine optimization way for it (Zhou et al., 2019). **(i)** We first train the encoder model to learn the embeddings of entities and relationships, by minimizing

---

[3] We choose ConvKB here, and it is not difficult for other KGC methods, such as CapsE (Nguyen et al., 2019), ConvE (Dettmers et al., 2018), etc. Note that we also tried different models as decoder, but found that ConvKB performs best.

Table 2: Statistics of datasets.

Datasets	#Entities	#Rel	#Edges				Mean in-degree	Median in-degree	Density
			Train	Validation	Test	Total			
Kinship	104	25	8544	1068	1074	10,686	82.15	82.5	0.998
FB15k-237	14,541	237	272,115	17,535	20,466	310,116	18.71	8	0.001
NELL-995	75,492	200	149,678	543	3992	154,213	1.98	0	2.71E-5

a *hinge-loss* function, as follows:

$$\mathcal{L}_1 = \sum_{t_{ij}^k \in \mathcal{G}} \sum_{{t_{ij}^k}' \in \mathcal{G}'} \max \left\{ h_{{t_{ij}^k}'} - h_{t_{ij}^k} + \gamma, 0 \right\} . \tag{12}$$

Here, $h_{t_{ij}^k} = \|\vec{\mathbf{e}_i}^{\star} + \vec{\mathbf{r}_k}^{L} - \vec{\mathbf{e}_j}^{\star}\|_{\ell 1}$ indicates the translational scoring function of the triple t_{ij}^{κ} (Bordes et al., 2013). $\gamma > 0$ is a margin hyper-parameter. **(ii)** We then train and learn the parameters of the decoder model ConvKB for link prediction , by minimizing a *soft-margin loss* function, as follows:

$$\mathcal{L}_2 = \sum_{t_{ij}^k \in \{\mathcal{G} \cup \mathcal{G}'\}} \log \left(1 + \exp \left(l_{t_{ij}^k} \cdot f(t_{ij}^k) \right) \right) + \lambda \left\| \mathbf{W} \right\|_2^2 , \tag{13}$$

in which, $l_{t_{ij}^k} = \begin{cases} 1, & t_{ij}^k \in \mathcal{G} \\ -1, & t_{ij}^k \in \mathcal{G}' \end{cases}$. $\mathcal{G}$ and $\mathcal{G}'$ are the sets of positive triples and negative triples, respectively.

$$\mathcal{G}' = \{t_{i'j}^k | e_i' \in \mathcal{E} \setminus e_i\} \cup \{t_{ij'}^k | e_j' \in \mathcal{E} \setminus e_j\} . \tag{14}$$

5 Experiments

We evaluate the effectiveness of our proposed model EIGAT by link prediction (determined by Equation 11), which aims to infer possible missing relations, i.e., predict e_j given $(e_i, r_k, ?)$ or predict e_i given $(?, r_k, e_j)$.

5.1 Datasets

We use three public benchmark datasets for link prediction experiments, including: *Kinship* (Lin et al., 2018), *NELL-995* (Xiong et al., 2017), *FB15K-237* (Toutanova et al., 2015), where we discard another popular dataset *WN18RR* due to its too sparse to learn global information. The basic statistics of all datasets are included in Table 2. To explore the performance of our proposed model on different datasets with different global topology characteristics, we compute their density value (Coleman and Moré, 1983) and report them in Table 2. Since the densities in *NELL-995* is sparser than *Kinship* and *FB15K-237*, and its median in-degree even is 0, it is relative hard for global entity importance estimation in *NELL-995*.

Definition 1. ***(Graph Density)****. Graph density aims to measure how sparse a graph is. Similar to (Coleman and Moré, 1983), given a graph $\mathcal{G}$, it's formally defined as follows:*

$$D(\mathcal{G}) = \frac{E}{N(N-1)} , \tag{15}$$

where N denotes the number of nodes in $\mathcal{G}$, and E denotes the number of edges in $\mathcal{G}$. The lower the $D(\mathcal{G})$, the sparser the graph is.

5.2 Baselines

To demonstrate the effectiveness of our proposed model EIGAT for link prediction, we compare it with the following state-of-the-art (SOTA) baselines:

- TransE (Bordes et al., 2013): a most widely used and early KGC models.
- DistMult (Yang et al., 2015): a popular tensor factorization-based KGC model which uses a bi-linear scoring function to calculate knowledge triples' scores.

- ComplEx (Trouillon et al., 2016): an advanced extension of DistMult which encodes entities and relationships into complex vector space instead of real-valued vector space.
- ConvE (Dettmers et al., 2018): a popular convolutional network-based KGC model.
- ConvKB (Nguyen et al., 2018): another SOTA convolutional network-based KGC model.
- R-GCN (Schlichtkrull et al., 2018): an advanced extension of GCN that can effectively model multi-relational data.
- Nathani's (Nathani et al., 2019): a recent KGC model that models the local neighborhood via graph relational attention network.
- A2N (Bansal et al., 2019): a recent model that learns query-dependent representations of entities based on a GNN structure.
- HAKE (Zhang et al., 2020b): a SOTA KGC model that models semantic hierarchies
- InteractE (Vashishth et al., 2020a):a recent extension of ConvE that increase the interaction between relation and entity embeddings.
- ReInceptionE (Xie et al., 2020): a recent extension of ConvE that uses local-global structural information.
- ParamE (Che et al., 2020): another extension of ConvE that use relation embeddings.
- ATTH (Chami et al., 2020): a SOTA model that use hyperbolic space and attention-based geometric transformation.
- RGHAT (Zhang et al., 2020c): a SOTA KGC model that models the local neighborhood via hierarchical attention mechanism.

5.3 Evaluation Protocol

We utilize ranking criteria for evaluation. For each testing triple, we remove the head entity or tail entity and replace it by each of the entities in $\mathcal{E}$ in turn. The model scores of the corrupted triples would be computed by the decoder model (Eq. 11) and then sorted by descending order. We can obtain the exact rank of the correct triple in the candidates. Similar to most baselines, we report the experimental results in "Filter" setting, i.e. removing corrupted triples that are already present in datasets during ranking. The evaluation metrics include: the mean reciprocal rank (MRR), mean rank (MR), and the proportion of correct entities ranked in the top N (HITS@N, N=1, 3, 10).

5.4 Training Protocol

Table 3 and Table 4 report the detailed hyperparameter settings of encoder and decoder models for EIGAT, respectively. In the training, we set M=2 heads attention mechanism. The final dimensions of entity and relation embeddings are set to 200. The slop parameter α of LeakyReLU in Eq. (2) is set as 0.2 on all datasets. We use auxiliary relations from 2-hop neighborhood to aggregate more information about the neighborhoods. EI scores are initialized randomly in (0,1). We utilize a typical value for d = 0.85 (Mihalcea and Tarau, 2004; Florescu and Caragea, 2017).

5.5 Results and Analysis

Table 5 and Table 6 demonstrate the results of link prediction (significance level of 0.05). We can observe that: **(i)** The results clearly indicate that

Table 6: **Link prediction results** on *FB15K-237*. The results of baselines are directly taken from the original papers. The best scores are in **bold**.

ParamE (Che et al., 2020)	-	0.399	31.0	43.8	57.6
RGHAT (Zhang et al., 2020c)	196	0.522	46.2	54.6	63.1
EIGAT (Ours)	**154**	**0.541**	**47.6**	**57.1**	**66.1**

EIGAT significantly and consistently outperforms all state-of-the-art baselines on most metrics in all benchmark datasets, which demonstrate the effectiveness of our proposed model. **(ii)** The advantages EIGAT compared to baselines on *NELL-995* seem to be smaller than others. It is because that rich global structural information in relative dense graphs, i.e., *Kinship*, and *FB15K-237*, leads to more effective entity importance estimation by global random walk methods, comparing with less global structural knowledge in relative sparse graphs, i.e., *NELL-995*. The results demonstrate *NELL-995* is more difficult than others for EIGAT to learn, but the comparable results also verify the effectiveness and robustness of our model on both scenarios.

5.6 Ablation Study

To analyze the behavior of global information in EIGAT, we compare EIGAT with EIGAT-Remove-global (i.e., removing global entity importance from EIGAT). The comparison results in Table 7 indicate that EIGAT achieves improvements against EIGAT-Remove-global on all metrics. In particular, on MR, EIGAT surpasses EIGAT-Remove-global by a large margin 56. The results demonstrate our model can successfully take account of global information in local attention to aggregate more effective entity representations.

5.7 Case Study

Table 8 gives examples of entity prediction results of EIGAT on the FB15k-237 testing set (predicting tail entities). This illustrates the efficacy of our proposed EIGAT. Given a head entity and a relation, the top predicted tail entities (and the true one) are depicted. Even if the true fact is not always at the best front, the predicted results can still reflect common-sense.

Table 7: **Ablation Study**. Link prediction results by different variants of our model on *FB15K-237*.

6 Conclusion and Future Work

In this paper, we propose to incorporate global information in local attention for knowledge representation learning and introduce a novel GAT-based model that incorporates global entity importance. In particular, we provide an attention-based global random walk approach to estimate entity importance. The experimental results of entity prediction demonstrate that our model can successfully take into account global information in local attention to improve knowledge representation learning. Interesting future work directions include generalizing EIGAT to other relational graphs (e.g. heterogeneous information network (HIN), user-item graph in recommendation system), and exploring an advanced variant of EIGAT in a semi-supervised learning scenario.

Exploiting Position Bias for Robust Aspect Sentiment Classification

Fang Ma*, **Chen Zhang***, **Dawei Song**†

`{mfang,czhang,dwsong}@bit.edu.cn`

Abstract

Aspect sentiment classification (ASC) aims at determining sentiments expressed towards different aspects in a sentence. While state-of-the-art ASC models have achieved remarkable performance, they are recently shown to suffer from the issue of robustness. Particularly in two common scenarios: when domains of test and training data are different (out-of-domain scenario) or test data is adversarially perturbed (adversarial scenario), ASC models may attend to irrelevant words and neglect opinion expressions that truly describe diverse aspects. To tackle the challenge, in this paper, we hypothesize that position bias (i.e., the words closer to a concerning aspect would carry a higher degree of importance) is crucial for building more robust ASC models by reducing the probability of mis-attending. Accordingly, we propose two mechanisms for capturing position bias, namely position-biased weight and position-biased dropout, which can be flexibly injected into existing models to enhance representations for classification. Experiments conducted on out-of-domain and adversarial datasets demonstrate that our proposed approaches largely improve the robustness and effectiveness of current models.[1]

1 Introduction

Aspect sentiment classification (ASC) is an important sub-task of sentiment classification. It aims to identify the sentiment polarity (i.e., negative, neutral, or positive) of a specified aspect in a sentence. Take "*Great food but the service was bad.*" as an example. For aspects *food* and *service*, their corresponding sentiment polarities are *positive* and *negative*, respectively.

Scenario	**Example**	**Pred./Lb.**
I.D.	Great food but the service was bad !	neg./neg.
O.O.D.	The battery has never worked well .	pos./neg.
Adv.	Awful food but the service was great !	neg./pos.

Figure 1: An illustration of how an ASC model IAN (Ma et al., 2017) might fail. Gradient saliency maps (Simonyan et al., 2014) with respect to the embedding of each word in I.D., O.O.D., and Adv. scenarios, along with the model predictions (Pred.) and corresponding ground truth labels (Lb.), are provided. Underlined words are aspects.

A challenge in ASC is how to model semantic relations between aspect terms and their contexts, which requires an ASC model to be only sensitive to the sentiment words actually depicting the target aspect terms. Although previous ASC models (Tang et al., 2016b; Li et al., 2018; Zhang et al., 2019a; Xu et al., 2019; Wang et al., 2020; Tang et al., 2020) have achieved promising results by modeling complex interactions between aspects and contexts, these models have recently been shown to suffer from the lack of robustness (Xing et al., 2020). The issue is particularly severe in two scenarios: 1) out-of-domain (O.O.D.) scenario: ASC models that perform well on training data often fail to generalize to test data in another domain; 2) adversarial (Adv.) scenario: ASC models can be easily fooled by small adversarially perturbed inputs, e.g. synonymous word substituted ones. To our best knowledge, none of current ASC models have been targeted at alleviating the robustness issue in above-mentioned two scenarios.

To fill this gap, inspired by a recent finding that highlighting words close to a target aspect (termed as *position bias*) would boost in-domain (I.D.) effectiveness of a model (Zhang et al., 2019b), we hypothesize that such position bias is also crucial for a robust ASC model in O.O.D. and Adv. sce-

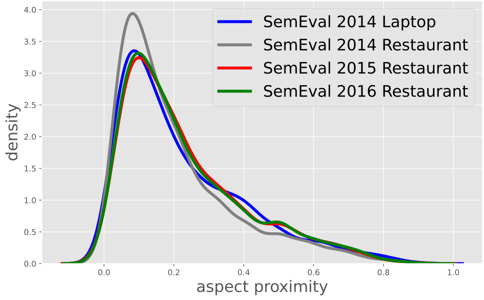

Figure 2: Aspect proximity distributions of different benchmarks, visualized with the kernel density estimation.

narios. Figure 1 shows an illustrative example of an ASC model that fails in the two scenarios due to mis-attending. In contrast, with position bias, a model tends to focus more on words nearer to the aspect, thus reducing the probability of mis-attending. Concretely, we propose two mechanisms: position-biased weight and position-biased dropout. The former assigns an inductive weight to each word according to its position proximity to the aspect. The latter gives each word a probability of being reserved (or dropped out) according to its proximity relation to the aspect. In doing so, position-biased weight degrades the significance of words that are not close enough to the aspect, while position-biased dropout will drop those likely irrelevant words at high probabilities.

Essentially, position bias is quantitatively evidenced in commonly used benchmarks. With annotated aspect-opinion pairs offered by Fan et al. (2019), we can calculate position proximity between any pair of aspect and opinion (in short, aspect proximity) in a sentence. The aspect proximity is computed by dividing the relative distance between a pair of aspect and opinion by the length of the corresponding sentence. Therefore, we can plot aspect proximity distributions of these benchmarks with kernel density estimation, as shown in Figure 2. These distributions indicate the aspect proximity is small at a high probability, thereby position bias is a reasonable inductive bias.

Extensive experiments are conducted on SemEval and ARTS datasets (Xing et al., 2020). The results show that incorporating the proposed position bias mechanisms would lead to more robust ASC models in both out-of-domain and adversarial scenarios. Furthermore, in terms of flexibility, the proposed methods can be easily adapted by subsequent models.

2 Capturing Position Bias

This section describes the proposed position-biased weight and position-biased dropout for capturing position bias. Formally, an n-word sentence containing a target m-word aspect term is formulated as $S = \{w_0, w_1, \ldots, w_\gamma, w_{\gamma+1}, \ldots, w_{n-1}\}$, where γ denotes the start index of the aspect term. By resorting to either a pre-trained word embedding (Bengio et al., 2003) or a pre-trained language model (Devlin et al., 2019), we can represent the sentence as $V = \{e_0, e_1, \ldots, e_\gamma, e_{\gamma+1}, \ldots, e_{n-1}\}$. We can then use the position-biased weight and dropout to refine V and generate an enhanced representation, denoted as $E = \{h_0, h_1, ...h_\gamma, h_{\gamma+1}, ..., h_{n-1}\}$. E can then be incorporated into the model, i.e., any further structures for the model will be built upon E, instead of V, to predict sentiment polarities associated with diverse aspects.

Position-biased Weight Generally, the sentiment polarity of an aspect term is determined by its context, which are the words around the aspect term (Zhang et al., 2019b). Thus we can leverage relative position information to calculate weights of context words, with the aim to degrade the significance of those words that are far away from the aspect. Position-biased weight, denoted as $p_i \in (0, 1)$, is computed as:

$$p_i = \begin{cases} 1 - \frac{\gamma - i}{n-m} & 0 \leq i < \gamma \\ \frac{1}{n-m} & \gamma \leq i < \gamma + m \\ 1 - \frac{i-\gamma-m+1}{n-m} & \gamma + m \leq i < n \end{cases} \quad (1)$$

Then we compute h_i as: $h_i = p_i \cdot e_i$.

Position-biased Dropout Dropout (Srivastava et al., 2014; Sennrich et al., 2016) randomly sets elements in a feature vector to zeros. The word-level dropout can model semantic and syntactic compositionality and reduce input redundancy (Iyyer et al., 2015). Motivated by this idea, we give each word a probability of being reserved according to its position proximity to the aspect. The aim is to preserve those words that are close enough to the aspect and drop the rest. The probability that the i-th word will be preserved can be computed as:

$$z_i \sim \text{Bernoulli}(p_i) \quad (2)$$

where $\text{Bernoulli}(p_i)$ denotes that z_i equals to 1 with p_i and equals to 0 with $1 - p_i$. The i-th word is dropped out if z_i is 0. Likewise, h_i can be attained by multiplying z_i and e_i.

3 Experiments

Datasets To empirically evaluate a model's O.O.D. robustness, we conduct experiments on two domains from SemEval 2014 (Pontiki et al., 2014) dataset (SEMEVAL): one is laptop (SEMEVAL-LAP) and the other is restaurant (SEMEVAL-REST). For Adv. robustness, we experiment with the Aspect Robustness Test dataset (ARTS) (Xing et al., 2020), which is derived from the SemEval 2014 dataset. Instances in ARTS are generated with three adversarial strategies. These strategies enrich the test set from 638 to 1,877 for the laptop domain (ARTS-LAP), and from 1,120 to 3,530 for the restaurant domain (ARTS-REST). Note that each domain from SEMEVAL consists of separate training and test sets, while each domain from ARTS only contains a test set. Since SEMEVAL dataset does not come with development sets, 150 instances from the training set in each domain are randomly selected to form the development set. Table 1 shows the statistics of the datasets.

Dataset		# pos.	# neu.	# neg.
SEMEVAL-LAP	train	930	433	800
	test	341	169	128
	dev	57	27	66
SEMEVAL-REST	train	2,094	579	779
	test	728	196	196
	dev	70	54	26
ARTS-LAP	test	883	407	587
ARTS-REST	test	1,953	473	1,104

Table 1: Statistics of datasets.

Target Models We conduct experiments on a wide range of existing models for a comprehensive study on whether position bias is beneficial. Specifically, we examine these models' performance before and after injecting the position bias, in terms of position-biased weight (`pos-wt`) and dropout (`pos-dp`) individually.

The target models include: (a) **LSTM** (Tang et al., 2016a) uses the last hidden state vector of the LSTM to predict sentiment. (b) **LSTM-Attn** (Wang et al., 2016) applies an attention-based LSTM on the concatenation of the aspect and word embeddings. (c) **IAN** (Ma et al., 2017) interactively learns attentions between context words and aspect terms. (d) **MemNet** (Tang et al., 2016b) applies attention multiple times on word memories, and the output of the last attention is used for prediction. While the original work utilizes word embeddings as memories, we instead choose to add a layer of bidirectional LSTM upon embeddings for more abstractive memories. (e) **AOA** (Huang et al., 2018) introduces an attention-over-attention based network to model interaction between aspects and contexts. (f) **RoBERTa** (Dai et al., 2021) is a strong baseline with an MLP built upon the pooled feature induced with RoBERTa (Liu et al., 2019).

Implementation Details In all our experiments, the 300-dimensional GloVe (Pennington et al., 2014) is leveraged to initialize the input embedding. All parameters of models are initialized with uniform distributions. During all experiments, a bidirectional LSTM is adopted if necessary instead of a unidirectional one. If a model takes advantage of the attention mechanism, then dot product based attention is employed. In case a model has hidden states, the dimensionality of hidden states is set to 300. The batch size is 64. We use Adam (Kingma and Ba, 2015) as the optimizer with a learning rate of 10^{-3}. The coefficient of L2 regularization is 10^{-5}. For experiments with RoBERTa as the input embedding (Liu et al., 2019), things may change. The dimensionality of hidden states is 768. The learning rate is 10^{-5}, while the regularization is rather removed.

Evaluation Metrics For O.O.D., models are trained separately on one domain and evaluated on another. For Adv., models are trained on the SEMEVAL dataset and tested on the ARTS counterpart. For every test, a model is trained on the I.D. training set, selected on the I.D. development set, and tested on the O.O.D. or Adv. test set. The experimental results are obtained by averaging 5 runs with random initialization, and we adopt Accuracy and macro-averaged F1 scores as evaluation metrics.

In-domain Generalization Results Table 3 shows the I.D. performance of the LSTM on both laptop and restaurant domains, which exhibits incorporating position bias does not harm, if this is the case, a model's generalization on I.D. test sets that much. On the contrary, position bias, especially with position-biased weight, can boost I.D. performance.

Table 2: Robustness results (%). O.O.D. on LAP or REST denotes a model is trained in current domain (LAP or REST) and tested on another (REST or LAP). Adv. denotes a model is trained in a domain and tested on its ARTS counterpart. Furthermore, w/ `pos-dp` means a model with position-biased dropout. w/ `pos-wt` means a model with position-biased weight. The small number next to each performance score indicates either performance improvement (↑) or drop (↓) compared with the original model without using position bias, and those highlighted in red are the best-performing ones among two variants.

Model	**LAP I.D.**		**REST I.D.**	
	Acc.	**F1**	**Acc.**	**F1**
LSTM	67.15	60.57	74.57	62.14
w/ `pos-dp`	67.34	60.27	74.23	61.55
w/ `pos-wt`	68.78	62.42	76.34	64.85

Table 3: I.D. results (%) of LSTM on LAP and REST.

Robustness Results The robustness results are shown in Table 2. We can see that performance of LSTM drops drastically, compared to I.D. performance, on O.O.D. and Adv. test sets, indicating the importance of studying the robustness issue. Our proposed two position bias mechanisms improve the target models' O.O.D. and Adv. performance in most cases. With position-biased dropout, F1 scores of models are improved by up to 5.32 pp on O.O.D. test sets, and 2.36 pp on Adv. test sets, though the efficacy of the position-biased dropout seems not stable across different target models and settings. In contrast, the impact of position-biased weight is much more prominent. With position-biased weight, Accuracy scores of models can be enhanced by up to 6.05 pp and 7.20 pp on O.O.D. and Adv. test sets, respectively. Further, F1 scores of models are improved by up to 9.51 pp and 8.14 pp on O.O.D. and Adv. test sets.

A highlight is that experimental results with RoBERTa as well exhibit the benefit of position bias, yet with caveats. Although pre-trained language models like RoBERTa are subject to positional encodings, such absolute position information is not enough to model relative position relations between aspect terms and contexts. Therefore, position bias matters during fine-tuning pre-trained language models for robust ASC performance. However, we observe that position-biased dropout is not an appropriate choice for pre-trained language models.

Case Study To understand the effect of position bias, we conduct a case study on the two robustness scenarios, as shown in Table 4. Specifically, we visualize the attention scores separately offered by an ASC model LSTM-Attn with and without position-biased weight method and trained on SEMEVAL-REST.

We can observe that before applying position bias, the model attends irrelevant words and fails in both scenarios. Specifically, in both cases, the model mis-attends to irrelevant opinion expressions. After injecting position bias, the attention scores become more accurate and the model attends to the correct opinion spans.

w/ `pos-wt`	Example
✘	The price is reasonable although the quality is poor .
✔	The price is reasonable although the quality is poor .
✘	Awful food but the service was great !
✔	Awful food but the service was great !

Table 4: **Case study.** The underlined words are aspects. The top two rows are O.O.D. examples, while the bottom two are Adv. examples. ✘ and ✔ refers to without and with `pos-wt` respectively.

4 Related Work

Fine-grained Sentiment Analysis ASC falls in the broad scope of fine-grained sentiment analysis. While ASC is basically formulated as determining sentiment polarity of a given aspect in a sentence (Tang et al., 2016b,a; Wang et al., 2016; Chen et al., 2017; Huang et al., 2018; Li et al., 2018; Xu et al., 2019; Zhang et al., 2019b,a; Wang et al., 2020; Tang et al., 2020), there is an emergent trend that treating fine-grained sentiment as an opinion triplet extraction task (Peng et al., 2020; Zhang et al., 2020; Wu et al., 2020). Recently, the robustness of ASC models becomes a critical issue that urges researchers to pay more attention on improving the robustness of ASC models (Xing et al., 2020). Our work is the first work to enhance the universal robustness of ASC models by capturing position bias. On another note, we believe opinion triplet extraction is exposed to the similar robustness issue, which should be explored in the near future.

Robustness in NLP Broadly, there are two kinds of robustness in NLP, i.e., O.O.D. and Adv. robustness. O.O.D. robustness in NLP has attracted extensive attention in recent work (Ng et al., 2020; Hendrycks et al., 2020; Xie et al., 2020). In terms of O.O.D. robustness, they often use the cross-domain setting to evaluate models (Benson and Ecker, 2020). Previous work mainly focuses on how to minimize the domain discrepancy and how to improve the feature adaptability of models (Rietzler et al., 2020; Ye et al., 2020). On the other hand, adversarial learning becomes the main method used to improve Adv. robustness of models (Xing et al., 2020). Prior methods consider using semantic operations, such as synonym replacement, random insertion, random swap, and random deletion to augment data (Wei and Zou, 2019). Other methods involve adding extra text (Wallace et al., 2019) and replacing sentences with semantically similar sentences (Ribeiro et al., 2018). Our work goes beyond the two forms of robustness and aims to achieve universal robustness for ASC with position bias.

5 Conclusion and Future Work

In this work, we find that state-of-the-art ASC models suffer from the issue of robustness, particularly in two scenarios: i) out-of-domain scenario, and ii) adversarial scenario. To address the issue, we propose a simple yet effective inductive bias that should be incorporated, that is, position bias. We proposed two mechanisms to capture position bias, namely position-biased weight and position-biased dropout. They are injected into existing models to enhance the representation. Extensive experiments demonstrate that the proposed methods can largely improve the models' robustness. The results verify our hypothesis that position bias is beneficial for building more robust ASC models.

The work shall be improved in the following two facets: i) Since the approach of incorporating position bias is straightforward yet naive, especially for pre-trained language models, it is meaningful to consider a nicely designed architecture to inject position bias in a more elegant manner. ii) It has been shown that position bias for ASC is highly correlated with the syntactic structure of the sentence. Hence, syntax can likewise be explored to enhance the robustness of ASC models.

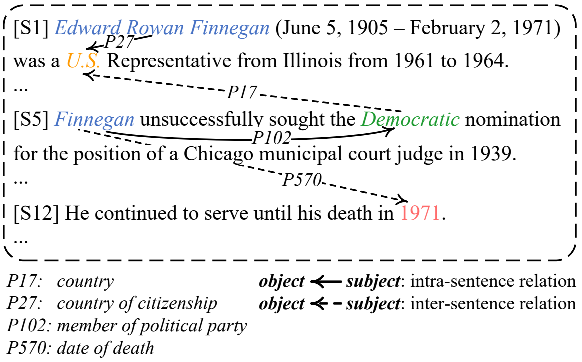
Abstract

Document-level relation extraction aims to detect the relations within one document, which is challenging since it requires complex reasoning using mentions, entities, local and global contexts. Few previous studies have distinguished local and global reasoning explicitly, which may be problematic because they play different roles in intra- and inter-sentence relations. Moreover, the interactions between local and global contexts should be considered since they could help relation reasoning based on our observation. In this paper, we propose a novel mention-based reasoning (MRN) module based on explicitly and collaboratively local and global reasoning. Based on MRN, we design a co-predictor module to predict entity relations based on local and global entity and relation representations jointly. We evaluate our MRN model on three widely-used benchmark datasets, namely DocRED, CDR, and GDA. Experimental results show that our model outperforms previous state-of-the-art models by a large margin.

1 Introduction

Relation extraction (RE), identifying the semantic relations among target entities in the text, has long been a fundamental task in the natural language processing (NLP) community (Zeng et al., 2014; Xu et al., 2015). Prior efforts largely focus on sentence-level RE (Lin et al., 2016; Zhang et al., 2018). However, recent studies reveal that a large number of relations can actually be expressed through multiple sentences, which necessitates document-level RE (Yao et al., 2019). Compared with sentence-level RE, the entities for document-level relations may be mentioned in multiple sentences across a document. Therefore, document-level RE requires capturing the complex interactions between all entities in the entire document (Nan et al., 2020; Zeng et al., 2020; Wang et al., 2020).



[S1] *Edward Rowan Finnegan* (June 5, 1905 – February 2, 1971) was a *U.S.* Representative from Illinois from 1961 to 1964.
...
[S5] *Finnegan* unsuccessfully sought the *Democratic* nomination for the position of a Chicago municipal court judge in 1939.
...
[S12] He continued to serve until his death in 1971.
...

Figure 1: An example of document-level RE from the DocRED dataset. We use the same color to denote the mentions of the same entity.

It is well known that local and global contexts are two key performance enhancers for the task. Intuitively, the former can benefit the identification of nearer (e.g., intra-sentence) relations, while the latter is more useful for distant (e.g., inter-sentence) relations. For document-level RE, such context information is closely related to the ubiquitous mentions in a document, so **mention-based reasoning** with different context granularities is highly important for the task. However, most previous studies have not distinguished local and global reasoning explicitly (Peng et al., 2017; Christopoulou et al., 2019; Sahu et al., 2019; Nan et al., 2020; Zhou et al., 2020; Zeng et al., 2020; Li et al., 2020; Zhang et al., 2020). Recently Wang et al. (2020) investigate local and global contexts for document-level RE by performing global and local reasoning consecutively. However, their pipeline method can be problematic because it ignores the interactions and communications of local and global contexts,[1] which limits the performance of the task.

---

[1] From Figure 1, it is shown that the intra-sentence relations $P27$ and $P102$ can help to identify the inter-sentence relation $P17$, since '*U.S.*' and '*Democratic*' are linked through '*Finnegan*'.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1359–1370
August 1–6, 2021.

In this paper, we aim to address the above issues for improving document-level RE by presenting a novel **M**ention-based **R**easoning **N**etwork (**MRN**). As shown in Figure 2, MRN consists of several innovative modules for modeling the relation reasoning locally and globally, including (1) a two-dimensional windowed convolution for capturing the local mention-to-mention interactions between the subject and object arguments of relations, and (2) a co-attention module for capturing the global interaction between each pair of entity mentions. Note that the above two modules also provide mutual information to each other, in order to capture the interactions between local and global contexts.

Moreover, different from previous work that expresses entities with just one kind of representation (Peng et al., 2017; Christopoulou et al., 2019; Sahu et al., 2019; Nan et al., 2020; Zhou et al., 2020; Zeng et al., 2020; Li et al., 2020; Zhang et al., 2020), our method distinguishes mentions into subjects and objects, and generates entity representations from both local and global mention-based reasoning. Specifically, we design a novel module, called **co-predictor**, to utilize both local and global entity representations for jointly reasoning the relations between close and distant entities.

We conduct extensive experiments on three widely-used benchmarks, including DocRED (Yao et al., 2019), CDR (Li et al., 2016) and GDA (Wu et al., 2019). The results show that our MRN model outperforms the current best model by a large margin, demonstrating its advances. In summary, we make the following contributions:

- We propose a mention-based reasoning network (MRN), to distinguish the impacts of close and distant entity mentions in relation extraction and meanwhile consider the interactions between local and global contexts, which we call locally and globally mention-based reasoning.
- We also propose a co-predictor to work in concert with the mention reasoning block, and predict the relation of a pair of entities using local and global features simultaneously.
- Our model achieves the state-of-the-art performances on three benchmark datasets for document-level RE. We also conduct extensive analyses of our model to better understand its working mechanism.[2]

2 Related Work

Relation extraction (RE), including sentence-level RE and document-level RE, plays a crucial role in a wide variety of knowledge-based applications, such as question answering (Hixon et al., 2015), dialogue generation (He et al., 2017), etc. Recent studies largely focus on sentence-level RE by various neural network methods, such as CNN (Zeng et al., 2014; dos Santos et al., 2015), BiLSTM (Zhang et al., 2015; Cai et al., 2016), attention mechanism (Wang et al., 2016; Lin et al., 2016), and neural graph models (Zhang et al., 2018; Zhu et al., 2019). However, in practice, many relational facts need to be inferred across multiple sentences in a document, so researchers have shown a growing interest in document-level RE.

Compared with sentence-level RE, document-level RE needs to consider the complicated interactions between entities across multiple sentences. With this in mind, researchers begin to use graph neural networks to reason intra- and inter-sentence relations and make certain progress in extracting inter-sentence relations with document-level graph convolutional neural network (Peng et al., 2017; Velickovic et al., 2018; Christopoulou et al., 2019). Sahu et al. (2019). For example, Zhou et al. (2020) use entities as nodes and the context between entity pairs as edges to construct graphs. Nan et al. (2020) treat the graph as a latent structure and perform relational reasoning. However, most existing approaches only use entity-level information and ignore mention-level information.

Some studies also take mentions into account by adding mention nodes in the graph. For instance, Christopoulou et al. (2019) put mentions and entities in the same graph. Li et al. (2020) utilize a dual-tier heterogeneous graph to propagate relational information among entity mentions, and then summarize them into corresponding entities. More recently, Wang et al. (2020) use multi-head attention to aggregate multiple mentions of specific entities. Different from the above methods, Zeng et al. (2020) propose a graph aggregation and inference network that includes two graphs, one for capturing complex interactions among different mentions, and the other for integrating mention-level information of the same entities. Although these methods introduce mention-level nodes or graphs, none of them consider local mention-based contextual information or mention-level relative distances, which are all considered in our model.

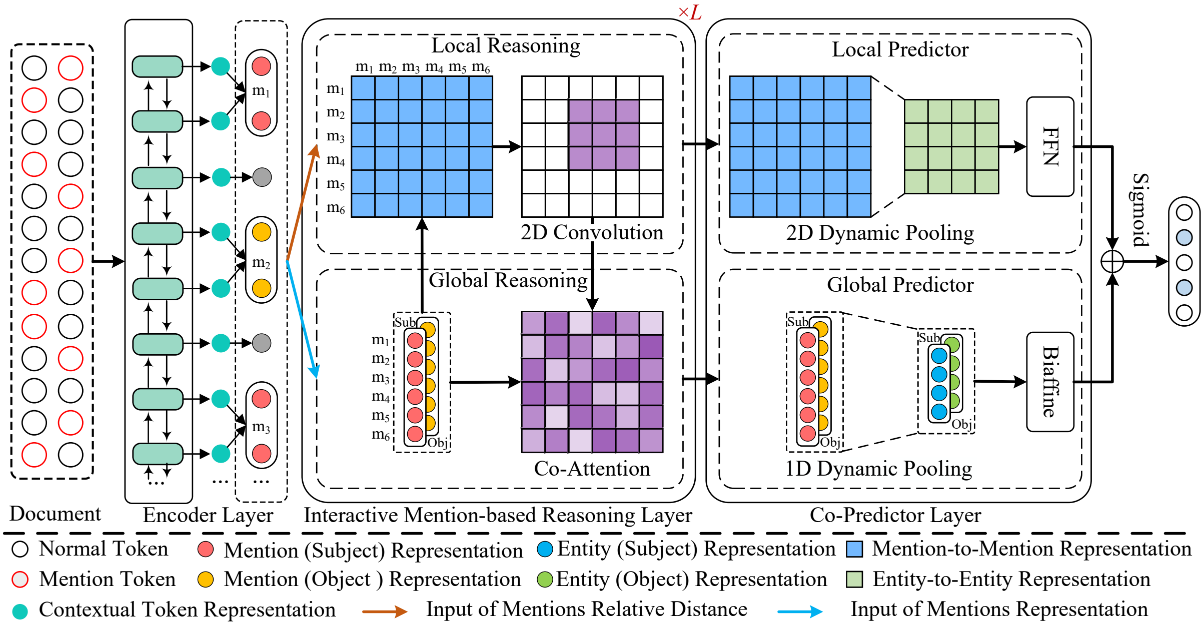

Figure 2: The overall architecture of our `MRN`, including three key components: encoder (§ 3.1), interactive mention-based reasoning (§ 3.2) and co-predictor (§ 3.3).

3 Methodology

Task Formulation Given an input document consisting of N tokens $\mathcal{D} = \{w_i\}_{i=1}^{N}$ and P entities $\mathcal{E} = \{e_i\}_{i=1}^{P}$, the task aims to extract a subset of relations from $\mathcal{R}$ between the entity pairs (e_i^s, e_j^o), where $\mathcal{R}$ is a pre-defined relation type set, e_i^s and e_j^o are identified as subject and object entities. An entity e_i can appear multiple times in the document via K_{e_i} mentions $\mathcal{M}_{e_i} = \{m_j\}_{j=1}^{K_{e_i}}$.

Framework As illustrated in Figure 2, the overall architecture consists of three tiers. An encoder first yields contextual representations, and then the mention-based reasoning block (in multiple layers) performs local-level feature extraction with a two-dimensional (2D) convolution, and global-level feature retrieval with a co-attention module. Afterward, a co-predictor layer that contains a 1D and 2D dynamic pooling aggregates the entity-level features from the mention-based reasoning block. Finally, a multi-layer perceptron and a biaffine classifier are leveraged for jointly reasoning the relations between subject and object entities.

3.1 Encoding Layer

We first map each word w_i into a vector, and concatenate it with its corresponding entity type t_i:[3]

$$\mathbf{x}_i = [\mathbf{x}_i^w; \mathbf{x}_i^t] \, . \tag{1}$$

Then, we adopt BiLSTM to encode the vectorial word representations into contextualized word representations:

$$\mathbf{h}_i = \text{BiLSTM}(\mathbf{x}_i) \, , \tag{2}$$

where $\mathbf{h}_i$ is the token hidden representation. Note that we also can use the BERT (Devlin et al., 2019) as an alternative to improve performances. Based on $\mathbf{h}_i$, we can obtain the mention representation:

$$\mathbf{m}_i = \text{Max}\{\mathbf{h}_j\}_{j=a_i}^{b_i} \, , \tag{3}$$

where a_i and b_i are the start and end positions of the i-th mention, respectively.

3.2 Interactive Mention-based Reasoning Layer

As we argued earlier, local and global context information is closely related to the ubiquitous mentions in a document. We thus propose a mention-based module for multi-hop reasoning among the relationships of all the mentions. Considering that there exist overlapping relations where multiple relations share the same mention, we distinguish mentions into subjects and objects by their directions. Moreover, near neighbors are more informative than distant ones for determining relations. To this end,

---

[3] t_i denotes the type of entity mention that contains this word (e.g. if an entity type is `Person`, its mention word type is also `Person`).

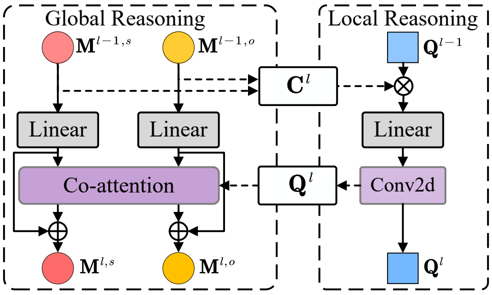

Figure 3: The interactive mention-based reasoning block. ⊕ and ⊗ represent the addition and concatenation operations.

we adopt a two-dimensional (2D) windowed convolution to capture local interactions between close subject and object mentions.

As shown in Figure 3, we perform multi-hop reasoning by stacking multiple layers (i.e., L) of our interactive mention-based reasoning blocks. The inputs of the l-th layer block include: (1) a set of subject mention representations $\mathbf{M}^{l-1,s} = \{\mathbf{m}_i^{l-1,s}\}_{i=1}^{T}$, (2) a set of object mention representations $\mathbf{M}^{l-1,o} = \{\mathbf{m}_i^{l-1,o}\}_{i=1}^{T}$, and (3) a set of mention relation representations $\mathbf{Q}^{l-1}$, where T is the number of mentions and $\mathbf{Q}_{ij}^{l-1}$ denotes the type of implicit relation between the subject i and object j. For initialization, $\mathbf{m}_i^{0,s} = \mathbf{m}_i^{0,o} = \mathbf{m}_i$, and $\mathbf{Q}^0$ denotes relative distance embeddings of mentions (Zeng et al., 2014).

Local Reasoning To model the interactions between near subjects and objects, we first build a relationship tensor $\mathbf{C}^l$ from $\mathbf{M}^{l-1,s}$ and $\mathbf{M}^{l-1,o}$, in which $\mathbf{C}_{ij}^{l} = [\mathbf{m}_i^{l-1,s}; \mathbf{m}_j^{l-1,o}]$. Next, we concatenate $\mathbf{C}^l$ and $\mathbf{Q}^{l-1}$, and adopt a Feedforward Network (FFN) to reduce their dimensions. We then employ a 2D convolution to capture local contextual interactions, which can be regarded as extracting subgraph representations from a fully-connected bipartite graph containing subject and object nodes. The overall process can be formulated as:

$$\mathbf{Q}^{l} = \sigma(\text{Conv2d}(\text{FFN}([\mathbf{Q}^{l-1}; \mathbf{C}^{l}]))) , \qquad (4)$$

where σ is a LeakyReLU activation function.

Global Reasoning We introduce a co-attention mechanism to compute attention coefficients that indicate the importance of subjects to objects and vice versa, so that the interaction between each pair of mentions can be considered. Inspired by the success of graph attention network (GAT) (Velickovic et al., 2018), we apply two learnable linear transformations to transform subject and object mention representations $\mathbf{M}^{l-1,s}$ and $\mathbf{M}^{l-1,o}$ into higher-level features. Then, we leverage the mention relation representation $\mathbf{Q}^l$ to calculate the coefficients and inject them into the co-attention process:

$$\hat{\mathbf{m}}_i^{l,\phi} = \sum_{j \in M^{l,\psi}} \alpha_{ij}^{l,\psi} \mathbf{W}^{l,\psi} \mathbf{m}_j^{l-1,\psi} , \qquad (5)$$

where $\mathbf{W}^{l,\psi}$ is a learnable parameter matrix, and $\alpha_{ij}^{l,\psi} = \text{Softmax}(\text{FFN}(\mathbf{Q}^l))$. Here $\phi, \psi \in \{s, o\}$. Afterward, the mention representation of the next layer $\mathbf{m}_i^{l,\phi}$ is generated by adding the residual of the last layer $\mathbf{m}_i^{l-1,\phi}$ and the non-linear transformation of the co-attention output $\hat{\mathbf{m}}_i^{l,\phi}$, which can be formulated as:

$$\mathbf{m}_i^{l,\phi} = \sigma(\hat{\mathbf{m}}_i^{l,\phi} + \mathbf{W}^{l,\phi}\mathbf{m}_i^{l-1,\phi}) + \mathbf{m}_i^{l-1,\phi} . \qquad (6)$$

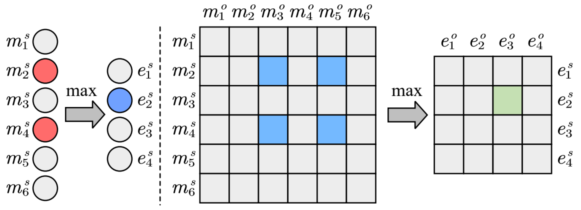

Figure 4: The 1D and 2D dynamic pooling.

3.3 Co-Predictor Layer

After the last reasoning block (i.e., the L-th block), we obtain the final mention representations $\mathbf{M}^{L,s}$ and $\mathbf{M}^{L,o}$, as well as the mention relation representation $\mathbf{Q}^L$. Since different mentions may belong to different entities, we apply 1D and 2D max-pooling to aggregate mention-level features into the entity level (Figure 4). Then, we apply two predictors to calculate two relation distributions for entity pair (e_i, e_j) and then combine them for obtaining the final prediction.

Local Predictor Based on the mention relation representation $\mathbf{Q}^L$ generated from the mention-based reasoning block, we adopt a 2D dynamic max-pooling (cf. Figure 4 right) to aggregate mention-level features into entity-level features:

$$\mathbf{G}_{ij} = \text{Max}\{\mathbf{Q}_{kt}^{L}\}_{k \in \mathcal{M}_{e_i}, t \in \mathcal{M}_{e_j}} , \qquad (7)$$

where $\mathcal{M}_{e_i}$ and $\mathcal{M}_{e_j}$ are the mention sets corresponding to the i-th and j-th entities, respectively.

Then we employ a FFN to generate prediction scores for entity pair:

$$y'_{ij} = \mathrm{FFN}(\mathbf{G}_{ij})\,. \tag{8}$$

Global Predictor Based on the mention representations $\mathbf{M}^{L,s}$ and $\mathbf{M}^{L,o}$, the representations of the i-th and j-th entities can also be generated by the 1D dynamic max-pooling (Figure 4 left).

$$\mathbf{e}_i^{\phi} = \mathrm{Max}\{\mathbf{m}_k^{L,\phi}\}_{k\in\mathcal{M}_{e_i}}\,, \tag{9}$$

where $\mathcal{M}_{e_i}$ is the mention set of the i-th entity, ϕ can be $\{s, o\}$ and $\mathbf{m}^{L,\phi} \in \mathbf{M}^{L,\phi}$. Then, a biaffine classifier (Dozat and Manning, 2017) is used to compute the relation scores between a pair of subject and object entities:

$$\mathbf{z}_i^s = \mathrm{MLP}^s(\mathbf{e}_i^s)\,, \tag{10}$$

$$\mathbf{z}_j^o = \mathrm{MLP}^o(\mathbf{e}_j^o)\,, \tag{11}$$

$$y''_{ij} = \mathbf{z}_i^{s\top}\mathbf{U}\mathbf{z}_j^o + \mathbf{W}[\mathbf{z}_i^s;\mathbf{z}_j^o] + b\,, \tag{12}$$

where $\mathbf{U}$, $\mathbf{W}$ and b are trainable parameters.

Joint Prediction The final relation probability for entity pair (e_i, e_j) with regards to the relationship r comes from the combination of the scores from both local and global predictors:

$$P(r|e_i, e_j) = \mathrm{Sigmoid}(y'_{ij} + y''_{ij})\,. \tag{13}$$

3.4 Learning

Considering the imbalance of positive and negative samples in document-level RE, we use asymmetric loss (ASL) (Ben-Baruch et al., 2020) instead of binary cross-entropy loss:

$$L_+ = (1 - P(r|e_i, e_j))^{\gamma+} \log(P(r|e_i, e_j))\,, \tag{14}$$

$$L_- = (P_n(r|e_i, e_j))^{\gamma-} \log(1 - P_n(r|e_i, e_j))\,, \tag{15}$$

where $\gamma+$ and $\gamma-$ are the focusing hyper-parameters for positive and negative samples, which aim to emphasize the contribution of positive samples and meanwhile down-weight the contribution of easy negatives samples ($\gamma_- > \gamma_+$). $P_n(r|e_i, e_j) = \max(P(r|e_i, e_j) - n, 0)$ is a probability shift mechanism that further filters out easy negative samples (probability margin $n \geq 0$ is a hyper-parameter). Here, the final loss function can be formulated as:

$$L = -\sum_{\mathcal{D}\in\mathcal{S}}\sum_{i\neq j}\sum_{r\in\mathcal{R}} \mathbb{I}\,(r=1)\,L_+ + \mathbb{I}\,(r=0)\,L_-, \tag{16}$$

where $\mathcal{S}$ denotes the whole dataset, and $\mathbb{I}(\cdot)$ refers to the indicator function.

4 Experimental Settings

4.1 Dataset and Evaluation

We conduct experiments on three benchmark datasets, including DocRED (Yao et al., 2019), CDR (Li et al., 2016) and GDA (Wu et al., 2019), and the statistical information is shown in Table 1. DocRED is a large-scale human-annotated dataset for document-level RE, including 3,053 documents for training, 1,000 for development and 1,000 for test. CDR and GDA are the widely-used document-level RE in the biomedical domain. CDR contains 1,500 PubMed abstracts with 3,116 relational facts, and GDA consists of 30,192 MEDLINE abstracts and 46,343 relational facts.

Following previous studies (Yao et al., 2019; Nan et al., 2020), we adopt F1 and Ign F1 as the evaluation metrics, where Ign F1 is calculated by excluding the common relation facts shared by the training, development and test sets. Depending on whether relation arguments occur within one sentence or not, F1 can be further split into intra-F1 and inter-F1. The results of our model are presented after a significant test (p$\leq$0.03).

4.2 Baselines

We make comparisons with the current state-of-the-art systems, including two categories. **1) Sequence-based methods**, which use different neural architectures to encode the entire document, include CNN (Zeng et al., 2014), BiLSTM (Cai et al., 2016), Context-Aware (Sorokin and Gurevych, 2017) and HIN (Tang et al., 2020). **2) Graph-based methods**, which construct homogeneous or heterogeneous graphs based on the whole document, include GAT (Velickovic et al., 2018), GCNN (Sahu et al., 2019), EoG (Christopoulou et al., 2019), LSR (Nan et al., 2020), GAIN (Zeng et al., 2020) and GLRE (Wang et al., 2020). Besides, some models leverage BERT (Devlin et al., 2019) for task improvements, including two-phase+BERT (Wang et al., 2019) and Coref+BERT

(Ye et al., 2020).

5 Results and Analyses

5.1 Results on DocRED

Table 2 shows the experimental results on the DocRED dataset. We can find that MRN achieves 56.19% Ign F1 and 58.46% F1 on the test set, outperforming the sequence-based models with large margins. Specifically, MRN outperforms the best sequence-based model HIN by 5.04% and 5.16% in terms of Ign F1 and F1, demonstrating the effectiveness of capturing the mention-level contextual information for document-level RE.

Moreover, we observe that graph-based models (e.g., LSR and GAIN) generally perform better than sequence-based models (e.g., BiLSTM and HIN). This verifies the usefulness of constructing informative graphs. In particular, our MRN achieves the best Ign F1 and F1 scores, and outperforms GAIN by 3.53% and 3.38%, respectively. This shows the importance of emphasizing local mention-level interactions for document-level RE.

Furthermore, we observe that the performance can be substantially boosted with the help of BERT, where the Ign-F1 and F1 increase by 3.33% and 3.28% on the test set. Notably, MRN with GloVe embeddings is able to achieve better results than several BERT-based models, such as CorefBERT and GLRE. This suggests that our model is more effective in capturing complex interactions between close and distant mentions even without the help of pre-trained embeddings.

Table 3: Results on CDR and GDA datasets.

5.2 Results on CDR and GDA

Table 3 shows the results on two biomedical datasets. Here, the baselines are also divided into sequence-based models (ME-CNN, BRAN, and C-CHAR) and graph-based models (GCNN, EoG, DHG, and LSR). Similar to the DocRED dataset, the graph-based models generally outperform the sequence-based models on CDR, which reveals the effectiveness of incorporating structural information and reasoning mechanisms in document-level

RE. Besides, our MRN model achieves better performances than the state-of-the-art models on CDR and GDA datasets, outperforming LSR by 1.1% and the DHG by 0.7% respectively.

5.3 Intra- and Inter-sentence Relation Extraction

According to recent work (Yao et al., 2019), identifying 40.7% relations need the information of multiple sentences, which indicates that the reasoning ability of a model plays an important role in document-level RE. Thus, we also report the performances of intra- and inter-sentence relation extraction on three datasets in Table 2 and 3. We find that our model outperforms the current best models on all datasets in regard to both intra- and inter-F1. For example, MRN improves the intra-F1 by 3.57% and inter-F1 by 2.14% compared with GAIN on the development set of DocRED. This shows that mention-level reasoning is highly effective to capture complex interactions between mention objects and subjects, especially when not only local contexts but also long-range dependencies are considered.

5.4 Ablation Studies

We ablate each part of our MRN model on the development set of DocRED, as shown in Table 4. First, without entity type embeddings at the encoding layer, we observe slight performance drops. By removing relative distance information, the performance also decreases in a small degree. Furthermore, after removing interactive mention-based reasoning layer, global or local predictors, the performance goes down significantly. In particular, we find that the decrease of inter-F1 after removing global predictor (3.92%=50.91%-46.99%) is obviously higher than that for local predictor (1.90%=50.91%-49.01%), which verifies the usefulness of global features for long-dependency relation reasoning. A significant drop can be found when replacing the dynamic max pooling with average pooling. Finally, sharing object and subject representations and using binary cross-entropy loss, the model also has a certain degree of degradation.

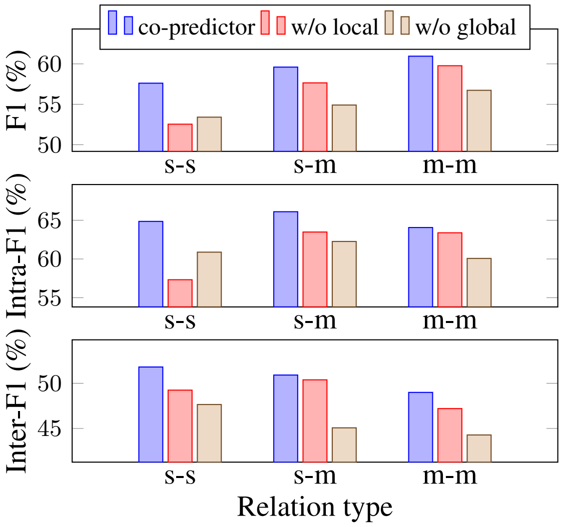

Figure 5: F1 scores of different relation types according to their entity arguments (e.g., (s)ingle mention and (m)ultiple mentions).

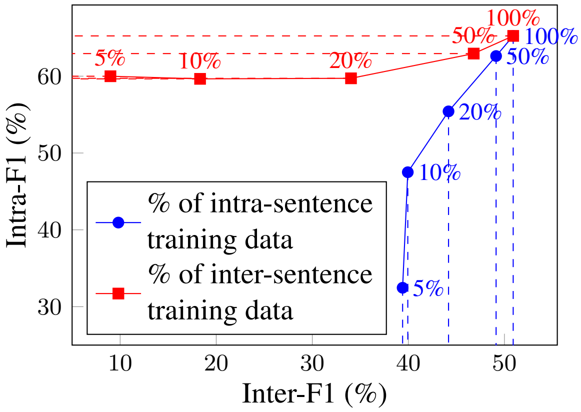

Figure 6: Intra- and inter-F1 scores vs. the proportions of inter- and intra-sentence training instances.

5.5 Effect Analysis for Co-Predictor

In this section, we investigate the effect of global and local predictors for MRN. We divide the relation instances in the development set of DocRED into three groups: the one where both subject and object arguments have single mention, the one where either subject or object argument has single mention, and the one where both subject and object arguments have multiple mentions. We also evaluate our model using different predictor configurations.

As shown in Figure 5, the model with both local and global predictors consistently outperforms

[S1] Allen Francis Moore (September 30, 1869 – August 18, 1945) was a U.S. Representative from Illinois. … [S4] He graduated from the Monticello High School in 1886 and from Lombard College, Galesburg, Illinois, in 1889. ...

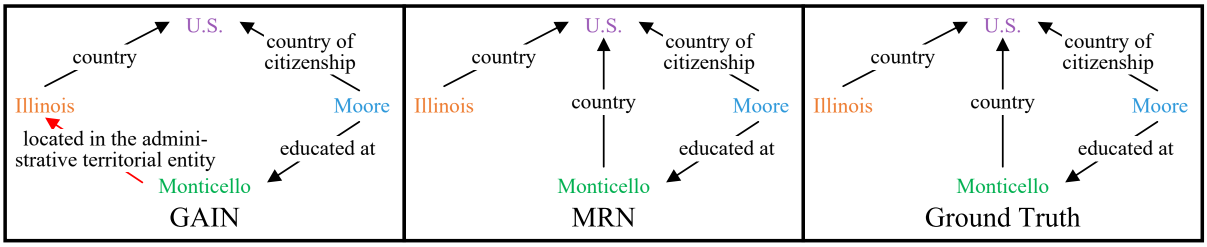

Figure 7: A case study for our model MRN and the state-of-the-art model, GAIN (Zeng et al., 2020). Only partial entities in the document are shown due to the space limitation. The red arrow denotes the wrong prediction.

the other ones. The F1s increase as the times that subjects and objects are mentioned increase (from s-s to m-m), indicating that multiple mentions appeared in various positions can provide more information to models. When removing the local predictor, we can observe that there is a huge drop for the s-s group, especially in Intra-F1. This demonstrates that the s-s group are mostly intra-sentence relations and they depend on local reasoning mostly. Moreover, if the global predictor is discarded, inter-F1 scores for the groups where subjects and objects are mentioned multiple times (s-m and m-m) drop the most. This reveals that the global predictor is more beneficial for extracting relations from multiple-mention entities or inter-sentence entities.

5.6 Effect Analysis for Inter- and Intra-sentence Training Data

As shown in Figure 6, we analyze the variation of inter- and intra-F1 scores when increasing or decreasing the proportions of intra- and inter-sentence training instances on the DocRED dataset. Note that the proportions of intra- and inter-sentence relation instances are 54.5% and 45.5% in the training set. The experimental setting is as below: first, we use 5% of inter-sentence training instances and observe the intra-F1. Then we gradually increase the percentage such as 10%, 20%, 50% and 100%. During this process, all intra-sentence training instances are used. The object for the above steps is to observe the effect of inter-sentence training instances on the intra-F1. In addition, we conduct similar experiments to observe the inter-F1 by gradually increasing the proportion of intra-sentence training instances.

As the red line shows in Figure 6, the inter-F1 is influenced slightly by the number of intra-sentence training instances. In contrast, the number of intra-sentence training instances has a significant impact on the inter-F1, since the inter-F1 grows dramatically (the blue line) when more intra-sentence training instances are added. This suggests that the interactions between intra- and inter-sentence relations indeed exist, and one may be helpful for reasoning the other.

5.7 Case Study

As shown in Figure 7, we present a case study to better understand the effect of our proposed MRN, in comparison with previous state-of-the-art baseline GAIN. We can observe that *Monticello* is the object of the intra-sentence relation triple (‘*Moore*’, *educated at*, ‘*Monticello*’) and also the subject of the inter-sentence (‘*Monticello*’, *country*, ‘*U.S*’). However, GAIN fails to identify the relation between ‘*U.S.*’ and ‘*Monticello*’, while MRN deduces it successfully. This demonstrates that the effectiveness of distinguishing subjects and objects at the inference stage, and MRN has strong capability for inter-sentence reasoning. Meanwhile, GAIN has made a wrong prediction between ‘*Monticello*’ and ‘*Illinois*’ in the 4-th sentence, indicating that our model has better local inference ability.

6 Conclusion

We propose a novel mention-based reasoning network (MRN) for document-level relation extraction. Our model is capable of capturing local and global contextual information as well as close and distant mention interactions, via multiple mechanisms such as a multi-hop mention-level reasoning block and collaborative predictors. Experimental results show that our proposed model achieves new state-of-the-art on three widely-used datasets. Through empirical analyses, we find that it is reasonable for document-level RE models to pay more attention on local context and close mentions. Meanwhile, global context and distant mention interactions are also highly important for document-level RE. Last but not least, joint reasoning with local and global context information is a reasonable and effective method for the task.

A Effect Analysis for Sentence Number

As shown in Figure 8, we display the F1 scores of MRN and GAIN in the development set of DocRED with regards to the document length. As seen, we count the document length using the number of sentences within a document, which varies from 3 to 13. Results show that MRN attains better performances than GAIN, no matter that how the document length changes. In addition, the performance difference between MRN and GAIN becomes larger, when the document becomes longer. For instance, MRN outperforms GAIN by about 10% with regards to the group where the document length is 13. This demonstrates that our model is more robust for long documents.

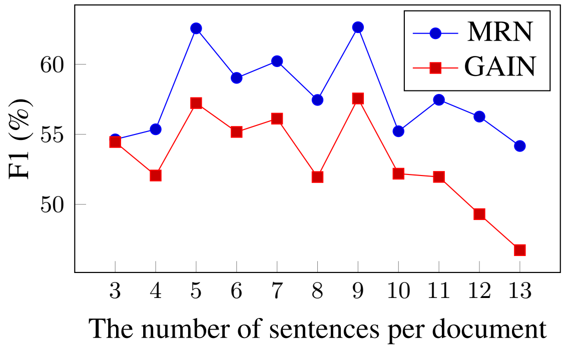

Figure 8: Comparisons between MRN and GAIN about the effect of the document length on the F1.

B Architecture Analysis for MRN Block

We conduct experiments for the interactive mention-based reasoning block based on the development set of DocRED, to understand which configuration works better. As shown in the left of Figure 9, our model performs the best when the kernel size is 3 in terms of all evaluation metrics. Meanwhile, the right part of Figure 9 shows that 3 seems to be a reasonable choice for the number of the MRN block.

C Analysis of Loss Functions

To compare the ASL and BCE loss, we compare their learning curves on DocRED and keep other settings of our model the same, as shown in Figure 10. With the comparisons of 80 epochs, we observe that the ASL loss helps our model converge to better performance than the BCE loss at a faster speed, demonstrating the effectiveness of the asymmetric strategies for positive and negative samples.

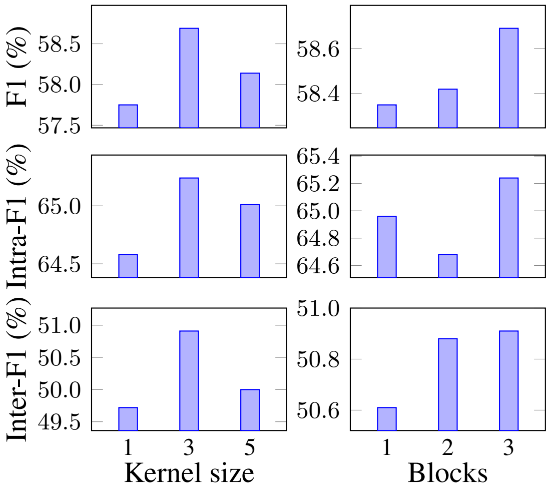

Figure 9: Analysis for the MRN block. The x-axis denotes the kernel size of 2D convolution in the local reasoning module (Left) and the number of used MRN blocks (Right).

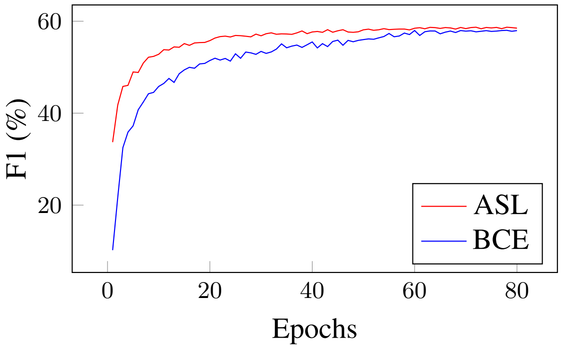

Figure 10: Comparison between the asymmetric loss (ASL) and binary cross-entropy (BCE) loss.

Hyper-parameter	DocRED	CDR	GDA
Batch size	32	16	32
Learning rate	1e-3	1e-3	1e-3
Gradient clipping	1	1	1
Weight decay	1e-5	1e-5	1e-5
Dropout for MRN block	0.5	0.5	0.5
Dropout for co-predictor	0.33	0.5	0.5

Negative focusing parameter	1	0	0
Probability margin	0.05	0.05	0.02

Table 5: Hyper-parameter settings for three datasets.

D Implementation Details

In this section, we provide more details of our experiments. We implemented MRN with PyTorch and trained it with a NVIDIA Tesla V100 GPU. Hyper-parameter settings for DocRED, CDR and GDA are listed in Table 5.

We adopt AdamW (Loshchilov and Hutter, 2019) as our optimizer. For fair comparisons, we utilize the GloVe embeddings (Pennington et al., 2014) for DocRED, pre-trained PubMed embeddings (Chiu et al., 2016) for CDR, and randomly initialized embeddings for GDA, following Yao et al. (2019) and Christopoulou et al. (2019). Moreover, we apply the uncased BERT-base model as our encoder for comparing with some baselines. We use the initial learning rate 1e-5 to fine-tune BERT.

Adversary-Aware Rumor Detection

Abstract

While social media becomes a primary source of news now, it also becomes more challenging for people to distinguish the rumors and non-rumors, which attracts malicious manipulation and may lead to public health harm or economic loss. Consequently, many rumor detection models have been proposed to automatically detect the rumors based on the contents and propagation path. However, most previous works are not aware of malicious attacks, e.g., framing. Therefore, we propose a novel rumor detection framework, Adversary-Aware Rumor Detection including Weighted-Edge Transformer-Graph Network and Position-aware Adversarial Response Generator, to improve the vulnerability of detection models. To the best of our knowledge, this is the first work that can generate the adversarial response with the consideration of the response position. Experimental results show that our model achieves the state-of-the-art on various rumor detection tasks by the proposed Weighted-Edge Transformer-Graph Network and can maintain the performance under the adversarial response attack after the adversarial learning by Position-aware Adversarial Response Generator.[1]

1 Introduction

With the popularity and accessibility of social media, social media becomes the primary source for obtaining information.[2] Compared with traditional news, posts on social media are usually with shorter lengths and faster transmission speed, which also increases the difficulty of message verification. As such, social media are increasingly targeted for manipulation, leading to tremendous economic losses, and even deaths.[3] Take the COVID-19 pandemic as an example, a newly published study shows that at least some 800 people died because of a rumor about drinking highly-concentrated alcohol can disinfect their bodies (Islam et al., 2020). Therefore, fighting against misinformation in social networks gains a great deal of attention and becomes essential and inevitable.

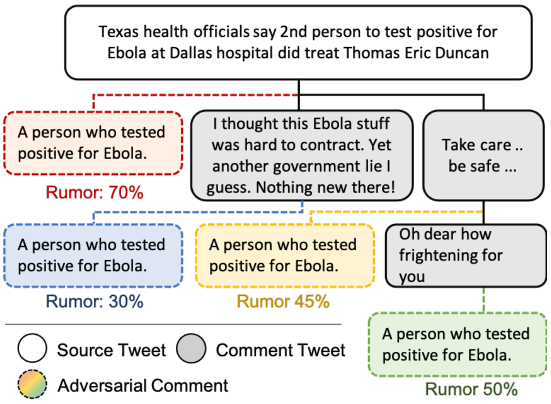

Figure 1: Position test for an adversarial response. The reply position can make an influence on the detection model.

In this paper, we study the problem of rumor detection on social media, where a rumor is defined as an unverified and instrumentally relevant information statement in circulation (DiFonzo and Bordia, 2007; Zubiaga et al., 2018). Given a conversation thread, including a source post and related responses, the rumor detection task aims to determine whether the source post is a rumor or not. Previous works of rumor detection can be categorized into three classes according to the data usage. Content-based approaches only use the textual information of the source posts and the user responses (Ma et al., 2016, 2019), while graph-

based methods (Ma et al., 2017, 2018; Bian et al., 2020) consider the message propagation paths or model the propagation paths as a tree. In addition to considering the textual information and propagation paths, user-based methods take user profiles into consideration (Giudice, 2010; Liu et al., 2015).

However, two challenges of detecting rumors have not been completely addressed. 1) *Robustness to different responses.* Previous works of rumor detection take all the responses in the conversation thread into consideration and extract important information in a data-driven manner. However, not all responses can help detect rumors, especially for the malicious framing responses, i.e., the responses promote a particular misleading interpretation. As such, it is necessary to provide a learning mechanism to enable the selection of important responses. 2) *Vulnerability to malicious attack.* Most of the existing methods only rely on datasets, which may be vulnerable to the adversarial attack, e.g., the attack of Twitter bots. (Ma et al., 2019) make the first attempt to utilize a GAN-based approach to produce adversarial text. Nevertheless, it does not consider the graph structure of the conversation thread, i.e., the generator cannot determine which responses it should reply to. In fact, the reply position can make an influence on the detection model. As shown in Figure 1, the predicted probability that the source post is a rumor ranges from 30% to 70% according to different positions of attached adversarial responses. It is challenging to generate an adversarial attack by simultaneously considering both structural and textual information since the gradient-based methods cannot be directly applied due to the discrete nature of text and structure.

To address these two challenges, we propose a novel framework, namely, Adversary-Aware Rumor Detection (AARD), which includes i) Weighted-Edge Transformer-Graph Network (WETGN) and ii) Position-aware Adversarial Response Generator (PARG). Specifically, given a source post, responses, and propagation structure as an input, we use a transformer-based encoder to encode each token in the whole conversation thread to exploit the existing pre-trained knowledge. Each token can jointly attend to different tokens regardless of the token position, which gives the model the flexibility to break the distance limit in the sequence. Since the transformer layer only takes the responses in the conversation thread as a sequential input, the propagation path is not considered. Therefore, a Graph Convolutional Network (GCN) is applied to embed the structure by taking the token embeddings as node features, and aggregates the features according to the propagation paths. Inspired by (Veličković et al., 2018), we construct the edge features from the incident nodes and build an edge filter before the GCN layers to address the first challenge. As such, we can leverage the advantages of both transformer and graph neural networks.

Moreover, to address the second challenge, we build a Position-aware Adversarial Response Generator (PARG) to train the detector by adding an adversarial response to the conversation thread. Specifically, based on a transformer-based encoder-decoder framework, PARG takes the source post with part of the corresponding responses as input to generate an adversarial response. Nevertheless, choosing the attached position for the structure-aware detection model is also crucial. PARG is trained to select the position by considering the correlation between the generated response and each of the existing posts. However, the position selection involves the argmax function, which is a non-differentiable operation. Therefore, to enable the backpropagation of gradients from the detector, PARG instead predicts the probabilities of attaching the generated response to each existing response. When updating the edge weights of the attached edges in the detection model, the generator can use the gradient to correct the predicted probabilities.

By fine-tuning WETGN with the adversarial data generated by PARG, WETGN is equipped with a certain degree of resistance to attack and maintains the performance on clean datasets. Nevertheless, although an attacker can generate adversarial examples with the detection model, it may create nonsense sentences, which can be manually excluded (noticeability). On the other hand, imposing constraints on the generated examples decreases the possibility of finding effective adversarial examples (success rate). This paper designs a training pipeline to strike a balance between success rate and noticeability. As such, the attacker is trained to decrease the detection performance and approach the real responses simultaneously.

Extensive experimental results manifest that the proposed WETGN outperforms state-of-the-art approaches on three rumor detection benchmarks by at least 4.9%, 2.89%, and 3.87% on Twitter15, Twitter16, and Pheme datasets. At the same time, AARD can resist the adversarial attack. Moreover, the proposed PARG can successfully attack existing detection models with a success rate of at least 25.08%. The success rate can be significantly reduced after fine-tuning, which shows the compatibility and usefulness of PARG.

2 Related Work

Early works rely on textual content to verify the authenticity of social media posts. For example, Badaskar et al. (2008) quantify the frequency of uncommon phrases in the articles and syntactic and semantic checking, while Potthast et al. (2018) detect the truthfulness of news by analyzing its writing style. Ma et al. (2016) use recurrent neural networks to learn both the temporal and textual representation of the source posts and user responses, which highly improves prior methods that utilize hand-crafted features. Also, Volkova et al. (2017) extract text features with LSTM and CNN structures to make the prediction.

On the other hand, a recent line of studies focuses on automatically detecting rumors based on the tree structure of the conversation thread (Ma et al., 2017; Wei et al., 2019; Kumar and Carley, 2019; Lu and Li, 2020). For instance, Ma et al. (2018) build a tree-structured recursive neural network to catch the hidden features from either top-down or bottom-up propagation structure and text content. However, it can only obtain the information of one propagation structure and ignore the other. To solve this problem, Bian et al. (2020) use the GCN-based model to embed both propagation and dispersion structures and enable the proposed method to process graph/tree structures and learn higher-level representation more conductive to rumor detection. Besides, by utilizing the hierarchical structure in the conversation thread (i.e., parent, child, before, after and self), Khoo et al. (2020) adopt the idea in Shaw et al. (2018) to perform structure-aware self-attention.

In addition, stance and user information are also used in several studies. By using stance prediction as the auxiliary task with multi-task learning, Wei et al. (2019); Li et al. (2019); Kumar and Carley (2019) have demonstrated that stance prediction plays a vital role in rumor detection. Furthermore, Li et al. (2019) incorporate the collected user credibility to supervise the detection model. Lu and Li (2020) construct the propagation network by using retweet sequences of users with user profiles to capture the correlation between user propagation and its source post. The uniqueness of our work lies in improving the vulnerability of detection models.

Due to the small or non-diversified training data, a recent line of studies utilizes the adversarial learning (Ma et al., 2019; Yang et al., 2020) or data augmentation to improve the detectors. For example, Ma et al. (2019) propose an RNN-based GAN model, where the generator aims to generate conflicting information in the conversation thread, and the discriminator is forced to learn more robust features. On the other hand, Han et al. (2019) augment data by using semantic relatedness to assign pseudo labels to unlabeled tweets. However, the structural information is important but not considered in these previous works.

3 Methodology

3.1 Problem Formulation

Given a conversation thread comprised of a source post and the corresponding responses, rumor detection aims to determine whether the claim of the source post is a rumor or not. Let $X = \{x_0, x_1, \cdots, x_i, \cdots, x_N\}$ denote a conversation thread, where x_0 represents the source post and $\{x_i\}_{i=1}^{N}$ represents the N responses. A graph $G = \langle V, E\rangle$ is constructed by taking each element in X as a node and the interactions between elements as the edge connections to form the node set V and the edge set E, respectively. For example, if nodes x_u and x_v have a direct interaction (e.g., commenting or retweeting) in the same conversation thread, an edge $(x_u, x_v) \in E$ is constructed accordingly. Due to the nature of social media, the graph G is an acyclic tree. Let $y \in \{\mathit{rumor}, \mathit{non\text{-}rumor}\}$ be the class label. Rumor detection aims to predict y given the graph G.

3.2 Rumor Detection Model

Transformer Encoder: To obtain the representation of text contents, we adopt the transformer-based encoder to explore the pre-trained knowledge. We first flatten the tree-structured graph in the chronological order, which constitutes a source post followed by a sequence of responses. Specifically, the source post and each response are started by a special token [CLS] and ended by another special token [SEP] to indicate the separation of nodes (Liu and Lapata, 2019). In this setting, we

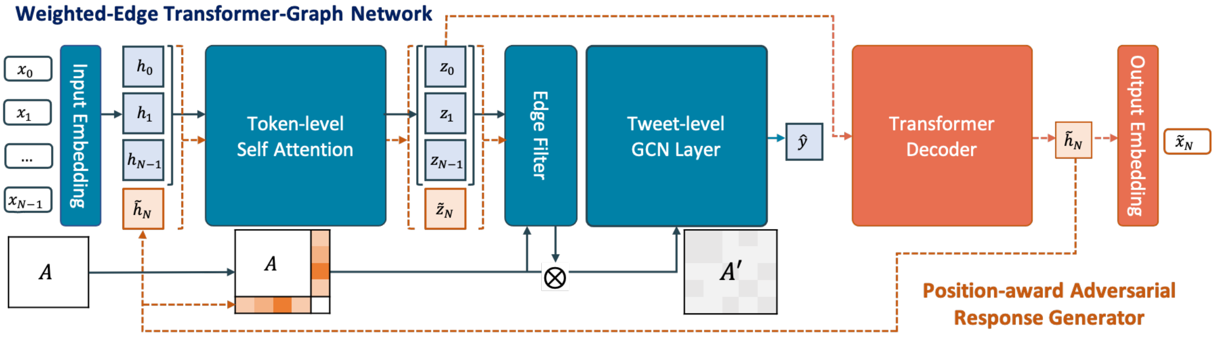

Figure 2: Overview of adversary-aware rumor detection framework.

allow each token to jointly attend to nodes in different positions for better capturing semantics. Let $h_i^{(0)} \in \mathbb{R}^{|x_i| \times d}$ denotes the d-dimensional embedding of a node x_i, which is constructed by token embedding, segment embedding, and position embedding (Devlin et al., 2019). The embedding of a conversation thread $H^{(0)}$ can thus be obtained as follows:

$$h_i^{(0)} = E_{in}(x_i) = E_{tok}(x_i) + E_{seg}(x_i) + E_{pos}(x_i),$$

$$H^{(0)} = [h_0^{(0)} \mid\mid h_1^{(0)} \mid\mid ... \mid\mid h_N^{(0)}] \in \mathbb{R}^{M \times d},$$

where $||$ is the concatenation operation, and $M = |x_1| + |x_2| + ... + |x_N|$ indicates the length of input sequence. The embedding is passed through several transformer layers. At layer $l+1$, the features from previous layer $H^{(l)}$ is transformed by three linear layers to form the query Q, key K, and value V matrices, and the output $H^{(l+1)}$ is computed as follows:

$$Q = H^{(l)} W_q, K = H^{(l)} W_k, V = H^{(l)} W_v,$$

$$H^{(l+1)} = softmax(\frac{QK^T}{\sqrt{d_k}} V),$$

where W_q, W_k, and W_v are trainable parameters and d_k is the scaling factor to prevent small gradients. The feature of token [CLS] from the last layer is taken to represent each node, which are denoted as $Z = [z_0 \mid\mid z_1 \mid\mid ... \mid\mid z_N] \in \mathbb{R}^{N \times d}$.

GCN Classifier: The interactions between responses, e.g., commenting or retweeting, are essential information for the detection model to judge the source post (Castillo et al., 2011). The responses not only contain the users' opinions but also reveal the propagation paths through social media. Since Graph Convolutional Network (GCN) is one of the most effective models for graph-structured data modeling, we leverage GCN to consider the propagation path. The message propagation function of a multi-layer GCN defined in the first-order approximation of Chebyshev polynomials is derived as follows:

$$Z^{(l+1)} = \sigma(\widetilde{D}^{-\frac{1}{2}} \widetilde{A} \widetilde{D}^{-\frac{1}{2}} Z^{(l)} W^{(l)}),$$

where $Z^{(l)} \in \mathbb{R}^{N \times d}$ is a hidden feature matrix at the l-th layer, $\widetilde{A} = A + I$ is a binary adjacency matrix with self-connection, $\widetilde{D}_{u,u} = \sum_v \widetilde{A}_{u,v}$ is a degree matrix, $W^{(l)}$ is a learnable matrix, and $Z^{(0)} = Z$ is the node features. Although GCN has been proved to be effective for extracting structural information, the information may not be faithful after aggregation with specific nodes, e.g. framing responses. Therefore, considering the potential existence of various redundant or adversarial messages, we propose to filter the edges by learning the importance of edges before the aggregation.[4] Specifically, based on the node features extracted by the transformer encoder, the importance of an edge $e_{u,v}$ between nodes x_u and x_v is constructed as follows:

$$e_{u,v} = f_{edge}(z_u, z_v) = \sigma([z_u \mid\mid z_v] W_{edge} + b_{edge}),$$

where W_{edge} and b_{edge} are trainable parameters. The predicted importance are then used to construct a weighted adjacency matrix as follows:

$$A'_{u,v} = A_{u,v} + I_{u,v} + e_{u,v}.$$

For the final prediction, the model considers the entire graph by taking mean pooling over all convolved node features instead of only taking the root

---

[4] We also simulate the generation process of adversarial responses in the next subsection and assess the attack performance in the experiment.

node's attribute. The prediction is calculated from the feature matrix of the last GCN layer L:

$$\hat{y} = softmax(Mean(z_0^L, z_1^L, .., z_N^L)W_o + b_o),$$

where W_o and b_o are trainable parameters.

3.3 Adversarial Response Generation

To further improve the vulnerability of the detection model, we explore adversarial learning under the setting of white-box attack, i.e., the parameters and gradients of the detector are exposed when updating the attacker. Specifically, we design a response generation model that attaches new adversarial responses to the conversation threads as an attacker against the detection model. For the text generation model, we adopt an encoder-decoder framework with transformer layers, which shows outstanding performance in text generation (Liu and Lapata, 2019). However, the gradients cannot be backpropagated from the detector to the generator for updating, due to the non-differentiable argmax function (de Masson d'Autume et al., 2019) in generation. To solve this problem, we tie the generator's output layer E_{out} with the embedding layer E_{in}, which means the weights of the two layers are mutually transposed. In this way, the features before the argmax function can be treated as the embedding of the generated response. Given an input sequence $\{x_i\}_{i=0}^{n-1}$, a response is generated as follows:

$$h_i = E_{in}(x_i),$$

$$\widetilde{h}_n = f_{dec}(f_{enc}(h_0, \cdots, h_{n-1})),$$

$$\widetilde{x}_n = argmax(softmax(E_{out}(\widetilde{h}_n))),$$

$$E_{in}(\widetilde{x}_n) \sim \widetilde{h}_n,$$

where f_{enc} and f_{dec} are the encoder and decoder. The features $\widetilde{h}_n$ can thus be directly used in the detector without breaking the gradient path. Besides, to reduce the model complexity, the encoder is shared between the generator and detector.

Nevertheless, for rumor detectors that incorporate propagation paths, the location to attach the generated responses is also a crucial problem. Similar to text generation, the operation of choosing the attached position is also discrete. To enable the model to simultaneously learn the position for generating responses, the generation model additionally predicts the edge weights $\{e_{n,i}\}_{i=0}^{n-1}$ between the generated response $\widetilde{x}_n$ and all existing nodes in the training process with Gumble softmax function (Jang et al., 2016), i.e.,

Table 1: Statistics of the datasets.

	Twitter15	Twitter16	Pheme
# of tree	1458	818	3720
# of node	41154	18618	67238
# of rumors	1086	613	1863
# of non-rumors	372	205	1863
Avg text length	15.84	15.87	17.79
Max text length	136	383	78
Min text length	2	2	2

$$\pi_i = [\widetilde{h}_n \mid\mid h_i]W_p + b_p, \ \forall i \in (0, \cdots n-1),$$

$$e'_{n,j} = softmax(log(\pi_i + g_i)/\tau),$$

where g_i is i.i.d sampled from Gumble distribution (0,1), τ is a hyper-parameter for controlling the smoothness of output distribution, and $W_p \in \mathbb{R}^{2d\times 1}$ and b_p are trainable parameters. A higher edge weight indicates a higher possibility that the attack can succeed at a specific position. It is worth noting that we focus on generating only one response to attack the model for validating the performance of the proposed attack. The proposed model can be extended to iteratively generate adversarial responses at different positions in the conversation thread.

3.4 Training Pipeline

The adversarial examples cannot only demonstrate the weakness of the detection model, but also provide the opportunity to improve the vulnerability. However, there is a trade-off between the attack success rate and the noticeability. To strike a balance between them, the attacker should generate a response that is close to the real ones. Base on this idea, we i) decompose the conversation threads into several subtrees for the attacker to predict the next real response and ii) design a three-stage learning pipeline to mutually learn the attacker and the detector.

Firstly, the generator is trained along with the detector to increase the detection accuracy. To generate quality responses, we provide the generator target sentence by decomposing one conversation tree into several subtrees. That is, given a subsequence of the conversation thread, the goal of the generator is to synthesize the next real response x. We only train the decoder layer θ_{dec} of the generation model while fixing the parameters of the encoder. For the detection model, the trainable layers are the encoder θ_{enc} layer, filter layer θ_{filter}

and the GCN layer θ_{gcn}. The objective function of generator is the binary-cross entropy for rumor classification and the cross entropy for text perplexity $L_{txt} = -\frac{1}{|x|}\sum_{m=1}^{|x|} logP_{gen}(w_m|w_{1:m-1})$, while the detector minimizes the rumor classification loss. The loss of the first stage (L^{1st}) is derived by summarizing L_{gen} and L_{det} with a weight λ:

$$L_{gen}(\theta_{dec}) = CE(\hat{y}, y) + L_{txt},$$

$$L_{det}(\theta_{enc}, \theta_{filter}, \theta_{gcn}) = CE(\hat{y}, y),$$
$$L^{1st} = \lambda L_{gen} + (1-\lambda)L_{det}.$$

The second training stage is to train the generator while fixing the detector. In this stage, the goal of the generator is to generate a response that can confuse the detector as an attacker. The detector takes the adversarial data as the input and makes a prediction, and the target label is reversed $\bar{y}$, i.e., the rumor becomes non-rumor and vice versa. To make the generated text unnoticeable, i.e., similar to human written sentences, the attacker is also trained to optimize L_{txt}. Therefore, the loss of the second stage is

$$L^{2nd} = L_{gen}(\theta_{dec}) = CE(\hat{y}, \bar{y}) + L_{txt}.$$

The third training stage is to fine-tune the detector under the fixed attacker. The detector is trained on the adversarial data and optimized to make the correct prediction. This training equips the detector with the ability to resist the attack and also learn to filter out the potential redundant or adversarial messages. The objective function is as follows:

$$L^{3rd} = L_{det}(\theta_{enc}, \theta_{filter}, \theta_{gcn}) = CE(\hat{y}, y).$$

4 Experimental Results

4.1 Experiment Settings

Datasets. We evaluate the proposed AARD on three public datasets including Pheme (Zubiaga et al., 2016), Twitter15 and Twitter16 (Ma et al., 2017) datasets since these datasets contain source posts, the corresponding responses, and the rumor labels. The original labels of Twitter15 and Twitter16 datasets include four classes, i.e., true rumor, false rumor, unverified rumor, and non-rumor. In this paper, we focus on differentiating rumors from non-rumors, and thus regard the first three classes as rumors. The Pheme dataset is collected based on five events with two classes, i.e., rumor and non-rumor. Due to the privacy protection policy of Twitter, the contents of responses are not included in the dataset. Therefore, we crawl the contents of responses by ourselves. If all contents have already been removed, we delete the empty tweet from the tree. Meanwhile, following the previous work (Khoo et al., 2020), we also eliminate retweets with an empty text description. The statistics are shown in Table 1.

Baselines. The selection of the baselines follows two criteria: 1) "rumor detection" or "rumor veracity classification" and 2) availability of source codes. Specifically, this paper designs a rumor detector and generator for the "rumor detection" task, which is a binary classification task. In contrast, the "rumor veracity classification" is a four-class classification task (non-rumor/true-rumor/false-rumor/unverified rumor). As Ma et al. (2019) also target the binary classification task between rumor and non-rumor, it is selected as baselines. For other works focusing on rumor veracity classification (Ma et al., 2018; Kumar and Carley, 2019; Yang et al., 2020; Khoo et al., 2020; Bian et al., 2020), one possible way for comparing with these works is to reimplement the models and change their settings to the binary classification. Therefore, Bian et al. (2020) and Ma et al. (2018) are used as baselines by reimplementing and changing the labels as binary classification. Unfortunately, it is hard to compare with some baselines that do not release the source code (Yang et al., 2020) or require additional information, e.g., user information and the stance of each response (Kumar and Carley, 2019). Finally, the baseline methods are listed: (1) RvNN (Ma et al., 2018), based on tree-structured recursive neural networks with GRU units to obtain representations from the propagation structure in the bottom-up (BURvNN) or top-down (TDRvNN) manners, (2) GAN-GRU (Ma et al., 2019), the GAN-style learning model where the discriminator and generator are recurrent neural networks with GRU units, (3) BiGCN (Bian et al., 2020), the GCN-based model that can embed both propagation and dispersion structures and enhance the root node features, and (4) GCAN (Lu and Li, 2020), which learns the retweet propagation features based on user features by a structure employed convolution and recurrent neural networks.

Implementation Details. We use the same hyperparameters for all datasets. Specifically, the batch

sizes of the detector and the generator are 48. The learning rate of the generator is 0.002 and warms up for 2000 steps. The learning rate of the decoder is set to 0.002. The token embeddings are initialized from BERT, therefore, the settings refer to the pretrained model bert-base-uncased (Devlin et al., 2019). The Transformer Encoder has 12 self-attention layers, and the layer number of GCN (L) is 2. The loss weight λ is 0.5.

Evaluation metrics. The evaluation metrics include accuracy, precision, recall and F1 score of two classes. We split each dataset into five-fold (80% for training and 20% for testing), and report the average results.

4.2 Rumor Detection

Overall Performance. Table 2 shows the performance of all models on the rumor detection task. The results manifest that the proposed AARD outperforms all the state-of-the-art models by at least 4.9%, 2.89%, and 3.87% on Twitter15, Twitter16, and Pheme datasets, respectively. Compared with the methods that use the recursive (BURvNN and TDRvNN) or recurrent (GAN-GRU) neural network, graph-network based models achieve better results, indicating that the propagation structure contains important information when detecting rumors. Different from the BiGCN, which uses the tf-idf vectors as the node features, AARD uses self-attention layers to encode the posts as the node features. The Transformer encoder enables the model to embed tokens across nodes, thus strengthening the node representation.

Moreover, the bottom rows of Table 2 show the ablation studies of the proposed AARD. The results show that both edge filter and data decomposition play important roles. On the other hand, the model can achieve a promising performance on the rumor detection task without adversarial learning. The goal of adversarial learning is to address the second challenge, i.e., vulnerability to malicious attacks. Accordingly, the Position-aware Adversarial Response Generator (PARG) is designed to improve the robustness under a malicious attack. As the original testing dataset is clean (without attacks) or only contains few manual attacks, the detection accuracy may not be significantly improved. However, when a detector is without adversarial learning (denoted by AARD-PARG in Table 2 and WETGN in Table 4), the performance drastically decreases when encountering an attack (adding one adversarial node to the conversation tree), which can be alleviated by fine-tuning on the adversar-

ial examples. The detailed analysis of adversarial learning is discussed in Sec. 4.3.

To further analyze the impact of data quantity on model performance, we train the models under different quantities of data, ranging from 5% to 100%, and evaluate them on the same testing set. Figure 4 shows the results, which indicate that our model can still achieve leading performance even with minimal training data.

True/False Rumor Detection. We separately compare AARD with another graph-based model, GCAN, since GCAN focuses on true rumor/false rumor classification task and evaluates on Twitter15 and Twitter16.[5] Table 3 shows the results of true rumor/false rumor classification, which indicates that AARD also has an excellent performance in the rumor classification. We consider it is because differentiating the false rumor from true rumor also requires the model to carefully examine the responses.

Early Detection. Early detection aims to detect rumors in the early stage, which is an important indicator for evaluating the detection model. We refer (Bian et al., 2020) and (Ma et al., 2019) to construct the detection deadlines of Twitter15 and Pheme datasets and only use the responses released before the deadlines to evaluate the accuracy. Figure 3 compares the accuracy with different detection deadlines. At the early stage, i.e., when a post just came out with extremely few responses, the accuracy of different models is around 0.75 on the Twitter15 dataset. After just a few minutes, the accuracy of our model reaches 0.85, whereas the accuracy of baselines only approximates 0.8. For the Pheme dataset, we squeeze the time sequence and find that the performances of all models become stable but our model stably outperforms others.

4.3 Adversarial Attack

Table 4 shows the model performance under an adversarial attack generated by PARG. The notation "→" indicates the performance before and after the attack, while "Diff." and "ASR" represent the accuracy difference and the Attack Success Rate (ASR) of PARG, respectively. The results indicate that the proposed PARG significantly reduces the accuracy of the detectors. The ASR is lower on the Pheme dataset than on Twitter15 and Twitter16 datasets because Pheme is a much larger dataset than the others. Therefore, the detector can learn more indicated features from Pheme and be more robust. Moreover, by comparing the performance of the detector with (WETGN) and without (-EF) edge filter, adding the edge filter can help the detector resist the attack, that is, the "Diff." is lower on

---

[5] The GCAN requires user profiles for training, which are not crawled in our datasets. Therefore, GCAN is not compared in the R/NR classification.

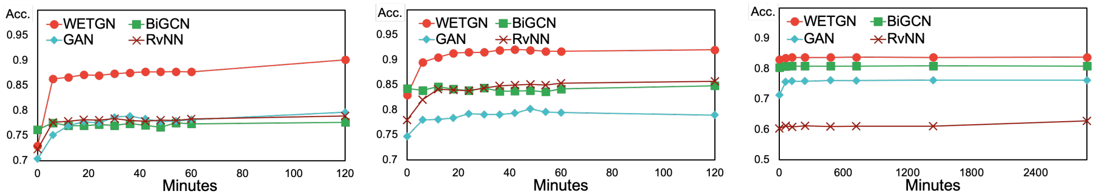

Figure 3: Early detection on Twitter15 (left), Twitter16 (middle) and Pheme (right).

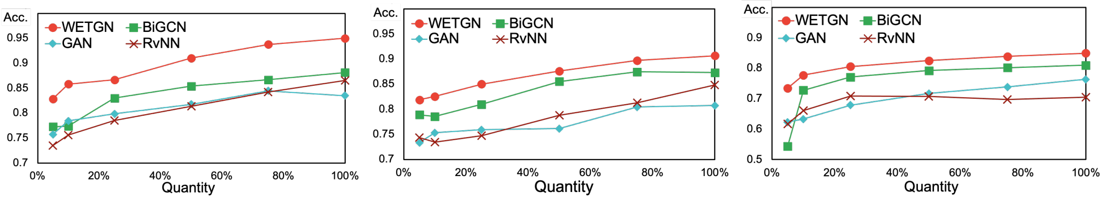

Figure 4: Data scarcity on Twitter15 (left), Twitter16 (middle) and Pheme (right).

WETGN for Twitter15 and Twitter16. In addition, we use the adversarial samples to fine-tune the detector (AARD). The bottom of Table 4 shows the results of the fine-tuned model, where the Adversarial/Clean indicates the accuracy tested on the dataset with/without adversarial attacks. The performance of the AARD without the edge filter is also provided, which also suggests the edge filter can improve the robustness.

When a detector is without adversarial learning (WETGN), the performance decreases by at least 20% on Twitter15 and Twitter16 datasets when encountering an attack. In contrast, the proposed detector with adversarial learning can maintain the performance even when the attacker has access to the model's parameters (white-box attack). It is worth noting that there may be a trade-off between the adversarial accuracy (test on adversary data) and the clean accuracy (test on clean data) (Raghunathan et al., 2019), depending on how we fine-tune the detection models, e.g., only using the adversarial data or using both kinds of data. The AARD is only fine-tuned on the adversarial data. By adjusting the experimental settings, the clean accuracy can be further improved in exchange for adversarial accuracy. Compared AARD to WETGN, it suggests that the fine-tuned detection model can resist the attack (adversarial accuracy increases from 71.13 to 92.44) while almost not affecting the clean accuracy (from 93.47 to 93.06) on the Twitter15 dataset.

Two examples of the generated adversarial responses that attack successfully are shown in Table 5. In the first example, the source post is a rumor, and PARG alters the prediction by inserting a response "not a false alarm", which conveys a signal that it is actually not a rumor. For the second example, which is a non-rumor, PARG attacks it with a certain attitude "can not believe" to deny that it is a "true" story. Similar responses can also be found in the real response written by human. If a rumor detector only captures simple patterns, it may easily misclassify the above examples and fail to adversarial attacks.

5 Conclusion

In this paper, we propose a novel rumor detection framework, AARD, to improve the vulnerability of detection models, which includes the Weighted-Edge Transformer-Graph Network (WETGN) and the Position-aware Adversarial Response Generator (PARG). Overall evaluation and ablation study results show the effectiveness of the proposed rumor detector on three public datasets. In addition, the adversarial attack results show the benefit of fine-tuning with the adversarial responses generated by PARG. In the future, we plan to further study the model generalization on rumor veracity classification tasks and combine the response stances.

Appendix

.1 Case Study

Table 6 and Table 7 show more generated examples of our Position-aware Adversarial Response Generator (PARG) for non-rumors and rumors, respectively. We highlight the possible detection signals for the rumor detectors. The detector may learn a better representation, when there are more controversial responses. These examples also show the good generation quality, which may help the noticeability.

Table 6: Generated adversarial examples of non-rumors. The table shows the source post, responses and the generated response for one data. The user names are replaced to remain anonymous.

Source: Videos show suffering of starving in Syrian town of #Madaya. **Response:** @name1 How about videos that show how many are benefiting. People would like to hear that side as well. @name1 DJ Trump and his stormtrumpers say let buddy Putin do whatever. @name1 You know what they r starving people/children as well in my Canadian city I pity the people but I take care of our own @name1 And who pray tell is starving these poor unfortunate people? @name1 If some of these countries truly loved their people.. I think we might be a better world... what a concept eh @name1 This war crime has been going on for months #cnn or do you break news on a need to know bases? @name1 Praying for their relief @name1 So sad her husband got refugee status in Germany and never looked back. @name1 This breaks my heart! @name1 The USA has the same problem. **Generated Response:** @name1 @name2: The world is not a better world.
Source: Breaking: patient being tested for Ebola in Kansas **Response:** @name1 Quick send him to the Westboro baptist church! @name1: Breaking: patient being tested for Ebola in Kansas this shit is getting out of hand @name1 Lock the door to all non-Americans attempting to flee from there to here until this is over. All except Americans!!! @name1 Why not just prevent travel from west Africa before all of this crap started happening @name1 But wait I thought there was no danger and we shouldn't be worried about the US, oh look like everything else that's ... @name1: Patient being tested for Ebola in Kansas sure this is how the walking dead began. @name1 This is getting serious by the minute in Kansas it is spreading fast @name1 You believe the government can handle this go talk to the Katrina survivors @name1: Breaking: patient being tested for Ebola in Kansas oh hell no @name1 How is these people are being infected with Ebola why are these people allowed to travel **Generated Response:** @name1 @name2: The first person to be tested for Ebola in the US.
Source: Elvis Presley was born on this day in 1935 **Response:** @name1 I have been to his birthplace, Tupelo, a week ago... @name1 @name2 What a beautiful voice @name1 @name2 And he's still dead. @name1 @name2 If Elvis was alive today he would be... 81 hundred pounds. @name1 @name2 Wow it's also David Bowie's birthday great day for music lovers? @name1 Elvis Presley.. I salute you the maestro of country music and rock.. Happy birthday and forever you are remembered. **Generated Response:** @name1 @name2 I'm still alive!

Table 7: Generated adversarial examples of rumors. The table shows the source post, responses and the generated response for one data. The user names are replaced to remain anonymous.

Source: The world is running out of chocolate, world's largest chocolate manufacturer warns **Response:** @name1 Let them eat buiscuits!! @name1 Try something else or chocs are gone for good @name1 To quote a great man. 'I don't believe it!' nooo... time to hoard #chocoholic @name1: The world is running out of chocolate @name1 Ukraine president has lots for sale... @name2 This jst sounds like a re-packaged story from the last 3 years. 'blame Asia' - 'blame poor harvest @name1 @name2 nooo! @name1 Where is congress on the really important stuff like this? where do republicans stand? how about the democrats? **Generated Response:** @name1: the world is running out of chocolate?
Source: 'Nine Britons, 23 US citizens and 80 children' feared dead after #MH17 jet 'shot down' [URL] **Response:** @name1 230 + dead in #gaza! Murdered openly by #Israel #Genocideingaza @name1 Shot down-that's not confirmed yet-just speculation-two crashes of a Malaysian airline 777 within 4 months that's a fact @name2 now that's disturbing! @name1 The added horror here will be if no-one does anything about it. If it was a Russian missile Putin will need to answer for it @name1 It is so very tragic and saddening that so many lives were lost, no matter whether they were American or Briton or neither. @name1 Why comment on the US citizen number? Are there lives worth more than other nations? @name1 I bet each one blames the other, but my thoughts are the rebels/Russians may be in line as the suspects. @name1 A tragic day-my deepest condolences and thoughts go to the relatives and loved ones of the 295 people **Generated Response:** @MH17 @name1: A list of the dead in the Malaysia airlines plane shot down.
Source: CDC has confirmed that the patient in Dallas has tested positive for the Ebola virus. We'll have more coming up on Khou 11 news **Response:** @name1 What?! I need to read about this. Is it saying this originated here in the states or is this someone who traveled abroad @name1: CDC has confirmed that the patient in Dallas has tested positive for the Ebola virus. Basically everyone in Texas is dead... RT @name1 CDC has confirmed that the patient in Dallas has tested positive for the Ebola virus. We'll have more... @name3 @name4 @name1 following strict medical guidelines is probably more effective than praying. right about less... @name1 We in the US are safe, we have the needs to treat Ebola at small numbers here. Plus he was traveling from west @name1: CDC has confirmed that the patient in Dallas has tested positive for the Ebola virus. g2g leaving the country @name5 @name1: CDC has confirmed that the patient in Dallas has tested positive for the Ebola virus... **Generated Response:** @name1 @name2: A patient in Texas has tested positive for the Ebola virus.

Abstract

Language model pre-training based on large corpora has achieved tremendous success in terms of constructing enriched contextual representations and has led to significant performance gains on a diverse range of Natural Language Understanding (NLU) tasks. Despite the success, most current pre-trained language models, such as BERT, are trained based on single-grained tokenization, usually with fine-grained characters or sub-words, making it hard for them to learn the precise meaning of coarse-grained words and phrases. In this paper, we propose a simple yet effective pre-training method named *LICHEE* to efficiently incorporate multi-grained information of input text. Our method can be applied to various pre-trained language models and improve their representation capability. Extensive experiments conducted on CLUE and SuperGLUE demonstrate that our method achieves comprehensive improvements on a wide variety of NLU tasks in both Chinese and English with little extra inference cost incurred, and that our best ensemble model achieves the state-of-the-art performance on CLUE benchmark competition.

1 Introduction

Pre-trained language models (PLMs) such as GPT (Radford et al., 2018), BERT (Devlin et al., 2019) and XLNet (Yang et al., 2019) have become enormously popular and achieved great success on diverse natural language understanding tasks, such as sentiment analysis, question answering, and language inference. These models usually utilize a transformer architecture (Vaswani et al., 2017) to capture the dependencies between tokens in the input text, to model the language information, and to learn contextual representations. It is first pretrained based on large-scale unlabeled corpora, and subsequently fine-tuned based on the labeled data from downstream tasks.

In many NLU applications, tokenization often affects the performance and needs to be chosen carefully. The input tokens for pre-trained language models are usually fine-grained, e.g., words and sub-words for English and characters for Chinese. Compared with coarse-grained tokens such as phrases, the advantage of fine-grained tokens is that they form a smaller vocabulary, yielding abundant training samples per token, and thus alleviating the data sparsity issue and out-of-vocabulary (OOV) problem (Li et al., 2019). However, even trained on large corpora, it is still hard for language models pre-trained with fine-grained tokens to learn the correct attention boundaries of larger semantic units in many languages (Zhang and Li, 2020).

To obtain a more accurate model, prior studies attempt to incorporate coarse-grained information into models trained with fine-grained tokenization by masking sequences of consecutive tokens in the pre-training stage (Joshi et al., 2020; Cui et al., 2019). Zhang and Li (2020) propose AMBERT, a Siamese network based on BERT to handle multi-grained input text, and uses two encoders with shared weights to separately encode fine-grained tokens and coarse-grained tokens into two sequences of contextualized representations. Despite its effectiveness, the inference cost of AMBERT almost doubles that of the original BERT due to the dual-encoder structure, which is often unacceptable in industrial scenarios.

In this paper, we propose a novel method named *LICHEE* designed to efficiently leverage the input information at multiple levels of granularity in the pre-training stage in order to enhance the representation ability of PLMs. Unlike AMBERT that encodes the fine-grained and coarse-grained tokens with two encoders, which significantly increases the inference cost, in *LICHEE* the fusion of multi-

---

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1383–1392
August 1–6, 2021.

grained information of input text happens at the embedding level, which requires no change on the original model structure of the PLM, and thus induces little extra inference cost when applied in online NLP applications. Specifically, *LICHEE* first pre-processes the input text into fine-grained and coarse-grained tokens, which are passed through two embedding layers, respectively, to derive their corresponding vector representations. Both vector representations are then merged via pooling to form the *multi-grained embedding vector*, which serves as the input to the PLM encoder. Finally, the enhanced contextual representations generated by the PLM encoder, with both fine-grained and coarse-grained information incorporated, are obtained and used for downstream tasks.

We have applied *LICHEE* to enhance multiple different pre-trained language models, including BERT (Devlin et al., 2019), ALBERT (Lan et al., 2019), and GPT (Brown et al., 2020), and conducted extensive evaluation of the resulted language models on Chinese natural language understanding (NLU) tasks evaluated by CLUE (Liang Xu, 2020) benchmarks. Results show that with *LICHEE*, the resulted pre-trained language models significantly outperform their single-grained counterparts on almost all tasks, by taking advantage of multi-grained information to effectively and efficiently produce more accurate representations.

In addition, we also participated in the CLUE benchmark competition with our best ensemble model built upon a collection of *LICHEE*-enhanced BERT-large models, and achieved the state-of-the-art performance of an average score of 80.42 (as of January 8, 2021) over 9 different Chinese NLU tasks, as well as the best scores on two individual tasks: IFLYTEK and CSL.

Moreover, we have also conducted English natural language understanding experiments based on SuperGLUE (Wang et al., 2019a) benchmarks. Significant improvements are observed when *LICHEE* is employed in the pre-training stage, which demonstrates that the proposed pre-training method is generally effective in different language settings.

2 Related Work

In this section, we give a brief overview of some popular pre-trained language models and studies on the training techniques related to tokenization.

Pre-trained language models are pre-trained on large unsupervised corpora and aim to produce meaningful representations for each input token not only considering the meaning of itself, but also with its surrounding contexts anticipated. ELMo (Peters et al., 2018) is one of the first pre-trained language models based on bidirectional LSTMs which produces the contextual representation of each token by concatenating its left-to-right and right-to-left representations. GPTs (Radford et al., 2018, 2019; Brown et al., 2020) leverage the powerful Transformer (Vaswani et al., 2017) to build an auto-regressive language model predicting the next token given its history context. BERT (Devlin et al., 2019) is a bidirectional auto-encoding language model also based on transformer. It consists of two pre-training objectives: masked language model (MLM) and next sentence prediction (NSP). Yang et al. (2019) point out the discrepancy of the pre-training and fine-tuning stage of BERT due to the masking symbol, and propose a permutation language model called XLNet (Yang et al., 2019).

The great popularity of BERT draws many researchers to make improvements on the architecture. RoBERTa (Liu et al., 2019) improves several training details of BERT including dynamic masking and the removal of the NSP pre-training task. ALBERT (Lan et al., 2019) reduces the model parameters with cross-layer weight sharing and accelerates the training process. ELECTRA (Clark et al., 2019) proposes a new token detection task and adopts a generator-discriminator framework to pre-train the language model.

Although most pre-trained language models are built on fine-grained tokenization, coarse-grained information proves to be helpful to the model performance. Cui et al. (2019) propose a masking scheme called “whole word masking” (WWM) for Chinese BERT, where the consecutive characters belonging to the same word are masked together. In ERNIE (Sun et al., 2019), knowledge graphs are added to enhance the model, and entity level masking is used during the pre-training, which is beneficial for language understanding tasks. SpanBERT (Joshi et al., 2020) proposes to mask random spans instead of random tokens, and adopts a new span boundary objective task to replace the next sentence prediction task in the pre-training. Instead of focusing on the masking scheme, AMBERT (Zhang and Li, 2020) proposes to adopt two encoders with shared parameters to learn the representations of fine-grained and coarse-grained tokens in parallel. However, even that the weight sharing setting reduces the number of model parameters, the dual-encoder structure of AMBERT induces twice the inference cost, which remains a huge issue when deployed in online applications.

Different from AMBERT, our work merges the fine-grained and coarse-grained tokenization at embedding level, and achieves significant performance gains with little additional computation costs.

3 Methodology

In this section, we present *LICHEE*, the general multi-grained framework for language model pre-training, and its detailed implementation, including the pre-training methods for both auto-regressive and auto-encoding tasks and fine-tuning details.

3.1 Model Architecture

Figure 1 gives an overview of *LICHEE* where the input information from multiple granularities is leveraged to enhance the representation ability for many pre-trained language models.

The framework takes in text sequences as input which are tokenized into token sequences. In this paper, we keep two vocabularies and use two tokenizers to perform fine-grained and coarse-grained tokenizations, where items in vocabularies are selected based on their token frequencies in pre-training corpora. Also, the definitions of “fine grain” and “coarse grain” vary across languages. For example, in English, words and phrases are often used as the fine-grained and coarse-grained tokens respectively. And in Chinese, characters and words are used instead. Officially, for a given input text sequence T, we use t_i^f to denote the i-th fine-grained token and $t_{j\text{-}k}^c$ to denote a coarse-grained token that is composed of fine-grained tokens $\{t_j^f, ..., t_k^f\}$ between j and k. For example, in figure 1, the coarse-grained token “New York Times” is composed of the first, sencond, and third fine-grained tokens, and is denoted as $t_{1\text{-}3}^c$.

After tokenization, two separate embedding layers are used to map the tokenized tokens to their vector representations. Specifically, each fine-grained token t_i^f is passed into a fine-grained embedding layer to produce the fine-grained embedding vector $\vec{e}_i^f \in \mathcal{R}^d$ of the token, where d denotes the dimension of the fine-grained embedding. Similarly, the coarse-grained embedding $\vec{e}_{j\text{-}k}^c \in \mathcal{R}^d$ is derived with the same dimension d by feeding token $t_{j\text{-}k}^c$ to the coarse-grained embedding layer, shown as:

$$\begin{aligned} \vec{e}_i^f &= embedding_{fine}(t_i^f), \\ \vec{e}_{j\text{-}k}^c &= embedding_{coarse}(t_{j\text{-}k}^c). \end{aligned} \tag{1}$$

For each token t_i^f, we construct its multi-grained embedding vector $\vec{e}_i \in \mathcal{R}^d$ by performing a max-pooling operation on the derived fine-grained embedding $\vec{e}_i^f$ and the coarse-grained embedding $\vec{e}_{j\text{-}k}^c$ of its corresponding coarse-grained token $t_{j\text{-}k}^c$:

$$\vec{e}_i = \textit{max-pool}(\vec{e}_i^f, \vec{e}_{j\text{-}k}^c), \tag{2}$$

where $j \leq i \leq k$. Note that d is equal to the original embedding dimension of the single-grained PLM, to prove that the performance gain is contributed to the introduction of multi-grained information other than modified model structure.

Finally, the combined embedding vectors $\vec{\boldsymbol{e}}$ are fed into the PLM encoder to construct the final contextualized representations $\vec{\boldsymbol{h}}$ enhanced with multi-grained information:

$$\vec{\boldsymbol{h}} = encode(\vec{\boldsymbol{e}}). \tag{3}$$

3.2 Pre-training

We have applied *LICHEE* on both auto-regressive and auto-encoding PLMs, such as GPT and BERT.

For ***auto-regressive PLMs***, the pre-training task is Next Token Prediction which aims to predict the next token t_i based on its previous context $t_{<i}$, by optimizing the following objective function

$$\min_\theta - \sum_i \log p_\theta(t_i | t_{<i}), \tag{4}$$

where the conditional probability p_θ is modeled with a network with parameter θ.

In our framework, we adjust the objective function to include both fine-grained context $t_{<i}^f$ and coarse-grained context $t_{<i}^c$, shown as:

$$\min_\theta - \sum_i \log p_\theta(t_i | t_{<i}^f, t_{<i}^c). \tag{5}$$

Note that when making predictions on any token within a coarse-grained span $t_i \in t_{j\text{-}k}^c$, the token embedding $\vec{e}_i$ will cause information leakage as it involves the coarse-grained token embedding $\vec{e}_{j\text{-}k}^c$ which contains information beyond the history context. For example, in the case illustrated in figure 1, the prediction on token “York” should not rely

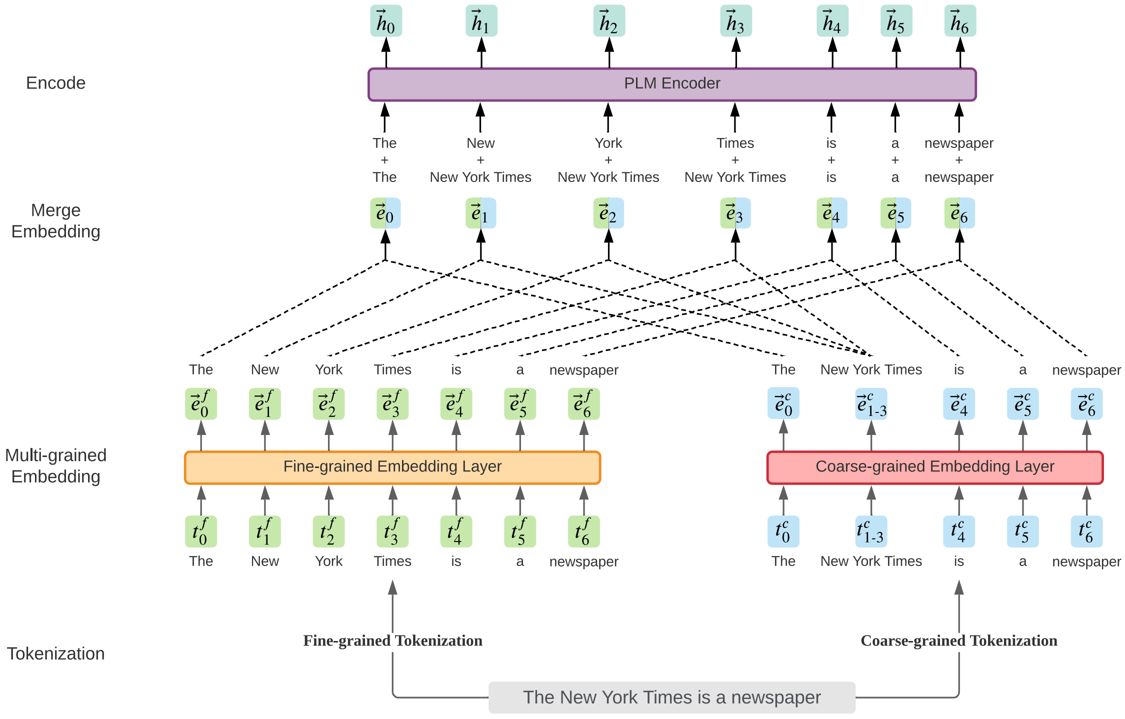

Figure 1: The overall structure of our proposed pre-training framework *LICHEE*. Fine-grained and coarse-grained tokens are first derived from the input text by tokenization, and separately passed into two individual embedding layers. The multi-grained embedding vectors are acquired by taking a max-pooling on the fine-grained and coarse-grained embedding vectors, and are fed into the PLM encoder to extract the final contextualized representations.

on token “New” and its embedding $\vec{e}_1$ as it discloses the entire information of the coarse-grained token of “New York Times” by the coarse-grained embedding $\vec{e}^c_{1\text{-}3}$. Therefore, we can only exploit the context before the start position of the coarse-grained token to make predictions, illustrated as:

$$\min_\theta - \sum_{j \le i \le k} \log p_\theta(t_i | t^f_{<j}, t^c_{<j}), \qquad (6)$$

where j and k are the start and end positions of the coarse-grained token.

For ***auto-encoding PLMs***, we only include Masked Language Modeling (MLM) task in the pre-training process, as Next Sentence Prediction (NSP) task is shown to have no benefits indicated in many recent studies (Lan et al., 2019; Liu et al., 2019; Zhang and Li, 2020). In MLM, 15% of the tokens are randomly selected and substituted with a set of tokens, in which 80% are replaced with *[MASK]* token, 10% are replaced with random tokens, and 10% stay unchanged.

The objective is to recover the masked tokens $T^m \subset T$ from the altered text input sequence $\tilde{T}$:

$$\min_\theta - \sum_{t^m \in T^m} \log p_\theta(t^m | \tilde{T}). \qquad (7)$$

In our framework, we propose to exploit the multi-grained information of the input in the MLM task, shown as:

$$\min_\theta - \sum_{t^m \in T^m} \log p_\theta(t^m | \tilde{T}^f, \tilde{T}^c), \qquad (8)$$

where $\tilde{T}^f$ and $\tilde{T}^c$ stand for the fine-grained and coarse-grained altered input text.

Similar to the strategy deployed in auto-regressive PLMs, we apply a masking strategy that when a fine-grained token t^f_i is to be masked, its corresponding coarse-grained token $t^c_{j\text{-}k}$ and all the fine-grained tokens $t^f_j, ..., t^f_k$ belonging to it are also masked, in order to avoid information leakage from the multi-grained embeddings.

3.3 Fine-tuning

In fine-tuning of downstream tasks, we append the special tokens (*[CLS]*, *[SEP]*) to both fine-grained and coarse-grained vocabularies. In sentence-level classification tasks, *[CLS]* is attached to the start of input sequences in auto-encoding PLMs like BERT, and to the end of the input in auto-regressive PLMs like GPT. Its multi-grained contextualized representation $\vec{h}_{[CLS]}$ is used to represent the whole input sequence and is passed into a projecting layer for the final prediction.

Similarly, for tasks that include token-level span detection, such as Question Answering, the contextual representation $\vec{h}_i$ for each token t_i is extracted and utilized in the task.

4 Experiments

We have carried out extensive experiments on various natural language understanding tasks on both Chinese and English datasets. In the following section, we will first introduce the pre-training datasets used in our evaluation and provide the implementation details of our framework. And we demonstrate the effectiveness of *LICHEE* by conducting comprehensive experiments on various Chinese NLU datasets with multiple different PLMs, and compare our method with other baseline methods. Next, we perform a thorough ablation study to evaluate different approaches of integrating input text information from multiple granularities. Finally, we adopt *LICHEE* to an English BERT to verify its efficacy on English NLU tasks.

4.1 Pre-Training Datasets

For Chinese language, there is no commonly used corpus for pre-training language models. We utilize a large corpus consisting of 450G text from a wide range of popular Chinese applications including Kandian, Zhihu, Wechat, and Weibo, in various fields of news, wiki, and blogs.

Similar to most Chinese PLMs, characters are used as fine-grained tokens due to the language nature of Chinese. For coarse-grained tokens, We use QQSeg which is a segmentation tool with an open API to perform segmentation on text, and the segmented words are treated as coarse-grained tokens. For the construction of vocabularies, we follow Google's Chinese BERT and include $21,128$ tokens in the fine-grained vocabulary. And in the coarse-grained vocabulary, we calculate the token frequencies and trimmed out tokens with frequency lower than 8, resulting in $210,946$ tokens. Note that in order to alleviate the out-of-vocabulary (OOV) problem, all tokens in the fine-tuned vocabulary are also included in coarse-grained vocabulary.

For English, a corpus with 6.2 million documents (18.9G compressed text) from Wikipedia is leveraged to pre-train the model. We first perform sub-word tokenization with BPE algorithm (Sennrich et al., 2015) on the English text, where the produced words and sub-words constitute the fine-grained vocabulary of $28,996$ tokens. In the coarse-grained vocabulary, we treat high-frequency words as coarse-grained tokens, resulting in $136,630$ tokens in total, which also include all tokens in the fine-grained vocabulary for the OOV concern.

4.2 Benchmarks

The evaluation of the pre-trained models is conducted on various downstream NLU tasks. In our experiments, all the Chinese PLMs are evaluated on Chinese Language Understanding Evaluation (CLUE) (Liang Xu, 2020) which is a comprehensive language understanding benchmark developed for Chinese containing 9 natural language understanding tasks. Within the 9 tasks, there are two single-sentence classification tasks that are TNEWS and IFLYTEK, four sentence-pair classification tasks that are AFQMC, OCNLI, CLUEWSC and CSL, and three question answering tasks that are CMRC2018, CHID, and C3. Note that OCNLI has replaced CMNLI since Oct 22, 2020. We compare the model performance by reporting the performance score of each task and the average score of all tasks.

For English tasks, we use the SuperGLUE benchmarks (Wang et al., 2019a) which is an extension of GLUE (Wang et al., 2019b) consisting of a collection of 8 NLU tasks of higher difficulty for comprehensively evaluating the performance of English PLMs. SuperGLEU contains a word sense disambiguation task (WiC), two textual entailment tasks (CB and RTE), two reasoning tasks (COPA and WSC), and three question answering tasks (BoolQ, MultiRC, and ReCoRD).

4.3 Experiment Setup

In order to demonstrate the general applicability and effectiveness of our framework, we have implemented three different pre-trained language models with our method including BERT, ALBERT and GPT, and compare the performances with their corresponding single-grained baseline methods.

For BERT and ALBERT, we follow the "base" structure in (Devlin et al., 2019) with an encoder of 12 layers. And the GPT model in our experiment is also made up of a 12-layer transformer decoder.

Table 2: Top-5 models on the CLUE benchmark leaderboard where our ensemble model achieves the state-of-the-art performance on the averaged CLUE score. These results are grabbed from the official CLUE website[1]on Jan 8, 2021.

Then, we apply the following training setting to the training process of all three models. For better scalability in large batch, we adopt LAMB (You et al., 2019) to replace Adam (Kingma and Ba, 2014) as the optimizer with a batch size of 768 and a learning rate of $2e-4$. We first train the model for 1M steps using 128 as the maximum sequence length, and increase the maximum length to 512 for another 100k steps, for better capturing the long distance dependencies. To enhance the training efficiency, we adopt mix-precision training technique (Micikevicius et al., 2017) during pre-training, which are performed on 4 Nvidia V100 gpus.

We have also implemented a *LICHEE*-enhanced ensemble model based on BERT-large to participate in the CLUE benchmark competition. During training, we adapt the batch size to $1,024$ and the maximum sequence lengths at the first and second stage are set to 256 and 512. And 64 Nvidia V100 gpus are used to train the model.

For the evaluation of each task, we derive 6 results with different random seeds and report the average performance in this paper.

4.4 Main Results

In table 1, we adopt our multi-grained pre-training method on three pre-trained language models: BERT, ALBERT, and GPT, and compare them with their single-grained baselines on CLUE benchmark. From the results, we can see that our method achieves significant performance gains by exploiting the multi-grained information of the text input. The averaged CLUE scores of our multi-grained BERT-*LICHEE*, ALBERT-*LICHEE* and GPT-*LICHEE* are 73.92, 69.30 and 68.73 respectively, producing significant absolute improvements of 2.80, 2.03, and 1.32 compared to their single-grained baseline models. Aside from the improvement on the averaged CLUE score, it is also worth to mention that our multi-grained BERT-*LICHEE* and GPT-*LICHEE* outperforms their single-grained baselines on all 9 NLU tasks in CLUE, while the ALBERT-*LICHEE* model also beat the single-grained ALBERT in 8 out of 9 tasks, which provides strong evidence that the benefits of our method are generally applicable to different pre-trained language models and diverse NLU tasks.

In order to further investigate the potential of *LICHEE*, we apply it on an ensemble model based on BERT-large and participate in the CLUE benchmark competition. As demonstrated in table 2, our method outperforms all other candidates on the average score of 9 CLUE tasks by a significant margin, and also achieves the state-of-the-art performance on two individual NLU tasks of IFLY-

Table 3: Ablation study of different pre-training strategies with BERT model on CLUE dataset. Two single-grained (SG) baselines and five multi-grained (MG) methods (*LICHEE* and its variants) with different ways of integrating the fine-grained and coarse-grained representations are evaluated.

TEK and CSL. This results further proves that our multi-grained pre-training method is able to bring significant improvements on the representation ability of language models and is generally effective to a wide range of downstream NLU tasks.

The reason of *LICHEE*'s success is that we adopt a multi-grained pre-training strategy to model the contextual information of the input text to leverage the advantages from both granularities, where fine-grained token representations are easier to learn considering the sufficient training samples, and coarse-grained tokens are more complete as lexical units and provide more accurate contextual information. Furthermore, in our framework, the combination of the multi-grained information is realized on the embedding level so that we can keep the model structure unaltered, showing that the benefits are achieved entirely through the information gains caused by multi-grained pre-training other than model-level modifications.

4.5 Ablation Analysis

We have conducted ablation analysis on CLUE benchmarks with BERT, to evaluate the impact of our multi-grained design, as well as perform a comprehensive study on the different methods of integrating the multi-grained embedding. Table 3 lists the performance of model variants with different training strategies, including two single-grained methods and five multi-grained methods.

The original single-grained BERT whose masking scheme is solely based on fine-grained tokens gives an average CLUE score of 71.12. The Whole Word Masking (WWM) technique (Cui et al., 2019) performs masking operations on continuous fine-grained tokens that form a coarse-grained token and improves the performance to 72.24. Note that although WWM utilizes coarse-grained token boundary information during the masking operations, it does not explicitly train representations for coarse-grained tokens. Therefore, we treat WWM also as a single-grained pre-training method.

For multi-grained pre-training methods, we have conducted experiments to explore five different approaches of combining embedding representations of fine-grained and coarse-grained tokens, including concatenating the embedding vectors with different dimension settings, and integrating them with mean-pooling and max-pooling. For the concatenation approaches, we keep the dimension of the concatenated multi-grained embeddings to 768 to align with the baseline models, and apply three settings to adjust the dimensions of fine-grained and coarse-grained embedding correspondingly to (384, 384), (256, 512) and (512, 256). Empirically, we discover that the three concatenation settings achieve similar performances, while having larger embedding vectors for fine-grained tokens and smaller embedding vectors for coarse-grained tokens produces a slightly better performance of 73.08 average CLUE score.

Exploiting mean-pooling to integrate the multi-grained information gives more performance gains compared with concatenation methods and reaches 73.22 average CLUE score, which may be attributed to the greater number of embedding parameters, as pooling methods do not require a shrink on the embedding dimension and allow both fine-grained and coarse-grained embedding dimension to stay 768. Finally, *LICHEE* with the max-pooling incorporated outperforms all the fore-mentioned approaches, attains an overall score of 73.92, and achieves the best score on 3 out of 9 CLUE tasks, due to its capability of extracting more representative features. Especially for the task of CLUEWSC, *LICHEE* acquires an accuracy of 81.03 while the second best method only reaches 76.54. We believe this is because the small training set of CLUEWSC

Model	**Avg.** -	**BoolQ** acc.	**CB** acc.	**COPA** acc.	**MultiRC** EM.	**ReCoRD** EM.	**RTE** acc.	**WiC** acc.	**WSC** acc.
BERT-WWM	63.64	77.13	79.76	62.83	24.88	65.20	70.88	64.50	63.94
BERT-*LICHEE*	**65.53**	**77.98**	**88.21**	**63.00**	**25.41**	**67.50**	**71.91**	**65.45**	**64.81**

Table 4: Comparison between our multi-grained BERT-*LICHEE* and the single-grained BERT-WWM on SuperGLUE tasks.

Model	FLOPs	Speedup
BERT	43.5B	1.0x
AMBERT	87.0B	0.5x
LICHEE	43.5B	1.0x

Table 5: Comparison of FLOPs and speedup among the single-grained BERT, AMBERT, and our method.

with only 532 examples makes it more dependent on powerful pre-trained representations, so that the advantage of the max-pooling method is amplified.

Overall, we can see from table 3 that all multi-grained pre-training methods outperform the single-grained baselines by a significant margin, which again proves that our idea of incorporating multi-grained information during the pre-training phase is efficacious and can benefit model performance considerably.

4.6 Inference Speed Analysis

We have also studied the inference speed of *LICHEE* and compare it with the original single-grained BERT and another multi-grained method AMBERT.

Table 5 gives a brief comparison in terms of FLOPs and speedup, tested on a binary classification task with 512 sequence length. FLOPs indicates the number of floating-point operations that the model performs for a single process, where generally speaking, the higher the model's FLOPs is, the slower the inference speed will be.

We can see that the FLOPs of the AMBERT is 87.0 billion, twice the number of the single-grained BERT. It means the inference time of AMBERT is almost doubled, which can cost a lot more time and resources, and often can be unacceptable for real-world applications. Meanwhile, our multi-grained method produces a model with 43.5 billion FLOPs with a negligible increase compared with the single-grained baseline, because the additional operations only include an embedding lookup operation for coarse-grained tokens and a max-pooling operation to integrate the fine-grained and coarse-grained embedding vectors. In summary, *LICHEE* can produce significant performance gains with negligible extra inference time needed.

4.7 English Tasks

We have also conducted experiments on SuperGLUE benchmarks to evaluate *LICHEE* on English language tasks, and compared it with the single-grained baseline: BERT-WWM (Cui et al., 2019).

As shown in table 4, the BERT model pre-trained with our multi-grained method outperforms the single-grained BERT-WWM on all 8 SuperGLUE tasks, and attains an average score of 65.53 surpassing the baseline by 1.89. This improvement over BERT-WWM demonstrates that the effectiveness of *LICHEE* is attributed greatly to the information gain of its multi-grained representations, more than just token boundary information. We also notice that, similar to the CLUEWSC task, a huge increase of 8.45 on accuracy is achieved for the CB dataset of 250 training samples, because our pre-training method leverages the information gains of multi-grained tokens and produces more accurate representations, which is especially effective on tasks with small training data.

This result evidently illustrates that *LICHEE* is not only effective on tasks of character based language like Chinese that highly relies on correct tokenizations, but can also produce significant improvements on languages that are naturally tokenized such as English.

5 Conclusion

In this paper, we have proposed a novel multi-grained method for language model pre-training named *LICHEE*, which can be applied to both auto-regressive and auto-encoding PLMs. In our method, the fine-grained embeddings and the coarse-grained embeddings are separately learned and integrated as the multi-grained embeddings, which is then passed into the encoder of the language model. Experiments show that *LICHEE* can significantly enhance the model performance by a great margin on downstream tasks of both Chinese and English, and significantly improve the inference speed compared to the prior multi-grained method.

Abstract

Neural sequence models can generate highly fluent sentences, but recent studies have also shown that they are also prone to hallucinate additional content not supported by the input. These variety of fluent but wrong outputs are particularly problematic, as it will not be possible for users to tell they are being presented incorrect content. To detect these errors, we propose a task to predict whether each token in the output sequence is hallucinated (not contained in the input) and collect new manually annotated evaluation sets for this task. We also introduce a method for learning to detect hallucinations using pretrained language models fine tuned on synthetic data that includes automatically inserted hallucinations. Experiments on machine translation (MT) and abstractive summarization demonstrate that our proposed approach consistently outperforms strong baselines on all benchmark datasets. We further demonstrate how to use the token-level hallucination labels to define a fine-grained loss over the target sequence in low-resource MT and achieve significant improvements over strong baseline methods. We also apply our method to word-level quality estimation for MT and show its effectiveness in both supervised and unsupervised settings [1].

1 Introduction

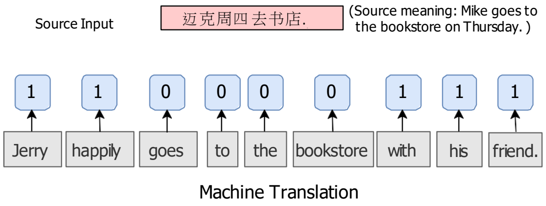

Figure 1: An example of token-level hallucination detection from MT. The grey box is an example of MT output and the labels above indicate if each word is faithful (0) to the input or hallucinated (1).

Neural sequence models for tasks such as data-to-text generation (Puduppully et al., 2019), machine translation (MT; Vaswani et al. (2017); Wu et al. (2016)) and text summarization (Rothe et al., 2020) can often generate fluent text that is sometimes *preferred* to human-written content (Läubli et al., 2018; Brown et al., 2020). However, they also often generate texts that lack global logical consistency (Marcus and Davis, 2020), are dull and repetitive (Welleck et al., 2019), or contain hallucinated content that is not entailed by the input (Maynez et al., 2020; Martindale et al., 2019). In this paper, we focus on tackling the latter problem, aiming to automatically identify and quantify content in the output that is not faithful to the input text.

The risk of generating unfaithful content impedes the safe deployment of neural sequence generation models. The first step to building models that do not suffer from these failures is the assessment and identification of such hallucinated outputs. Prior work has shown that standard metrics used for text evaluation, such as BLEU scores (Papineni et al., 2002; Post, 2018), ROUGE (Lin and Hovy, 2004) and BERTScore (Zhang et al., 2019), do not correlate well with the faithfulness of model outputs (Maynez et al., 2020; Wang and Sennrich, 2020; Tian et al., 2019). They also require reference output text, limiting their applicability in a deployed system at run-time. Very recent efforts have started to develop automatic metrics to measure the faithfulness of output sequences using external semantic models, e.g. the question-generation and question-answering systems (Wang et al., 2020a; Durmus et al., 2020) or textual entailment inference models (Maynez et al., 2020), to score faithfulness tailored for abstractive text summarization. However, these scores do not directly identify hal-

lucinated tokens and only correlate weakly with human judgements.

We propose a new task for faithfulness assessment - hallucination detection at the token level, which aims to predict if each token in the machine output is hallucinated or faithful to the source input. This task does not use the reference output to assess faithfulness, which offers us the ability to also apply it at run-time. Similar to the spirit of our proposed task, word-level quality estimation (Specia et al., 2018; Fonseca et al., 2019) in the MT community predicts if tokens are correctly translated based on human post-editing. However, these methods generally do not distinguish errors in terms of fluency and adequacy (Specia et al., 2011), with the exception of a subset of the WMT 2020 shared task on quality estimation (Specia et al., 2020), where different types and levels of severity of word-level errors are defined. Our proposed task specifically focuses on hallucination errors, and we define these errors in a simpler way with only binary labels, which we argue makes them simpler to use and more conducive to labeling at large scale. The proposed hallucination detection method (described below) is also applicable to the word-level quality estimation task as demonstrated in §5.4.

We measure hallucination for two conditional sequence generation tasks – abstractive summarization and MT. For the former, we produce a benchmark dataset from recently released annotations (Maynez et al., 2020). For MT, we carefully design human assessment guidelines and create high-quality annotations, which will be released to aid future research. To learn token-level hallucination prediction for general conditional sequence generations tasks, we propose a novel method that creates synthetic "hallucinated" data and finetunes a pretrained language model (Liu et al., 2019; Conneau et al., 2020) on it. Without any human annotated supervised training data, we achieve an average F1 of around 0.6 across all the benchmark datasets, setting initial performance levels for this new task.

Predicting hallucination labels at the token level provides a tool for diagnosing and interpreting model outputs, which allows us to flag potential risks when the model is applied to previously unseen inputs. Additionally, we show how to use these token-level hallucination labels in two case studies to improve self-training (Scudder, 1965) and learning from noisy mined bitext (Koehn et al., 2019) in low-resource MT. In both cases, there can be noise in the target text, either produced by the self-training teacher or errors in the mining process. However, most outputs are only partially erroneous (see examples in Appendix E.3) and the rest of the output is still useful for training, as we show by introducing different token-level loss truncation schemes that use our proposed hallucination detection methods. Our best methods outperform strong baselines by a large margin, and reduce the number of hallucinations.

2 Token-level Hallucination Prediction

For source sequence S and generated output sequence G, following Maynez et al. (2020) we define any span $g_i, \cdots, g_{i+j}$ $(j >= 0)$ in G as being "hallucinated" if it is not supported by the source input S.[2] More specifically, we consider two types of hallucination, which are not mutually exclusive:

Extrinsic hallucinations: a span $g_i, \cdots, g_{i+j}$ in G consists of additional content without clear grounding in the input. In Fig. 1, the word *"happily"* in the machine translation belongs to this case, as there is no word in the input sentence that clearly corresponds to "happy".

Intrinsic hallucinations: a span of word(s) in G contains incorrect information due to synthesizing content using information present in S. In Fig. 1, *"Jerry"* in the MT is a hallucinated word and should be replaced by *"Mike"*. Note that multi-word phrases can also be marked intrinsic hallucinations, such as "this is a book" being hallucinated from "this is not a book", where "this is" is a minimal span corresponding to the hallucination.

The above definitions are for illustrative purposes; we do not explicitly label whether a hallucination is intrinsic or extrinsic, only whether one exists at all. Given these spans, we aim to identify all the span(s) satisfying the above conditions in machine generation G.[3]

Human Assessment of Hallucinations To facilitate the assessment of hallucinations in MT, we conduct human annotations on outputs of MT models in the patent and COVID-19 domain. Three bilingual annotators were presented the source sentence, the reference sentence and the MT output, and they were asked to label each sentence with

---

[2] Content that is paraphrased or can otherwise be inferred by the source document is not considered hallucinated.

[3] We do not annotate under-generations e.g. the source input is only partially translated or summarized.

one of the three types of labels: incomprehensible, faithful, and contains hallucinations. If the translation contains hallucinations, we asked the annotators to tag all the tokens that were not faithful to the source. The final benchmark datasets were created by taking majority labels among three annotators. We present more details regarding annotation guidelines and pipelines in Appendix A.

We compute the Fleiss's Kappa (Fleiss, 1971) (FK) scores of our annotations for MT and the processed annotations from (Maynez et al., 2020) on abstractive summarization (Tab. 5 in Appendix A). We achieved moderate agreement (FK≈0.56) on the token-level hallucination annotations and substantial agreement (FK≈0.67) on the sentence-level annotations, while Maynez et al. (2020) achieved substantial or almost perfect agreement (FK≈0.8) on the XSUM dataset. For MT, we conjecture that it is relatively hard to achieve consistent agreement among annotators for several reasons. First, although we have made detailed annotation guidelines following the definition of hallucination in § 2, it could still be difficult for annotators to distinguish between ungrammatical translations and hallucinations. Second, it was sometimes difficult for annotators to understand the specialized text in the patent domain.

3 Token-level Hallucination Detection

We propose a general-purpose method for token-level hallucination detection for conditional sequence generation tasks. Given the source input S, we first formulate the task of token-level hallucination detection as a sequence labeling problem where a binary label is predicted at each position G_t of the machine generation G. One straightforward way of learning this task is to train a model with supervised data in the form of $((S, G), L_G)$ where L_G are the labels at every position of G that indicate if each word is a hallucinated one or not. However, because such labeled training data is not readily available, we propose an approach to automatically create synthetic training data.

3.1 Synthetic Data Creation

We use bi-text from the training data to create synthetic examples by automatically inserting new, hallucinated target-side tokens. More specifically, we take target sequence T and create a hallucinated version of it denoted T' with associated hallucination labels for each token in T'. Then we can train a supervised model on this synthetic labeled data set of $((S, T'), L_{T'})$. The key challenge is that T' should be a fluent sentence that does not differ too much from T.

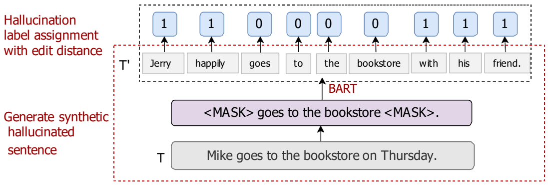

Figure 2: Generation of synthetic data with hallucination labels. A hallucinated version of T is generated by feeding the noised sentence to the encoder-decoder model BART. Hallucination labels are assigned to each token by computing the edit distance between T' and T. Labels of 1 refer to hallucinated words.

Generation of hallucinated sentences To control this synthetic hallucination process, we build on a pre-trained denoising autoencoder, which maps a corrupted sentence back to the original text it was derived from, learning to reconstruct missing words that have been arbitrarily masked out. Specifically, we use the BART model (Lewis et al., 2020), without providing it any access to the source sentence, thereby encouraging it to insert new content as needed to ensure fluency. As shown in Fig. 2, we first apply a noising function that removes words from the original target sentence T[4] and then use a pretrained BART to generate T' conditioned on the noised T with beam search.

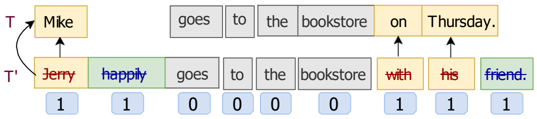

Figure 3: An example of label assignment.

Label assignments After obtaining the hallucinated sentence T' with BART, we need to assign appropriate labels to each token in T' to mark which words are hallucinated. We compute the edit distance between T' and T, and back-trace the deletion and substitution operations with dynamic programming. All the positions in T' involving these two operations are labeled as hallucinations and everything else is considered faithful to T. Fig. 3 shows an example of label assignment with edit distance, where words in red are replaced and words in blue are deleted to convert T' to T. Assigning labels with edit-distance can not always guarantee correct labels, but we find that this simple approach

---

[4] We also applied other noising functions, please see §5.1

provides sufficiently high quality training data for effective hallucination detection in practice.

3.2 Finetuning on Synthetic Data

Hallucination prediction loss We follow the common practice in natural language understanding (NLU) tasks and finetune a pretrained language model (LM) on our synthetic data. We finetune a cross-lingual LM (Conneau et al., 2020) for MT and a monolingual LM (Liu et al., 2019) for summarization. In both cases, we concatenate the input, true target and hallucinated target denoted (S, T, T') as a single input sequence to the model. Then we minimize the standard classification loss $\mathcal{L}_{pred}$ over the pseudo hallucination labels $L_{T'}$ on top of the final hidden vectors of each token in T' as shown in Fig. 4.

Although using only the source text and hallucinated target (S, T') as the input should be sufficient to learn to predict hallucinations, we can also easily measure the extent to which including the true target T in the input could help the model. At test time, when evaluating the faithfulness of the machine outputs G, we do not use the true target T and perhaps surprisingly find our model can generalize well without references, even when they were present during training.

To prevent the model from overly relying on the true target T and learning spurious correlations (e.g. the edit distance), we explored two techniques: (1) *dropout* – randomly drop out tokens in T to force the dependence on the source input; (2) *paraphrase* – recall that at synthetic data generation time, we generate T' from BART conditioned on the noised T. Instead, we can apply noise functions to the paraphrased sentence of T. We create paraphrased targets via knowledge distillation (Kim and Rush, 2016) where we use the output from pretrained Seq2Seq model conditioned on the source sentence in the bi-text corpus as the paraphrased target. Let D denote the paraphrased sentence of T and D' denote the generation from BART conditioned on the noised D. Then we create pseudo labels of D' denoted $L_{D'}$ by computing the edit-distance between the D' and D and use $((S, T, D'), L_{D'})$ as the training data for finetuning. Since the pseudo labels are created based on D, it can prevent the model from learning the edit-distance between T and D' easily. We provide ablation studies in Appendix D.

Masked LM loss We also add the masked language model loss (MLM) $\mathcal{L}_{mlm}$ following (Devlin et al., 2019). To learn this loss, we create a different batch from the above by concatenating only the source S and target T as the input, since the hallucinated target T' could provide erroneous information for predicting masked words in T. We find that such multi-task learning objective helps learn better representations of the input and further improves performance on predicting hallucination labels. The final loss is $\mathcal{L} = \mathcal{L}_{pred} + \alpha \cdot \mathcal{L}_{mlm}$ where α is a hyperparameter.

4 Evaluation Tasks and Data

We examine hallucination in abstractive text summarization and machine translation (MT) tasks, using the models and datasets described below.

4.1 Abstractive Text Summarization

Maynez et al. (2020) studied hallucination problems in extreme summarization on the XSUM dataset which comprises 226,711 British Broadcasting Corporation (BBC) articles paired with their single-sentence summaries. They randomly sampled 500 articles from the XSUM test set and evaluated summaries from four abstractive summarization systems: **PtGen** (See et al., 2017), **TConvS2S** (Narayan et al., 2018), **TranS2S** (Vaswani et al., 2017) and **BERTS2S** (Rothe et al., 2020). Maynez et al. (2020) asked human annotators to label the spans in the machine generated summaries if they were unfaithful to the article. We post-processed their human annotations by majority voting and created test datasets for each of the summarization systems.

4.2 MT

Previous work (Wang and Sennrich, 2020; Müller et al., 2019; Koehn and Knowles, 2017) has shown that translation models are particularly prone to hallucination when tested out of domain. We similarly focus on this regime and additionally consider the low resource case where a modest amount of out of domain data is available at training time.

Data We use a multi-domain Chinese-English (Zh-En) translation dataset (Wang et al., 2020b) which consists of four balanced domains: *law, news, patent* and *subtitles*. We create a new training data $\mathcal{D}_{train}$ with *law* (1.46M sentences), *news* (1.54M), *subtitles* (1.77M) train data and randomly sample 870 parallel sentences from the *patent* training data. We train two NMT models (described below) on this dataset and test on 150 examples from

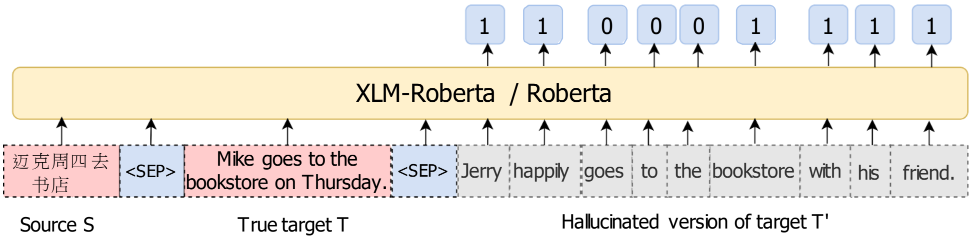

Figure 4: Finetuning XLM-Roberta (for cross-lingual generation task, e.g. MT) or Roberta (for monolingual generation task, e.g. text summarization) on the synthetic training data.

Methods	**MT**		**Summarization**

Table 1: F1 (x100) of hallucination labels on MT (seesection 4.2) and abstractive summarization (XSUM). The first block are baseline methods and the second block are our results. Bold indicates best results not using references.

the patent test data. In addition, we also test the NMT models on the COVID-19 domain, sampling 100 examples from the dataset of Anastasopoulos et al. (2020). We denote this 250-sentence dataset as $\mathcal{D}_{eval}$ and ask human annotators to evaluate the level of hallucinations thereof.

Models Our data is generated from two models on which we will measure hallucination (see Appendix B for more details): (1) **TranS2S** (Vaswani et al., 2017) is the standard Transformer Seq2Seq model with 6 encoder layers and 6 decoder layers. (2) **MBART** (Liu et al., 2020) is a Seq2Seq denoising auto-encoder pretrained on large-scale monolingual corpora in many languages. We finetune the 12 layer model on $\mathcal{D}_{train}$.

5 Experiments

5.1 Experimental setup

Synthetic Data Generation We use a pretrained 12 layer BART (Lewis et al., 2020) model in the fairseq toolkit (Ott et al., 2019) for synthetic labeled data generation. We uniformly sample the percentage of tokens p_m to mask from $[0, h_m]$ for each sentence. We also uniformly sample the probability of replacing a token with a random token from $[0, h_r]$ denoted p_r. p_m and p_r are two important factors that affect the noise level when generating the synthetic data. For MT, we set h_m and h_r to 0.6 and 0.3 respectively. For abstractive summarization, we use 0.4 and 0.2. We use beam search for decoding from BART with beam size of 4 and length penalty of 3. For MT, we first create paraphrased target sentences D' through knowledge distillation (Kim and Rush, 2016) by using the outputs from the same trained TranS2S model on the source inputs.

Hallucination Predictor For MT, we finetune XLM-R (Conneau et al., 2020) on the synthetic dataset with batch size of 128, and we annotated 50 examples (different from those in $\mathcal{D}_{eval}$) from the patent test data as the validation dataset. For summarization, we finetune RoBERTa (Liu et al., 2019) with batch size of 96 and early stop training with 10K update steps. In addition, we dropout tokens from the reference T in the input with a rate of 0.5 and 0.3 respectively for summarization and MT to learn $\mathcal{L}_{pred}$. We set α to be 0.6 for MT and 0.5 for summarization based on the scales of $\mathcal{L}_{pred}$ and $\mathcal{L}_{mlm}$. For both tasks, we set the mask probability used for $\mathcal{L}_{mlm}$ to be 0.5, and the initial learning rate to be $2e-5$ with polynomial decay. We describe other hyperparameters, including training of MT models, in the Appendix B and C.

5.2 Evaluation of hallucination prediction

In Tab. 1, we present the F1 of token-level hallucination labels across six benchmark datasets for MT and abstractive summarization (full results of precision, recall and F1 are presented in Tabs. 7 and 9 in the appendix). We compare with three baseline methods that we proposed for this new task: **(1)** The **alignment-based** method uses a word alignment model for hallucination assessment. We em-

Methods	MT		Summarization			
	TranS2S	**MBART**	**PtGen**	**TConvS2S**	**TranS2S**	**BERTS2S**
True hal. tokens (%)	18.12	11.10	46.09	52.89	46.74	37.51
Pred hal. tokens (%)	18.56	7.99	57.22	57.68	55.78	48.84

Table 2: Annotated (True) and predicted (Pred) percentage of hallucinated tokens on benchmark test sets.

ploy SimAlign (Sabet et al., 2020), an unsupervised aligner, that extracts word alignments from similarity matrices induced from pretrained word embeddings. SimAlign is essentially used for crosslingual tasks, and we adapt it to summarization by using embeddings from the pretrained BERT-large (Devlin et al., 2019). We predict a target token as being hallucinated if it is not aligned to the source tokens. **(2)** The **overlap-based** method is a heuristic one that predicts a target token as being hallucinated if does not appear in the source. Since it's not feasible to perform string matching between two languages for MT, we use a bilingual lexicon induction method (Zhou et al., 2019) to first translate each English word into a Chinese word and then check its existence in the source text. **(3)** We go further by exploiting **synonyms** to assess hallucination in the summarization task where we use WordNet (Miller, 1998) to find synonyms of nouns, verbs, adjectives and adverbs of the target summary and the source article; we predict a target as being hallucinated if its synonym can not be found in the set of the source synonyms.

From Tab. 1, we note: **(1)** The proposed method achieves decent performance on this task and ranks the best among all baseline methods. However the task is still far from being solved is worthy of study in the future. **(2)** We can see that even though our model learns hallucination prediction with reference T during training (Sec. 3.2), by applying token dropout to T, our model generalizes well without feeding the reference at test time. As a contrast, we report the results of predicting with reference at test time and observe that the model can achieve a significantly higher recall but worse precision (Tab. 9 in appendix). **(3)** The two non-neural baselines we proposed work surprisingly well on the summarization datasets, especially the synonym-based system. We guess this is because the information of the summaries should come from the source article and a majority of hallucinated words are nouns (§5.3) which can be easily detected by string matching or synonym matching. Our neural system performs better than these baseline methods but not significantly, and we hypothesize that this is because the RoBERTa model we finetune on only allows a maximum input length of 512, which results in an average cutoff of 158 subwords from the source article and hence loss of source information. By taking the union of the predictions from the synonym-based and our models, we can further obtain improvements on the summarization datasets. We believe the advances in long sequence modeling (Beltagy et al., 2020; Kitaev et al., 2020) could help here, and are important to study in future work. **(4)** At the same time, the baseline methods can not obtain reasonable performance for MT since crosslingual semantic matching is more challenging and our model shows significant improvements.

In Tab. 2, we show the percentage of annotated and model predicted hallucinated tokens across the six benchmark sets. We can see that model predictions correlate well with human assessment and have a Pearson correlation coefficient of 0.986.

5.3 Analysis

Analysis on Pretrained Models for Conditional Sequence Generation Recent work (Maynez et al., 2020) has shown that pretrained models are better at generating faithful summaries as evaluated by humans. In Tab. 2, summaries generated from BERTS2S contain significantly fewer hallucinations than other model outputs. We also confirmed this trend in MT that translations from MBART contain less hallucinated content than that from TranS2S.

Analysis on Hallucinated Words and their Part-of-Speech Tags In Fig. 5, we present the percentage of hallucinated tokens categorized by their part-of-speech tags predicted by a POS tagger (Toutanova et al., 2003). First, we see that for both MT and summarization datasets, nouns are the most hallucinated words. In abstractive summarization, verbs also account for a certain number of hallucinations. Second, our model predicted hallucinated words match well with gold annotations on the distributions of POS tags. We also compare the percentage of hallucinations within each POS tag in Appendix E.2. In addition, we provide more

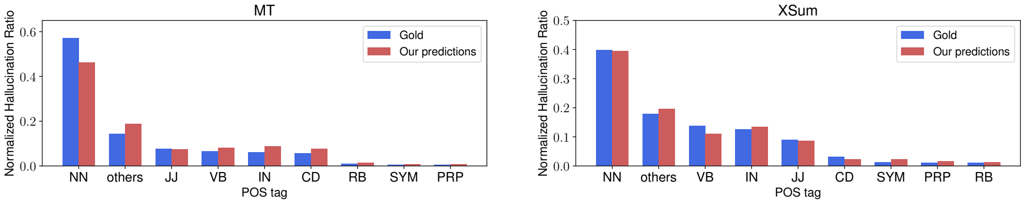

Figure 5: Relationship of POS tags and percentage of hallucinations for MT (left) and summarization (right).

ablation studies in Appendix D.

5.4 Evaluation on Word-level Quality Estimation

As noted in §1, our model is also readily applicable to word-level quality estimation (QE) for MT (Fonseca et al., 2019; Specia et al., 2020), which aims to detect word-level errors in MT output. In the WMT shared task of word-level QE, each token of the target sentence is labeled as OK/BAD based on the post-edited target sentences. We evaluate our model on the WMT18 en-de word-level QE shared task (Specia et al., 2018) in both the unsupervised and supervised setting. There are 13,442 labeled parallel sentences where the tagged target sentences are from an NMT model. In our supervised setting, we finetune the XLM-R model on these parallel sentences with the objective: $\mathcal{L}_{pred} + 0.5 * \mathcal{L}_{mlm}$. In the unsupervised setting, we first create the synthetic data (§3.1) using the post-edited target sentences from the labeled parallel set (13,442) and an additional 50K target sentences from the provided unlabeled parallel set. Then we finetune XLM-R on the created synthetic labeled data. For both settings, we set the weights of the cross-entropy loss for the bad-token labels to be 2.0 because the labels are imbalanced with fewer bad-token labels.

Models	BAD-F1	OK-F1	F1-MULT
OpenKiwi	-	-	44.77
1^{st} place in WMT18	48.00	91.00	44.00
3^{rd} place in WMT18	36.00	85.00	30.00
Ours (unsupervised)	37.09	92.54	34.32
Ours (supervised)	**50.78**	**91.91**	**46.68**

Table 3: F1 scores (x100) on the test set of WMT18 word-level QE. OpenKiwi (Kepler et al., 2019) is the state-of-the-art result on this task. 1^{st} and 3^{rd} place are results from the shared task (Specia et al., 2018).

Results We present results in Tab. 3, where F1-Mult is the multiplication of F1-scores for the OK and BAD labels. Note that all the baseline models are in the supervised setup and the best baseline OpenKiwi (Kepler et al., 2019) is a strong ensembled system using predictions from multiple models. In contrast, our supervised model only leverages the parallel labeled data without using other resources. Among all the supervised settings, our model outperforms the best system by 2 points in F1-Mult. To make it clear how our unsupervised model performs, we also show the best performed systems in the shared task of WMT18. We observe that our unsupervised setting achieves descent performance and even outperforms the 3^{rd}-ranked system. These results demonstrate that both the full version and the finetuning part of our method provide strong results for word-level QE.

6 Case Study I: Improving Self Training in Machine Translation

Predicting hallucination labels at token-level not only allows us to flag potential risks in generation models, but also opens up the possibility of providing fine-grained signals which can be used to define new learning objectives. In this section and the following one, we demonstrate how to leverage the hallucination labels to reduce adverse effects of noisy training instances. Specifically, we show that the fine-grained hallucination signals allow for improved semi-supervised learning (§6) and training with noisy parallel data (§7).

6.1 Rectified Self-Training for Neural MT

Self training (Scudder, 1965) is an important semi-supervised approach that utilizes unlabeled source data to improve system performance. In a conditional sequence generation task, a teacher model is first trained with bitext $\mathcal{D}_l = \{\mathbf{s}_i, \mathbf{t}_i\}_{i=1}^{N}$ and used to make predictions on each sequence in a unlabeled dataset $\mathcal{D}_u = \{\mathbf{s}_j\}_{j=N+1}^{N+M}$ to create *pseudo parallel data* $\mathcal{D}_p = \{\mathbf{s}_j, \mathbf{t'}_j\}_{j=N+1}^{N+M}$. The model is then trained on $\mathcal{D}_l \cup \mathcal{D}_p$. He et al. (2020) finds that with self-training the student model can benefit from such pseudo-parallel data. However, such results require a relatively high-quality teacher, and performance suffers in low-resource setting where no such teacher is available.

We propose to use our token-level hallucination predictions to define a fine-grained loss during training in MT, by penalizing errors less on tokens that more likely to be hallucinated. This is in contrast to previous data filtering methods for MT, which remove entire sentence pairs (Junczys-Dowmunt, 2018; Kang and Hashimoto, 2020).

First, we predict the token-level hallucination labels on the target side of the pseudo parallel data $\mathcal{D}_p$. Then we propose two simple methods of using these labels in self-training: (1) We discard the losses of tokens that are predicted as hallucinations and compute the loss on the remaining tokens for each target sequence (**token loss truncation**). (2) Instead of adjusting losses, we mask the decoder hidden states of those hallucinated positions after the target-to-source cross attention in each decoder layer (**decoder HS masking**).[5]

Methods	BLEU	BLERUT	Hal (%)
baseline	16.14	-0.166	13.69
ST	19.31	-0.059	10.00
ST + paraphrase noise (ST-P)	19.05	-0.051	13.48
ST + random noise (ST-R)	19.97	-0.041	12.55
ST + seq loss truncation	19.91	-0.048	8.26
ST-R + seq loss truncation	19.37	-0.057	10.06
ST + token loss truncation	20.32	0.00244	**6.37**
ST + decoder HS masking	20.57	-0.0001	6.38
ST-R + token loss truncation	**21.02**	**0.043**	7.34
ST-R + decoder HS masking	20.64	0.0308	8.70

Table 4: BLEU(↑), BLEURT(↑) and hallucinated tokens (Hal, ↓) on the CWMT2017 test set. We compare with noised self-training and sequence-level loss truncation in the second and third blocks respectively.

6.2 Experimental Setup and Results

Experimental Setup To train a teacher model (baseline in Tab. 4), we use the same training data described in §4.2 using *patent* (870) as the low-resource domain. We evaluate on the full patent test set (1,500) from CWMT2017 (Wang et al., 2020b). For the unlabeled data, we use the withheld Chinese patent training data (2.9M).

Baselines We compare with the state-of-the-art self-training (ST) method of He et al. (2020), which injects two types of noise into the input sentences: (1) paraphrase noise created by round-trip translations, and (2) random noise from dropping, masking and shuffling input tokens. We also compare with the recently proposed loss truncation method (Kang and Hashimoto, 2020) that adaptively removes entire examples with high log loss, which was shown to reduce hallucinations.

Results and Analysis We present the tokenized BLEU score (Papineni et al., 2002), BLEURT score (Sellam et al., 2020) and the percentage of hallucinated tokens predicted by our system in Tab. 4. We can see that ST improves over the baseline by around 3 BLEU and our best result further improves ST by 1.7 BLEU. Compared with strong baseline methods, our method not only achieves the best translation quality measured by BLEU and BLEURT but also the largest hallucination reduction. We also observe that: (1) Our method with ST alone can outperform other baseline methods, when combined with perturbed ST (noise), and using fine-grained control over the target tokens can further improve the results. (2) ST with paraphrase noise (by round-trip translation) does not perform as well as the random noise, which further confirms that the noisy outputs from a teacher model may hurt the student model. (3) The sequence-level loss truncation approach can improve over the vanilla ST and reduce the level of hallucinations as measured by our system. However, the performance drops when combined with the noised ST.

7 Case Study II: Improving Corpus Filtering for Low-Resource MT

High-quality parallel data is critical for training effective neural MT systems, but acquiring it can be expensive and time-consuming. Many systems instead use mined and filtered parallel data to train NMT models (Junczys-Dowmunt, 2018; Zhang et al., 2020; Koehn et al., 2019). Nonetheless, the selected parallel data can still be noisy, containing misaligned segments. In this section, we demonstrate that token-level hallucination labels can allow us to make better use of noisy data to and improve the overall translation quality. We apply the token loss truncation method proposed in §6 to the filtered parallel data and evaluate it on the WMT2019 low-resource parallel corpus filtering shared task.

Experimental Setup The WMT19 shared task focuses on two low-resource languages – Nepali and Sinhala. It released a very noisy 40.6 million-word (English token count) Nepali-English and a 59.6 million-word Sinhala-English corpus crawled

---

[5] We also tried removing hallucinated target words before training. This underperformed, likely because it produces too many ungrammatical target sentences.

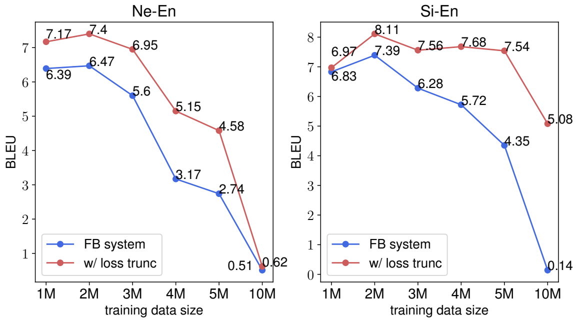

Figure 6: The BLEU scores of the best submission (FB system) in the WMT19 shared task on parallel noisy corpus filtering and our method (w/ loss trunc) on the Ne-En and Si-En flores test sets.

from the web. Participants were asked to score each sentence pair in the noisy parallel set. Scores were used to subsample sentence pairs amounting to 1 million and 5 million English words, which were used to train an MT system that was evaluated on the test set using SacreBLEU (Post, 2018). In addition, the shared task also provides additional clean parallel data for Nepali-English (564K), Sinhala-English (646K) and Hindi-English (1.6M), but they can not be used for training the final NMT system.

First, we train a token-level hallucination prediction system with the combined parallel data from all the three language pairs (as Hindi is related to Nepali). Second, we use the scores (Chaudhary et al., 2019) that achieve the best overall performance for both language pairs among all the submissions to select the top-scored 1M, 2M, 3M, 4M, 5M, and 10M data (in English tokens) and predict the token-level hallucination labels on the target side. We follow the same setup and use the script provided by the shared task to train the NMT model with the selected subsets. During training, we discard losses of tokens that are predicted as hallucinations and only compute the losses for the remaining tokens. We use the validation and test data from the flores dataset (Guzmán et al., 2019) during training and evaluation.

Results and Analysis In Fig. 6, we present the BLEU of the best submission (FB system) and our method on the Ne-En and Si-En test sets of the flores dataset. First, with token-level loss truncation, our model achieves the new best results on the flores test set in this shared task for both Ne-En (7.4) and Si-En (8.11). Second, for both language pairs our method further improves the state-of-the-art system when varying the training data sizes. Notably, in the extreme case of 10M training data, which is very noisy, the baseline can not obtain decent BLEU scores for Si-En while our method still achieves reasonable performance (0.14 vs. 5.18). However, for Ne-En data sizes after 2M causes performance of both the baseline and our method to drop significantly, possibly because the dataset contains many pairs of misaligned sentences (the source is not Nepali and the target is not English).

8 Conclusions

This work proposed a new task of token-level hallucination detection, created human-annotated benchmark datasets, proposed a method for unsupervised learning of hallucination detectors, and showed that the models can be used to define fine grained losses that improve MT training. We demonstrate the remark performance of the proposed hallucination detection method in several downstream tasks, including word-level quality estimation and noisy neural machine translation. In the future, we hope to create a large-scale pretrained hallucination detector for any dataset or model, and also would extend our method to data-to-text generation scenarios. We are also interested in investigating how to leverage our detection methods to mitigate hallucination problems in conditional sequence generation.

Abstract

We study the problem of injecting knowledge into large pre-trained models like BERT and RoBERTa. Existing methods typically update the original parameters of pre-trained models when injecting knowledge. However, when multiple kinds of knowledge are injected, the historically injected knowledge would be flushed away. To address this, we propose K-ADAPTER, a framework that retains the original parameters of the pre-trained model fixed and supports the development of versatile knowledge-infused model. Taking RoBERTa as the backbone model, K-ADAPTER has a neural adapter for each kind of infused knowledge, like a plug-in connected to RoBERTa. There is no information flow between different adapters, thus multiple adapters can be efficiently trained in a distributed way. As a case study, we inject two kinds of knowledge in this work, including (1) factual knowledge obtained from automatically aligned text-triplets on Wikipedia and Wikidata and (2) linguistic knowledge obtained via dependency parsing. Results on three knowledge-driven tasks, including relation classification, entity typing, and question answering, demonstrate that each adapter improves the performance and the combination of both adapters brings further improvements. Further analysis indicates that K-ADAPTER captures versatile knowledge than RoBERTa. [1]

1 Introduction

Language representation models, which are pre-trained on large-scale text corpus through unsupervised objectives like (masked) language modeling, such as BERT (Devlin et al., 2019), GPT (Radford et al., 2018, 2019), XLNet (Yang et al., 2019), RoBERTa (Liu et al., 2019) and T5 (Raffel et al., 2020), have established state-of-the-art performances on various NLP downstream tasks. Despite the huge success of these pre-trained models in empirical studies, recent studies suggest that models learned in such an unsupervised manner struggle to capture rich knowledge. For example, Poerner et al. (2020) suggest that although language models do well in reasoning about the surface form of entity names, they fail in capturing rich factual knowledge. Kassner and Schütze (2020) observe that BERT mostly did not learn the meaning of negation (e.g. "*not*"). These observations motivate us to study the injection of knowledge into pre-trained models like BERT and RoBERTa.

Recently, some efforts have been made to exploit injecting knowledge into pre-trained language models (Zhang et al., 2019; Lauscher et al., 2019; Levine et al., 2020; Peters et al., 2019; He et al., 2020; Xiong et al., 2020). Most previous works (as shown in Table 1) augment the standard language modeling objective with knowledge-driven objectives and update the entire model parameters. Although these methods obtain better performance on downstream tasks, they struggle at supporting the development of versatile models with multiple kinds of knowledge injected (Kirkpatrick et al., 2017). When new kinds of knowledge are injected, model parameters need to be retrained so that previously injected knowledge would fade away. Meanwhile, the resulting models produce entangled representations, so that it is hard to investigate the effect of each kind of knowledge.

In this paper, we propose K-ADAPTER, a flexible and simple framework that supports the infusion of multiple kinds of knowledge into large pre-trained models. K-ADAPTER leaves the original representation of a pre-trained model unchanged and exports different representations for different types of infused knowledge. This is achieved by

Table 1: Comparison between our approach (K-ADAPTER) and previous works on injecting knowledge into BERT.

the integration of compact neural models dubbed adapters. Adapters are knowledge-specific models plugged outside of a pre-trained model, whose inputs are the output hidden-states of intermediate layers of the pre-trained model. We take RoBERTa (Liu et al., 2019) as the base pre-trained model and integrate two types of knowledge, including factual knowledge obtained by aligned Wikipedia text to Wikidata triplets and linguistic knowledge obtained by applying off-the-shell dependency parser to web texts. In the pre-training phase, we train two adapters independently. Since adapters have much less trainable parameters compared with RoBERTa, the training process is memory efficient.

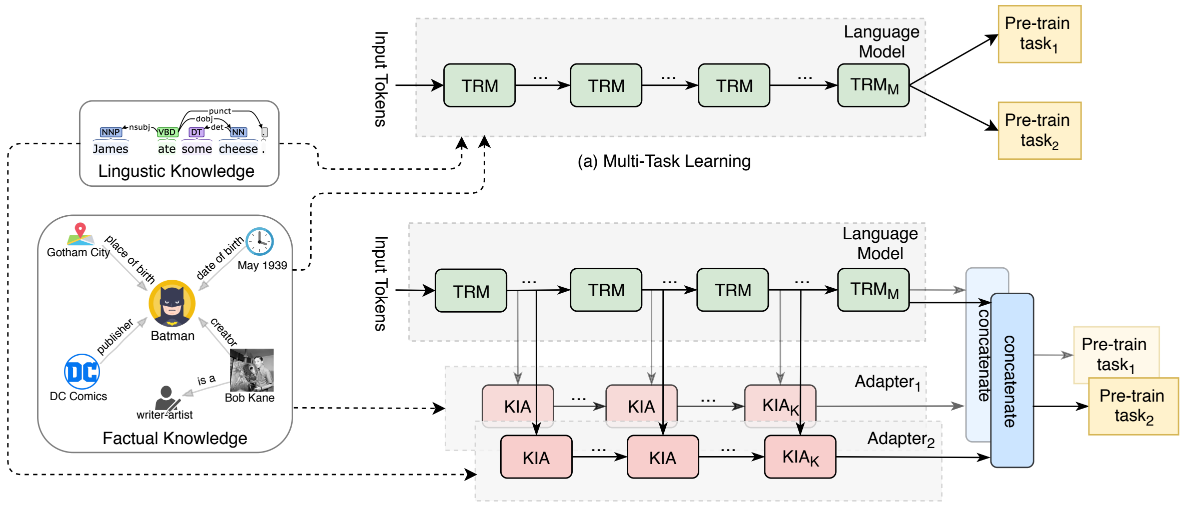
We conduct extensive experiments on six benchmark datasets across three knowledge-driven tasks, i.e., relation classification, entity typing, and question answering. Experiments show that K-ADAPTER consistently performs better than RoBERTa, and achieves state-of-the-art performance on five datasets. Case study and probing experiments indicate that K-ADAPTER captures versatile knowledge than RoBERTa.

2 Related Work

Our work relates to the area of injecting knowledge into pre-trained models. As stated in Table 1, previous works mainly differ from the knowledge sources and the objective used for training.

ERNIE (Zhang et al., 2019) injects a knowledge graph into BERT. They align entities from Wikipedia sentences to fact triples in WikiData, and discard sentences with less than three entities. In the training process, the input includes sentences and linked facts, and the knowledge-aware learning objective is to predict the correct token-entity alignment. Entity embeddings are trained on fact triples from WikiData via TransE (Bordes et al., 2013). **LIBERT** (Lauscher et al., 2019) injects pairs of words with synonym and hyponym-hypernym relations in WordNet. The model takes a pair of words separated by a special token as the input, and is optimized by a binary classification problem, which predicts whether the input holds a particular relation or not. **SenseBERT** (Levine et al., 2020) considers word-supersense knowledge. It inject knowledge by predicting the supersense of the masked word in the input, where the candidates are nouns and verbs and the ground truth comes from WordNet. **KnowBERT** (Peters et al., 2019) incorporates knowledge bases into BERT using Knowledge attention and recontextualization, where the knowledge comes from synset-synset and lemma-lemma relationships in WordNet, and entity linking information in Wikipedia. If entity linking supervision is available, the model is learned with an additional knowledge-aware log-likelihood or max-margin objective. **WKLM** (Xiong et al., 2020) replaces entity mentions in the original document with names of other entities of the same type. The model is trained to distinguish the correct entity mention from randomly chosen ones. **BERT-MK** (He et al., 2020) integrates fact triples from knowledge graph. For each entity, it sample incoming and outcoming instances from the neighbors on the knowledge graph, and replaces head or tail entity to create negative instances. The model is learned to discriminate between real and fake facts.

As shown in Table 1, our model (K-ADAPTER) differs from previous studies in three aspects. First,



(a) Multi-Task Learning

(b) K-Adapter

Figure 1: (a) Pre-trained language models inject multiple kinds of knowledge with multi-task learning. Model parameters need to be retrained when injecting new kinds of knowledge, which may result in the catastrophic forgetting (b) Our K-ADAPTER injects multiple kinds of knowledge by training adapters independently on different pre-train tasks, which supports continual knowledge infusion. When we inject new kinds of knowledge, the existing knowledge-specific adapters will not be affected. KIA represents the adapter layer and TRM represents the transformer layer, both of which are shown in Figure 2.

we consider both fact-related objective (i.e. predicate/relation prediction) and linguistic-related objective (i.e. dependency relation prediction). Second, the original parameter of BERT is clamped in the knowledge infusion process. Third, our approach supports continual learning, which means that the learning of different adapters are not entangled. This flexibility enables us to efficiently inject different types of knowledge independently, and inject more types of knowledge without any loss on the previously injected knowledge.

3 K-ADAPTER

As illustrated in Figure 1 (a), most of the previous works enhance pre-trained language models by injecting knowledge and update model parameters through multi-task learning. Regardless of these different versions of knowledge-injected methods with multi-task learning, common issues not fully studied are catastrophic forgetting of previous knowledge. To address this, we present K-ADAPTER as shown in Figure 1(b), where multiple kinds of knowledge are injected into different compact neural models (i.e., adapters in this paper) individually instead of directly injecting knowledge into pre-trained models. It keeps the original representation of a pre-trained model fixed and supports continual knowledge infusion, i.e., injecting each kind of knowledge into the corresponding knowledge-specific adapter and producing disentangled representation. Specifically, adapters are knowledge-specific models (with few parameters) plugged outside of a pre-trained model. The inputs of adapters are the output hidden-states of intermediate layers of the pre-trained model. Each adapter is pre-trained independently on different tasks for injecting discriminative knowledge while the original parameters of the pre-trained model are frozen. In this paper, we exploit RoBERTa (Liu et al., 2019) as the pre-trained model, and mainly infuse factual knowledge and linguistic knowledge with two kinds of adapters, i.e., factual adapter and linguistic adapter which are pre-trained on the relation classification task and dependency relation prediction task respectively. In this section, we first describe the structure of our adapter, and then present the process of pre-training knowledge-specific adapters.

3.1 Adapter Structure

In this work, we present a different adapter structure as shown in Figure 2, which is referred to as the knowledge-specific adapter. In contrast to Houlsby et al. (2019) add adapter layers into each transformer layer, our adapter works as outside plug-ins. Each adapter model consists of K adapter layers that contain N transformer (Vaswani et al., 2017) layers and two projection layers. A skip-connection is applied across two projection layers. Specifically, for each adapter model, we plug

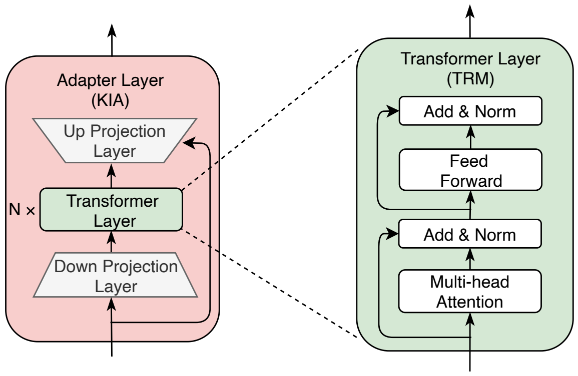


Figure 2: Structure of the adapter layer (left). The adapter layer consists of two projection layers and N=2 transformer layers, and a skip-connection between two projection layers.

adapter layers among different transformer layers of the pre-trained model. We concatenate the output hidden feature of the transformer layer in the pre-trained model and the output feature of the former adapter layer, as the input feature of the current adapter layer. For each knowledge-specific adapter, we concatenate the last hidden features of the pre-trained model and adapter as the final output feature of this adapter model.

In the pre-training procedure, we train each knowledge-specific adapter on different pre-training tasks individually. For various downstream tasks, K-ADAPTER can adopt the fine-tuning procedure similar to RoBERTa and BERT. When only one knowledge-specific adapter is adopted, we can take the final output feature of this adapter model as the input for task-specific layers of the downstream task. When multiple knowledge-specific adapters are adopted, we concatenate the output features of different adapter models as the input for task-specific layers of the downstream task.

3.2 Pre-training settings

We use RoBERTa$_{LARGE}$ (L=24, H=1024, A=16, 355M params) implementation by Huggingface[2] as the pre-trained model in all our experiments. As for each adapter layer, we denote the number of transformer layer as N, the hidden dimension of transformer layer as H_A, the number of self-attention heads as A_A, the hidden dimension of down-projection and up-projection layers as H_d and H_u. In detail, we have the following adapter size: $N = 2$, $H_A = 768$, $A_A = 12$, $H_u = 1024$ and $H_d = 768$. The RoBERTa layers where adapter layers plug in are {0,11,23}, and different adapter layers do not share parameters. Thus the total parameters for each adapter model are about 42M, which are much smaller than RoBERTa$_{LARGE}$ and make the training process memory efficient. It should be noticed that RoBERTa is fixed during training and the parameters of adapters are trainable and initialized randomly. Then we describe how to inject different knowledge into knowledge-specific adapters as below.

3.3 Factual Adapter

Factual knowledge can be described as the basic information that is concerned with facts. In this work, we acquire factual knowledge from the relationships among entities in natural language. We extract a sub-dataset T-REx-rc from T-REx (ElSahar et al., 2018) which is a large scale alignment dataset between Wikipedia abstracts and Wikidata triples. We discard all relations having less than 50 entity pairs, collecting 430 relations and 5.5M sentences. In order to inject factual knowledge, we propose to pre-train a knowledge-specific adapter called facAdapter on the relation classification task. This task requires a model to classify relation labels of given entity pairs based on context. Specifically, the last hidden features of RoBERTa and facAdapter are concatenated as the input representation, and the pooling layer is applied to the input representations of the given entities. Then, we concatenate two entity representations to perform relation classification.

3.4 Linguistic Adapter

Linguistic knowledge is implicitly contained in natural language texts, e.g., syntactic and semantic information. In this work, we acquire linguistic knowledge from dependency relationships among words in natural language text. We build a dataset consisting of 1M examples. In particular, we run the off-the-shell dependency parser from Stanford Parser[3] on a part of Book Corpus (Zhu et al., 2015). To inject linguistic knowledge, we pre-train another knowledge-specific adapter called linAdapter on the task of dependency relation prediction. This task aims to predict the head index of each token in the given sentence. We concatenate the last hidden features of RoBERTa and linAdapter as the input representation, and then apply a linear layer

to input representations of each token to perform classification. More training details of facAdapter and linAdapter can be found in the Appendix.

4 Experiments

We evaluate our K-ADAPTER on three knowledge-driven downstream tasks, i.e., entity typing, question answering and relation classification. Furthermore, we conduct detailed analyses with the case study and probing experiments to explore the effectiveness and ability of models for learning factual knowledge. The notations of K-ADAPTER (F+L), K-ADAPTER (F), and K-ADAPTER (L) denote our model which consists of both factual adapter and linguistic adapter, only factual adapter and only linguistic adapter, respectively. Implementation details, and statistics of datasets are in the Appendix.

4.1 Entity Typing

We conduct experiments on fine-grained entity typing which aims to predict the types of a given entity and its context. We evaluate our models on OpenEntity (Choi et al., 2018) and FIGER (Ling et al., 2015) following the same split setting as Zhang et al. (2019). To fine-tune our models for entity typing, we modify the input token sequence by adding the special token "@" before and after a certain entity, then the first "@" special token representation is adopted to perform classification. As for OpenEntity, we adopt micro F_1 score as the final metric to represent the model performance. As for FIGER, we adopt strict accuracy, loose macro, loose micro F_1 scores (Ling and Weld, 2012) for evaluation following the same evaluation criteria used in previous works.

Baselines **NFGEC (Shimaoka et al., 2016)** employs attentive recursive neural networks to compose context representations. **KEPLER (Wang et al., 2021)** integrates factual knowledge with the supervision of the knowledge embedding objective. **RoBERTa+multitask** is our RoBERTa model pre-trained with multi-task learning (as shown in Figure 1(a)) for injecting multiple kinds of knowledge on two pre-training tasks. **K-ADAPTER (w/o knowledge)** consists of a RoBERTa model and an adapter without being injected knowledge. Other baseline models are described in Section 2.

Results and Discussion The results on OpenEntity and FIGER are shown in Table 2. K-ADAPTER (F+L) achieves consistent improvements across these datasets. As for OpenEntity, our RoBERTa achieve better results than other baseline models. K-ADAPTER (F+L) further achieves improvement of 1.38% F_1 over RoBERTa, which means factual knowledge and linguistic knowledge help to predict the types more accurately. As for FIGER, it covers more entity types, and is more fine-grained than OpenEntity. Compared with WKLM, K-ADAPTER (F+L) improves the macro F_1 by 2.88%, micro F_1 by 2.54% and accuracy by 1.60%. This demonstrates that K-ADAPTER (F+L) benefits fine-grained entity typing.

In addition, we further conduct several experiments on our ablated model K-ADAPTER (w/o knowledge), to explore whether the performance gains came from introducing knowledge or additional parameters. Results show that K-ADAPTER (F) significantly outperforms K-ADAPTER (w/o knowledge). Moreover, it is worth noting that on OpenEntity dataset, K-ADAPTER (w/o knowledge) even performs slightly worse than RoBERTa.

Model	SearchQA		Quasar-T		CosmosQA

Table 3: Results on question answering datasets including: CosmosQA, SearchQA and Quasar-T.

These results demonstrate that our model gains improvement from knowledge instead of more parameters. Thus, for simplicity, we don't discuss K-ADAPTER (w/o knowledge) in the following experiments.

4.2 Question Answering

We conduct experiments on two question answering (QA) tasks, i.e., commonsense QA and open-domain QA. Commonsense QA aims to answer questions with commonsense. We adopt CosmosQA (Huang et al., 2019) dataset to evaluate our models. CosmosQA requires commonsense-based reading comprehension, formulated as multiple-choice questions. To fine-tune our models for CosmosQA, the input token sequence is modified as *"<SEP>context </SEP>question</SEP>answer</SEP>"*, then the representation of the first token is adopted to perform classification, and will get a score for this answer. After getting four scores, the answer with the highest score will be selected. We report accuracy scores obtained from the leaderboard.

Open-domain QA aims to answer questions using external resources such as collections of documents and webpages. We evaluate our modes on two public datasets, i.e., Quasar-T (Dhingra et al., 2017) and SearchQA (Dunn et al., 2017). Specifically, we first retrieve paragraphs corresponding to the question using the information retrieval system and then extract the answer from these retrieved paragraphs through the reading comprehension technique. Following previous work(Lin et al., 2018), we use the retrieved paragraphs provided by Wang et al. (2017) for these two datasets. To fine-tune our models for this task, the input token sequence is modified as *"<SEP>question </SEP>paragraph</SEP>"*. We apply linear layers over the last hidden features of our model to predict the start and end position of the answer span. We adopt two metrics including ExactMatch (EM) and loose F_1 (Ling and Weld, 2012) scores to evaluate our models.

Baselines BERT-FT$_{RACE+SWAG}$ (Huang et al., 2019) is the BERT model sequentially fine-tuned on both RACE and SWAG datasets. **BiDAF (Seo et al., 2017)** adopts a bi-directional attention network. **AQA (Buck et al., 2018)** proposes to re-write questions and aggregate the answers generated by the re-written questions. **Rˆ3 (Wang et al., 2018a)** is a reinforced model making use of a ranker for selecting most confident paragraph. **Evidence Agg. (Wang et al., 2018b)** proposes making use of the aggregated evidence from across multiple paragraphs. **WKLM (Xiong et al., 2020)** is adopted as the reader model to read multiple paragraphs to predict a single answer. **WKLM + Ranking (Xiong et al., 2020)** is a WKLM paragraph reader plus with a BERT based paragraph ranker to assign each paragraph a relevance score.

Results and Discussion The results on CosmosQA are shown in Table 3. Compared with BERT-FT$_{RACE+SWAG}$, our RoBERTa significantly achieves 11.89% improvement of accuracy. Compared to RoBERTa, K-ADAPTER (F+L) further improves the accuracy by 1.24%, which indicates that K-ADAPTER can obtain better commonsense inference ability. Moreover, the perfor-

Model	**P**	**R**	**F_1**
C-GCN (Zhang et al., 2018)	69.90	63.30	66.40
BERT-base (Zhang et al., 2019)	67.23	64.81	66.00
ERNIE (Zhang et al., 2019)	69.97	66.08	67.97
BERT-large (Baldini Soares et al., 2019)	-	-	70.10
BERT+MTB (Baldini Soares et al., 2019)	-	-	71.50
KnowBERT (Peters et al., 2019)	71.60	71.40	71.50

K-ADAPTER (F)	69.39	74.59	71.89
K-ADAPTER (L)	68.85	75.37	71.96
K-ADAPTER (F+L)	70.14	74.04	**72.04**

Table 4: Results on the relation classification dataset TACRED.

mance of ablated K-ADAPTER models, i.e., K-ADAPTER (F) and K-ADAPTER (L) are clearly better than RoBERTa, but slightly lose compared with RoBERTa+multitask. It is notable that K-ADAPTER (F+L) makes obvious improvement comparing with RoBERTa+multitask. This demonstrates that the combination of multiple knowledge-specific adapters could achieve better performance.

The results for open-domain QA are shown in Table 3. K-ADAPTER models achieve better results compared to other baselines. This indicates that K-ADAPTER models can make full use of the infused knowledge and accordingly benefit understanding the retrieved paragraphs to answer the question. Specifically, on SearchQA, K-ADAPTER (F+L) makes significant improvement of 4.01% F_1 scores, comparing with WKLM where the ranking scores are not used, and even has a slight improvement as compared to WKLM+Ranking. It is worth noting that K-ADAPTER models do not consider the confidence of each retrieved paragraph, while WKLM+Ranking utilizes ranking scores from a BERT based ranker. On the Quasar-T dataset, K-ADAPTER (F+L) also outperforms WKLM by 3.1% F_1 score and slightly outperforms WKLM+Ranking.

4.3 Relation Classification

Relation classification aims to determine the correct relation between two entities in a given sentence. We adopt a large-scale relation classification dataset TACRED (Zhang et al., 2017). To fine-tune our models for this task, we modify the input token sequence by adding special token "@" before and after the first entity, adding "#" before and after the second entity. Then the token representations of the first special token "@" and "#" are concatenated to perform relation classification. We adopt micro F_1 score as the metric to represent the model performance as previous works.

Baselines **C-GCN (Zhang et al., 2018)** employs graph convolutional networks to model dependency trees. **BERT-large (Baldini Soares et al., 2019)** is a baseline BERT-large model. **BERT+MTB (Baldini Soares et al., 2019)** is a method of training relation representation without supervision from a knowledge base by matching the blanks. Other baseline models are described in Section 2 and 4.1.

Results and Discussion Table 4 shows the performances of different models on TACRED. The results indicate that K-ADAPTER models significantly outperform all baselines, which directly demonstrate our models can benefit relation classification. In particular, (1) K-ADAPTER models outperform RoBERTa, which proves the effectiveness of infusing knowledge into pre-trained model with adapters. (2) K-ADAPTER models gain more improvement compared with *RoBERTa+multitask*. This directly demonstrates injecting knowledge individually in K-ADAPTER way would help models make full use of knowledge.

4.4 Case Study

Table 5 gives a qualitative comparison example between K-ADAPTER and RoBERTa on relation classification dataset TACRED. The results show that, in most cases, the wrongly predicted logit value of RoBERTa and the logit value of the true label are actually quite close. For example, given "*New Fabris closed down June 16*", RoBERTa predicts "no_relation", but the true label "*city_of_birth*" ranks in second place. If a model could correctly predict the relationship between "*New Fabris*" and "*June 16*", then it needs to know that "*New Fabris*" is a company. Thanks to the factual knowledge in K-ADAPTER, it can help the model from predicting "no_relation" to predicting the correct category label.

In addition, we utilize a LAMA (LAnguage Model Analysis) probe (Petroni et al., 2019) to examine models' ability to memorize factual knowledge. Specifically, the LAMA probing task is under a zero-shot setting, which requires the language model to answer cloze-style questions about relational facts without fine-tuning, For example, given "Simon Bowman was born in [MASK]" as the input, models are asked to predict the correct token

Input	True label	Model	Predicted label	Predicted logits
His former student Mark Devlin of the University of Pennsylvania was co-leader of the other , known as the Microwave Anisotropy Telescope .	schools_attended	K-Adapter	['schools_attended', 'no_relation','founded']	[12.6, 9.5, 5.2]

		K-ADAPTER	**Malayalam**, Tamil, Hindi, Mandarin, English
Ravens can [MASK].	fly	RoBERTa	win, play, score, lose, run, drink, **fly**, roll, wait
		K-ADAPTER	**fly**, swim, sing, shoot, kill, go, fish, drink, die
Sometimes virus causes [MASK].	infection	RoBERTa	cancer, death, illness, blindness, paralysis
		K-ADAPTER	cancer, illness, death, **infection**, disease
Sunshine Coast, British Columbia is located in [MASK].	Canada	RoBERTa	Florida, California, Texas, Hawaii, Mexico
		K-ADAPTER	**Canada**, Vancouver, Victoria, BC, Australia
iPod Touch is produced by [MASK].	Apple	RoBERTa	**Apple**, Samsung, Qualcomm, LG, Microsoft
		K-ADAPTER	**Apple**, HTC, Samsung, Motorola, Intel

Table 6: Examples of LAMA generation for RoBERTa$_{LARGE}$ and K-ADAPTER. The last column reports the top ranked predicted tokens. Correct predictions are in **bold**.

which is masked. Table 6 shows several examples for the generation of RoBERTa$_{LARGE}$ and K-ADAPTER for LAMA queries. From these examples, we can find that the objects predicted by K-ADAPTER are more accurate, which demonstrate that K-ADAPTER captures richer factual knowledge than RoBERTa. More details about this probing experiments can be found in the Appendix A and E.4.

5 Conclusion

In this paper, we propose a flexible and simple approach, called K-ADAPTER, to infuse knowledge into large pre-trained models. K-ADAPTER remains the original parameters of pre-trained models unchanged and supports continual knowledge infusion, i.e., new kinds of injected-knowledge will not affect the parameters learned for old knowledge. Specifically, factual knowledge and linguistic knowledge are infused into RoBERTa with two kinds of adapters, which are pre-trained on the relation classification task and dependency relation prediction task, respectively. Extensive experiments on three knowledge-driven downstream tasks demonstrate that the performance of each adapter achieves a significant improvement individually, and even more together. Detailed analyses further suggest that K-ADAPTER captures richer factual and commonsense knowledge than RoBERTa, and provide insights on the effectiveness of knowledge infusion. In future work, we will infuse more types of knowledge, and apply our framework to more pre-trained models.

Appendix

A Probing Experiments

Although K-ADAPTER models have shown superior performance on knowledge-driven downstream tasks, it does not directly provide insights into whether our models infuse richer factual knowledge. Thus we utilize a LAMA (LAnguage Model Analysis) probe (Petroni et al., 2019) to examine the ability to memorize factual knowledge. Specifically, the LAMA probing task is under a zero-shot setting, which requires the language model to answer cloze-style questions about relational facts without fine-tuning, e.g., "Simon Bowman was born in [MASK]". The model needs to predict a distribution over a limited vocabulary to replace [MASK]. We report mean precision at one (P@1) macro-averaged over relations.

Settings We consider several language models including: ELMo (Peters et al., 2018), ELMo5.5B (Peters et al., 2018), Transformer-XL (Dai et al., 2019), BERT$_{LARGE}$ and RoBERTa$_{LARGE}$. We focus on LAMA-GoogleRE and LAMA-T-REx, which are aimed at factual knowledge. We also conduct probe experiments on LAMA-UHN (Poerner et al., 2020), a more "factual" subset of LAMA, by filtering out queries that are easy to answer from entity names alone. Different models have different vocabulary sizes. To conduct a more fair comparison experiment, we adopt the intersection of vocabularies and let every language model rank only tokens in this vocabulary following Petroni et al. (2019). For simplicity, we only compare K-APDATER (F) which is infused with factual knowledge, with other baseline models.

Results and Discussion Results are shown in Table 7. It is surprising that BERT$_{LARGE}$ performs better than RoBERTa$_{LARGE}$. There is one possible reason: BERT uses a character-level BPE (Gage, 1994) vocabulary, while RoBERTa considers byte-level BPE vocabulary. This finding indicates that, although using bytes makes it possible to learn a subword vocabulary that can encode any text without introducing "unknown" tokens, it might indirectly harm the model's ability to learn factual knowledge, e.g., some proper nouns may be divided into bytes. Thus in the following experiments, we do not take BERT into account.

K-ADAPTER outperforms other models (except for BERT) by a huge margin. As for LAMA, compared to RoBERTa$_{LARGE}$, K-ADAPTER obtains 2.2% and 1.2% P@1 improvement across Google-RE and T-REx, respectively. Moreover, compared to RoBERTa$_{LARGE}$, K-ADAPTER still achieves better results on LAMA-UHN. The results demonstrate that K-ADAPTER captures richer factual and commonsense knowledge than RoBERTa.

B Pre-Training Details

B.1 Factual Adapter

The pre-trained model is fixed during training and the parameters of the factual adapter are trainable and initialized randomly. The model is trained with cross-entropy loss. To accelerate the training process, we set the max sequence length as 64 as the average sequence length of T-REx-rc is only 22.8. We train the model for 5 epochs using a batch size of 128. We use AdamW to optimize our models with the initial learning rate of 2e-5. We train the model with 4 16G NVIDIA V100 GPUs.

B.2 Linguistic Adapter

Same as the training process of the factual adapter, the pre-trained model is fixed during training and the parameters of the linguistic adapter are trainable and initialized randomly. The model is trained with BCEWithLogits loss. We set the max sequence length as 128. We train the model for 10 epochs using a batch size of 256. We use AdamW with the initial learning rate of 1e-5. We train the model with 4 16G NVIDIA V100 GPUs.

C Applying K-adapter on Downstream Tasks

For the downstream tasks, the key point here is the combination of the pre-trained model's representations and adapter's representations, that is to say: leveraging the general information of the pre-trained model on one hand, and the specific knowledge in the adapter on the other. To use K-ADAPTER for downstream tasks is very simple as shown in Figure 5. Usually, when we use pre-trained language models such as BERT and RoBERTa for downstream tasks, we feed the output features from the pre-trained model into the task-specific layer, and then do the corresponding downstream task. As for the K-ADAPTER, we finetune it just like what the orginal BERT or RoBERTa does. We concatenate the output features of the pre-trained model with the features of the adapter, and then feed them to the task-specific layer.

Corpus	Models					
	ELMo	ELMo5.5B	TransformerXL	BERT-large	RoBERTa$_{LARGE}$	K-APDATER
LAMA-Google-RE	2.2	3.1	1.8	12.1	4.8	7.0
LAMA-UHN-Google-RE	2.3	2.7	1.3	6.5	2.5	3.7
LAMA-T-REx	0.2	0.3	19.5	33.9	27.1	29.1
LAMA-UHN-T-REx	0.2	0.2	12.6	26.2	20.1	23.0

Table 7: P@1 on LAMA and LAMA-UHN across Google-RE and T-REx corpora.

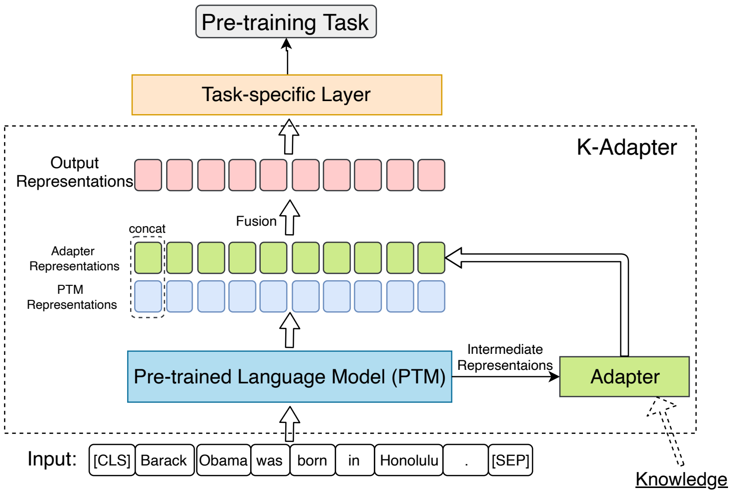

Figure 3: An overview of our K-ADAPTER to inject specific knowledge by training a knowledge-specific adapter on the pre-training task.

D Dataset statistics

In Table 8, we present the statistics of one relation classification dataset TACRED, and two entity typing datasets OpenEntity and FIGER. In Table 9, we present the statistics of one commonsense QA dataset CosmosQA and two open-domain QA datasets SearchQA and Quasar-T.

Dataset	Train	Dev	Test	Relation/Type
TACRED	68,124	22,631	15,509	42
Open Entity	2,000	2,000	2,000	6
FIGER	2,000,000	10,000	563	113

Table 8: The statistics of the relation classification dataset TACRED and entity typing datasets, i.e., Open Entity and FIGER.

Dataset	Train	Dev	Test
CosmosQA	25,588	3,000	7,000
SearchQA	99,811	13,893	27,247
Quasar-T	28,496	3,000	3,000

Table 9: The statistics of the question answering datasets, i.e., CosmosQA, SearchQA and Quasar-T.

E Fine-tuning Details

We implement our experiments using Huggingface[4]. For all fine-tuning experiments, we use AdamW as the optimizer. The parameters of adapters are fixed during the fine-tuning process and the parameters of RoBERTa are trainable and initialized from Huggingface checkpoint. We select the best hyperparameters on the validation set. For all experiments, we set the random seed to be 42 for reproductibility.

E.1 Entity typing

For Open Entity dataset, we set the max sequence length to be 256 and select the hyperparameters from batch size: {4, 8}, learning rate: {2e-5, 1e-5, 5e-6} and warmup step: {0, 200, 500, 1000, 1200}. For K-ADAPTER (F), the best performance is achieved at batch size=4, lr=5e-6, warmup=500 (it takes about 2 hours to get the best result running on singe 16G P100). For K-ADAPTER (L), the best performance is achieved at batch size=4,

---

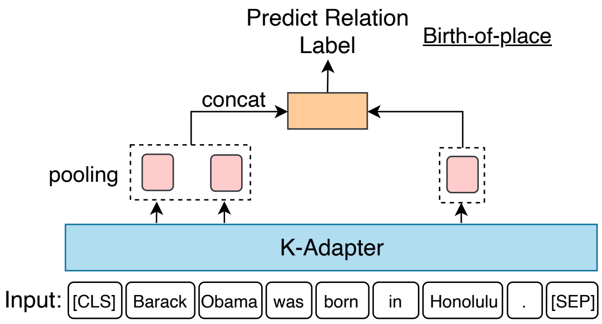

Figure 4: An example of using relation classification as a pre-training task to inject knowledge into K-Adapter: given *"Barack Obama was born in Honolulu"*, and then predicts the relationship between "Barack Obama" and "Honolulu" is "Birth-of-place".

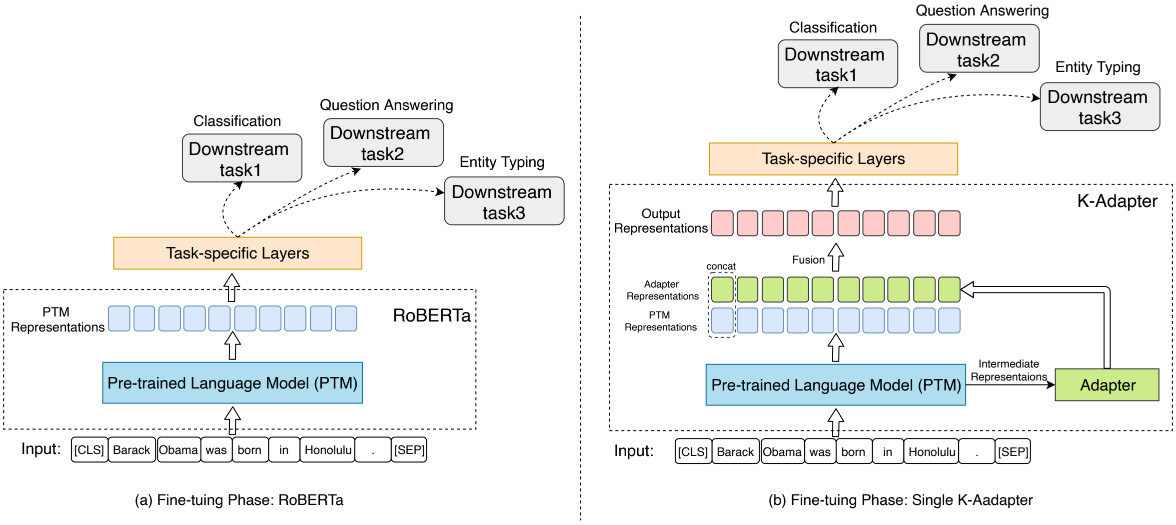

(a) Fine-tuing Phase: RoBERTa

(b) Fine-tuing Phase: Single K-Aadapter

Figure 5: Fine-tuning K-Adapter just like what the original RoBERTa or BERT does.

lr=5e-6, warmup=1000 (it takes about 2 hours to get the best result running on singe 16G P100). For K-Adapter (F+L), the best performance is achieved at batch size=4, lr=5e-6, warmup=1000 (it takes about 3 hours to get the best result running on singe 16G P100). For FIGER dataset, we run experiments on 4 16G P100 for 3 epochs, set the max sequence length to be 256, and select the hyperparameters from batch size: {64, 512, 2048}, learning rate: {2e-5, 1e-5, 5e-6} and warmup step: {0, 200, 500, 1000, 1200}. For K-Adapter (F), the best performance is achieved at batch size=2048, lr=5e-6, warmup=500. For K-Adapter (L), the best performance is achieved at batch size=2048, lr=5e-6, warmup=200. For K-Adapter (F+L), the best performance is achieved at batch size=2048, lr=5e-6, warmup=1000.

E.2 Question Answering

For CosmosQA dataset, we run experiments on one single 16G P100 for 3 epochs, set the max sequence length to be 256, and select the hyperparameters from batch size: {16, 32, 64, 128}, learning rate: {2e-5, 1e-5, 5e-6} and warmup step: {0, 200, 500, 800, 1000}. For K-Adapter (F+L) and its ablated models, the best performance is achieved at batch size=64, lr=1e-5, warmup=0 (it takes about 8 hours to get the best result).

For SearchQA dataset, we run experiments on one single 16G P100 for 2 epochs, set the max sequence length to be 128, and select the hyperparameters from batch size: {2, 4, 8, 16}, learning rate: {5e-5, 2e-5, 1e-5, 5e-6} and warmup step: {0, 500, 1000}. For K-Adapter (F+L) and its ablated models, the best performance is achieved at batch size=8, lr=5e-6, warmup=0. For Quasar-T dataset, we run experiments on one single 16G P100 for 5 epochs, set the max sequence length to be 256, and select the hyperparameters from batch size: {2, 4, 8, 16}, learning rate: {5e-5, 2e-5, 1e-5, 5e-6} and warmup step: {0, 500, 1000}. For K-Adapter (F+L) and its ablated models, the best performance is achieved at batch size=16, lr=1e-5, warmup=0.

E.3 Relation Classification

For TACRED dataset, we run experiments on 4 16G P100 for 5 epochs, set the max sequence length to be 184, and select the hyperparameters from batch size: $\{4, 8, 16, 32\}$, learning rate: $\{2e\text{-}5, 1e\text{-}5, 5e\text{-}6, 1e\text{-}6\}$ and warmup step: $\{0, 200, 500, 800, 1000, 1200\}$. For K-ADAPTER (F), the best performance is achieved at batch size=32, lr=1e-5, warmup=500. For K-ADAPTER (L), the best performance is achieved at batch size=32, lr=1e-5, warmup=200. For K-ADAPTER (F+L), the best performance is achieved at batch size=32, lr=5e-6, warmup=1000.

E.4 Probing Experiments

We implement our probing experiments using LAMA[5]. When we infuse knowledge into knowledge-specific adapters, we do not change the original parameters of the pre-trained model and thus do not adopt the masked language model (MLM) as a pre-training task. Therefore, before we conduct probing experiments, we need to add and train a linear layer as the mlm layer for predicting the [MASK] entities. Specifically, we fix all the parameters of K-ADAPTER and only update the parameters of the mlm layer using a masked language modeling (MLM) loss. We adopt the raw WikiText-2 dataset (181M). We train the mlm layer with one single 16G P100 for 2 epochs. We set the max sequence length to be 512, batch size to be 1024 and warmup step to be 0.

Abstract

Recent progress has been made in using BERT framework for Chinese spelling error correction (CSC). However, most existing methods correct words based on local contextual information, without considering the influence of error words in sentences. Imposing attention on error contextual information could mislead and decrease the overall performance of CSC. To address this issue, we propose a **G**lobal **A**ttention **D**ecoder (GAD) approach for CSC. Specifically, the proposed method learns the global relationship of the potential correct input characters and the candidates of potential error characters. Rich global contextual information is obtained to alleviate the impact of the local error contextual information. In addition, a BERT with **C**onfusion set guided **R**eplacement **S**trategy (BERT_CRS) is designed to narrow the gap between BERT and CSC. The candidates generated by BERT_CRS covering the correct character with more than 99.9% probability. To demonstrate the effectiveness of our proposed framework, we test our method on three human-annotated datasets. The experimental results show that our approach outperforms all competitor models by a large margin of up to 6.2%, achieving state-of-the-art methods on all datasets.

1 Introduction

Spelling error correction plays an important role in NLP domain. A good spelling error system is the key to improve the performance of upper-layer applications. Spelling error correction aims to detect and correct erroneous characters/words. These spelling errors are mainly from human writing, speech recognition and optical character recognition (OCR) (Afli et al., 2016) systems. In Chinese, erroneous type is usually from character/word's phonological, visual and semantic similarity. According to (Cheng et al., 2020), about 83% and 48% of errors are related to phonological and visual similarity respectively. Although lots of researches have made great progress, Chinese spelling error correction (CSC) still remains a challenging task. Moreover, because the Chinese is composed of pictographic characters without word delimiters, methods from the languages like English can hardly be used for the Chinese. In addition, the meaning of same character in different contexts may change greatly.

Input	餐厅的换经费产适合约会 The restaurant's swap property is suitable for dates
BERT_CRS	餐厅的环经非常适合约会 The restaurant's ring is perfect for dates
+GAD	餐厅的环境非常适合约会 The restaurant environment is perfect for dates

Table 1: A sample data from SIGHAN 2014 (Yu et al., 2014), the incorrect and correct characters marked in red and green color respectively. Since ”经” is highly related to ”费” in its context, BERT_CRS is difficult to correct. GAD method learns the global relationship between ”环” and ”境” in candidates of input error characters ”换” and ”经” respectively (see Fig.1). Rich global contextual information is learned to alleviate the impact of the local noisy contextual information.

Many methods have been proposed for CSC task, which are mainly divided into two categories: 1) based on language models (Yeh et al., 2013; Yu and Li, 2014; Xie et al., 2015); 2) based on seq2seq model (Wang et al., 2019, 2018). Specially, with the emerge of the pre-trained BERT model, many methods (Hong et al., 2019; Zhang et al., 2020; Cheng et al., 2020) are proposed and made great progress. Almost all methods leveraged a confusion set, which contains a set of similar character group in terms of phonological and visual. Specifically, (Yu and Li, 2014) proposed to generate candidates based on confusion set and find the best

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1419–1428
August 1–6, 2021.

candidate with highest language model probability. (Cheng et al., 2020) introduced a convolutional graph network that captures similarity and prior dependencies among characters using confusion set. (Wang et al., 2019) proposed a pointer network to generate a character from the confusion set. Previous methods predict each character or word based on its local context that may has noisy information (other errors). So far, no method has been proposed to alleviate the impact of this noisy information.

In this paper, we firstly introduced a BERT with confusion set guided replacement strategy (BERT_CRS), that narrows the gap between BERT and CSC task. Then, we proposed a novel global attention decoder (GAD) based on our BERT_CRS model (see Fig.1), which learns rich global contextual representations to alleviate the influence of the error contextual information during correction. Specifically, in order to solve the impact of the local error contextual information, we introduce additional candidates of potential error characters and hidden state generated by BERT_CRS. Next, global attention component learns the relationships of candidates to obtain the global hidden state and latent global attention weights of candidates. Then, weighted sum operator is adopted among candidates of each character to generate a rich global contextual hidden state. Finally a fully-connected layer to generate the correct characters. As shown in Table.1, Our proposed method is able to correct all spelling errors correctly. It is worthwhile to highlight the following aspects for the proposed approach:

- To narrows the gap between BERT and CSC, we introduce a BERT with confusion set guided replacement strategy, that contains a decision network and a fully-connected layer to simulate the detection and correction subtasks of CSC respectively.
- We proposed a global attention decoder model, which learns the global relationships of the potential correct input characters and the candidates of potential error characters. Rich global contextual information is learned to effectively alleviate the influence of local error contextual information.
- Experiments on the three benchmark datasets demonstrate that our method outperforms the state-of-the-art methods by a large margin of up to 6.2%.

2 Related Work

There is a vast prior research on Chinese spelling error correction (CSC) task so far. Next, We will discuss the algorithms in different periods.

N-gram period. Early research in CSC follow the pipeline of error detection, candidate generation and candidate selection. Almost all proposed methods (Yeh et al., 2013; Yu and Li, 2014; Xie et al., 2015; Tseng et al., 2015) employed an unsupervised n-gram language model to detect errors. Next, a confusion set which is an external knowledge of the similarity between characters is introduced to confine the candidates. Finally, the best candidate with highest n-gram language model probability is considered as correction character. Specifically, (Yeh et al., 2013) proposed an inverted index based n-gram to map the potential spelling error character to the corresponding characters. (Xie et al., 2015) utilizes the confusion set to replace the characters and then evaluates the modified sentence via a joint bi-gram and tri-gram language model. In (Jia et al., 2013; Xin et al., 2014), a graph model is used to represent the sentence and a single source shortest path (SSSP) algorithm is performed on the graph to correct spell errors. The others viewed it as a sequential labeling problem and employed conditional random fields or hidden Markov models (Tseng et al., 2015; Wang et al., 2018).

Deep learning period. With the development of deep learning methods (Vaswani et al., 2017; Zhang et al., 2020; Hong et al., 2019; Wang et al., 2019; Song et al., 2017; Guo et al., 2016), great progress has been made in all NLP tasks. BERT (Devlin et al., 2018), XLNET (Yang et al., 2019), and Roberta (Liu et al., 2019), and ALBERT (Lan et al., 2019) achieve superior performance in almost all NLP task. Confusion set is still an important part in recent research for CSC task, but more upgrades have been made. Specifically, in (Hong et al., 2019), a pre-trained masked language model is employed as encoder. A confidence-similarity decoder utilizes similarity score to select candidates instead of the confusion set. (Vaswani et al., 2017) proposed a specialized graph convolutional network to incorporate phonological and visual similarity knowledge into BERT model. In (Zhang et al., 2020), a GRU based detection network is introduced and connected with BERT based correction network by a soft-masking technique. The others (Wang et al., 2019) employed a Seq2Seq model with copy mechanism, which generates a new sentence considering the extra candidates from confusion set.

3 The Proposed Approach

In this section, firstly, the problem formulation is elaborated. Then, we briefly describe how to narrow the gap between BERT (Devlin et al., 2018) and Chinese spelling error correction (CSC) using our BERT_CRS model. Finally, we introduce our novel global attention decoder (GAD) framework.

3.1 Problem Formulation

CSC aims to detect and correct errors in Chinese text. Given a sequence $X = \{x_1, x_2, \cdots, x_n\}$, n denotes the number of characters, our BERT_CRS model encodes it into a continuous representation space $\mathbf{V} = \{\mathbf{v}_1, \mathbf{v}_2, \cdots, \mathbf{v}_n\}$, $\mathbf{v}_i \in \mathbf{R}^d$ is the contextual level feature of the i-th character, and it is d-dimensional. Here a decision network Φ_d models $\mathbf{V}$ to fit a sequence $Z = \{z_1, z_2, \cdots, z_n\}$, where z_i denotes the detection label of the i-th character, and z_i=1 means the character is incorrect and z_i=0 means it is correct. A fully-connected layer on the top of BERT_CRS as correction network Φ_c models $\mathbf{V}$ to fit a sequence $Y = \{y_1, y_2, \cdots, y_n\}$, where y_i is the correction label of the i-th character. Instead of a simple fully-connected layer as a decoder, our GAD models the additional candidates $c = \{c_1, c_2, \cdots, c_n\}$ to alleviate the impact of local error contextual information, where c represents the potential correct input characters and the candidates of potential error characters and:

$$c_i = \begin{cases} c_{i1}, c_{i2}, \cdots, c_{ik}, & if\ P(z_i = 1) \geq t \\ x_i, & if\ P(z_i = 1) < t \end{cases} \quad (1)$$

where k is the number of candidates. t is the threshold of error probability for characters.

3.2 BERT_CRS approach for CSC

In this section, we take advantage of previous models (Devlin et al., 2018; Liu et al., 2019; Cui et al., 2020) and introduce a replacement strategy using confusion set that narrows the gap between BERT and CSC model. There we call this model as BERT_CRS (BERT with **C**onfusion set guided **R**eplacement **S**trategy). Unlike BERT tasks, BERT_CRS has several modifications.

- We drop NSP task and adopt a decision network for detecting error information, that is similar to detection sub-task of CSC.

- As MacBERT (Cui et al., 2020), instead of masking with [MASK] token, we introduce confusion set guided replacement strategy by replacing phonological and visual similar character for masking purpose. Rarely, when there is no confusion character, we will maintain [MASK] token. The strategy similar to correction sub-task of CSC

- We use 23% of input characters for masking. To keep the balance of detection targets (0 for un-replacement, 1 for replacement), we set 35%, 30%, 30%, 5% probability for un-masking, replacing with confusion character, masking with [MASK] token and replacing with random word respectively. Calculated, the replacing and masking probabilities are approximately the same as masking probabilities of BERT.

With model trained by confusion set guided replace strategy, the top-k candidate characters are almost from the confusion set. That prepares for our GAD model.

Learning. Similar to RoBERTa (Liu et al., 2019), confusion set guided replace strategy uses a dynamic approach during training. Error detection and correction is optimized simultaneously in the learning process.

$$L_d = -\sum_{i=1}^{n} logP(z_i|\Phi_d(\mathbf{V})) \quad (2)$$

$$L_c = -\sum_{i=1}^{n} logP(y_i|\Phi_c(\mathbf{V})) \quad (3)$$

$$L = L_c + \lambda * L_d \quad (4)$$

where L_d and L_c is the objective of detection and correction loss respectively, L is the overall objective that linearly combines L_d and L_c, and $\lambda \in [0, 1]$ denotes the coefficient of detection loss L_d. Specially, $\lambda = 0$ represents that detection loss is not considered.

3.3 Global Attention Decoder

In this paper, we propose an global attention decoder (GAD) model to alleviate the impact of the local error contextual information. Our GAD is an extension of transformer layer (Vaswani et al., 2017), shown in Fig.2.

Self Attention. Relatively, the self-attention mechanism is part of the transformer layer, which takes the output of previous transformer layer or input embedding layer as input to obtain the hidden states with higher semantic representation, as shown in left part of Fig.1. Token representation $\mathbf{VA}_i^l$ at i-th position of l-th layer in self-attention method is defined as below:

$$\mathbf{VA}_i^l = \sum_{p=1}^{n} a_i^p \mathbf{V}_p^{l-1}\mathbf{W}^V \quad (5)$$

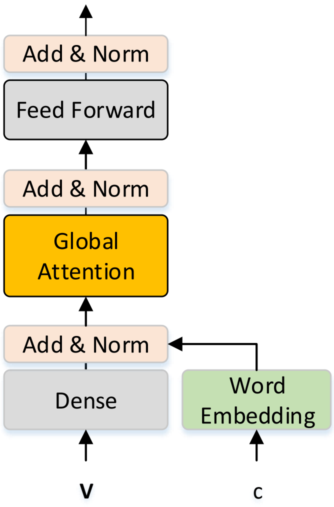

Figure 2: The global attention decoder architecture.

where a_i^p is the attention weight from i-th to p-th token, and $\sum_{p=1}^{n} a_i = 1$, $\mathbf{V}_p^{l-1}$ is the p-th token representation of (l-1)-th layer, $\mathbf{W}^V$ is a learnable projection matrix. This strategy could effectively encode rich token and sentence-level features. However, spelling error information also encoded into hidden states for CSC. Then, Imposing attention on error contextual information could mislead and decrease the overall performance of CSC.

Global Attention. Instead of using only local input information (see Eq.5), we consider potential correct inputs and the candidates of potential error characters to learn their latent relationships, that alleviate the influence caused by local error context. Specifically, as shown in Fig.2, we consider two input sources:

- Contextual representation $\mathbf{V}$, that contains rich semantic information
- Top-k candidates c generate by Φ_c correction network. To reduce the confusion of our GAD during learning, we only generate candidates for the potential error characters (see Eq.1).

To model the two different information, we first embed candidates into continuous representation using the word embedding $\mathbf{E}$ from BERT_CRS. Then, dense and layer-norm layers are introduced to model $\mathbf{V}$ and $\mathbf{E}(c)$ into input state $\mathbf{GI}$:

$$\mathbf{GI} = LayerNorm(\mathbf{Dense}(\mathbf{V}) + \mathbf{E}(c)) \quad (6)$$

Our global attention is introduced to learn the latent relationships between candidates c. Token representation $\mathbf{GA}_{i,j}$ at j-th candidate of i-th token of global attention component is defined as below:

$$\mathbf{GA}_{i,j} = \sum_{p=1}^{n} \sum_{q=1}^{k} a_{i,j}^{p,q} \mathbf{GI}_{p,q} \mathbf{W}_g^V \tag{7}$$

where $\mathbf{W}_g^V$ is a learnable projection matrix and $a_{i,j}^{p,q}$ is the attention weight from j-th candidate of i-th token to q-th candidate of p-th token, $\mathbf{GI}_{p,q}$ denotes the input state of q-th candidate from p-th token. Masking strategy is adopted between candidates from the same token.

$$a_{i,j}^{p,q} = 0,\ if\ i = p\ \&\ j \neq q \tag{8}$$

and $\sum_{p=1}^{n} \sum_{q=1}^{k} a_{i,j}^{p,q} = 1$. Finally, the global attention state $\mathbf{GA}_i$ at i-th position of of global attention component is defined as below:

$$\begin{aligned} \mathbf{GA}_i &= \sum_{j=1}^{k} \beta_{i,j} \mathbf{GA}_{i,j} \\ \epsilon_{i,j} &= \sum_{p=1}^{n} \sum_{q=1}^{k} \epsilon_{i,j}^{p,q} \\ \beta_{i,j} &= \frac{exp(\epsilon_{i,j})}{\sum_{q=1}^{k} exp(\epsilon_{i,q})} \end{aligned} \tag{9}$$

where $\beta_{i,j}$ is the global attention weight at j-th candidate of i-th token which quantifies the global relevance of feature $\mathbf{GA}_{i,j}$, $\epsilon_{i,j}^{p,q}$ and $\epsilon_{i,j}$ denote the unnormalized relevant scores of $a_{i,j}^{p,q}$ and $\beta_{i,j}$ respectively. Similar to standard transformer layer, feed forward and layer normalization to encode $\mathbf{GA}$ into final global continuous representation. Moreover, We adopt the multi-head technique used in the transformer layer in our global attention.

Learning. Given hidden states $\mathbf{V}$ and candidates c generated by our BERT_CRS, our GAD model fit the correct sequence Y in the learning process.

$$L_g = -\sum_{i=1}^{n} logP(y_i|\Phi_g(\mathbf{V})) \tag{10}$$

where Φ_g is our GAD network and L_g denotes our overall objective of GAD

4 Experiments

In this section, we evaluate our algorithm on the task of Chinese spelling error correction (CSC).

Training Data	**# Sent**	**Avg.Len**
UnLabeled corpus	3 million	-
(Wang et al., 2018)	271,329	44.4
SIGHAN 2013	350(350)	49.2
SIGHAN 2014	6,526(3432)	49.7
SIGHAN 2015	3,174(2339)	30.0
Total Labeled	281,379	44.4
Test Data	**# sent**	**Avg.Len**
SIGHAN 2013	1000(996)	74.1
SIGHAN 2014	1062(529)	50.1
SIGHAN 2015	1100(550)	30.5

Table 2: Statistics of datasets. The number in the bracket in #Sent column is the count of erroneous sentences

We first present the training data, test data and the evaluation metrics. Secondly we introduce our main results compared with previous state-of-the-art baselines. Then we conduct ablation studies to analyze the effectiveness of the proposed components. Finally, case study are explored.

4.1 Datasets

We consider three publicly available SIGHAN datasets from the 2013 (Wu et al., 2013), 2014 (Yu et al., 2014) and 2015 (Tseng et al., 2015) Chinese Spell Check Bake-offs. Following (Cheng et al., 2020), we adopted the standard split of training and test data of SIGHAN. We also follow the same data pre-processing, that converted the characters in dataset from traditional Chinese to simple Chinese using OpenCC[1].

For training dataset, we also collect 3 million unlabeled corpus from news, wiki and encyclopedia QA domains to pre-train our BERT_CRS model. Following (Wang et al., 2019), we also include additional 271K samples as the labeled training data, which are generated by an automatic method (Wang et al., 2018). The statistics of the data is showed in Table.2

4.2 Baselines

To evaluate the performance of our proposed algorithm, we compare it with following baseline methods.

- JBT (Xie et al., 2015): This method utilizes the confusion set to replace the characters and then evaluates the modified sentence via a **J**oint **B**i-gram and **T**ri-gram LM.
- Hybird (Wang et al., 2018): This method proposes a pipeline where a bidirectional LSTM

Table 3: The character level performance on both detection and correction level. Our BERT_CRS model achieves similar performance compared with previous state-of-the-art models. Our GAD model achieves better performance.

based sequence labeling model is adopted for detection.

- Seq2Seq (Wang et al., 2019): This method introduces a Seq2Seq model with a copy mechanism to consider the extra candidates from the confusion set.
- FASpell (Hong et al., 2019): This model changes the paradigm by utilizing the similarity metric to select candidate instead of a pre-defined confusion set.
- Soft-Masked BERT (Zhang et al., 2020): This method proposes a detection network, which connected error correction model by a soft-masking technique.
- SpellGCN (Cheng et al., 2020): This model incorporate phonological and visual similarity knowledge into language models for CSC via a specialized graph convolutional network.
- BERT (Devlin et al., 2018): The word embedding on the top of BERT as correction decoder for the CSC task.

4.3 Implementation Details

Training Details. Our code is based on the repository of Transformers[2]. We first fine-tune our BERT_CRS model in 3 million unlabeled corpus based on the pre-trained whole word masking BERT[3]. The procedure runs 5 epochs with a batch size of 1024, learning rate of 5e-5 and max sequence length of 512. Then, we performed the fine-tuning process for our BERT_CRS model in all labeled training data with 6 epochs, a batch size of 32 and a learning rate of 2e-5. Next we fix our BERT_CRS model, and set the number of candidates k and error detection probability t as 4 and 0.25 respectively. Finally we fine-tune our GAD model with 3 epochs, a batch size of 32 and a learning rate of 5e-5. For SIGHAN 13 dataset, we performed additional fine-tune steps for 6 epochs as the data distribution in SIGHAN13 differs from other datasets, e.g. ”的”, ”得” and ”地 are rarely distinguished.

Evaluation Metrics. To evaluate the performance, we employ character and sentence-level accuracy, precision, recall and F1 followed by (Cheng et al., 2020), which are commonly used in the CSC task. In addition, we introduce the official evaluation metrics tool[4], which gives False Positive Rate (FRT), precision, recall, F1 and accuracy in sentence level.

	+GAD	**75.6**	**80.4**	**77.9**	**73.2**	**77.8**	**75.4**

Table 4: The sentence level performance on both detection and correction level. Specially, SpellGCN (Cheng et al., 2020) reports correction level F1 as 75.9 in SIGHAN15. However, 74.8 is calculated by corresponding precision and recall. There the latter value is reported in the table.

4.4 Main Results

We compare our model with the state-of-the-art methods on the three test datasets, and the results are shown in Tab.3 and Tab.4, that compared the results in character-level and sentence level respectively. BERT_CRS outperforms almost all methods in three datasets, and combined with GAD achieving the best performance. Specifically, under the same amount labeled training data, for character level metric, our method gains the improvement against previous best results (SpellGCN) are 0.4%, 2.1%, 0.7% respectively for correction level F1 metric. For sentence level score, our model outperform SpellGCN by a margin of 6.2%, 2.2%, 0.6% respectively for correction level F1 metric. In addition, Soft-Masked BERT uses 5 million examples that generate by replaced strategy for extra training data. our method outperforms it by a large margin in SIGHAN15 test dataset.

We further consider the official evaluation results of BERT_CRS and GAD to compete with BERT and SpellGCN in SIGHAN15, shown in Tab.6. Our proposed BERT_CRS+GAD achieving better performance than SpellGCN by a margin of 0.2% for correction level F1 metric. In addition, the FPR are 13.1% (BERT_CRS+GAD) v.s. 13.2% (SpellGCN).

4.5 Ablation Studies

In this sub-experiment, we explore the impact of several components, including the coefficient λ and learning rate lr in BERT_CRS and the effective parameter k that is the number of candidates in GAD

Model	Parameters	Value	**F1(%)**
BERT_CRS	λ	1	72.0
		0.5	73.4
		0.1	74.8
	lr	2e-5	74.8
		5e-5	74.6
GAD	k	3	75.4
		4	75.1
		5	74.7

Table 5: The effect of parameters in BERT_CRS and GAD for correction level F1 metric on SIGHAN15.

The Effect of BERT_CRS. Our BERT_CRS introduces confusion set guided replacement strategy using BERT model. Compared with BERT model, for character level metric in Table.3, BERT_CRS improves the performance by a margin 6.6%, 2.5%, 1.8% respectively for correction level F1. For sentence level metric in Table.4, we achieving the scores 81.2% (BERT_CRS) v.s. 74.6% (BERT) on SIGHAN 13, 66.7% (BERT_CRS) v.s. 64.3% (BERT) on SIGHAN 14 and 74.8% (BERT_CRS) v.s. 73.0% (BERT) on SIGHAN 15.

We also show the effect of coefficient λ and learning rate during fine-tuning in all labeled datas, shown in Tabel.5. First we fix learning rate as 2e-5 and tune $\lambda \in [0.1, 0.5, 1]$ on SIGHAN15. When λ=0.1, the best performance is achieved. In addition, big variation is shown with different λ, That is to say, if more attention of detection loss, the performance is unsatisfactory. The reason of the situation may be caused by the imbalance of detection label during the fine-tuning process. In the following

Model	FPR	Detection Level				Correction Level			
		Acc.	**Pre.(%)**	**Rec.(%)**	**F1(%)**	**Acc.**	**Pre.(%)**	**Rec.(%)**	**F1(%)**
SpellGCN (Cheng et al., 2020)	13.2	**83.7**	85.9	**80.6**	83.1	82.2	85.4	77.6	81.3
BERT (Cheng et al., 2020)	13.6	83.0	85.9	78.9	82.3	81.5	85.5	75.8	80.5
BERT_CRS	14.0	83.1	85.1	80.2	82.6	81.9	84.8	77.8	81.1
+GAD	**13.1**	83.6	**86.0**	80.4	**83.1**	**82.4**	**85.6**	**77.8**	**81.5**

Table 6: The sentence level performance evaluated by official tools on SIGHAN 2015. The smaller FPR score indicates the better performance.

experiments, we set λ=0.1. We tune learning rate from [2e-5, 5e-5]. When 2e-5 is adopted, the better performance is achieved. We set learning rate equal to 2e-5 during experiments.

The Effect of GAD When combined with GAD in BERT_CRS model, the performance is improved under character and sentence level metric, shown in Tabel.3 and Tabel.4. Specifically, for sentence level metric, BERT_CRS+GAD outperform BERT_CRS by a margin of 0.4%, 0.8% and 0.6% respectively for correction level F1 metric.

We also study the impact of candidate number k. Since k is the key parameter which determines the coverage of correct character in candidates, it affects the performance of our algorithm. We study the performance variance with different $k \in [3, 4, 5]$ on SIGHAN15. Shown in Tabel.5, more candidates may degrade the performance. According to statistics, there are 161,365 error characters in all test data and 106, 75, 64 not in candidates for k equal to 3, 4, 5 respectively. The candidates generated by BERT_CRS model have 99.9% probability covering the correct character. Consider the trade-off between cover rate of candidates and performance, We set $k = 4$ in our experiments.

4.6 Case Study

To further analyze our approach, we show some correction results on test data (see Table.7). In Table.7, three categories of spelling error are selected: 1) Continuous characters error; 2) Single character error; 3) No character error. For Continuous characters error instance, ”介绍” (introduce) was misspelled as ”借少” (borrow less). Due to the influence of error characters, BERT_CRS is difficult to correct them all correctly. However, BERT_CRS+GAD alleviates the impact of the local error contextual to correct them all correctly. For single character error instance, ”抱” (pick up) was misspelled as ”包” (pack). Our BERT_CRS+GAD can also learns richer global contextual information to correct it than BERT_CRS. Here it has the same meaning of ”提议” (suggestion) and ”建议” (suggestion) in no character instance, BERT_CRS miscorrects it. These cases prove that our GAD can learn rich global contextual information to alleviate the impact of the local error contextual for CSC.

Continuous characters error
...语言。去外国可以认识很多的人，就可以借少
...语言。去外国可以认识很多的人，就可以借绍
...语言。去外国可以认识很多的人，就可以介绍
... you can meet a lot of people abroad, and introduce these languages.
Single character error
我把小猫抱起来，赶紧包出去到马路边求救...
我把小猫抱起来，赶紧跑出去到马路边求救...
我把小猫抱起来，赶紧抱出去到马路边求救...
I picked up the kitten and hurried out to the side of the road for help.
No character error
...课堂之前可以先有一些提议或许参考的资料...
...课堂之前可以先有一些建议或许参考的资料...
...课堂之前可以先有一些提议或许参考的资料...
Some suggestions or reference materials can be available before the class.

Table 7: Examples of CSC results, the incorrect and correct characters marked in red and green respectively. The first line in the block is input sentence. The second and third line is corrected by BERT_CRS and BERT_CRS+GAD respectively. And the rest is the English translation of the correct sentence.

We also showed some incorrect case to further analyze our model. For example, for the sentence ”希望您帮我素取公平，得到他们适当的赔偿”(I hope you can help me x for justice and get proper compensation from them) where the incorrect word ’x’ is not comprehensible, our GAD changes ”素取”(x) to ”争取”(strive for) that is appropriate in the context, but ground-truth ”诉取”(sue for) is more suitable because the context contains the meaning of litigation. Our GAD model also lacks the inference ability of context strong correlation as described in (Zhang et al., 2020).

5 Conclusions

In this paper, we propose a novel global attention decoder (GAD). Condition on the potential correct input characters and the candidates of potential error characters, GAD reforms the self attention mechanism to learn their global relationships and obtains the rich global contextual information to alleviate the influence caused by error context. In addition, a BERT with **C**onfusion set guided **R**eplacement **S**trategy (BERT_CRS) is designed to narrow the gap between BERT and spelling error correction. Experimental results on three datsets show that our BERT_CRS outperform almost all previous state-of-the art methods, and higher performance is obtained by combining with our GAD.

Abstract

Rhetorical implicit emotion identification is one of important and challenging tasks in natural language processing. We observe that each rhetoric may express certain evidence of semantic and syntactic patterns. Then, we design a gate mechanism based classification module to capture respective rhetorical representation and identify each rhetoric. Moreover, sentences carved with rhetoric tends to express emotions in subtle ways. We thus propose a new multi-task learning framework that can encode the categorical correlation between tasks to improve the performance of rhetoric and emotion identification problem. Experimental results validate the benefit of the proposed model over state-of-the-art baselines for rhetoric and emotion identification tasks. In addition, a new Chinese rhetorical implicit emotion dataset was constructed and will be released in this work.

1 Introduction

Rhetoric is formed by decorating the semantics and adjusting the structure of sentences in text (Kennedy, 2009; Wang, 2013). The sentences that express implicit emotions via rhetorics are commonly used in literary works and spiritual user reviews. They tend to express semantics at a high cognitive level and convey emotions in an obscure way. The example sentence below actually expresses the emotion of "love" and meanwhile consists of two rhetoric forms of parallelism and simile.

> 宽容是一块块木板，可以架起人与人之间的桥梁；宽容是一根根丝带，可以系住人与人之前的友谊；宽容是一团团火焰，可以融化人与人之间的隔阂。(*Tolerance is a piece of board, which can build a bridge between people; Tolerance is a ribbon, which can tie the friendship between people; Tolerance is a flame, which can melt the barriers between people.*)

Clearly, one can understand and predict the emotion ("love") and rhetoric ("simile" and "parallelism") of the sentence by capturing the semantic meanings of content words ("tolerance", "board", "bridge", "ribbon", "friendship") as well as the syntactic structure and pattern of parallelism clauses in the sentence ("Tolerance is ⋯, which can⋯"). Semantics and syntax are pivotal cornerstones for rhetoric, and are attached to different rhetoric. Moreover, positive emotions are more likely to be expressed by rhetorical categories such as simile, parallelism and so on, while negative emotions are more commonly conveyed by the rhetorical categories such as rhetorical questions, irony and so on.

Sentences carved with rhetoric can convey emotions in an implicit way, without explicitly using emotional words, which pose new challenges for textual understanding and rhetorical emotion analysis in natural language processing.

Various efforts have been made to cope with emotion identification (Delbrouck et al., 2020; Chen et al., 2018; Klinger et al., 2018) and rhetoric detection (Liu et al., 2018; Wen et al., 2019; Mao et al., 2019). However, constructing heuristic rules and syntactical patterns for rhetoric identification is time-consuming and labor-intensive, and it may perhaps result in poor generalization to develop a specific detection model for each rhetoric category (Liu et al., 2018; Mao et al., 2019). To our knowledge, the correlation between rhetoric and emotion identification tasks has not been exploited in previous work.

In this work, we aim to cope with rhetoric and emotion analysis. Following previous studies, we formulate each of the rhetoric and emotion identification as a multi-label classification problem.

Then, we propose a new multi-task learning model called REI-MUL, which can jointly leverage the task correlation to address the rhetoric and emotion identification in a unified framework.

In particular, a pre-trained language model (Devlin et al., 2019) and a tree-structured long short-term memory networks (Tree-LSTMs) (Tai et al., 2015) are used to encode the semantic and syntactic representations of sentences, respectively. Taking the representations as input, two correlation modules are introduced to learn the categorical correlations between rhetoric and emotion tasks. One key benefit of REI-MUL is that it exploits the correlation between the two tasks, and may allow better learning of model parameters from real-life natural language data.

2 Methodology

2.1 Overview

Formally, let C be a labeled set of sentences, $C = \{(S_1, Y_1^r, Y_1^e), (S_2, Y_2^r, Y_2^e), \cdots, (S_L, Y_L^r, Y_L^e)\}$, where S_l is an input sentence, while $Y_l^r = \{y_{l_1}^r, y_{l_2}^r, ..., y_{l_R}^r\}$ and $Y_l^e = \{y_{l_1}^e, y_{l_2}^e, ..., y_{l_E}^e\}$ denote the rhetoric label set (with R categories) and the emotion label set (with E categories) of the sentence S_l, respectively. Note that $y_{l_i}^r$, $y_{l_j}^e \in \{0, 1\}$, $y_{l_i}^r = 1$ and $y_{l_j}^e = 1$ mean the S_l is labeled as the i-th rhetoric and j-th emotion categories.

Based on the labeled set C, we develop a new multi-task learning model (REI-MUL), as shown in Figure 1, which can exploit task correlation to deal with rhetoric identification and emotion recognition in a unified framework.

2.2 Semantic Representation

As one of the state-of-the-art language representation models, the BERT model (Devlin et al., 2019) is employed to learn the sematic representations of sentences. Specifically, the contextualized representation of $[CLS]$ token is used as the encoding of whole sequence, which is denoted by $sr^{sem} \in \mathbb{R}^{d_1}$. For simplicity, we omit the subscript of input sentence "l" for subsequent sections.

2.3 Syntactic Representation

A well-known Tree-LSTMs (Tai et al., 2015) is exploited to encode syntactic representations of sentences. Word sense is a critical factor for structural representation. We thus represent the meaning of a word via connecting the *comprehensive* embedding (Song et al., 2018) and the *sememes knowledge* embedding from SE-WRL Model (Niu et al., 2017).

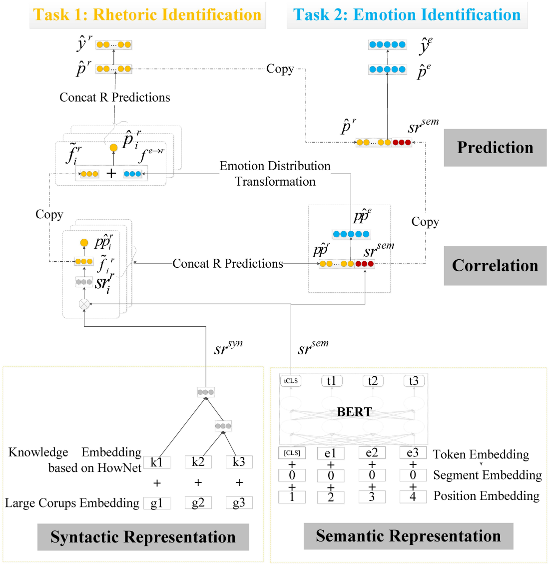

Figure 1: The architecture of the proposed multi-task learning model for rhetoric and emotion identification (REI-MUL). REI-MUL consists of four parts.

Taking the word representations as input, the hidden state of root node in Tree-LSTMs model is taken as syntactic representation of each input sentence, as shown in Eqn (1).

$$sr^{syn} = Tree - LSTMs(X, X^{syn}) \qquad (1)$$

where $X = \{x_1, x_2, ..., x_N\}$, x_i means the input embedding of each word w_i, X^{syn} is the dependency parsing of S by using Stanford Parser, and $sr^{syn} \in \mathbb{R}^{d_2}$.

2.4 Correlation Layer

Both rhetorical and emotional modules of correlation layer are designed to obtain the label distributions of sentences, which can help to explicitly encode the semantic and syntactic correlations between rhetoric and emotion identification tasks.

2.4.1 Rhetoric Distribution

A gate mechanism (Cho et al., 2014) based classification model is proposed for each type of rhetoric, which assigns different weights to semantic and syntactic representations. Taking the i-th rhetoric identification as an example, the classifier can derive three types of representations, i.e., sentence representation, feature representation, and rhetoric distribution via Eqn (2)-(7).

$$r_i = \sigma(W_i^r * [sr^{syn}, sr^{sem}]) \qquad (2)$$

---

https://nlp.stanford.edu/software/lex-parser.html ("version 4.0.0, Chinese")

$$z_i = \sigma(W_i^z * [sr^{syn}, sr^{sem}]) \tag{3}$$

$$\tilde{sr}_i = tanh(W_i^{\tilde{sr}} * [r_i \odot sr^{syn}, sr^{sem}]) \tag{4}$$

$$sr_i^r = (1 - z_i) * sr^{syn} + z_i * \tilde{sr}_i \tag{5}$$

where r_i, z_i and $sr_i^r \in \mathbb{R}^{d_2}$ denote the reset gate, update gate and sentence representation, respectively. σ and $tanh$ denote the sigmoid and hyperbolic tangent activation functions, and $\odot$ is elementwise multiplication.

$$\tilde{f}_i^r = sr_i^r W_i^{fr} \tag{6}$$

where $\tilde{f}_i^r$ is the feature representation for i-th rhetoric identification, and $\tilde{f}_i^r \in \mathbb{R}^{d_3}$.

$$p\hat{p}_i^r = \tilde{f}_i^r W_i^{pr} \tag{7}$$

where $p\hat{p}_i^r$ refers to rhetoric distribution for i-th rhetoric identification, and $p\hat{p}_i^r \in \mathbb{R}^1$.

Next, the respective R rhetoric distributions are concatenated as one comprehensive rhetoric distribution via Eqn (8), which would be used to compute the emotion distribution.

$$p\hat{p}^r = [p\hat{p}_1^r || p\hat{p}_2^r || ... || p\hat{p}_R^r] \tag{8}$$

where $p\hat{p}^r \in \mathbb{R}^R$.

2.4.2 Emotion Distribution

The emotional features are constructed by concatenating the semantic representation and rhetorical distribution of S. Taking the features as input, a classification model can be adopted to compute emotional distribution via Eqn (10), which would be next used to improve the rhetorical prediction task.

$$sr^e = [sr^{sem} || p\hat{p}^r] \tag{9}$$

$$p\hat{p}^e = sr^e W^{pe} \tag{10}$$

where $p\hat{p}^e$ denotes emotional distribution of input sentence S, and $p\hat{p}^e \in \mathbb{R}^E$.

2.5 Prediction Layer

2.5.1 Rhetoric Prediction Layer

An emotional distribution is incorporated into original rhetorical features, which is extracted from sentence representations. Then a sigmoid classifier is designed to take the correlated representation of a sentence as input, and predicts rhetorical probability scores. Formally, Eqn (11)-(13) calculate the transformed features based on emotional distribution ($f^{e \rightarrow r}$), new correlated features (f_i^r) and predicted probability ($\hat{p}_i^r$), respectively, for i-th rhetoric identification task.

$$f^{e \rightarrow r} = p\hat{p}^e W^{e \rightarrow r} \tag{11}$$

$$f_i^r = \tilde{f}_i^r + f^{e \rightarrow r} \tag{12}$$

$$\hat{p}_i^r = \sigma(f_i^r W_i^{pr}) \tag{13}$$

where $W^{e \rightarrow r}$ represents the feature transformation matrix of emotional distribution.

Next, the R predicted scores are concatenated as one rhetorical predicted probability distribution $\hat{p}^r \in \mathbb{R}^R$.

2.5.2 Emotion Prediction Layer

Similarly, a new correlated representation of input sentence is computed based on the predicted rhetorical distribution and semantic representation of the sentence via Eqn (14). And then we predict probability scores of emotion by a sigmoid classifier via Eqn(15).

$$sr^e = [sr^{sem} || \hat{p}^r] \tag{14}$$

$$\hat{p}^e = \sigma(sr^e W^{pe}) \tag{15}$$

where $\hat{p}^e \in \mathbb{R}^E$ denotes the emotional prediction probabilities of input sentence.

3 Experiments

3.1 Data

To our knowledge, there is a labeled dataset for emotion analysis of metaphorical expressions, which was constructed from a cognitive process (Zhang et al., 2018). However, there are no datasets available for joint rhetoric and emotion identification problem from the perspective of linguistics. We constructed the first dataset in Chinese, where each sentence may contain multiple rhetoric/emotion labels. Table 1 shows the detailed statistics of the dataset.

Category Name	Train	Val	Test	All
similes/metaphors	5,121	650	652	6,432
parallelism	1,903	238	234	2,375
personification	1,755	223	226	2,204
rhetorical questions	1,582	180	183	1,945
irony	649	82	82	813
Total	11,010	1,373	1,377	13,760
joy	133	22	22	177
love	6,329	784	808	7,921
anger	109	15	10	134
sadness	724	91	78	893
fear	97	12	13	122
disgust	2,042	256	239	2,537
surprise	58	5	14	77
Total	9,492	1,185	1,184	11,861
Sentence Number	9,456	1,182	1,182	11,820

Table 1: The statistics of the annotated dataset.

Each sentence of the dataset was collected from

	joy	love	anger	sadness	fear	disgust	surprise
similes/metaphors	83	5,446	25	406	88	376	23
parallelism	51	2,034	2	181	8	125	2
personification	29	1,876	17	149	24	71	7
rhetorical questions	21	272	87	232	9	1,282	43
irony	0	4	6	10	0	790	3

Table 2: The correlation between rhetorical and emotional classes on the dataset.

various sources such as literary works, textbooks, microblog, and websites. Three graduate students were hired to annotate the rhetorical and emotional labels of each sentence, where the inter-rater kappa coefficients are 0.848, 0.692, 0.757 for rhetoric annotation task and 0.458, 0.512, and 0.556 for emotion task, respectively. We randomly selected 80% of the annotated dataset as training data, while the rest 20% was equally divided as testing (test) and development (dev) data. All the models were evaluated on the same data split.

Table 2 shows the correlation statistics between rhetorical and emotional categories on the dataset. For example, the emotion "love" of a sentence is more likely to be expressed by rhetorical categories such as simile, parallelism and personification, while the emotion "disgust" is more commonly conveyed by the rhetorical categories such as rhetorical questions and irony.

3.2 Comparison Systems

We compared the proposed models with the following well-established baselines and ablation models.

- **CNN-Adversarial-MUL**: Liu et al. (2017) proposed an adversarial multi-task learning framework for text classification, alleviating the shared and private latent feature spaces from interfering with each other.

- **BERT-MUL**: Liu et al. (2019, 2020) presented a multi-task deep neural network for learning representations across multiple natural language understanding tasks.

- **RI-Single, EI-Single**: the proposed model is simplified a single task model for rhetoric or emotion identification.

- w/o ***RheFusing***, w/o ***EmoFusing***: the proposed model without predicted rhetorical or emotional distribution.

- w/o ***Gate***: the proposed model without a gate mechanism.

- w/o ***Tree***: the proposed model without syntactic representation.

- w/o ***ComprehensiveEmb***, w/o ***KnowledgeEmb***: the proposed model without *comprehensive* or *sememes knowledge* embedding in Tree-LSTMs.

3.3 Experimental Setting

The version "bert-base-chinese" was employed for the BERT module in the framework. The dimensionality of word embeddings in Tree-LSTMs was set 200. We carefully tuned and specified the values of the dimensionalities of Tree-LSTMs hidden state and feature representation of rhetoric identification as 64. We employ a heuristic threshold method to specify and predict rhetorical and emotional labels for each sentence, where different threshold scores were evaluated by the grid search method and selected as 0.88 and 0.73 on validation sets, respectively.

The joint one-versus-all cross-entropy loss was used to train the proposed multi-task learning. We applied the Adamax optimizer (Kingma and Ba, 2014) with learning rate as 0.00005, the batch size was set as 6, and the training epoch was set as 15. In addition, we applied dropout (Srivastava et al., 2014) on per layer of BERT model and prediction layers, and the value was 0.1.

3.4 Experimental Results

We compare the proposed method with state-of-the-art multi-task learning methods. Table 3 shows the results of rhetoric and emotion identification.

In particular, the proposed REI-MUL model achieves the best performance in terms of F1 for both tasks. Generally, the disadvantage of CNN-Adversarial-MUL may lie in the fact that the sentence representation by CNN module is not as good as the semantic representation of the BERT module of the proposed model. Compared to BERT-MUL, the proposed REI-MUL attains better results. This may suggest that the learning from associations

Model	Rhetoric(%)			Emotion(%)		
	P	R	F1	P	R	F1
CNN-Adversarial-MUL	89.56	87.80	88.67	87.16	86.57	86.86
BERT-MUL	92.11	93.32	92.71	88.27	87.67	87.97
REI-MUL	94.88	92.81	**93.83**	91.05	86.74	**88.84**

Table 3: The rhetoric and emotion identification results (P: Precision, R: Recall, F1: F1-score). Our proposed method is significantly better than the baselines given p-value 0.05 for the emotion identification.

Model	Rhetoric(%)			Emotion(%)		
	P	R	F1	P	R	F1
REI-MUL	94.88	92.81	**93.83**	91.05	86.74	**88.84**
RI-Single/EI-Single	92.84	93.79	93.31	89.74	87.76	88.74
w/o RheFusing	94.80	92.59	93.68	90.90	86.06	88.42
w/o EmoFusing	91.40	94.12	92.74	91.63	85.98	88.71
w/o Gate	93.77	92.88	93.32	88.63	88.26	88.45
w/o Tree	94.55	91.94	93.23	91.89	85.14	88.38
w/o ComprehensiveEmb	93.88	92.52	93.20	90.69	86.40	88.49
w/o KnowledgeEmb	92.66	93.54	93.10	88.95	88.34	88.64

Table 4: The ablation study results of rhetoric and emotion identification via the proposed model.

between rhetoric and emotion categories is really beneficial for rhetoric and emotion tasks. In addition, the improved results of rhetoric detection show the independent rhetorical classifiers for each rhetoric detection are effective.

3.5 Ablation Study

We designed the ablation study to evaluate the impact of different parts of the proposed REI-MUL model for rhetoric and emotion identification. Specifically, we removed each of the following modules from our proposed model, i.e., correlation between two tasks, independent rhetorical classifier based on gating mechanism, word embedding of Tree-LSTMs. Table 4 shows the comparison results of REI-MUL and reduced models on annotated dataset. Clearly, these results manifest remarkable capability of each part of the proposed model.

Table 5 shows the detailed identification results for each rhetorical category. Experimental results show that the proposed method performs well for minority categories, such as parallelism and rhetorical questions. In addition, the results for personification and irony are not as good as the rest, which may lie in their higher dependence on human cognition and pose a challenge for the identification.

Category	P	R	F1
similes/metaphors	95.50	97.55	96.51
parallelism	94.21	97.44	95.80
personification	91.44	75.66	82.81
rhetorical questions	96.24	97.81	97.02
irony	96.97	78.05	86.49

4 Conclusion

In this paper, we have proposed a new multi-task and multi-label learning model, which can exploit the task correlation to jointly address the rhetoric and emotion identification in a unified framework. The experimental results show the benefit of the proposed model over the state-of-the-art baselines.

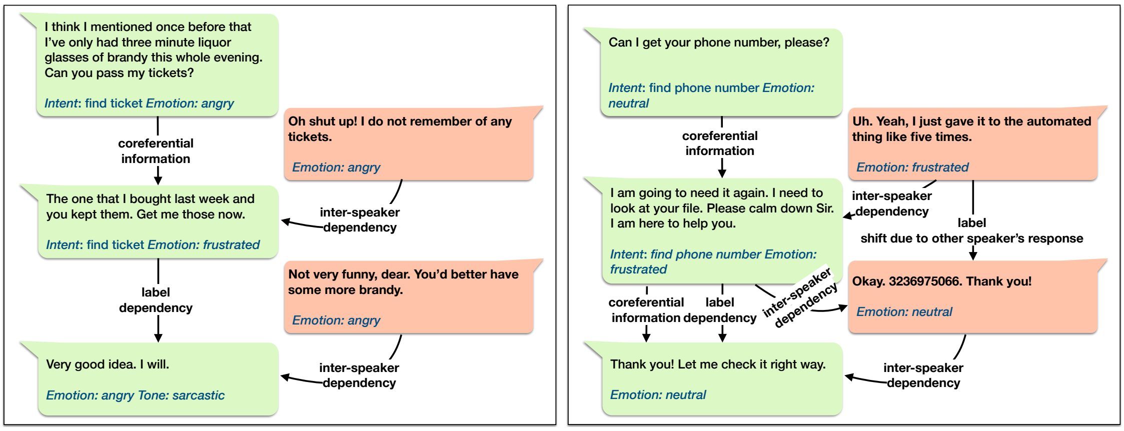

Figure 1: Role of Context in Utterance Level Dialogue Understanding.

Abstract

The recent abundance of conversational data on the Web and elsewhere calls for effective NLP systems for dialogue understanding. Complete utterance-level understanding often requires context understanding, partly defined by the nearby utterances and by the user intention and background. In recent years, a number of context-aware approaches have been proposed for various utterance-level dialogue understanding tasks. In this paper, we explore and quantify the role of context for different aspects of a dialogue, namely *emotion, dialogue act,* and *intent* identification, using state-of-the-art dialogue understanding methods as baselines. Specifically, we employ various perturbations to distort the context of a given utterance and study its impact on the different tasks and baselines. This provides us with insights into the fundamental context factors that have immediate implications on different aspects of a dialogue. Such insights may inspire more effective dialogue understanding models and provide support for future text generation approaches.

1 Introduction

Human-like conversational systems are a long-standing goal of Artificial Intelligence (AI). However, the development of such systems is not a trivial task, as we often participate in dialogues by relying on several contextual factors such as emotions, prior assumptions, intent, or personality traits. It is thus not surprising that the landscape of dialogue understanding research embraces several challenging tasks, such as, emotion recognition in conversations (ERC), dialogue intent classification, user-state representation, and others. These tasks are often performed at utterance level and can be conjoined together under the umbrella of *utterance-level dialogue understanding*. Due to the fast-growing research interest in dialogue understanding, several novel approaches have recently been proposed (Qin et al., 2020; Rashkin et al., 2019; Xing et al., 2020; Lian et al., 2019; Saha et al., 2020) to address the tasks by adopting speaker-specific and contextual modeling. However, to the best of our knowledge, the role of context has not been thoroughly explored across these tasks, partly due also to the lack of an unified framework across various utterance-level dialogue understanding tasks. In this work, we explore the role of context in utterance-level dialogue understanding. We use a contextual utterance-level dialogue understanding baseline (bcLSTM (Poria et al., 2017)) as

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 1435–1449
August 1–6, 2021.

a strong baseline for the six dialogue-understanding tasks in four datasets. We propose several unique context probing strategies and experimental designs that test and measure: (1) speaker-specific context; (2) context order; (3) paraphrased context; (4) label shifts; (5) role of CRF in the sequence tagging of utterances in a dialogue. These strategies can be easily adapted for other tasks for similar purposes and provide insights into the development of new approaches to address these tasks.

Task Definition: Given a conversation along with speaker information of each constituent utterance, the utterance-level dialogue understanding task aims to identify the label of each utterance from a set of predefined labels that can be a set of emotions, dialogue acts, intents etc. Fig. 1 illustrates one such conversation between two people, where each utterance is labeled by emotion and intent. Formally, given the input sequence of N utterances $[(u_1, p_1), (u_2, p_2), \dots, (u_N, p_N)]$, where each utterance $u_i = [u_{i,1}, u_{i,2}, \dots, u_{i,T}]$ consists of T words and spoken by party p_i, the task is to predict the label e_i of each utterance u_i. The classifier can make use of the conversational context in the process.

2 Models

We train our classification models in an end-to-end setup. We first extract utterance level features with a CNN module with pretrained GloVe vectors. The resulting features are non-contextual in nature as they are obtained from utterances without the surrounding context. We then classify the utterances with one of the following two models: i) Logistic Regression, or ii) bcLSTM. Among these, the Logistic Regression model is non-contextual in nature, whereas the bcLSTM is contextual. We expand on the feature extractor and the classifier in detail next.

2.1 Utterance Feature Extractor

Utterance level features are extracted using the following method:

GloVe CNN. A convolutional neural network (Kim, 2014) is used to extract features from the utterances of the conversation. We use a convolutional layer followed by max-pooling and a fully-connected layer to obtain the representation of the utterance. Each word in the utterances is initialized with 300d pretrained GloVe embeddings (Pennington et al., 2014). We pass these to convolutional filters of sizes 1, 2, and 3, each having 100 feature maps. The output of these filters are then max-pooled across all the words of an utterance. These are then concatenated and fed to a 100 dimensional fully-connected layer with ReLU activation (Nair and Hinton, 2010). The output after the activation form the final representation of the utterance.

2.2 Utterance Classifier

The representations obtained from the *Utterance Feature Extractor* are then classified using one of the following two methods:

Without Context Classifier. In this model, classification of an utterance is performed using a fully connected multi-layer perceptron layer. This classification setup is non-contextual in nature as there is no flow of information from the contextual utterances. We call this model **GloVe CNN**.

GloVe bcLSTM. The Bidirectional Contextual LSTM model (bcLSTM) (Poria et al., 2017) creates context-aware utterance representations by capturing the contextual content from the surrounding utterances using a Bi-directional LSTM (Hochreiter and Schmidhuber, 1997) network. bcLSTM is a strong contextual utterance-level dialogue understanding baseline, with consistent performance across all six dialogue-understanding tasks considered in this work. In our experiments, on an average bcLSTM is only 1% worse than the state of the art across the six tasks that we address in this work. As opposed to more complicated models (Majumder et al., 2019; Qin et al., 2020; Zhong et al., 2019), the simpler architecture of bcLSTM is devoid of complicated interactions amongst the contextual utterances, as attention. This enables easier interpretation of the effects of the perturbations of the context.

The feature representations extracted by the *Utterance Feature Extractor* serve as the input to the bcLSTM network. Finally, the context-aware utterance representations from the output of the bcLSTM are used for the label classification. The bcLSTM model is speaker independent as it does not model any speaker level dependency. In our implementation, we add a residual connection between the first and the output from the final layer to improve the network's stability. We call this model **GloVe bcLSTM**.

Why GloVe based CNN and LSTM-based Models: In this study, we consider GloVe CNN, GloVe bcLSTM and set up different scenarios to analyze them because these models are conceptually much more straightforward than other state-of-the-art models such as DialogueRNN (Majumder et al., 2019) and DialogueGCN (Ghosal et al., 2019). For example, DialogueRNN also tracks the speaker states in addition to context. Thus, perturbations in the input would influence speaker modeling along with context modeling. This results in more complex deviations than bcLSTM, and are more difficult to analyze. Simple models are likely to be more interpretable. E.g., owing to DialogueRNN's complexity, we need to perform different levels of ablation studies to explain its behavior.

Furthermore, we use GloVe embeddings as recent transformer based models such as BERT (Devlin et al., 2018) is trained using the masked language model (MLM) objective that is already very powerful in modeling cross sentential context representation as demonstrated by other works (Liu et al., 2019; Lewis et al., 2019). Hence, to conduct a fair comparison between non-contextual and contextual models and further, for an easier apprehension on the role of contextual information in utterance-level dialogue understanding, we resort to the GloVe CNN and LSTM-based models. Additionally, as we perform a number of analysis studies, the GloVe based models were computationally much more efficient and faster to train and analyze.

3 Experimental Setup

3.1 Datasets

All the dialogue classification datasets that we consider in this work consists of two-party conversations in English language. We benchmark the models on the following datasets (see Table 1):

IEMOCAP (Busso et al., 2008) is a dataset of two person conversations among ten different unique speakers. The train set dialogues come from the first eight speakers, whereas the test set dialogues are from the last two. Each utterance is annotated with one of the following six emotions: *happy, sad, neutral, angry, excited,* and *frustrated*.

Dataset	# dialogues			# utterances		
	train	val	test	train	val	test
IEMOCAP	108	12	31	5163	647	1623
DailyDialog	11,118	1,000	1,000	87,179	8,069	7,740
MultiWOZ	8,438	1000	1,000	113,556	14,748	14,744
Persuasion	220	40	40	7902	1451	1511

Table 1: Statistics of splits and evaluation metrics used in different datasets. *Neutral** classes constitutes to 83% of the DailyDialog dataset. These are excluded when calculating the metrics in DailyDialog.

DailyDialog (Li et al., 2017) covers various topics about our daily life and follows the natural human communication approach. All utterances are labeled with both emotion categories and dialogue acts. The emotion can belong to one of the following seven labels: *anger, disgust, fear, joy, neutral, sadness*, and *surprise*. The dataset has over 83% *neutral* labels and these are excluded during Macro-F1 evaluation. In comparison, the dialogue act label distribution is relatively more balanced. The act labels can belong to the following four categories: *inform*, *question*, *directive*, and *commissive*.

MultiWOZ (Budzianowski et al., 2018) or Multi-Domain Wizard-of-Oz dataset is a fully-labeled collection of human-human conversations spanning over multiple domains and topics. The dataset has been created for task-oriented dialogue modelling and has 10,000 dialogues, which is atleast an order bigger than previously available task-oriented corpora. The dialogues are labelled with belief states and actions. It contains conversations between an user and a system from the following seven domains: restaurant, hotel, attraction, taxi, train, hospital and police. Here we focus on classifying the intent of the utterances from the user which belong to one of the following categories: *book restaurant*, *book train*, *find restaurant*, *find train*, *find attraction*, *find bus*, *find hospital*, *find hotel*, *find police*, *find taxi*, and *None*. The *None* utterances are not included in evaluation. Note that, utterances from the system side are not labelled and thus are not classified in our framework.

Persuasion For Good (Wang et al., 2019) dataset is a persuasive dialogue dataset where one participant aims to persuade the other participant to donate his/her earning using different persuasion strategies. The two participants are denoted as *Persuader* aka **ER** and *Persuadee* aka **EE** respectively. In this work, we formulate our problem to classify the utterances of Persuader and Persuadee separately using the full context of the conversation. This task can also be considered as a dialogue act classification task. The Persuader strategies are to be classified into the following eleven categories: *donation-information*, *logical-appeal*, *personal-story*, *foot-in-the-door*, *credibility-appeal*, *emotion-appeal*, *personal-related-inquiry*, *source-related-inquiry*, *self-modeling*, *task-related-inquiry*, and *non-strategy-acts*. The strategy can belong to one of the following thirteen categories for Persuadee,: *disagree-donation-more*, *ask-org-info*, *agree-donation*, *provide-donation-amount*,

Model	IEMOCAP	DailyDialog		MultiWOZ	Persuasion	
	Emotion	Emotion	Act	Intent	ER	EE
GloVe CNN	51.08	38.72	71.20	84.64	54.44	39.95
GloVe bcLSTM	61.90	**41.16**	**79.46**	**96.22**	**56.28**	**44.83**
w/o Inter-Speaker Dependency	**63.73**	39.99	74.50	95.05	53.24	40.63
w/o Intra-Speaker Dependency	56.45	35.93	78.69	95.75	52.23	38.93

Table 2: Classification performance in test data for the different tasks. Utterances from other speakers and the same speaker are absent respectively in the *w/o inter* and *w/o intra* settings. Scores are W-Avg F1 in IEMOCAP Emotion and MultiWOZ Intent; Macro F1 in the rest. All scores are average of 20 different runs. Test F1 scores are calculated at best validation F1 scores.

disagree-donation, *personal-related-inquiry*, *task-related-inquiry*, *ask-donation-procedure*, *negative-reaction-to-donation*, *positive-reaction-to-donation*, *ask-persuader-donation-intention*, *neutral-reaction-to-donation*, and *other-acts*.

3.2 Evaluation Metrics

In our experiments, we use Weighted average (W-Avg) F1 score in IEMOCAP emotion and MultiWOZ intent classification. For the other tasks – DailyDialog emotion, DailyDialog act, Persuader and Persuadee strategy classification – the label distribution is highly imbalanced, hence we report Macro F1 scores. In DailyDialog emotion classification, neutral labels are excluded (masked) while calculating the metrics. However, these utterances are still passed in the input of the different models.

4 Analysis

4.1 Speaker-specific Context Control

We first report the performance of the baseline GloVe CNN and GloVe bcLSTM model in the first two rows of Table 2. To further evaluate the intra- and inter-speaker dependence and relation across the different tasks in the GloVe bcLSTM model, we adopted two different settings as follows –

- **w/o Inter-Speaker Dependency:** when classifying a target utterance from speaker A, we drop the utterances of the speaker B from the context and vice versa.
- **w/o Intra-Speaker Dependency:** when classifying a target utterance from speaker A, we only keep utterances of the speaker B and drop all other utterances of speaker A from the context and vice versa.

Utterances of the Non-target Speaker are Important. The first setting coerces LSTM to only rely on the *target* speaker's (speaker of the target utterance) context in prediction. The results are reported in Table 2. As expected, performance drops are observed for all the datasets but IEMOCAP for emotion recognition, reinforcing the fact that the contextual utterances from the non-target speakers are important. Performance drop in DailyDialog dataset for act classification is noticeably the steepest. In the IEMOCAP dataset, we observe a pattern of the speakers maintaining the same emotion along a dialogue. This suggests that the speakers in the IEMOCAP dataset repeat the same emotion along consecutive utterances. Consequently, this induces a dataset bias. Hence, unlike the task of dialogue generation where the role of listener's utterance is key in generating speaker's response, we suspect in the case of emotion recognition in IEMOCAP dataset, removing other interlocutor's utterances from the context makes it easier and less confusing for the LSTM-based model to learn relevant contextual representations for the prediction. Contrary to this, although existing, repetitions of same or similar emotions in consecutive utterances of a speaker are less prevalent for emotion recognition in the DailyDialog dataset.

Utterances of the Target Speaker are *also* Important. 'w/o Intra-Speaker Dependency' scenario reported in Table 2 exhibits the importance of the utterances of the non-target speaker in the classification of the target utterance. In DailyDialog act and MultiWOZ intent classification, even when we remove the contextual utterances from the same speaker, the utterances from the non-target speaker provides key contextual information as evidenced by the performance in the 'w/o Intra-Speaker Dependency' setting. In those tasks, dropping the utterances of the non-target speaker results in more performance degradation as compared to the case when utterances from the target speaker are removed from the target utterance's context. This observation also supports the dialogue generation works (Zhou et al., 2017) that mainly consider previous utterances of the non-target speaker as the context for response generation. For emotion classification in DailyDialog and strategy classification in Persuasion For Good, the results obtained from 'w/o Intra-Speaker Dependency' setting are also relatively lesser compared to the baseline bcLSTM setting. This confirms the higher contextual salience of the target speaker's utterances over the non-target speaker's utterances for these particular tasks. In the case of the IEMOCAP emotion classification, removing the target speaker's utterances from the context causes a substantial performance dip for the reasons stated earlier.

Interestingly, the ‘w/o Inter-Speaker Dependency’ setting in the DailyDialog dataset manifests two distinct trends for two different tasks – act classification and emotion recognition. While non-target speakers’ utterances carry a little value for emotion recognition, they are extremely beneficial for act classification. This calls for task-specific context modeling techniques which should be the focus of the future works.

Key Takeaways of this Experiment. Although both target and non-target speakers’ utterances are useful in several utterance-level tasks, we observe some divergent trends in some of the tasks in our experiments. Hence, we surmise that a task-agnostic unified context model may not be optimal in solving all the tasks. In the future, we should strive for task-specific contextual models as each task can have unique features that make it distinct from others. One can also think of multi-task architectures where two tasks can corroborate each other in improving the overall performance.

Logically, dropping contextual utterances in a dialogue leads to inconsistency in the context and consequently, it should degrade the performance of a model that relies on the context for inference. Hence, given an unmodified dialogue flow, an ideal contextual model is expected to refer to the right amount of contextual utterances relevant in inferring the label of a target utterance. In contrast, bcLSTM shows performance improvement for IEMOCAP emotion classification when utterances from the non-target speaker are dropped (refer to the ‘w/o Inter-Speaker Dependency’ row in Table 2). The performance does not change much for dialogue act and intent classification in the DailyDialog and MultiWOZ, respectively, when we drop utterances of the target speaker. These contrasting results indicate a potential drawback of the bcLSTM model in efficiently utilizing contextual utterances of both interlocutors in unmodified dialogues for the above mentioned tasks.

4.2 Classification in Shuffled Context

To analyze the importance of context, we shuffle the utterance order of a dialogue and try to classify the correct label from the shuffled sequence. For example, a dialogue having utterance sequence of $\{u_1, u_2, u_3, u_4, u_5\}$ is shuffled to $\{u_5, u_1, u_4, u_2, u_3\}$. This shuffling is carried out randomly, resulting in an utterance sequence whose order is different from the original sequence.

Context Shuffling Strategy			**IEMOCAP**	**DailyDialog**		**MultiWOZ**	**Persuasion**	
Train	Val	Test	Emotion	Emotion	Act	Intent	ER	EE
✗	✗	✗	**61.90**	**41.16**	**79.46**	**96.22**	**56.28**	**44.83**
✓	✓	✗	59.74	36.87	74.88	91.34	54.91	41.52
✗	✗	✓	57.63	34.58	66.81	67.91	50.69	37.17
✓	✓	✓	59.82	37.69	74.62	90.78	53.60	40.96

Table 3: Test performance of GloVe bcLSTM models in the different tasks for various shuffling strategies. In Train, Val, Test column ✓denotes shuffled context and ✗denotes unchanged context. Scores are W-Avg F1 in IEMOCAP Emotion and MultiWOZ Intent; Macro F1 in the rest. Test F1 scores are calculated at best validation F1 scores.

We design three such shuffling experiments: i) dialogues in train and validation sets are shuffled, test set is unchanged, ii) dialogues in train and validation sets are kept unchanged, but dialogues in test set are shuffled, iii) dialogues in train, validation and test sets are all shuffled.

We analyze these shuffling strategies in the GloVe bcLSTM model. In theory, the recurrent nature of the LSTM model allows it to be capable of modelling contextual information from the beginning of the sequence to the very end. However, when classifying an utterance, the most crucial contextual information comes from the neighbouring utterance. In an altered context, the model would find it difficult to predict the correct labels because the original neighbouring utterances may not be in immediate context after shuffling. This kind of perturbation would make the context modelling less efficient, and performance is likely to drop compared to their non-shuffled context counterparts. This is empirically shown in Table 3.

We observe that, whenever there is some shuffling in train, validation, or test set, the performance decreases a few points in all the datasets across all tasks and evaluation metrics. Notably, the performance drop is highest when the dialogues in train, validation sets are kept unchanged and dialogues in test set are shuffled. Note that, the result for this shuffling strategy (only test set is shuffled) in MultiWOZ stands at 67.91%, much lower than the original baseline of 96.22%. This is because, the test score of 67.91% is reported at the best validation score, even though we obtain better test scores at the initial epochs of training (around 78%).

Our reported results and observations are contradictory to the claims made by Sankar et al. (2019). According to Sankar et al. (2019), the shuffling of contextual utterances does not affect the response generation performance of a seq2seq model. There can be a number of reasons for these two contradicting observations: 1) first, the characteristics of utterance labels in a dialogue are different

#	Attack Method	Strategy Past	 Future	 Target	Window	**IEMOCAP** Emotion	**DailyDialog** Emotion	 Act	**MultiWOZ** Intent	**Persuasion** ER	 EE

from responses—responses are subjective and not unique, however labels are usually agreed upon by the observers to some degree—, 2) second, instead of reporting qualitative results, Sankar et al. (2019) only reported the perplexity score of their experiments. As stated in (Cai et al., 2019), perplexity and BLEU scores may not correctly represent the quality of the response generation.

4.3 Attacks with Context and Target Paraphrasing

Modern machine learning systems are often susceptible to attacks that slightly perturb the input without any drastic change in the semantics. Although prevalent in images, adversarial examples also exist in neural network-based NLP applications. In the context of NLP, crafting adversarial examples would require making character-, word-, or sentence-level modifications to the input text to trick the classifier into misclassification. Paraphrasing sentences is one such method to construct effective adversarial examples (Iyyer et al., 2018). We conduct several experiments to evaluate the sensitivity of utterance-level dialogue understanding systems to input paraphrasing. It should be noted that although task-specific adversarial strategies could be adopted, we chose to use a general set of attacking strategies in order to understand the behavior of the baseline across different tasks and datasets. This also facilitates a fair comparison among the tasks and whether there is a confounding factor that differentiates one task from another under the same attacking strategies.

Method. We use the following scheme to analyze this effect:

- The input utterances are modified at word level. For this modification, an average of 3 to 4 words are selected per utterance and masked. The pretrained RoBERTa model is then used to fill the masks with the most likely candidates. The utterance with substituted words form the new input. We call this method *Paraphrasing-based Attack* (PA).
- For each utterance (u_t) in a dialogue, we take a window of w immediate neighbouring utterances (context) on which the above modifications are performed. The window is selected as follows:
  - Only past w utterances: $u_{t-w}, .., u_{t-1}$
  - Only future w utterances: $u_{t+1}, .., u_{t+w}$
  - Past w and future w utterances: $u_{t-w}, .., u_{t-1}, u_{t+1}, .., u_{t+w}$
  - Past w, future w, and the target utterance: $u_{t-w}, .., u_{t-1}, u_t, u_{t+1}, .., u_{t+w}$
  - Only the target utterance: u_t

  In the last case, the window is empty. In other cases, we experiment with window size $w = 3, 5, 10$.

We train a GloVe bcLSTM and a GloVe CNN model with unadulterated train and validation data. During evaluation, however, the context and target are paraphrased as described before. The results of these experiments for bcLSTM and GloVe CNN are shown in Table 4 and Table 5, respectively.

Observations. We observe that the *Paraphrasing-based Attack* is quite effective in fooling the classifier in a number of tasks. The classification performance progressively deteriorates with larger window sizes.

In DailyDialog act classification, *Paraphrasing-based Attack* on only future utterances doesn't affect the results at all. The classification performance still remains very close to the original score of 79.46 %. We observe that there is a strong reliance on the label and content of past utterance in this task. For example, a *question* is likely to be followed by an *inform* or another *question* and much less likely to be followed by a *commissive* utterance. Unchanged past context thus results in performance that is very close to the original setup. Attacking the past utterances combined with future and/or target utterances results in a relatively bigger performance drop. We also notice that the drop in performance is relatively much lesser than the other tasks except in MultiWOZ for intent classification. This is possibly because the act labels are mostly driven by the sentence type and hence unlikely to be affected from paraphrasing perturbations. For instance, around 30% of the act labels are of type *question*, and our attack strategy is almost guaranteed not to change an utterance with label *question* to something which might be classified as *inform*, *commissive*, or *directive*. Overall, we observe a consistent plunge in the performance when the target utterance is attacked by the *Paraphrasing-based Attack* method. For intent classification in MultiWOZ, utterances often have keywords which indicate the label (presence of *train* might indicate class label of *find train* or *book train*). In these cases, if the target utterance is not paraphrased, the model is still likely to predict the correct label. Finally, in Persuasion for Good, we observe that the attack method is slightly more effective in fooling the classifier for persuadee strategy classification.

In terms of window direction, we observe that perturbations in the past or future utterances result in a similar range of reduction in performances. One notable exception is act prediction in DailyDialog, where the model continues to perform near the original score of 79.46% irrespective of the attack in future utterances in the window.

Performance Comparison for Attacks in GloVe CNN and GloVe bcLSTM. We summarize the performance of GloVe CNN and GloVe bcLSTM models against *Paraphrasing-based Attack* in Table 5. For all the tasks, we observe a very significant drop in performance for GloVe CNN. For example, in emotion classification, the drop is around 23% and 40% for *Paraphrasing-based Attack* in IEMOCAP and DailyDialog respectively. However, for the same setting, the relative decrease in performance is only around 6% and 10% for bcLSTM. We observe the same trend in other tasks where it can be seen that the bcLSTM model is much more robust against the attack compared to the CNN model. This is because contextual models such as bcLSTM are harder to fool as the context carry key information regarding the semantics of the target and salient information can be inferred about the target using its' context. It is thus evident that even when the target utterance is corrupted, bcLSTM is capable of using contextual information to predict the label correctly, and subsequently the decline in performance is much lesser.

In principle, our findings in Table 5 can be related to how transformer-based pre-trained language models work. For example, in BERT (Devlin et al., 2018), the masked language modeling (MLM) and the next sentence prediction (NSP) objective forces the model to infer or predict the target using contextual information. Such contextual models are more powerful and robust because context information plays a crucial role in almost every natural language processing task. An objective similar to next sentence prediction in BERT or permutation language modeling in XLNET (Yang et al., 2019) can be used for conversation level pre-training to improve several downstream conversational tasks. Such approaches have been found to be useful in the past (Hazarika et al., 2019).

4.4 Performance for Label Shift

As discussed before, a few of our tasks of interest exhibit the label copying property which means consecutive utterances from the same speaker or different speakers often have the same or similar emotion, act, or intent label. The inter-speaker and intra-speaker label copying is especially prevalent in the IEMOCAP emotion task, the DailyDialog act task, and the MultiWOZ intent task. Contextual models such as bcLSTM make correct predictions when utterances display such kind of continuation of the same label. But what happens when there is a change of label? Does bcLSTM continue to perform at the same level or is it affected from the change? To understand this occurrence in more detail, we define this event as *Label Shift* and look at the following two different kind of shifts that could happen in the course of a dialogue:

- *Intra-Speaker Shift*: The label of the utterance is different from the label of the previous utterance from the same speaker.
- *Inter-Speaker Shift*: The label of the utterance is different from the label of the previous utterance from the non-target speaker.

In these two scenarios explained above, we are interested to see how bcLSTM performs at the utterances were the label shift takes place.

We report results for utterances in the test data that show *Intra-Speaker Shift* and *Inter-Speaker Shift* in Table 6. The *Inter-Speaker Shift* is not

Setup	**IEMOCAP**	**Dailydialog**		**MultiWOZ**	**Persuasion**	
	Emotion	Emotion	Act	Intent	ER	EE
Original	61.90	41.16	79.46	96.22	56.28	44.83
Intra-Speaker Shift	52.01 (13.2)	44.23 (1.0)	76.18 (2.9)	94.91 (1.6)	57.84 (6.9)	49.4 (4.7)
Inter-Speaker Shift	52.37 (22.0)	47.77 (1.3)	78.80 (4.9)	-	-	-

Table 6: Classification performance for utterances which exhibits *Label Shift* in test data. Numbers in parenthesis indicate the average count of the corresponding shifts per dialogue. There is no *Inter-Speaker Shift* in MultiWOZ or Persuasion for Good as we only classify user, persuader, or persuadee utterances. Scores are W-Avg F1 in IEMOCAP Emotion and MultiWOZ Intent; Macro F1 in the rest.

defined in MultiWOZ as we don't have intent labels for system utterances. We also don't report *Inter-Speaker Shift* results in Persuasion for Good as the persuader and persuadee strategy set is different.

The emotion labels in IEMOCAP display the largest extent of label copying. We also observe in Table 6 that label shifts occur with high frequency in IEMOCAP. These are the likely reasons why we observe significant number of errors for utterances with *Label Shift* for this task in Table 6. The performance for both *Intra-Speaker Shift* and *Inter-Speaker Shift* stands at around 52.0%, much lesser than the overall average of 61.9% in test data. Although not as strong as IEMOCAP, the intra-speaker label copying feature can also be seen in MultiWOZ intent and DailyDialog act labels. For these two tasks, we again observe a drop of performance when either *Intra-Speaker Shift* or *Inter-Speaker Shift* occurs. In contrast, the extent of transition is spread over a much larger combination of labels in DailyDialog emotion and Persuasion for Good. We observe that the results for utterances with *Label Shift* in those tasks are in fact better than the overall score. In DailyDialog emotion, the scores are 44.23% and 47.77%, which is an improvement over the original 41.16%. The scores of 57.84% and 49.4% in Persuasion for Good also stand over the scores of 56.28% and 44.83% in the original setup.

4.5 Sequence Tagging using Conditional Random Field (CRF)

On the surface, the task of utterance level dialogue understanding looks similar to sequence tagging. Are there any distinct label dependency and patterns across the tasks that are dataset agnostic and likely to be captured by CRF (Lafferty et al., 2001)? In the quest to answer this, we plug in three different CRF layers on top of the bcLSTM network.

Global-CRF. It is a linear chain CRF used on top of bcLSTM. In this setting, we do not consider speaker information.

It can be defined using the equations below:

$$P(Y|D) = \frac{1}{Z(D)} \prod_{i=1}^{n} \phi_T(y_{i-1}, y_i)\phi_E(y_i, u_i), \quad (1)$$

$$Z(D) = \sum_{y' \in \mathcal{Y}} \prod_{i=1}^{n} \phi_T(y'_{i-1}, y'_i)\phi_E(y'_i, u_i). \quad (2)$$

Global-CRF$_{\text{ext}}$. The linear-chain CRF is extended to include not only the transition potential from the previous label to the current label, but also from the prior-to-previous label. Concisely, the current label is predicated on the previous two labels. Therefore, the transition potential function ϕ_T takes one extra argument y_{i-2}. The advantage here is it also considers the previous label from the target speaker should utterance $i-2$ have come from the target speaker. This becomes useful in the tasks where the speakers tend to retain label from its last utterance. It can be defined using the equations below:

$$P(Y|D) = \frac{1}{Z(D)} \prod_{i=1}^{n} \phi_T(y_{i-2}, y_{i-1}, y_i)\phi_E(y_i, u_i), \quad (3)$$

$$Z(D) = \sum_{y' \in \mathcal{Y}} \prod_{i=1}^{n} \phi_T(y'_{i-2}, y'_{i-1}, y'_i)\phi_E(y'_i, u_i). \quad (4)$$

Speaker-CRF. In this setting, we use two distinct CRFs for the two speakers in a dialogue. Inter-speaker label dependency and transitions are not likely to be captured in this setting by the CRFs.

Negative Results. We report the results for CRF experiments in Table 7 and Table 8. Aside from the well-known sequence tagging tasks, such as, Named Entity Recognition (NER) and Part of Speech Tagging, CRF does not improve the performance of utterance-level dialogue understanding tasks. There could be multiple reasons as below:

1: A dialogue is governed by multiple variables or pragmatics, e.g., topic, personal goal, past experience, expressing opinions or presenting facts based on personal knowledge, and the role of the interlocutors. Hence, the response pattern can vary depending on these variables. The personality of the speakers add an extra layer of complexity to this which causes speakers to respond differently under the same circumstances. An identical utterance can be uttered with different emotions by two different speakers. CRF relies on surface label patterns which can vary with datasets. Due to this dynamic nature of dialogues and the presence of latent controlling variables, the label transition matrix of CRF does not learn any distinct

Methods	**IEMOCAP**	**DailyDialog**

w/ global-CRF$_{\text{ext}}$	95.51	69.23	**56.80**	**61.89**	**43.68**

Table 8: Classification performance in test data for MultiWOZ and Persuasion for Good using different CRF configurations. All scores are average of atleast 10 different runs. Test F1 scores are calculated at best validation F1 scores. In MultiWOZ and Persuasion for Good, the global-CRF and speaker-CRF setting are identical as we only classify utterances coming from one of the speakers (user in MultiWOZ, persuader or persuadee in Persuasion for Good).

pattern that is complementary to what is learned by the feature extractor. **2**: Some of the datasets — IEMOCAP and MultiWOZ — contain distinct label-transition patterns between the same and distinct speakers e.g., the label copying feature in the IEMOCAP dataset where the same or similar emotions are repeated by the same or both the speakers. Similarly, in the MultWOZ dataset, the intent *book restaurant* to be frequently followed by the intent *find taxi*. **We believe the distinct label patterns in the IEMOCAP and MultiWoZ datasets is potentially one of the reasons why contextual models perform so well on these three datasets and tasks compared to the rest.** On these two daatsets, we expected bcLSTM w/ global-CRF to outperform vanilla bcLSTM. However, we do not observe any statistically significant improvement using bcLSTM w/ global-CRF over bcLSTM. We posit that the evident label-transition patterns that exist in these two datasets are straightforward to capture without a CRF. In fact, we also tried GloVe CNN with a CRF layer on it, and surprisingly the result was not significantly higher than that of GloVe CNN. This can be attributed to the absence of explicit contextual and label transition-based features in the CRF.

Results in IEMOCAP and Persuasion for Good Datasets. We observe a *minor* performance improvement in the IEMOCAP dataset using speaker-CRF for emotion recognition. This observation directly correlates to the experiment under "w/o Inter-Speaker Dependency" setting in Table 2 and can be largely attributed to the label copying feature in the IEMOCAP dataset as explained in the last paragraph. In "w/o Inter-Speaker Dependency" setting, contextual utterances of the speaker B are not utilized to classify utterances of speaker A vice versa. The results do not improve when we use speaker-level CRF on bcLSTM under the "w/o Inter-Speaker Dependency" setting. From these observations, we can conclude that CRF is not learning any distinct label dependency and transition patterns that are not learned by the feature extractor or bcLSTM alone.

Global-CRF$_{\text{ext}}$ shows significant performance improvement on the Persuasion for Good dataset. Some of the key controllable factors of the dialogues such as topics in this dataset are fixed and can be learned intrinsically by the classifier. The scope of the dialogues in this dataset is very limited as there are only two possible outcomes of the dialogues – *agree to donate*, and *disagree to donate*. Hence, there can be some label transition patterns learned by the Global-CRF$_{\text{ext}}$ using a larger label-context window in the transition potential.

5 Conclusion

In this paper, we explored the role of context for six utterance-level dialogue understanding tasks in four different datasets. Using a strong contextual baseline system (bcLSTM), we gained insights into the behavior of such contextualized models in the presence of various context perturbations. Such probes have bolstered many interesting intuitions about utterance-level dialogue understanding—the role of label dependency and future utterances; the role of speaker-specific contextual modelling; and the robustness of contextual models as opposed to their non-contextual counterparts against adversarial probes. We believe that these probing strategies can be straightforwardly adapted to other context-reliant tasks. The implementation pertaining to this work is available at `https://github.com/declare-lab/dialogue-understanding`.

A Label Transitions.

To check whether there lies any patterns in the label sequences of the datasets, in Fig. 2 and 3, we plot frequency of the label pairs (x, y) where x and y are the labels of $U_{s_{t-1},t-1}$ and $U_{s_t,t}$ respectively. Figure Fig. 2 explains inter-speaker label transition and Fig. 3 illustrates the intra-speaker label transition. Both these plots reveal the same emotion labels appearing in the consecutive utterances with high frequency in the IEMOCAP dataset. This induces label dependencies and consistencies and can be called as the **label copying feature** of the dataset. From our empirical analysis in Section 4, we confirm this property of the IEMOCAP dataset. Although not as strong as IEMOCAP, the intra-speaker label copying feature is also prevalent in the MultiWOZ and DailyDialog (Act) dataset (refer to Fig. 2). Moreover, we observe interesting patterns in DailyDialog (Act). A directive utterance is commonly followed by a commissive utterance. This indicates that utterances with acts such as request and instruct (directive label) are followed by accepting/rejecting the request or order (commissive label). We also notice that an utterance with the act of questioning is commonly followed by the utterances with the act of answering (which is quite natural). Fig. 2 also corroborates the high frequent joint appearance of similar emotions in both speaker's utterances e.g., negative emotions — *anger, frustration, sad* expressed by one speaker is replied with a similar negative emotion by the other speaker. Interestingly, the DailyDialog dataset for emotion classification does not elicit any such patterns. We can attribute this to the scripted utterances present in the IEMOCAP that has specifically been designed to invoke more emotional content to the utterances. On the other hand, the DailyDialog dataset comprises naturalistic utterances that are more dynamic in nature as they depend on interlocutors' personality. In both IEMOCAP and DailyDialog datasets, the repetitions of the same emotions can be found in consecutive utterances of a speaker. The repetition of the same or similar emotions for a speaker is frequent and often forms long chains in IEMOCAP. However, such repetitions are much less prevalent in DailyDialog. Readers are referred to Fig. 3 for a clearer view. **This two different types of datasets used in this work is purposefully crafted in order to study dataset-specific nuances to attempt the same task.** In DailyDialog, approximately 80% of utterances are labeled as *no-emotion* (see Fig. 4) which poses a difficult challenge to perform emotion classification. These two datasets also differ from each other in the average dialogue length. While the average number of utterances per dialogue in the IEMOCAP dataset is more than 50, the average number of utterances per dialogue in the DailyDialog dataset is just 8 which is much shorter.

Among other semantically plausible label transitions, we can see in Fig. 3, the intent *book restaurant* to be frequently followed by the intent *find taxi* in the MultiWOZ dataset. **We believe this is potentially one of the reasons why contextual models perform so well on these three datasets and tasks** compared to the rest which we discuss in the subsequent sections. Further, label dependency and consistency can aid filtering likely labels given the prior labels. Notably, such patterns are not visible in the other datasets. Hence, one can use Conditional Random Field (CRF) to find any hidden label patterns and dependencies.

B Utterance Classifier

cLSTM. Similar to bcLSTM but without the bidirectionality in the LSTM, this model is intended to ignore the presence of future utterances while classifying an utterance U_t.

DialogueRNN. (Majumder et al., 2019) is a recurrent network based model for emotion recognition in conversations. It uses two GRUs to track individual speaker states and global context during the conversation. Further, another GRU is employed to track emotion state through the conversation. In this work, we consider the emotion state to be a general state which can be used for utterance level classification (i.e., not limited to only emotion classification). Similar to the bcLSTM model, the features extracted by the *Utterance Feature Extractor* is the input to the DialogueRNN network. DialogueRNN aims to model inter-speaker relations and it can be applied on multiparty datasets.

cLSTM, bcLSTM and DialogueRNN with Residual Connections. Deep neural networks can often have difficulties in information proropagation. Multi-layered RNN-like in particulars often succumb to vanishing gradient problems while modeling long range sequences. Residual connections or skip connections (He et al., 2016) are an intuitive way to tackle this problem by improving information propagation and gradient flow. Inspired by the early works in residual LSTM (Wu

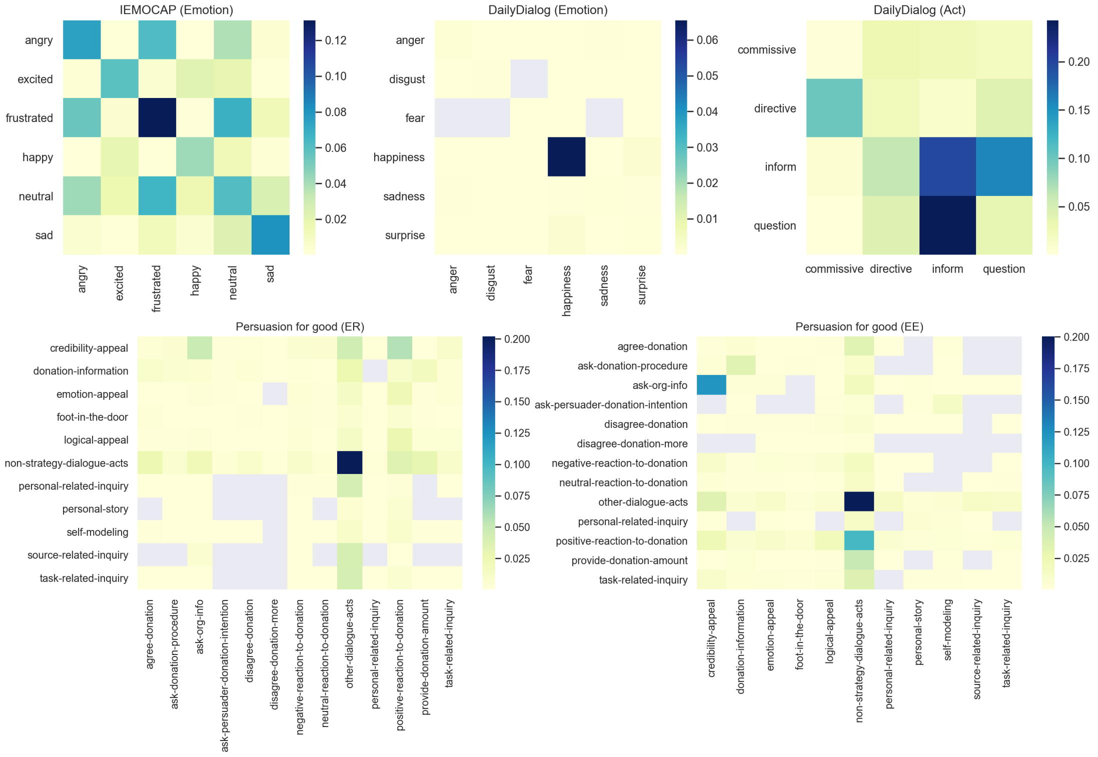

Figure 2: The heatmap of inter-speaker label transition statistics in the datasets. The color bar represents normalized number of inter-speaker transitions such that elements of each matrix add up to 1. Inter-speaker transitions are not defined in MultiWOZ as system side utterances are not labeled. Note: For the DailyDialog dataset, we ignore the *neutral* emotion in this figure.

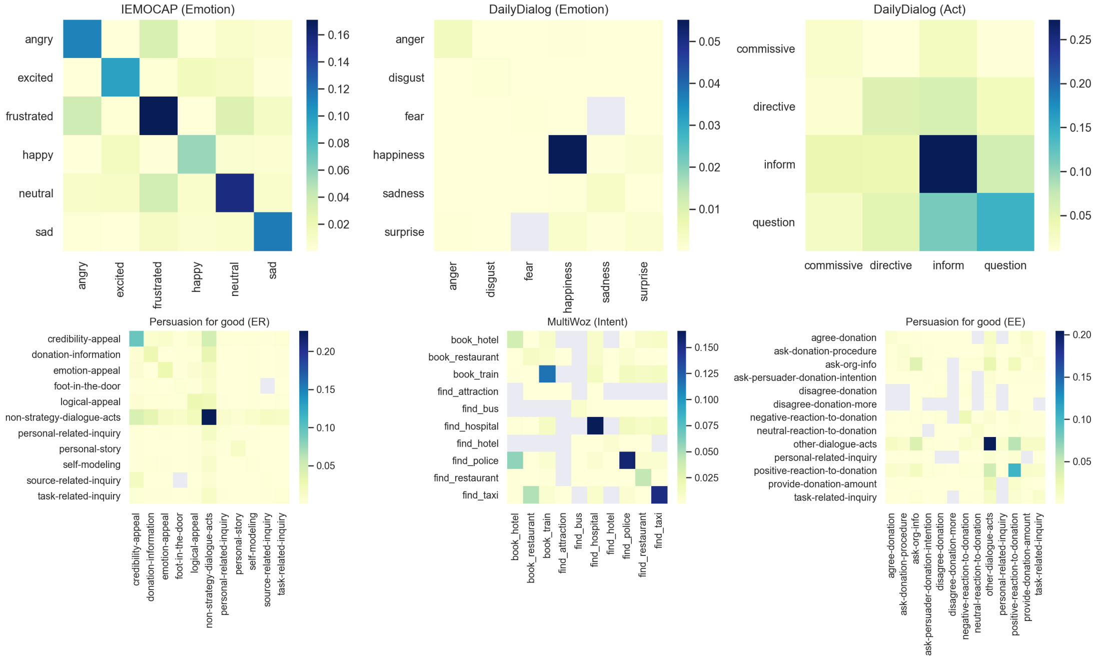

Figure 3: The heatmap of intra-speaker label transition statistics in the datasets. The color bar represents normalized number of intra-speaker transitions such that elements of each matrix add up to 1. Note: For the DailyDialog dataset, we ignore the *neutral* emotion in this figure.

et al., 2006; Kim et al., 2017), in our recurrent contextual models - bcLSTM and DialogueRNN we adopt a simple strategy to introduce a residual connection. For each utterance, a residual connection is formed between the output of the feature extractor and the output of the bcLSTM/DialogueRNN module. These two vectors are added and the final classification is performed from the resultant

Table 10: Classification performance in test data for intent prediction in MultiWOZ, persuader and persuadee strategy prediction in Persuasion for Good. Scores of the Glove-based models are reported after averaging 20 different runs. RoBERTa-based models were run 5 times and we report the average scores. Test F1 scores are calculated at best validation F1 scores.

We report results for IEMOCAP, DailyDialog dataset in Table 9 and MultiWOZ, Persuasion for Good dataset in Table 10. We ran each experiment multiple times and report the average test scores based on the best validation scores.

We observe that there is a general trend of improvement in performance when moving to the RoBERTa based feature extractor from the GloVe CNN feature extractor except in the intent prediction task in MultiWOZ dataset. As the RoBERTa model has been pre-trained on a large amount of textual data and has considerably more parameters, this improvement is expected. The results could possibly be improved even more if a RoBERTa-Large model is used instead of the RoBERTa-Base model that we use in this work.

We also observe that contextual models — bcLSTM and DialogueRNN perform much better than the non-contextual Logistic Regression models in most cases. Context information is crucial for emotion, act, and intent classification and models such as bcLSTM or DialogueRNN are some of the most prominent methods to model the contextual dependency between utterances and their labels. In IEMOCAP, DailyDialog and MultiWOZ there is a sharp improvement in performance in contextual models compared to the non-contextual models. However, for the strategy classification task in *Persuasion for Good dataset*, the improvement in contextual models is relatively lesser. Notably, for Persuadee classification, the RoBERTa non-contextual model achieves the best result, outperforming the contextual models. Without the presence of residual connections, the *GloVe cLSTM* and *GloVe bcLSTM* baselines perform poorly than the non-contextual *GloVe CNN* baseline in the *Persuasion for Good dataset*. This beckons the need for better contextual models for this dataset. To analyze the results of the different models we look at the following aspects:

Importance of the Residual Connections in the Models. It is also to be noted that the introduction of the residual connections generally improves the performance of the contextual models. We obtain better performance and improved stability during training for most of the models with residual connections. In particular, residual connections are mostly effective in IEMOCAP and Persuasion for Good datasets that comprise long dialogues. Residual connections are used in deep networks to aid information propagation and tackle vanishing gradient problems (Wu et al., 2006; Kim et al., 2017) in RNNs by improving gradient flow. As multi-layered RNN-like architectures often find it difficult to model long-range dependencies in a sequence due to vanishing gradient problems (Pascanu et al., 2013), we conjecture, that could be one of the reasons why we see a great performance boost with residual connections by helping propagate key information form the CNN layers to the output of LSTM layers that might be lost due to the long deep sequence modeling in the LSTM layer. Residual connections also help in combating vanishing gradient issues by improving gradient flow. Unlike IEMOCAP and Persuasion for Good, in DailyDialog and MultiWOZ datasets, the improvement in performance caused by the residual connections is only little which can be attributed to the relatively shorter dialogues present in these two datasets.

Variance in the Results. As deep learning models tend to yield varying results across multiple training runs, we trained each model multiple times and report the average score in Table 9 and Table 10. In general, we observed that the RoBERTa-based models show lesser variance compared to the GloVe-based models.

Variance in the Glove-based models: The observed variance is higher for emotion classification in IEMOCAP and DailyDialog as compared to act and intent classification in DailyDialog and MultiWOZ, respectively. Both baseline models – Glove CNN and bcLSTM show standard deviation of about 1.28% in the IEMOCAP dataset across different runs. In the Persuasion for Good dataset, for both persuader's and persuadee's act classification tasks, the deviation remains around 1.6% when we consider the Macro-F1 metric. However, for the Weighted-F1 metric, the performance is relatively stable as upon accumulating multiple runs the standard deviation is about 0.99% across the baselines. A similar trend is also prevalent in the DailyDialog dataset for emotion classification. In this task, the baselines – Glove CNN and bcLSTM show standard deviation of about 1.19% when Weighted-F1 and Micro-f1 are considered. According to Macro-F1 metric, however, these baselines are exposed to relatively higher standard deviation of 2.88%. This is likely to be a consequence of severe label imbalance in the dataset, that is having 80% neutral utterances. We have observed that a majority of these neutral samples do not exhibit neutral emotion. Therefore, this poor labeling quality may have precipitated this large variance in the results. On the other hand, the baseline models perform consistently in the intent and act classification tasks in MultiWOZ and DailyDialog datasets respectively showing standard deviation of around 0.55% across different runs. When comparing among the baselines, we found higher variances in the results obtained with the Glove CNN than the bcLSTM.

One possible reason behind the variances in the results of the GloVe-based models could be the end-to-end training setup that renders the model deeper. The original bcLSTM and DialogueRNN model employed a two-stage training method where the utterance feature extractor is first pretrained and then kept unchanged during the contextual model training. This setting may make those original models more stable. Similarly, we think, in our end-to-end setup, a more sophisticated training regime could result in a lesser variance of the results. For example, the utterance feature extractor could be trained only for the first few epochs and then kept frozen during subsequent epochs of the training. Due to this high variance in the end-to-end Glove-based models, the future works on these datasets and tasks which employ this setting should report the average results of multiple runs for a fair comparison of the models.

Variance in the RoBERTa-based models: The RoBERTa based models show much lesser variance in performance across different runs. In particular, the standard deviations in the results of Roberta-based bcLSTM are 0.57 on the IEMOCAP, 0.08, and 0.48 in the DailyDialog for emotion and act classification tasks, respectively, 0.07 in the MultiWoz dataset, 0.9 and 1.04 in the Persuasion for Good dataset for persuader's and persuadee's act classification tasks respectively. RoBERTa-based DialogueRNN shows a similar trend. We surmise that this is the case because the feature extractor's weights are initialized from a pretrained checkpoint. Thus, the feature extractor already provides meaningful features from the beginning of training and is not required to be trained from scratch, resulting in greater stability in the performance.

Encouraging Neural Machine Translation to Satisfy Terminology Constraints

Abstract

We present a new approach to encourage neural machine translation to satisfy lexical constraints. Our method acts at the training step and thereby avoiding the introduction of any extra computational overhead at inference step. The proposed method combines three main ingredients. The first one consists in augmenting the training data to specify the constraints. Intuitively, this encourages the model to learn a copy behavior when it encounters constraint terms. Compared to previous work, we use a simplified augmentation strategy without source factors. The second ingredient is constraint token masking, which makes it even easier for the model to learn the copy behavior and generalize better. The third one, is a modification of the standard cross entropy loss to bias the model towards assigning high probabilities to constraint words. Empirical results show that our method improves upon related baselines in terms of both BLEU score and the percentage of generated constraint terms.

1 Introduction

Neural Machine Translation (NMT) systems enjoy high performance and efficient inference (Sutskever et al., 2014; Bahdanau et al., 2014; Luong et al., 2015; Vaswani et al., 2017). However, when it comes to domain specific scenarios, where it is often necessary to take into account terminology constraints, NMT models suffer from the lack of explicit source-target correspondences making it challenging to enforce such constraints. For instance, consider the following sentence from the financial domain : *“**Holders** may submit instructions based on a minimum quantity being accepted by the **offeror.**”*. According to the financial terminology, the words *Holders* and *offeror* should be translated *porteurs* and *initiateur* respectively. Unfortunately, a generic English-French NMT model would translate the above sentence as: *“Les **titulaires** peuvent soumettre des instructions en fonction d’une quantité minimale acceptée par l’**offrant**.”*, where the words *Holders* and *offeror* are translated into *titulaires* and *offrant* respectively. To address this limitation various approaches have been proposed. They can be grouped into two categories based on whether they enforce constraints at inference or at training time. The former family of methods changes the decoding step to inject the constraint terms in the output. While effective at satisfying constraints, these techniques tend to suffer from several weaknesses such as high computational cost at the decoding stage, decreased translation quality due to strict enforcement of terminology constraints (Hokamp and Liu, 2017; Post and Vilar, 2018), or ineptness if there are multiple constraints in the input/output (Susanto et al., 2020).

The other category of methods, which we follow in this work, integrates lexical constraints during training (Dinu et al., 2019). More precisely, they augment the training data in such a way as to inform the NMT model of the constrains that need to be satisfied (Crego et al., 2016; Song et al., 2019; Dinu et al., 2019). This type of approaches has the advantage of not changing the NMT model as well as of not introducing any additional computational overheads at inference time. One limitation of these methods is their soft nature, i.e, not all constraints are guaranteed to be present in the output.

In this paper we pursue the latter line of research and improve upon the recent work of Dinu et al. (2019) by (i) only using tags –without source factors – to distinguish between constraints and other words, (ii) performing constraint token masking for robustness/generalization purposes and (iii) modifying the standard cross-entropy loss to bias the model towards generating constraint terms. Empirical results show that our approaches improve both the BLEU sore and the number of satisfied constrains compared to previous work.

2 Related Work

Existing approaches can be cataloged based on whether they integrate constraints at inference/decoding (Chatterjee et al., 2017; Hasler et al., 2018; Hokamp and Liu, 2017) or at training time (Dinu et al., 2019).

Among methods of the first category, we can mention the Grid Beam Search (GBS) algorithm, which consists in reorganizing the vanilla beam search to place constraints correctly in the output as well as infer accurately the constraints-free parts. While successful in placing constrains compared to the original BS algorithm, GBS suffers from a high decoding time, it increases inference complexity exponentially with the number of constraints. To alleviate this issue, several improvement have been proposed, such as Dynamic Beam Allocation (DBA) (Post and Vilar, 2018) and its optimized extension, namely vectorized DBA (Hu et al., 2019). Despite an important gain in computational time, these methods still significantly increase the decoding time. For instance, the method of Post and Vilar (2018) is three times slower than the constraint-free beam search. More recently, Susanto et al. (2020) rely on the levenstein transformer (Gu et al., 2019), which uses an edit-based decoder iteratively refining the output using deletion and insertion operations. To enforce constraints using this model, Susanto et al. (2020) add one step to the decoder that consists in placing constraint terms in the output, and they further disallow the deletion operation on constraint terms. Albeit effective, the main limitation of this approach is in constraint ordering – when there is more than one constraint term in the output. That is, the initial order in which constraints have been placed remains unchanged.

Different from the above, the second family of methods integrates lexical constraints at training time. For instance, Crego et al. (2016) replace the terminology terms with placeholders during training and then add them back in a post-processing step. Song et al. (2019) proposed to annotate the training set by adding the target side of the terminology terms in the source sentences. A transformer model (Vaswani et al., 2017) is then trained on this augmented training set. This training data annotation has been also explored to teach the NMT to use translation memories (Gu et al., 2018) or to enforce copy behavior (Pham et al., 2018). Dinu et al. (2019) proposed two different ways to augment the training data, namely the append and the replace approaches. The former is similar to approach proposed in (Song et al., 2019), and the second requires to replace the source term of the constraints in the source sentence by its corresponding target side in the terminology entries. This method further uses source factors in order to distinguish the constraints from the rest of the source sentence. This is the closest approach to ours. The key differences are as follows. Our method uses only tags (without source factors) to specify constraints in the training set, and we further perform constraint-token masking, which improves model robustness/generalization as supported by our experiments. Moreover, we investigate a biased cross-entropy loss to encourage the NMT model to assign higher probabilities to constraint words.

3 Method

Our objective is to encourage neural machine translation to satisfy lexical constraints. To this end we introduce three changes to the standard procedure, namely training data augmentation, token masking, and cross-entropy loss modification.

TrAining Data Augmentation (TADA). Similar to previous work, the key idea is to bias the NMT model to exhibit a copy behavior when it encounters constraints. To this end, given some source sentence along with some constraints, we use tags to specify the constraints in the source sentence where relevant, as depicted in Figure 1. Note that as opposed to previous work, we do not introduce any further information (e.g., source factors), the constraints are specified using tags only.
